As noted by Plotkin (2014), perhaps most defining in the history of older adult work are the theories of Erik Erikson (1959), who extended notions of human growth and psychological change into the later decades of life. His was a true lifespan developmental perspective that directly countered the opinions of Freud. The last stage of his theory, entitled “Integrity vs. Despair,” reflects the belief that broader and more complex ego strength, nurtured and sustained in the context of significant others, is one of the potential gains acquired through aging. In 1956 Erikson wrote, “I have characterized the psychosocial gains of adult ego development with the terms intimacy, generativity, and integrity . . . their very alternative, isolation, self-absorption, and despair, can be held in check only by the individual’s fitting participation in social endeavors” (Plotkin 2014). As elaborated by Garner (Garner 2002), “Integrity” is the ability to hold esteem for one’s life experiences and one’s self, “to be through having been.” It exists in a dialectical tension with “Despair,” the notion that

sometimes we must face what we have not been, or what we did not do well in being (Garner 2002).

Knight (1996, 2004) proposed a model based in the “life-span developmental” approach termed the “contextual, cohort-based maturity/specific challenge” model. In this, older adults are viewed as having gained maturities that are not found in younger adults. As evidence, Knight cited findings that older adults tend to be less impulsive, to experience greater role competence, and to experience more complex emotions but in a less reactive way. These characteristics are developed only by experience across the lifespan. In contrast to the “loss-deficit model,” his maturity/challenge model emphasizes the need to reconstruct and improve life following a loss. More fundamentally, the maturity/challenge model does not view older adults as unavoidably prone to emotional difficulties. And, when they do enter therapy, they are seen as having significant potential for increased self-understanding and growth, both core components of psychodynamic therapy (Knight 1996).

Empirical Support

Randomized, placebo controlled studies of psychodynamic therapy with older adults are few (Plotkin 2014; Roseborough et al. 2013). However, a systematic review of effective treatments for depression in older adults located six studies that evaluated psychodynamic treatments in a randomized, controlled fashion. This review found that psychodynamic therapy for depression in older adults was effective. Moreover, it was found to be as effective as cognitive behavioral therapy (CBT). Benefits were noted in immediate symptom relief as well as maintenance of change over years to follow. The conclusion of the review was that psychodynamic therapy is well supported as a treatment option for depressed older adults (Frazer et al. 2005). More generally, Plotkin (2014) summarized data from multiple points including case studies, longitudinal studies, and neuroimaging studies. In keeping with Knight’s (1996) work, these data suggested that older adults remain able to learn and change, and that

among the benefits of aging are improvement and stabilization in emotional life (Plotkin 2014).

Core Psychodynamic Issues in Older Adulthood

Old age is notable for stresses that are unique, including physical changes, loss of significant others, changes in role status, and existential questioning. But, as noted previously, current conceptualizations of the later years of life are more complex than decay under stress. Rather than simply constricting with age, we have the capacity to become more diverse and individualized (Leigh and Varghese 2001). Thus, as described by Garner (2002), Hildebrand (1982) outlined an interrelated group of core developmental tasks that arise in later life. These are, working through fears of diminution and loss of potency, working through experiences of being replaced in one’s career by younger people, and remaking the marital and family relationships after children are grown. Also, an older person must confront and accept his or her own aging, and accept that there are things that will not be done or undone in life at that point (Garner 2002).

Furthermore, increasing dependency brings to the forefront the person’s capacity to trust and to tolerate a loss of autonomy. Those with problematic histories of malformed relationships or violated trust may become symptomatic at this point. Common reactions can be those of depression or anxiety, especially revolving around concerns that the caregiver is adequate, and whether the caregiver will grow to hate, reject, or be repulsed by the patient (Garner 2002). Doubtless the greatest developmental challenge in late life, though, is coming to terms with the end of that life. It has been referred to as the single event in life that is our “most own.” Nothing is our own like our own death; we share it with no one else. This degree of aloneness can be overwhelming and it is not an uncommon issue facing older adults in therapy (Leigh and Varghese 2001).

In keeping with the notion that aging offers growth through its difficulties, Garner (2002)

offered the words of Salzberger-Wittenberg (1970) who stated, "Some losses are an inevitable part of our life experiences and are indeed necessary for the attainment of mature adulthood. For the work of mourning can lead to greater integration, strengthening of character, the development of courage, and to deeper concern for others as we come to appreciate the preciousness of others' and our own time of life."

As people age, there are commensurate changes in relationships with family and other loved ones. Likewise, the roles the older person fulfills in his or her family system change, owing to a host of physical and psychological factors. Particularly notable change can occur in relationships with adult children. It is not uncommon for the roles to reverse as the parent ages, such that the adult child enters the caretaker role for the parent. For the older adult, this can be an uncomfortable dependant position. The ability to successfully make this transition can depend on the quality of earlier relationships with the children, how the older adult addresses and manages fears of dependency, and the degree of acceptance of limitations that can be achieved as age advances (Wheelock 2001).

Likewise, the notions of reciprocity and equity can, and hopefully do, enter into the family circumstance. The ability and willingness of an adult child to care for an aging parent can depend on that child's experience of being cared for by the parent in years past. In a related theme, so older adults may go as far as feeling entitled to such care, given the care and devotion they have given to the children. Other role changes that can occur in families include the transition away from a leadership role, to one more characterized by following (Wheelock 2001).

The issue of caregiver stress can be as important as any other. In large part, interventions for this population focus on enhancing behavioral coping skills and stress management. To be sure, these are vital components of care for caregivers. However, they can be undermined if the caregiver's internal dynamics related to caregiving are not respected. How did the caregiver come to

be in that role? Was it a choice made voluntarily, or involuntarily? What was the relationship between the older adult and caregiver previously? Was it hostile, dependent, distant, or mutually supportive? Lastly, how well integrated is the role of caregiving for the caregiver? Is it ego syntonic, or dystonic? (Garner 2002).

On the other hand, contemporary aging can also mean the assumption of new roles. Within a marriage, a spouse may find herself or himself having to assume functions filled by the other spouse, if that spouse becomes disabled in some way or dies. Chief among these is the role of caregiver for a disabled spouse. Or, needs in the younger generations of the family may require the older adult members to begin duties such as caring for young grandchildren. Especially in the current times, it is not uncommon to find an older adult still employed, having decided to delay retirement. Alternately, economic need can lead some older adults to come out of retirement. On a more positive note, some older adults find that they begin into a unique role in the family, that of the family historian, and the holder of a unique connection to the family past.

A unique relational issue that is sometimes a goal in therapy is assisting the older adult in negotiating successfully interactions with his or her other medical providers. The relationship with a physician, nurse practitioner, or the like can be pivotal in the life of an older adult. These individuals are a source of a unique type of nurturing and caring, and they can represent hope. Indeed, it is fair to say that these individuals can become internalized and incorporated among the older adult's self-objects. Being able to advocate and assert oneself with medical providers is a relational and interpersonal skill and one that older adults may have to work in developing.

Psychodynamic ideas, especially those from the object relations and ego developmental systems, have been used to inform an understanding of the subjective experience of advancing cognitive loss. Indeed, in a unique way, cognition loss is an area in which the role of neurology and neuropsychology in undergirding

psychodynamics becomes clear. From this perspective, cognition loss weakens ego functioning, and thus erodes mastery over the environment and increases dependency. The person's ego defenses (e.g., executive functions) become less potent, and may regress slowly over time. Along with reduced ability to manage current stressors, previously mastered emotional conflicts may return, as the person is no longer able to engage the psychological mechanisms that once contained them. Also, as cognition loss progresses the neuropsychological substrates (e.g., memory) for maintaining a coherent sense of selfhood via internalized self-object relations fade. In response the person comes to rely more and more on others for day-to-day ego functions and reinforcement of sense of self. Out of these changes can come the anxiety, depression, catastrophic reactions, highly dependent attachments, and related emotional challenges seen in people with advanced cognitive loss (Kasl-Godley and Gatz 2000).

Process and Technical Aspects

As noted by Leigh and Varghese (2001), the elemental question of how to live as an older adult is, at least partially, answered by the story of one's younger life. Depending on the experiences of earlier life, older age can be a peaceful time, or one of profound dysphoria. Authors such as Jung have described a process whereby older adults can become more introspective, more accepting of the changes inherent in living, and more accepting of the finite nature of human existence. Out of such awareness can come a commitment to living life in the present moments, and it is this drive that psychodynamic psychotherapy seeks to potentiate (Leigh and Varghese 2001).

Thus, the overarching goal of psychodynamic therapy for an older adult is to support investment in current life and attachments, while minimizing as possible the degree of retrospective and anticipatory anxieties. Said another way, helping the older adult maintain investment in "nowness" is

felt to provide the best opportunity for expanding experience and integration into the world. If this connection with "the now" is broken, it can be seen as a form of psychological death, even predated physical death (Leigh and Varghese 2001).

Respect for the patient's autonomy and potential for growth are paramount. This is especially so for older adult patients, whose life circumstances may well have disempowering features that undermine their independence and autonomy. The therapeutic relationship can represent a vital exception, particularly in psychodynamic work, as it is a place where the older adult has more autonomy than they have elsewhere in life. Therefore, the therapist must be attuned to the therapeutic process unfolding so as to monitor for any signs of slippage into therapeutic paternalism (Leigh and Varghese 2001). The therapist and older adult patient have developed in different historical contexts, and these differences can actually become part of the therapeutic dialog, instead of an impediment (Wheelock 2001). As expressed by Knight, "understanding aging is about maturation; understanding working with older individuals is about understanding people who matured in a different era" (Knight 1996).

The concept of transference is at the core of psychodynamic therapy. Briefly, this refers to the phenomenon whereby a patient experiences and reacts to the therapist based on emotions and patterns laid down with significant figures from the patient's past. In the therapy, transference is used as a venue through which the patient can learn to reframe and respond to these forces in a new, more developed, and healthier way. Work with older adults is noted for some unique transference phenomena. For example, given that the therapist is commonly younger than the older adult patient, a so-called "reverse transference" can occur. In this, the patient reacts to the therapist as he or she might to their own adult child. This can manifest in feelings of protectiveness of the therapist, difficulty sharing sensitive or emotionally laden material with the therapist, or excessive interest in the therapist's personal life. As another

example, romantic transferences can occur in therapy with an older person just as they can with any patient. A challenge for the therapist in working with these can be even recognizing them in the first place, or being comfortable acknowledging them. This stems from widespread ageist assumptions that older adults are not sexually active or do not harbor romantic needs (Leigh and Varghese 2001). The older adult patient can also develop feelings of anger and envy towards the therapist who, by virtue of being younger, may be more physically vital and may have more life left to live.

Just as the patient can respond to the therapist based on experiences in previous relationships or other past circumstances, the therapist can respond in kind to the patient. The term countertransference as discussed here, though, refers to the therapist's experience of the patient, no matter its origins. This is a broader definition than some others, but is used here on the belief that all of the therapist's reactions to the patient can hold clinically meaningful relevance, not just those based solely in the therapist's own transference issues. Regardless of the definition, it is critical that the therapist be aware of these and process them appropriately. Otherwise they can affect the therapy and become harmful to the patient (Leigh and Varghese 2001).

Therapists can react to older adults in both positive and negative ways. As one example, "idealization" of the patient can occur, in which the older adult is experienced unidimensionally as someone with only the best of human qualities (wisdom, nurturance, contentment). Related to this, therapists can experience the older adult patient through the frame of a parent or grandparent. In either case, if these feelings are not managed, they can lead the therapist to limit the nature of the therapy and the treatment relationship. As related by Leigh and Varghese (2001), Hess (1987) explained that the therapist may fail to address, "the complex mixture of strength and frailty which is at the heart of these patient's psychic dilemma and which needs to be understood for change to occur and peace of mind to be restored" (Leigh and Varghese 2001).

Negative countertransference can also emerge in working with older adults. These can occur because of the therapist's own feelings about aging and death, or unresolved relational problems with their own parents or grandparents. Common examples include feelings of powerlessness and pessimism in the face of intractable issues such as chronic illness, rescue fantasies, internalizing the despair of the patient, or fear when confronting inevitable life changes and losses associated with aging (Leigh and Varghese 2001). For other therapists, working with older adults can engender feeling like a dutiful child rather than a competent adult (Dalzell 2001). Most fundamentally, younger therapists may need to confront their own guilt for simply being younger.

From a practical standpoint, it is important in working with an older adult to be aware of any physical or sensory deficits, and to accommodate for these accordingly. Something as simple as talking loudly enough to be heard can bring significant depth to the therapy relationship. Cognition changes (even normal age-related changes) likewise may require accommodations; or, may even reach a point where psychodynamic work is no longer appropriate. Important points in therapy can be written down in a journal, material can be distilled down to key points, and sessions can be slowed down or shortened. Also, collateral information from other significant individuals can facilitate gathering a good case history in the event the patient has some problems with recall or synthesis of information (Leigh and Varghese 2001).

Collateral others can also serve as a source of between-session coaching, helping the patient to maintain connection with information from sessions (Leigh and Varghese 2001). Older adults themselves are from a cohort for whom mental health care was mysterious or suspicious. On entering therapy, it can be helpful to explain the therapy process to the patient, describing what it is and is not, presumed mechanisms of action, goals of intervention, and the like. And lastly, but very critical, the physical changes of aging mean that symptoms such as memory problems, shortness of breath, headaches, or gastrointestinal distress

must be evaluated medically, before they can be assumed to be somatic experiences of emotion. Particularly when working with older adults, medical factors must be ruled out before attributing any symptom to psychic causation.

When making the determination whether or not an older adult is appropriate for a psychodynamic approach, the same general rules apply as with younger patients. First, the person needs good verbal skills. As a variation of this, a patient with a milder degree of aphasia might still be able to engage in psychodynamic therapy as long as adequate accommodations were made. Also, it is important for the patient to have good self-observation and self-reflective abilities. As noted earlier, older adults can develop these abilities over the course of their lives to an extent greater than younger adults. Lastly, it is important that the older adult can develop a trusting therapeutic alliance. This may require extra skill from the therapist. For example, the older adult may be reluctant to engage beyond a shallow level out of concern that the therapist, who is likely younger than the patient, cannot truly understand the patient's experiences. The patient has lived longer, experienced more things in life, and may be grappling with issues such as medical changes that are foreign to a younger, healthier therapist (Dalzell 2001).

Once a determination is made that the patient is a good candidate for psychodynamic work, there is a continuum of approaches from which to choose. These range from ego supportive therapy, such as those incorporating self-psychology, to full spectrum psychoanalysis. Only a small proportion of patients will be appropriate for an in-depth psychoanalysis, in keeping with this modality for adults in general. However, less intensive approaches can be helpful, whether as a primary intervention, or as part of an integrated case conceptualization. As noted by multiple authors, both in the psychodynamic arena and in geriatric mental health in general, it is critical that the therapist be able to work flexibly and to shift intervention styles as needed (Dalzell 2001).

Self-psychology, noted above, can lend itself to working with older adults given the issues they often face. It can articulate with other theoretical

systems as well, such as Acceptance and Commitment Therapy (ACT), Life Review, and Interpersonal Psychotherapy (IPT). Self-psychology is based on the tenant that older adults who are able to maintain a coherent sense of a congruent self, across time and circumstances, are best able to cope and maintain themselves psychologically. The "self" is conceptualized as the scaffold of personality. It is theorized to develop as the confluence of inborn traits, temperament, and interactions with the environment and those significant figures in it. These significant others are known as "self-objects" and are experienced by the person as almost an extension of the self. More than simply people that are known, these are figures that are metabolized and incorporated into the person's psychic world. Self-objects can meet a variety of potential needs, including those for reflection and affirmation (mirroring), soothing and guiding insights (idealizing), and sharing of interests and values (twinsip). From the perspective of self-psychology, the stability, maturity, and health of the person psychologically rest on that of the self, derived from the quality of self-object relations (Dalzell 2001).

For some older adults, aging brings a reduced connection with self-objects, for example, through death. Furthermore, illness, functional limits, and other age related changes can interfere with positive self-object relations as well. The overall result is a weakened sense of self, or disgust with the perceived new self that is seen to have emerged, and increased vulnerability to psychopathologies. These include depression, existential crisis, anger, anxiety, and a host of others. For some, aging can mean the death of the self well before the actual death of the body (Dalzell 2001).

Thus, the role of the therapist is to become a newer self-object. The first step in this process is to create a therapeutic holding environment in which the patient can find the mirroring that forms the basis for the therapy as it moves forward. This can require the therapist to confront and manage potential countertransference issues without delay, as their operation can undermine the therapy before it even begins.

The development of idealizing transference, by which the patient is able to find soothing and reassurance in the therapeutic relationship, emerges from the soil of a rich therapeutic holding environment. The overarching goal of the therapy is to restore and reactivate the patient's sense of self-coherence. It is as if restarting a movie that had been assumed over, and finding that the story actually continues, and the lead actress or actor is still there and recognizable (Dalzell 2001).

This restoration may be facilitated by any of the number of specific techniques. It is here that psychodynamic work, ACT, Life Review, and IPT can mingle. Through the relationship with the therapist, the patient may learn to find-self acceptance and thereby develop more realistic yet fulfilling expectations for living. As stated by Carl Rogers, "The curious paradox is that when I accept myself just as I am, then I can change." Additionally, the patient may develop new skills to re-connect with previous self-objects or develop new ones. Or, the patient may enhance ego strength by developing new coping skills that function in spite of the limits imposed by functional changes (Dalzell 2001). Through positive Life Review (i.e., with an emphasis on positive recall vs. negative rumination), the older adult has an opportunity to cast back to past notions of selfhood, strengths and accomplishments, and core values that have transcended phases in life. These can then be brought forward to reinforce coping and, more fundamentally, sustain the person's sense of a coherent narrative.

Conclusion

As the human lifespan lengthens and the older adult cohort grows, so must our options for understanding their complex lives and emotional experiences. At one time, the possibility that emotional life and growth could occur in later life was dismissed out of hand. It has only been through years of research and clinical work that these ageist assumptions have given way, albeit not entirely. With the aging of the "Baby Boom" will come new challenges for the mental health field, not only curative but preventative. What can

we say about optimal psychological and emotional health in aging? What strengths and resiliencies can facilitate a person's transitions and resolutions as they grow older? Psychodynamic thought, unique in its appreciation of the depth of human experience, is well positioned to inform these discussions.

Definition

Psychological testing refers to the evaluation and identification of measurable behaviors using assessment tools. Psychological testing is often utilized to supplement a clinical psychological evaluation; however, psychological testing can also encompass broader interests, including educational and achievement testing, vocational testing, and intellectual testing. Individual tests are not suitable for diagnosing patients; rather, testing is used to provide quantifiable measurements of certain behaviors in order to complement a full evaluation (Edelstein et al. 2008; Lichtenberg 2010). In the geriatric population, psychological testing is generally used for psychodiagnostic clinical purposes (Segal et al. 1998). There

can be a variety of reasons for psychological evaluations in a clinical setting for a geriatric population, including assessment of current behaviors, severity of clinically significant behaviors, diagnostic implications, and treatment planning purposes. Psychological testing instruments or tools describe certain sets of behaviors or traits of clinical interest, and specific instruments have been developed for this population or have been applied to this population.

Personality testing is a sub-section of psychological testing that identifies individual personality characteristics or dispositions. Personality traits are believed to remain stable across the adult life span, including into older adulthood, and as such, there are no personality assessment measures that have been developed specifically for older adults, although many personality assessment tools can be applied to the older adult population (Edelstein et al. 2008). Currently, personality testing is less emphasized as a psychodiagnostic tool and more of an assessment of behavioral syndromes or profiles, which have been identified scientifically and empirically (Weiner and Greene 2008).

Psychological Testing

There are important factors to consider involving psychological testing with older adults, including the psychometric properties of the measures and the appropriateness of the specific measure applied to an older adult population. In particular, issues to consider include reliability and validity of the measurement and whether the normative data include the older adult population. Popular psychological tests for assessing common mental health problems and issues in adults and older adults alike are enumerated below, namely depression, anxiety, anxiety-related issues, and psychosocial functioning.

Depression

While prevalence rates for depression in community-dwelling older adults is approximately 2–5%, rates of depressive symptoms and

subsyndromal depression range from 8% to 37% (Edelstein et al. 2008). Many of the assessments used to measure depression in older adults were initially developed for use with younger adults. This can be problematic when using these assessments with older adults, as older adults are more likely to report somatic symptoms and are less likely to report affective symptoms such as sadness, dysphoria, and worthlessness (Edelstein et al. 2008). It is important for both clinicians and researchers to keep this in mind when choosing an assessment for use with older adults. Common measurements of depression are often self-report inventories that are clinically feasible and have support from research.

Beck depression inventory. The Beck Depression Inventory – II (BDI-II) is a 21-item self-report measure, widely used in both clinical and research settings (Edelstein et al. 2008). Each of the items measure for a specific symptom of depression, assessing behavioral, cognitive, and somatic symptoms that closely match the diagnostic criteria set forth in the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV). Studies have shown that the BDI-II has high internal consistency, moderate convergent validity, and low to moderate divergent validity (Edelstein et al. 2008). While the BDI-II is widely used and has been widely studied, its focus on somatic complaints may not accurately reflect depressive symptoms commonly experienced by older adults. Further, it could underestimate the prevalence and severity of depressive symptoms in older adult populations (Edelstein et al. 2008).

Hamilton rating scale for depression. The Hamilton Rating Scale for Depression (HRSD) has long been considered a gold standard for assessing depression. It is most typically used in the context of research. The HRSD is a clinician-rated measure that was originally developed in the 1950s and first published in 1960 to be used in research assessing the effectiveness of the first generation of antidepressant medication (Bagby et al. 2004). HRSD has good internal consistency and interrater reliability, as well as moderate convergent and divergent validity. However, intraclass correlations vary widely (Edelstein et al. 2008; Bagby et al. 2004). Although the

measure is cost-effective because it is in the public domain, it has been criticized as having poor psychometric properties and being outdated because the original measure was developed to assess depression outcomes from first generation antidepressant medication (Bagby et al. 2004).

Patient health questionnaire. The Patient Health Questionnaire (PHQ-9) is a nine-item depression screening instrument developed for primary care settings. It has a telephone administered version that can be read to the examinee, making it acceptable for use with older adults who have vision problems. The PHQ-9 has moderate internal consistency as well as moderate convergent validity and test-retest reliability in adults, but there is no psychometric data for older adult populations (Edelstein et al. 2008).

Geriatric depression scale. The Geriatric Depression Scale is a self-report questionnaire developed specifically to assess depressive symptoms in older adults (Edelstein et al. 2008). The GDS has a standard 30-item form as well as a 15-item short form, both of which are in the public domain. The short form is an effective screening tool in primary care, nursing home settings, or for use with patients with cognitive limitations. Patients answer items in a dichotomous yes/no format. The assessment focuses on cognitive and behavioral symptoms of depression and no items of the GDS assess somatic symptoms. Thus, the GDS may be a better measure of depressive symptoms most common in older adult populations. The GDS shows good internal consistency and moderate convergent validity. While the GDS was developed and normed with older adults, there are no items that address suicidal ideation and the dichotomous format could create difficulties if the patient cannot discriminate between a “yes” or “no” answer to the question (Edelstein et al. 2008). When using the GDS with older adults, it is important to also separately assess for suicidal ideation.

Anxiety

Anxiety is more common in older adults than depression, with prevalence rates for anxiety in community-dwelling older adults ranging from

4% to 7% (Stanley et al. 1996). As is the case with assessments measuring depression, many assessments measuring anxiety were initially developed and normed with younger adults. Using these assessments with older adults can be problematic because medical conditions and their pharmacological treatments may affect the presentation of anxiety in older adults. Further, older adults tend to have different types of worries than young adults (Edelstein et al. 2008; Kogan et al. 2000).

Beck anxiety inventory. The Beck Anxiety Inventory (BAI) is a 21-item self-report measure of general anxiety (Kogan et al. 2000). Patients answer items about symptom severity using a 4-point Likert-type scale, ranging from 0 (not at all) to 3 (severe). Total scores range from 0 to 63, with higher scores signifying more severe anxiety. The BAI has high internal consistency; however, it has moderate concurrent and divergent validity (Edelstein et al. 2008; Kogan et al. 2000). The BAI has a two-factor (somatic and subjective subscale) structure for younger adults and a four-factor (cognitive, autonomic, neuromotor, and panic subscale) structure for older adults, suggesting that older adults experience different constellations of symptoms than younger adults.

State-trait anxiety inventory. The State-Trait Anxiety Inventory (STAI) is a self-report measure that consists of two 20-item scales measuring two factors of general anxiety: state anxiety, which is thought to be a situation-specific anxiety; and trait anxiety, a personality characteristic (Kogan et al. 2000). Patients answer items on a four-point Likert-type scale, with total scores for each scale ranging from 20 to 80. Higher scores indicate greater levels of anxiety. Further, the STAI shows moderate to good test-retest reliability and moderate convergent validity with the BAI (Edelstein et al. 2008; Kogan et al. 2000). While the STAI has good psychometric properties, psychometric data for older adults is limited. The two-factor state-trait structure may not apply to older adults (Kogan et al. 2000). Further, the two-factor structure does not align with the diagnostic criteria set forth in the DSM-IV, and the STAI does not provide a good indication of symptom severity. While the STAI might not be

appropriate for clinical evaluation of older adults, it is popularly used in research.

Hamilton Anxiety Rating Scale (HAM-A) and the Structured Interview Guide for HAM-A (SIGH-A). The Hamilton Anxiety Rating Scale (HAM-A) is a widely used clinician-rated measure of anxiety symptom severity, mainly utilized in a research setting. It is a 14-item measure of defined symptoms rated by a 5-point likert scale (Hamilton, 1959). Interrater reliability for individual items and total scores have been found to be sufficient (Maier et al. 1988). Although sensitivity is considered fair, criticisms of this measure include the lack of specificity (Maier et al. 1998). The Structured Interview Guide for the Hamilton Anxiety Scale (SIGH-A) is a corresponding guide of instructions for interviewers to aid in rating the HAM-A. The SIGH-A has been found to have good reliability (Shear et al. 2001).

Geriatric anxiety inventory. The Geriatric Anxiety Inventory (GAI) is a 20-item self-report questionnaire developed to measure general anxiety symptoms in older adults. The GAI was developed and normed with samples of community dwelling older adults and older adults seeking psychiatric services (Therrien and Hunsely 2012). The GAI employs dichotomous agree/disagree formatting, with the number of “agree” responses summed together for the total score. Total scores range from 0 to 20, with higher scores indicating greater levels of anxiety (Kogan et al. 2000; Therrien and Hunsely 2012). The original validation study showed excellent internal consistency for both the community dwelling and clinical samples (Kogan et al. 2000; Therrien and Hunsely 2012). Test-retest reliability data is limited, though one study showed moderate test-retest reliability (Therrien and Hunsely 2012). The GAI shows moderate to strong concurrent validity (Kogan et al. 2000). The GAI has a simple format, good psychometric data, and focuses on older adult symptoms of anxiety, making the GAI a good assessment option for use with older adults. Further, the GAI has been translated into many languages, making it available for use with older adults who do not speak English.

Geriatric anxiety scale. The Geriatric Anxiety Scale (GAS) is a 30-item self-report measure, developed for use with older adults. The scale contains 25 items related to symptoms of anxiety and five items related to common worries of older adults (Kogan et al. 2000). Patients rate symptoms on a four-point Likert-type scale for how often symptoms were experienced over the past week, with 0 indicating the symptom was not experienced to 3 indicating it was experienced all of the time. Total score range from 0 to 75, with higher scores suggesting greater anxiety. The measure consists of three subscales of anxiety symptoms (somatic, cognitive, and affective), which allows the clinician to better determine which symptom cluster is most bothersome for the patient, and thus adjust treatment to target those specific symptoms (Kogan et al. 2000). The GAS has shown good internal consistency, however, research has shown correlations between the somatic scale and self-reported medical problems. The GAS has a short form consisting of three questions from the somatic scale, three questions from the affective scale, and four questions from the cognitive scale (Mueller et al. 2014). Research has shown good internal consistency for the short form and high concurrent validity with the standard form of the GAS (Mueller et al. 2014). The short form of the GAS appears to be a good measure for use in clinical settings; however, more validation is needed. With more validation, the short form GAS may prove useful in primary care and nursing home settings, as well as with patients with cognitive limitations.

Anxiety-Related Measures

Posttraumatic Stress Disorder (PTSD)

PTSD prevalence rates in those above 60 years old in the general population have ranged from 1.5% to 4% (Acierno et al. 2007). PTSD symptoms can begin at a younger age and persist into older adulthood, or develop in late life. Traumatic life events in the context of aging may include issues related to death and loss, as well as chronic and comorbid medical conditions. Additionally, with

the onset of dementia, PTSD symptoms can develop as the individual undergoes changes impacting their concept of time and distant memories. Studies have also noted that older Veterans with PTSD had a higher risk of developing dementia (Yaffe et al. 2010).

There are different methods to assess for PTSD, however there is no measure developed specific to older adults, and so age-related issues must be conceptualized by the clinician as part of the overall assessment. Most common measurements for PTSD include interviewer-rated and self-report measures.

Interview-rated measures. Common interviewer-rated measures of PTSD include the Structured Clinical Interview for DSM-IV (SCID) PTSD Module and the Clinician Administered PTSD Scale (CAPS). With the recent criteria changes between DSM-IV to DSM-5, modified measures' psychometric properties remain under review, and thus current validated and standard interviewer-rated measures still utilize the criteria of DSM-IV. The most commonly used measures include the PTSD module from the SCID and DSM-IV CAPS (although the CAPS has been updated to correspond to the DSM-5 criteria, studies reviewing the psychometric properties are underway). The SCID is in a structured clinical interview format, with questions corresponding with each criteria of the specific diagnosis of interest. Lifetime and current profiles are assessed. It has adequate reliability and validity (Hyer and Sohnle 2001). The CAPS historically is viewed as the most empirically supported measure for assessing PTSD (Hyer and Sohnle 2001). It is an interview-rated measure that reviews not only the onset of symptoms but also the intensity and frequency of specific PTSD symptoms (Hyer and Sohnle 2001). Psychometric properties of the DSM-IV CAPS have also been found to be adequate in adults, although psychometric data on older adults is limited.

Self-report measures. The PTSD Checklist (PCL) consists of items that correspond directly to that of the criteria as set by the DSM-IV and has different versions. PCL-M is a military version, PCL-S is a nonmilitary version that identifies a specific traumatic event, and PCL-C is for the

general civilian population that does not identify a specific event. Again, a modified version (PCL-5) has been developed to correspond with the DSM-5, but it has yet to undergo validation studies. The PCL items are each rated along a five-point Likert-type scale as an indication of symptom severity (Flack et al. 2002). It is considered to have high reliability and intern consistency, and it correlates strongly with other common measures of PTSD. The Mississippi Scales for PTSD has two versions, a combat related version and civilian. These are 35-item scales that have been highly correlated with other PTSD measures. It has also been extensively studied in the older adult military population and found to be an accurate diagnostic measure (Stanley et al. 1996; Flack et al. 2002). Lastly, the Impact of Event Scale (IES) is another common self-report. A traumatic event is identified, frequency of each symptom is assessed and severity measured along a four-point scale. It is often utilized due to its strong convergent validation (Flack et al. 2002). Most of the outlined self-report measures were developed for the general adult population yet has been used to assess older adults. Although there is limited validation with older adults for most of these self-reports, studies involving the use of the Mississippi Scales for combat related trauma have been found to be adequate for the older adult military population.

Fear of Falling

Fear of falling has been defined as low perceived efficacy or confidence at the ability to avoid or prevent a fall (Tinetti et al. 1990). It has been estimated that one in three older adults falls each year, and that these falls are a leading cause of both fatal and nonfatal injuries in older adults (Tromp et al. 2001). The gold standard in assessing the fear of falls in older adults is the Fall Efficacy Scale (FES). The FES is a ten-item scale that assesses a patient's confidence in their ability to avoid falling while completing nonhazardous activities of daily living (Tinetti et al. 1990). The FES-I, a 16-item scale, has been developed for use with many different languages and in many cultural contexts. The FES-I has shown to have moderate reliability and

construct validity. The Activities-specific Balance Confidence Scale (ABC-16), is a 16-item face-to-face clinician administered interview that does not explicitly measure fear of falling, but instead measures a patient's confidence in their balance when completing 16 specific daily activities (Tromp et al. 2001). The ABC-16 also has a short form, consisting of six of the most feared daily activities from the standard version. Both the ABC-16 and the ABC-6 have shown good internal consistency as well as good sensitivity and specificity (Tromp et al. 2001).

Psychosocial Measures

In addition to psychodiagnostic measures, psychological testing can also obtain information regarding individuals' psychosocial circumstances. There is a wide range of psychosocial measures relevant to the elderly population. A few in particular can be used to help assess pertinent issues such as resiliency, caregiver burden, psychosocial support, health concerns such as fear of falling and sexual functioning.

Resiliency. Resiliency is a concept that could help explain psychological responses in the face of stressors and challenges across the lifespan. There remains the need to develop validated and reliable measures of resiliency in the older adult population. The Resilience Scale is a self-report specifically developed to identify the personality characteristics of resilience in the older adult population, however further validation and reliability studies remain recommended (Resnick and Inguito 2011). The Connor-Davidson Resilience Scale (CD-RISC) is clinical self-report developed to analyze coping styles for stress and includes older adults in its sample population (Windle et al. 2011). Although not specifically developed for older adults, the CD-RISC has empirical support regarding sound psychometric properties.

Caregiver burden. Caregiving can be very demanding and stressful, and as family members become informal caregivers for their aging loved ones, or an elderly individual must care for their aging significant other, caregiver burden or stress is an important issue to assess as it relates to the

health of the caregiver. A review of approximately 28 self-report measures of caregiver burden concludes that the majority of self-report measures have inadequate validity (Deeken et al. 2003). Nonetheless, a widely used measure in aging agencies is the Zarit Burden Interview, which is a caregiver self-report. It has 22 items, in which the caregiver is asked to endorse an item using a five-point scale. However, given poor psychometric properties its utility remains limited (Deeken et al. 2003).

Perceived psychosocial support. Perceived social support is important to assess for in older adult populations, as higher levels of perceived social support are correlated with better physical and mental health, as well as perceived quality of life and positive adaptation to serious life stressors. There are a number of ways to assess for social support, however, it is most often assessed using self-report measures. One of the most common measures used is the Duke Social Support Index (DSSI). This is a 35-item self-report measure that examines social networks, social interactions, subjective support, and instrumental support. Abbreviated versions containing 23 items and 11 items have been created. All versions of the DSSI have shown good reliability and validity with use in older adult populations (Koenig et al. 1993).

Sexual functioning. The sexual function and sexual activity of older adults is an uncommonly researched area, and an area often overlooked by clinicians. There are no formal measures to assess for sexual function in older adults; however Zeiss, Zeiss, and Davies have suggested that best method of assessment is a comprehensive interview with the patient and his or her partner (Zeiss et al. 1999). Zeiss, Zeiss, and Davies have also written semi-structured interviews to assess for sexual quality-of-life and sexual dysfunction (Peretz et al. 2006; Zeiss et al. 1999). Special care should be made when working with patients whose partner may have dementia.

In summary, psychological testing with older adults can be utilized for psychodiagnostic purposes and gathering psychosocial information. Aspects of reliability, validity, and normative data remain important considerations when

choosing appropriate measures for the older adult population and for particular clinical settings. Furthermore, depending on the abilities of the patient and the context of the clinical setting, issues such as ease of use and question response style can be important considerations when choosing the best measure. This section briefly sampled common psychological test measures and reviewed their psychometric properties and normative sample qualities. Cautious interpretation of results should be taken when psychometric properties of the measure are limiting and the normative sample does not incorporate older adults.

Personality Testing

Another aspect of psychological testing includes personality assessment. Often, personality testing is administered through self-report questionnaires. Research studies have identified response pattern profiles, which attempt to profile major personality traits. The common measures described below were developed based on empirical methods. Historically, personality measurements have not been developed specifically for use with an older adult population, but they can be used with this population given the underlying theory that personality traits remain stable throughout adulthood.

Common Personality Measures

Minnesota multiphasic personality inventory-2. The Minnesota Multiphasic Personality Inventory-2 (MMPI-2) is one of the longest standing self-report inventories still being used today. It is a 567-item, self-report inventory, consisting of true-false questions. Originally published in 1943 (MMPI), it underwent a significant revision in 1989 (MMPI-2). The MMPI-2 was standardized on over 2,600 people who represented the makeup of the US Census. Although older adults were included in the sample, older adults over the age of 85 are underrepresented, and therefore, results may be skewed for adults in this age group. The revisions to the MMPI that led to the MMPI-2 were based on a new statistical approach with an updated normative sample. The MMPI-2

measures symptoms and creates profiles accordingly. Unlike some of the other self-report inventories, it is not intended to diagnose disorders based upon the Diagnostic and Statistical Manual of Mental Disorders; rather, it is meant to be a guide for treatment and case conceptualization. Additionally, it must be noted that because the MMPI-2 focuses only on symptoms, issues faced by older adults (e.g., increased health problems, increased physical pain) may result in apparent pathology (Greene 2011). Therefore, physical and health related scale elevations (e.g., Scales 1, 2, and 3) should be considered along with the patient's medical condition and history before making conclusions regarding pathology. The MMPI-2 Restructured Form (MMPI-2-RF) was developed in 2008 (Ben-Porath 2012) and although based on the same normative sample as the MMPI-2, important changes were made in removing significant cross-loading of items throughout the inventory and revising certain scales (PSY-5). Additionally, this most recent version has fewer items 338 items compared to the original MMPI-2 567 items, which would likely make administration easier for older adults who might become cognitively or physically fatigued more easily.

Million clinical multiaxial inventory. The Million Clinical Multiaxial Inventory (MCMI-II) is a relatively short self-report inventory containing 175 true-false questions. It was originally published in 1983 and has been revised several times, with the most recent revision in 1997 (MCMI-III). The MCMI-III was revised to better correlate with DSM-IV diagnoses; however there are some subtle discrepancies in personality disorder conceptualization (Weiner and Greene 2008). The MCMI-III was standardized on a clinical sample (e.g., patients seen in a variety of clinical settings, such as private practice, hospital, forensic, and so on), while most other personality tests were standardized with "normal" samples. The authors of the MCMI suggest that it should only be used on clinical populations, in general, due to the normative samples being of a purely clinical population. Even so, many clinicians still find it useful for use with nonclinical populations.

Personality assessment inventory. The Personality Assessment Inventory (PAI), published in 1991, was standardized with both clinical and normal patient groups, and assesses multiple domains, which are correlated with the DSM-IV. The PAI is a 344 item self-report inventory, with each item rated on a four-point Likert-type scale (ranging from "false, not at all true" to "very true"). The PAI has become more popular due to its ability to be used in a variety of settings, ease of use, and validity.

NEO Personality Inventory-Revised. The NEO Personality Inventory-Revised (NEO PI-R) is based upon the five-factor model of personality, empirically derived general personality factors, which includes the domains of Neuroticism, Extraversion, Openness, Agreeableness, and Conscientiousness. It is a self-report inventory containing 243 items that are rated on a five-point Likert-type scale, which ranges from "Strongly Disagree" (SD) to "Strongly Agree" (SA). This inventory includes a self-report form (Form S) and an observer form (Form R), which should be completed by someone who is very familiar with the person being evaluated. Criticisms of the NEO PI-R have included the fact that it was based on an atheoretical model of psychology and there is no reliable method of assessing validity. Additionally, all items on the evaluation are face-valid, or transparent, and therefore may be easily manipulated to garner a more, or less, favorable profile (Weiner and Greene 2008). The NEO PI-R is less commonly used in the clinical setting, perhaps due the possibility that it can be easily distorted. It is, however, often used in educational, organizational, and research settings. The NEO PI-R was not normed on any particular population, nor does it correlate with any particular diagnoses or psychopathology. However, it may be a useful tool to inform the administrator about more positive aspects of the older examinee, and may aid with treatment planning by understanding the patient's personality dimensions.

Other Personality Tests

Less common measures of personality include the Personality Diagnostic Questionnaire – Fourth

Edition Plus (PDQ 4+) and the Coolidge Axis II Inventory (CATI). PDQ 4+ is a relatively short self-report inventory, which contains 99 true-false items. The PDQ 4+ is based upon the diagnoses from the DSM-IV. It includes two validity scales (“Too Good” and “Suspect Questionnaire” scales). Nonetheless, due to the weak psychometric properties (tendency to give false-positives and weak validity scales), it is best used as a screening measure, rather than a comprehensive assessment. The CATI is a 225-item self-report inventory that is rated on a four-point Likert-type scale, which ranges from “Strongly False” to “Strongly True.” This scale was designed to correspond with the DSM-IV-TR, but also includes some descriptions from the appendices of the DSM-IV-TR and DSM-III (Sadistic and Self-Defeating Personality Disorders; Passive-Aggressive and Depressive Personality Disorders, respectively). The CATI is set apart from other measures because it includes an 18-item neuropsychological dysfunction scale and an informant report, allowing informants to report any observed traits or behaviors that the patient may be unaware of. Additionally, the CATI views personality disorder as dimensional, making it possible to utilize the test for both clinical and normal populations.

Other forms of personality testing include projective measures, which are characterized by the examinee’s responses to ambiguous and unstructured stimuli. The interpretations of these responses are believed to reveal aspects of the examinee’s personality or innermost feelings and beliefs. Common projective personality tests include the Rorschach and the Thematic Apperception Test (TAT). These particular projective measures however were not designed specifically for the older adult population, yet they have been applied to this population nonetheless (Segal et al. 1998). Studies have shown variable results in terms of the validity of these measures for this population. More specialized measures such as the Senior Apperception Test and Geriatric Sentence Completion Form have been developed with what is believed to be more relevant stimuli for the older adult cohort (Segal et al. 1998).

Clinical Considerations in Testing Older Adults

Health Considerations

Various health conditions can impact the accuracy and proper interpretation of psychological testing with older adults. Medical issues related to vision and hearing deficits as well as physical limitations are highly common in the older adult population and can interfere with the administration of the aforementioned test measures (Edelstein et al. 2008; Segal et al. 1998). Thus, it is often necessary to provide or inquire about accommodations that will allow older adults to properly respond to questionnaires, including larger size font for questionnaires or assistive hearing devices.

Additionally, a medical workup is highly recommended to rule out medical conditions that can impact mood. Medical and laboratory workup is important when assessing older adults given the increased likelihood of comorbid medical illnesses that can also influence psychological conditions. For instance, thyroid dysfunction is known to impact mood, wherein hypothyroidism can cause depressive symptoms; hyperthyroidism can cause anxiety symptoms (Thakur and Doraiswamy 2009). Furthermore, as previously mentioned, it remains important to note the difficulties of distinguishing between somatic symptoms related to mood and comorbid medical illnesses as well as the tendency of older adults to report somatic complaints compared to affective symptoms (Edelstein et al. 2008).

Cognitive Impairment

Cognitive functioning in older adults is another clinically significant factor that impacts psychological testing. As one ages, the vulnerability for dementia can impact cognition and judgment and thus responses to psychological test measures. The current DSM-5 refers to cognitive disorders as neurocognitive impairments, and further delineates between minor and major severity. Dementia, a syndrome of cognitive and functional impairments, is subsumed under this diagnosis.

Dementia can be assessed through cognitive screens and neuropsychological evaluations, of which cognitive functioning across multiple domains is assessed along with impairments in managing activities of daily living (Segal et al. 1998). By assessing cognitive abilities, decisions on what psychological test measures would be most helpful for treatment planning purposes.

Cultural Factors

Cultural factors are also important to note with regards to psychological testing. Education level and specifically reading level would impact the patient's ability to read and possibly understand the questions from the test measures. Depending on the historical context in which the older adult was born, older patients might have a range of reading and educational experiences. Clinicians may have to rephrase questions so that some older patients can comprehend what is being asked (Segal et al. 1998). Also, based on the qualities of the normative sample, education level of the normative sample may be significantly different than the patient assessed. Furthermore, the cultural background of the older patient can impact the validity of the test itself. For instance, if English is not the primary language or the patient is of a certain ethnic background, its compatibility with the respective normative sample would be questionable. The common measures as outlined may not be reflective of different ethnicities and thus the generalizability of the measures should be with caution.

Conclusion

With increased rates of older adults seeking medical services and the move toward integrated health care settings that include a team of medical and mental health providers, mental health services may witness an influx of older adults. Psychological disorders in the aging population can develop in later in life or may be long-standing chronic conditions. Nonetheless, psychological testing with the aging population is an essential

aspect of a full evaluation and can be helpful in quantifying and monitoring behavioral symptoms. Furthermore, personality testing can help identify key character traits that can aid intervention approaches and treatment planning. This section reviewed common clinical disorders as well as test measures that often used and considered suitable for working with older adults. As noted by the brief sampling of measures, close examination of the psychometric properties is important to ensure the appropriateness of the test measure. However, special accommodations and cautious interpretation of results may be warranted despite measures developed specific to older adults given possible medical conditions, cognitive limitations, and cultural background that may impact the test results.

Definition

“Psychological aspects of diabetes” refers to the psychological aspects that should be considered when providing care or treatment to an older person with diabetes mellitus. Throughout this chapter, the term “psychological” relates to an individual’s thoughts, emotions, feelings, and ability to cope with their environment or medical condition. Additionally, “diabetes” refers to a group of metabolic diseases characterized by hyperglycemia resulting from defects in insulin secretion, insulin action, or both (American Diabetes Association 2015).

Introduction

Diabetes mellitus (DM) is among the most common noncommunicable diseases globally, and the number of DM cases is rising in every country (International Diabetes Federation 2013a). The prevalence of diagnosed and undiagnosed DM has consistently been shown to increase with age up to 80–85 years, after which time a plateau or slight decrease is commonly observed. Estimates from the USA indicate that within the age groups 70–74, 75–79, 80–84, and ≥ 85 years, the prevalence of DM was shown to be 20%, 21.1%, 20.2%, and 17.3% respectively (McBean et al. 2004). In China, similar increases in prevalence have also been found. For the age groups 40–49, 50–59, 60–69, and ≥ 70 years, the prevalence of DM in 2013 was 11.3%, 17.6%, 22.5%, and 23.5%, respectively (Xu et al. 2013). The burden of DM among older adults is expected to grow substantially in the coming years alongside global population aging.

There are two major categories of DM relevant for the older adult: type 1 diabetes mellitus (T1DM) and type 2 diabetes mellitus (T2DM). Although T1DM is present in older populations, T2DM is the most prevalent form of DM, accounting for approximately 90–95% of all DM cases (American Diabetes Association 2015). As such, the DM category of interest throughout this chapter will be T2DM.

The primary aim of T2DM management for functionally independent older adults is to maintain blood glucose, blood pressure, and cholesterol levels within normal ranges in order to prevent or delay T2DM-related complications (Association to American Diabetes Association 2015; International Diabetes Federation 2013b). Considerable emphasis has typically been placed on the prevention of acute and vascular complications associated with T2DM, but it is now well established that older adults with T2DM have a higher prevalence of clinical and subclinical levels of mental health disorders compared to the general population. Additionally, individuals are likely to exhibit psychological vulnerability upon diagnosis, when their medical status changes, when the need for intensified treatment (e.g.,

insulin) is apparent, and when physical complications are identified (American Diabetes Association 2015). Throughout this chapter, the most salient psychological problems associated with T2DM among older adults will be examined.

Psychological Comorbidities Associated with Type 2 Diabetes Mellitus

Depression

Depression is a common mental disorder, characterized by sadness, loss of interest or pleasure, feelings of guilt or low self-worth, disturbed sleep or appetite, feelings of tiredness, and poor concentration. According to the Diagnostic and Statistical Manual of Mental Disorders-5 (DSM-5), an individual can be diagnosed with major depressive disorder (MDD) when five or more of the symptoms listed in Box 1 have been present for the majority of days within the same two-week period and at least one of the symptoms is depressed mood or loss of interest or pleasure. These symptoms must also cause clinically significant distress or impairment in functioning and may not be attributable to the physiological effects of a substance or to another medical condition (American Psychiatric Association 2013). Among individuals with T2DM, the distinction between the physical symptoms of T2DM and those attributed to the diagnostic criteria of MDD (such as weight change, fatigue, etc.) can be difficult for health professionals. This poses significant challenges to detection and diagnosis of clinical and subclinical levels of depression.

Box 1: Associated Symptoms of Major Depressive Disorder

- Depressed mood most of the day, nearly every day, as indicated by either subjective report (e.g., feels sad or empty) or observation made by others (e.g., appears tearful)
- Markedly diminished interest or pleasure in all, or almost all, activities most of the

(continued)

day, nearly every day (as indicated by either subjective account or observation made by others)

- Significant weight loss when not dieting or weight gain (e.g., a change of more than 5% of body weight in a month) or decrease or increase in appetite nearly every day
- Insomnia or hypersomnia nearly every day
- Psychomotor agitation or retardation nearly every day (observable by others, not merely subjective feelings of restlessness or being slowed down)
- Fatigue or loss of energy nearly every day
- Feelings of worthlessness or excessive or inappropriate guilt (which may be delusional) nearly every day (not merely self-reproach or guilt about being sick)
- Diminished ability to think or concentrate, or indecisiveness, nearly every day (either by subjective account or as observed by others)
- Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide

Adapted from the American Psychiatric Association (2013)

Prevalence rates of MDD among older people are relatively low (1–3%) compared to younger age groups (~15%); however, much larger numbers of older people experience clinically significant depressive symptoms (8–27%) (Nouwen and Oyeboode 2009). Despite often falling short of the diagnostic threshold for MDD, studies have indicated that older adults with clinically significant depressive symptoms have a comparable disease burden with regard to functional impairment, poorer health outcomes, as well as increased health-care expenditure and utilization (Park and Reynolds 2015).

Elevated depressive symptoms and MDD are also common among individuals with T2DM, and prevalence rates have been estimated to be twice that of the general population. These estimates have largely been based on adults with T2DM as the majority of research has not specifically targeted older samples (Poulsen and Pachana 2012). A limited number of studies have examined the incidence of depression in older adults with T2DM; however, findings have been mixed. Although some studies have identified an increased risk of up to 30% in the incidence of depressive disorder and depressed mood in older people with T2DM, other studies did not support these findings. Where studies did observe an increase in incidence, older adults with inadequate glycemic control ($HbA1c \geq 8.1\%$) were found to have the highest risk of developing recurrent depressive symptoms (Nouwen and Oyeboode 2009).

A multitude of risk factors have been identified that increase the likelihood of developing depression in later life. Consistent with those observed in younger age groups, being female, unmarried, of low socioeconomic status, and/or socially or geographically isolated are relevant for the older population. A previous diagnosis (or family history) of depression, as well as the presence of a chronic condition (e.g., T2DM), can also enhance an individual's risk. Specific risk factors that are considered particularly important for older adults include bereavement, loss of certain roles, caregiver burden, a fall event, family conflict, limited social networks, and/or those living in residential or nursing homes. Conversely, strong social support, religious participation, spirituality, as well as partaking in social activities have been shown to decrease depression risk. For older individuals classified as medically ill, the risk of depression is also higher among individuals with cognitive impairment, active alcohol dependence, lower educational attainment, and those of advanced age (>75 years) (Nouwen and Oyeboode 2009; Park and Reynolds 2015).

Previous research has demonstrated a link between depression and T2DM-related outcomes

such as regimen adherence, health-related quality of life, glycemic control, T2DM-related complications, health-care costs, and mortality (Nouwen and Oyeboode 2009; Park and Reynolds 2015). Increases in depressive symptom severity scores have also been found to be incrementally associated with decreases in T2DM self-care behaviors, including lower adherence to general diet, physical activity recommendations, self-monitoring of blood glucose, and prescribed medications (Nouwen and Oyeboode 2009).

The early identification of depression among older adults with T2DM should be prioritized given the increased potential for this population group to experience depressive symptoms and the negative consequences associated with such comorbidity. While a number of scales assessing depression exist for use in the general adult population (i.e., Center for Epidemiological Studies Depression (CES-D) scale, Beck Depression Inventory (BDI)), one of the most widely used measures for older adults is the Geriatric Depression Scale (GDS). Both the 30-item GDS and its shorter 15-item scale have been found to have good internal consistency, and scores correlate highly with clinical diagnoses of depression. Four-item versions of the GDS scale are also available that are reasonably accurate and are particularly suitable for use within routine clinical consultations. For older adults with dementia, however, the Cornell Scale for Depression in Dementia (CSDD) is better suited than the GDS (Nouwen and Oyeboode 2009).

Anxiety

Anxiety disorders encompass a suite of mental disorders that share features of excessive fear and anxiety and related behavioral disturbances. Generalized anxiety disorder (GAD) appears to be the most common anxiety disorder among both older adults and individuals with T2DM. However, within both of these patient groups, anxiety disorders have received much less research attention compared to depression or dementia (Poulsen and Pachana 2012). According to the DSM-5, an individual can be diagnosed with GAD when they have experienced at least

six months of excessive and uncontrollable worry, as well as three or more of the symptoms listed in Box 2 for the majority of days within the same six-month period. These symptoms must also cause clinically significant distress or impairment in functioning, may not be attributable to the physiological effects of a substance or to another medical condition, and should not be better explained by another mental disorder (Nouwen and Oyeboode 2009). Similar to that noted for depression, distinguishing between the physiological effects of T2DM and the symptoms associated with GAD is often complicated.

Box 2: Associated Symptoms of Generalized Anxiety Disorder

- Restlessness or feeling keyed up or on edge
- Being easily fatigued
- Difficulty concentrating or mind going blank
- Irritability
- Muscle tension
- Sleep disturbance (difficulty falling or staying asleep, or restless, and unsatisfying sleep)

Adapted from the American Psychiatric Association (2013)

Studies comparing the prevalence rates for GAD among different age groups generally report a decline in prevalence with age. For example, previous research comparing GAD prevalence across the lifespan have found for the age groups 45–64 and ≥ 65 years; the 12-month prevalence of GAD ranged between 3.2–4.2% and 1.0–2.3%, respectively (Wolitzky-Taylor et al. 2010). However, rates of clinically significant symptoms of anxiety are much higher in older populations (15–20%), and among older individuals with a disability or chronic medical condition, prevalence rates have been reported to be $>40\%$ (Tampi and Tampi 2014). It is also well

established that among older adults, anxiety often co-occurs with other mental disorders, particularly depression (Wolitzky-Taylor et al. 2010).

While the majority of anxiety research has not specifically focused on older adults with T2DM, substantially higher rates of GAD (14%) have been reported for adults with T2DM when compared to the general population (3–4%) (Poulsen and Pachana 2012; Gonzalez et al. 2011). Adults with T2DM have also been found to have higher rates of clinically significant symptoms of anxiety (40%), and not surprisingly, these rates are similar to that observed for older adults with a disability/chronic condition (Poulsen and Pachana 2012). Even at subclinical levels, individuals with T2DM who experience anxiety are more likely to develop T2DM-related emotional distress (i.e., worries about long-term complications, burnout symptoms, and anxiety when self-management problems occur). Consequences of such distress have been associated with reduced glycemic control, increased T2DM-related complications, greater disability, and reduced quality of life (even after adjusting for the effects of comorbid depression) (Poulsen and Pachana 2012; Gonzalez et al. 2011).

A number of risk factors have been associated with an increased likelihood of having an anxiety disorder in late age. Many of these risks are consistent with that observed for depression and include being female, unmarried, of low educational attainment, and having multiple chronic conditions. Stressful life events, impaired subjective health, physical limitations in daily activities, concerns about personal safety, adverse events in childhood, and neuroticism are additionally pertinent for anxiety (Wolitzky-Taylor et al. 2010). Individuals who are taking insulin to control their blood glucose levels have also been associated with increased levels of anxiety, which is predominantly attributed to fear of hypoglycemia. Certain aspects of the T2DM self-care regimen, such as frequent self-monitoring of blood glucose, may also exacerbate anxiety symptoms (Gonzalez et al. 2011).

Although older adults with a chronic condition (including T2DM) commonly experience anxiety, GAD and elevated anxiety symptoms frequently remain unrecognized and untreated. Health professionals need to be alert to the aforementioned risks

and symptoms of anxiety among older adults with T2DM. Where there is heightened potential for elevated symptoms of anxiety, adequate assessments should be performed. A vast number of screening and assessment scales have been utilized in adults with T2DM (e.g., Generalized Anxiety Disorder (GAD-7) scale, Beck Anxiety Inventory (BAI)); however, the Geriatric Anxiety Inventory (GAI) is a 20-item measure that has specifically been designed for use within older populations. The GAI has been validated in a range of older populations and has performed well psychometrically (Poulsen and Pachana 2012).

Psychiatric and Other Psychological Disorders

Relative to anxiety and depression, psychiatric and other psychological disorders (i.e., eating disorders and substance use disorders) are not frequently observed among older adults with T2DM. While an in-depth discussion of these additional disorders is outside the scope of this chapter, the consequences of these comorbid disorders can be substantial and therefore warrant brief mention.

There is an increased prevalence of T2DM among individuals with major psychiatric disorders such as bipolar disorder and schizophrenia. Rates of T2DM are more prominent among younger individuals with schizophrenia, but individuals with bipolar disorder and comorbid T2DM tend to be older. Screening for T2DM should be performed for older adults with psychiatric disorders. Following diagnosis of T2DM, adherence to components of the T2DM self-care should be adequately assessed. Obesity, physical inactivity, smoking, poor treatment adherence, and reduced diet quality frequently occur among individuals with psychiatric disorders. All of these factors have the potential to increase T2DM-related complications and reduce quality of life (Gonzalez et al. 2011).

When present, eating disorders and substance use disorders among older adults with T2DM have the potential to reduce adherence to the T2DM self-care regimen and increase the likelihood of acute and long-term complications. As such, the screening and assessment of these

additional psychological disorders should be routinely performed as part of standard T2DM care.

Evidence-Based Treatment

The current evidence base supports the use of both psychological and pharmacological approaches for the treatment of depression among individuals. These studies have predominantly included samples of adults with T2DM, and consequently, it is not yet clear which approaches are most effective for older adults. Additionally, studies investigating the effects of psychological and/or pharmacological interventions for the treatment of anxiety disorders are largely missing for individuals with T2DM (adults and older adults). Despite this lack of evidence, a vast number of self-management interventions have been implemented over the last two decades that have aimed to enhance adherence to the T2DM self-care regimen and prevent or delay T2DM-related complications. These interventions can broadly be classified as largely having an educational or psychological basis.

Diabetes Self-Management Education for Type 2 Diabetes Mellitus

A large portion of the T2DM self-management interventions that have been published to date are based on diabetes self-management education (DSME) principles. DSME refers to “the ongoing process of facilitating the knowledge, skill, and ability necessary for diabetes self-care...The overall objectives of DSME are to support informed decision making, self-care behaviours, problem solving, and active collaboration with the health-care team to improve clinical outcomes, health status, and quality of life in a cost-effective manner” (Association to American Diabetes 2015). DSME interventions range from didactic lectures through to interventions that require individual participation (e.g., problem-solving, goal setting) and collaboration (e.g., cooking classes and walking groups) and are delivered in both individual and group formats. Current best

practice of DSME is a skill-based approach that focuses on empowering and assisting individuals with T2DM in making informed self-management choices (Association to American Diabetes 2015).

The effectiveness of DSME in the management of T2DM have been assessed, and three widely cited meta-analyses have concluded that DSME training has short-term (<6 months) positive effects on knowledge, frequency, and accuracy of SMBG, self-reported dietary habits, and glycaemic control (Norris et al. 2001, 2002). However, these observed benefits declined between 1 and 3 months post-intervention (Norris et al. 2002). The efficacy of delivery mode (individual/group format) was also assessed in subsequent reviews (Duke et al. 2009; Deakin et al. 2005; Steinsbekk et al. 2012). For group-based DSME programs, significant improvements were found for glycaemic control, DM knowledge, blood glucose concentration, and body weight in both the short (4–6 months) and long term (12–24 months) (Deakin et al. 2005; Steinsbekk et al. 2012). Significant improvements were also observed for self-management skills and self-efficacy at 6 months (Steinsbekk et al. 2012). In contrast, individual education programs (compared with usual care) were only found to be effective for glycaemic control in individuals with inadequate glycaemic control ($HbA1c \geq 8\%$) (Duke et al. 2009). Despite the positive associations observed within these reviews, the number of included studies for some of these analyses was small (two to four), particularly for outcomes assessed at 24 months and for measures of self-efficacy and self-management skills. The active ingredients of DSME interventions were also not able to be determined by these reviews due to large variety in program content across included studies.

Evidence-based guidelines endorse the periodic assessment of an individual’s self-management knowledge and skills, yet the majority additionally recommend the incorporation of behavioral strategies and psychological interventions into routine care, as well as the routine assessment of psychosocial factors (Association to American Diabetes 2015). Previous reviews of DSME interventions have also called for further research that better defines effective interventions for sustaining

behavior change and maintaining long-term glyce-mic control in individuals with T2DM. It has been suggested that these interventions should focus on identifying the predictors and correlates of glyce-mic control (particularly psychological attributes such as depression) (Norris et al. 2001, 2002).

Psychological Interventions for Type 2 Diabetes Mellitus

In contrast to DSME interventions which aim to improve DM-related knowledge and skills among individuals with T2DM, psychological interven-tions “use the therapeutic alliance between the patient and the therapist to bring about change in emotional, cognitive, and behavioural function-ing, including adherence” (Ismail et al. 2004). The term “psychological interventions” is a broad one and encompasses a wide range of tech-niques that can be delivered in both individual and group formats, including supportive or counseling therapy (i.e., nondirective counseling/client-centered therapy), motivational interviewing (MI), brief psychodynamic therapy, interpersonal psychotherapy, and cognitive behavior therapy (CBT), and its associated techniques including contract setting, goal setting, problem-solving, activity scheduling, stress management, and relaxation (Alam et al. 2009).

The efficacy of psychological interventions on T2DM-related outcomes has been assessed in two widely cited meta-analyses (Ismail et al. 2004; Alam et al. 2009). Ismail and colleagues (Ismail et al. 2004) identified 25 clinical trials for inclu-sion in their review (twelve of which assessed glycated hemoglobin, eight assessed blood glu-cose concentration, nine assessed body weight, and five assessed psychological status). The majority of the clinical trials ($k = 21$) utilized CBT or its associated techniques, four utilized counseling techniques, and no trials were identi-fied that used either a psychodynamic or interper-sonal model of therapy. This review found significant associations between psychological interventions and glycated hemoglobin and psy-chological status; however, blood glucose

concentration and body weight were not signifi-cant. Of particular clinical significance was the reduction in glycated hemoglobin, which resulted in an absolute decrease of 0.76% HbA1c. Addi-tionally, when studies were excluded from analy-sis in which the control condition was a less intensive psychological therapy, a difference of 1.00% in HbA1c was observed. This finding is similar to that of the landmark United Kingdom Prospective Diabetes Study (UKPDS) which uti-lized pharmacological therapies, indicating that psychological interventions are as effective as pharmacological therapies in reducing glycated hemoglobin.

As a follow-up to the 2004 review, Alam and colleagues (Alam et al. 2009) utilized the original 2004 review protocol and additionally compared the effects of psychological interventions when delivered by generalist clinicians compared to psychological specialists. In addition to the origi-nal 25 clinical trials, a further 10 clinical trials were identified for inclusion in the updated review ($k = 7$ glycated hemoglobin, $k = 5$ psychological status). Consistent with the original review, the majority of the ten studies utilized CBT or its associated techniques ($k = 7$), two trials utilized counseling techniques, and one trial used psycho-dynamic therapy. With regard to psychological status, the meta-analysis of 13 trials found statisti-cally significant improvements favoring the intervention -0.56 (95% CI, -1.00 to -0.13).

The abovementioned meta-analyses have dem-onstrated that psychological interventions are effective in improving glycemic control and psy-chological status; however, the type of therapy that is most effective and the subgroups of patients most likely to benefit are not yet clear. The major-ity of included studies within previous reviews have utilized CBT or its associated techniques, and there is a pressing need for studies to be conducted that utilize additional psychotherapies (e.g., MI). This would allow for meta-analyses to be conducted for each of the specific therapeutic types rather than grouping psychological inter-ventions as a whole. Additionally, previous reviews have combined depression, anxiety, well-being, and quality of life into one outcome.

As a result, the differential effect of psychological interventions on each psychological outcome has not previously been noted.

Conclusion

Clinically significant symptoms of depression and/or anxiety are common among older adults and among individuals with T2DM. Although the majority of research has not specifically focused on older adults with T2DM, a multitude of risk factors place this population group at increased psychological risk. The negative consequences associated with comorbid depression and/or anxiety necessitate the routine screening and assessment of these disorders among older adults with T2DM. The GDS and the GAI are valid and reliable measures that have been specifically designed for use within older populations. Additionally, psychological interventions are promising tools for the improvement of T2DM-related outcomes; however, their effectiveness within older populations needs to be established.

Psychological Interventions in Long Term Care settings

Victor Molinari and Michelle L. Ellis
School of Aging Studies, University of South
Florida, Tampa, FL, USA

Synonyms

Role of geropsychology in long-term care; State of mental health in long-term care

Definition

Long-term care may be defined as care for frail older adults with chronic medical or psychological problems. This entry will discuss the various mental health conditions that a geropsychologist must treat in long-term care settings and then discuss the important role geropsychologists play in integrated care, flourishing of residents, and staff and professional training. A focus on services provided by geropsychologists in institutional long-term care settings will be made, but it should be noted that in the USA and worldwide, more long-term care is delivered in home settings. The principles of assessment, intervention, and consultation underlying long-term care for frail older adults in institutional settings can easily be transferred to services delivered in the community.

Long-Term Care Settings and the Aging Population

Although aging demographics and worldwide increases in longevity have been known for many years (WHO 2001), many countries have not adequately prepared. Over the next century, the 30 oldest countries in the world will reside in Europe, with the oldest country in the world, Japan, remaining an outlier. The USA, in comparison, will continue to feel the effects of the baby boomers transitioning into late age until 2050

(Laidlaw and Pachana 2009). The predicted growth of those 80 years and older is a global concern as the oldest old will increase the demand for care and social resources in both community and institutional settings. Some countries are aging faster than others, but all are dealing with the important public health issues of caring for those who cannot care for themselves (Vongxaiburana et al. 2014).

Nursing homes and assisted care facilities have a high proportion of residents with significant mental health problems. More than half of all nursing home residents have cognitive impairment and half of these have significant behavior problems (Magaziner et al. 2000). Despite the Preadmission Screening and Resident Review (PASRR) process as mandated by the Omnibus Budget Reconciliation Act (OBRA) to triage those with serious mental illness (SMI) to the least restrictive environment, approximately 10% of nursing home residents in Florida have SMI. However, there is significant variability across the USA regarding these rates depending upon narrow or wide definitions of SMI (Grabowski et al. 2009). Many nursing home residents are reeling from the psychological sequelae of medical problems causing impairments in daily living necessitating institutional care. Adjustment disorders with depressed and/or anxious mood are thereby quite common. Other individuals with long-standing exaggerated characterological traits may be admitted to nursing homes due to deaths or aging stressors because they have worn out already strained social supports and no one is available to take care of them in a community setting. In the USA, assisted living facilities also admit a high proportion of individuals with dementia and psychiatric problems, with less than optimal rates of recognition and treatment (Rosenblatt et al. 2004). Compared to the medical model of care that has traditionally guided nursing home culture, assisted living facilities operate under a service care model, resulting in even less qualified staff to tend to the wide-range of resident conditions. Indeed, long-term care settings can be considered psychiatric institutions without the trained staff to effectively and humanely deal with the residents living in them.

Treatment of Patients with Severe Mental Illness in Long-Term Care

Those with SMI are often admitted to nursing homes without a primary mental health diagnosis and without a full PASRR diagnostic screening. In contrast to those with SMI living in the community, individuals in nursing homes with SMI have great functional impairment and symptom burden (Bartels et al. 2003). These individuals are often feared by the nursing home staff because they tend to be male and younger than the typical nursing home resident, with particular concern over aggressive behavior toward feeble women. SMI residents often do not “fit in” with the other nursing home residents, and activities are less geared to meet their needs. Nursing home aides may have a tough time discriminating between a resident with dementia and one with SMI, and thereby they may have low expectations regarding improvement or stabilization in status over time for those with SMI. It should be noted that mental health professionals have been unduly pessimistic about the outcomes for older adults with SMI and that improved quality of life may be achieved in a variety of settings with the proper environmental modifications and staff training. Geropsychologists should be guided in their assessment and treatment decisions by the recovery movement principles of self-direction, empowerment, not being defined by the limitations of one’s illness, and living in the least restrictive environment so that those with SMI manage their life choices as much as possible and are engaged in meaningful life activities.

Dementia in Long-Term Care Services

Caring for persons with dementia will be of national and international concern as the prevalence of dementia rises worldwide from 35.6 million in 2010 to 115.4 million in 2050, with the highest growth of cases in low- to middle-income countries with less established long-term care services (Alzheimer’s Disease International 2013). Still developing regions rely on informal caregiving systems that can benefit from many

of the strategies and frameworks put forth to improve care in nursing homes and institutional settings.

Lawton and Nahemow (1973) promoted the idea of a person-environment match to enhance quality of life for residents with dementia through an ecological gerontology. Nursing home residents are often at different stages of cognitive impairment, and person-centered care guides the geropsychology professional working in long-term settings to individualize care and provide supportive services commensurate with (but not more than) the needs of the individual. It is now recognized that a person-centered assessment approach which honors the client as the main focus of the evaluation and emphasizes strengths as well as weaknesses will yield the maximal information to assist with intervention decisions based on a choice of these models.

There are a variety of conceptual models to guide a geropsychologist when trying to manage the behavioral problems that may arise during the course of dementia. The most fundamental learning-based framework is the antecedent-behavior-consequences model (A-B-C approach). After describing a particular disruptive behavior, geropsychologists must determine what occurs before and after in order to define and change reinforcement contingencies. Kunik et al. (2003) identified mutative and non-mutative factors that are related to behavior problems and emphasize the need for a thorough assessment of the mutative variables such as depression, psychosis, pain, delirium, anxiety, etc. Volicer et al. (2007) view non-aggressive agitation as caused by understimulation and lack of engagement in meaningful activities. On the other hand, aggression is caused by poor caregiver technique such as rushing the person with dementia and not communicating with the person in a clear fashion. Algase et al. (1996) understand disruptive behavior as being caused by an “unmet need”; the job of mental health professionals in long-term care settings is to identify the need and organize the system to satisfy the need. All of these models may be viewed as complementary and not mutually exclusive. The role of the geropsychologist is to choose between these options on the basis of

which yields the most appropriate and viable interventions fitting particular residents.

There are a variety of studies documenting the effectiveness of behaviorally based psychological methods to reduce the problem associated with dementia and to help them engage in more prosocial attitudes. However, it should be emphasized that the existence of evidence-based interventions alone is not sufficient and that systemic change is necessary for an overall program to be sustained over time. For example, it has long been known of the necessity of “buy-in” from the administration to maintain ongoing training to uphold behavioral programs (Burgio and Burgio 1990). Making use of learning chunks and principles of immediate differential reinforcement, Camp et al. (2002) document many innovative strategies that mental health professionals can use to prompt residents to engage in more prosocial activities. In one recent large randomized controlled trial study that took place in a variety of Veterans Affairs sites across the USA, a combination of meaningful activities, teaching nursing aides improved communication skills, and the A-B-C approach produced statistically and clinically significant improvements in resident behavior (Karlin et al. 2014).

Treatment of Patients with Adjustment Disorders (Anxiety, Depression)

In the recent years, there has been a growth in the evidence base for the treatment of depression and anxiety, often caused by difficulties in adjustment to long-term care settings. Cognitive behavioral therapy (CBT) is one such evidence-based strategy for use in the treatment of depression in older adults, as well as a variety of other psychological problems across the lifespan (Gallagher-Thompson et al. 2008), but needs to be modified for frail older adults. There is an accumulating body of knowledge that such CBT adaptations work and that treatment of depression may also yield benefits in self-esteem and functional abilities, although it is unclear how long such effects last. Another intervention that has been used to decrease depressive symptoms in long-term care

residents with depression is reminiscence. Haight et al. (2000) conducted a study of 52 newly admitted nursing home residents who were not severely cognitively impaired and who received a life review intervention. The authors found reductions in depression and improvements in quality of life and self-esteem that maintained for 3 years.

Research on the treatment of anxiety disorders in long-term care settings has lagged behind research on depression, even though anxiety disorders often co-occur with physical and psychiatric conditions such as depression. It should be noted that in general the treatment of anxiety in community-dwelling older adults has yielded somewhat disappointing outcomes in terms of effect sizes compared with younger adults. Nonetheless, evidence-based interventions that have been used with some success for older adults in community settings may be altered for implementation in long-term care settings. Creative non-pharmacological strategies such as mindfulness, commitment therapy, and spirituality are currently being piloted with older adults and may then be modified for use in long-term care.

Existing chronic conditions in addition to normal, age-related declines in sensory systems may impair the identification of adjustment disorders. Left undetected or untreated, adjustment disorders can exacerbate comorbid medical or psychiatric conditions, extend recovery time, and increase risk for mortality (Prince et al. 2007). Successful treatment of depression and anxiety through a combination of non-pharmacological and pharmacological interventions suited to the needs of the infirm individual will reduce disease burden and improve quality of life.

Residents with Personality Disorders

Residents with personality disorder (PD) are frequently brought to the attention of nursing home staff. Lifelong behavioral patterns that grate on others may be further exacerbated in a communal living situation which the individual with PD often feels was involuntarily imposed and unnecessary. Those with Cluster B PDs (i.e., borderline, antisocial, histrionic, narcissistic) have particular

difficulties in these settings where long-suffering spouses or relatives no longer buffer their impulsive, self-indulgent personality styles. Geropsychologists may be forced to generate treatment options that take into account the limited strengths of their overall personality profile and must model a way of engaging with the resident in a respectful manner without endorsing their disagreeable behaviors. They must work closely with the rest of the treatment team to coordinate plans of care and prevent the splitting which transforms staff members into adversaries rather than collaborators in providing consistent care. However, those with Cluster A (schizoid, schizotypal, paranoid) PDs stay to themselves and may become reclusive. Although such isolation may not cause problems for the staff and other residents, it could maintain a low quality of life for the resident if active attempts are not made to engage with the resident. It should be mentioned that Cluster C dependent PDs may do well in the hierarchical environment of the nursing home where they can easily find some staff member willing to tell them what to do. One other note regarding PDs in long-term care settings is that geropsychologists must use their expertise in assessment to determine when psychiatric symptoms are exacerbating premorbid personality traits. In these cases, protocols that address both symptoms and interpersonal styles should be recommended.

There is little controlled research on the treatment of PDs in long-term care, but dialectical behavior therapy and schema therapy, which address a PD person's core beliefs about oneself, relationships, and the world, hold promise for the treatment of older adults with PD in community settings and may be adapted for use in institutional settings for those with significant cognitive impairment.

Interdisciplinary Treatment Teams

Although it has been known clinically for many years, a growing science now supports integrated care, suggesting that the coordination of care in interdisciplinary settings is especially effective for older adults. Countries where the long-term care

continuum is still developing should establish coordinated care systems throughout the formal and informal network that encourage an interdisciplinary team-based approach. This affords these countries an opportunity to set interdisciplinary treatment teams as the standard for care practices, avoiding any resistance that may occur when incorporating treatment teams into existing health-care systems. Bartels et al. (2002) maintain that a multidisciplinary team approach with a psychiatrist integrated into the team framework (combining education of staff and consultation with residents) trumps a traditional consultative model. In like manner, as a member of an integrated team, geropsychologists must be aware of the roles of the other team members, respect the professional activities of the other disciplines, and yet also provide the psychological specific aspects of care. For example, responding to a national Centers for Medicare and Medicaid Services (US government-sponsored health programs) initiative to reduce antipsychotic medications in nursing homes, geropsychologists are now working with geriatricians, pharmacists, nurse practitioners, and social workers to achieve this worthy goal. This initiative requires a coordinated effort from a variety of disciplines, but geropsychologists have a specific role to play to educate other professionals, particularly long-term care staff, regarding how to implement learning principle-based psychological protocols to reduce the behavior problems that so often trigger the prescription of psychoactive medications.

Flourishing: Quality of Life in Long-Term Care

Long-term care settings frequently stir negative images of aging and of dying without proper care. However, it is important to realize that there are many long-term care geropsychologists who believe that humans are very adaptable and can have a good quality of life at any developmental stage given the proper environmental support. Individuals who endorse the Pioneer Network philosophy adhere to the idea that those with dementia should always be accorded respect and

be allowed to make decisions consistent with their own unique pattern of abilities and interests (Fagan 2003). The Eden Alternative philosophy promotes a person-centered positive relational environment to counter the “three scourges of loneliness, boredom and meaningfulness” (Thomas 1994). In recent years, “small houses” have been built that further humanize the environment and allow more of a homelike atmosphere where the boundaries are further broken down between resident and formal caregivers. Kane et al. (2007) evaluated these programs and find that they do promote better care and better quality of life, although the specific ingredients of “edenization” that are core components of successful outcomes have not yet been identified.

Training in Long-Term Care

As experts on mental health care in the long-term care setting, geropsychologists must spend time educating nursing home staff about the psychological needs of residents and particularly how to prevent mental health problems. Nursing aides are the least educated nursing home staff, yet spend more time with the residents than any other staff members. There are a number of excellent online programs that can help train nursing home staff to address the psychological needs of residents with dementia, and geropsychologists can play a role in moderating discussions of the content of these programs as well as consulting with difficult “live” cases. They will need to supplement this material on dementia with presentations on SMI, depression, anxiety, PD, etc., to satisfy hardworking and motivated administrators and staff who try to “do the right thing” and yearn for more knowledge in these areas.

Perhaps an even more important issue is the lack of geropsychology training in psychology graduate school programs and specifically regarding mental health in long-term care. Standards of practice for long-term care psychological services have been published, and there are a number of books and edited volumes in this area. However, many psychiatrists providing services in long-term care settings may not be aware of the growing evidence base in this area, especially if they have

not taken formal coursework in graduate school or supervised externship, internship, or fellowship practice in long-term care. Psychologists in Long-Term Care (PLTC) is a group of psychologists who provide services, do training, and conduct research in long-term care settings. This organization is a wonderful resource with an active LISTSERV that serves all those who work in long-term care. Unfortunately, a well-defined set of competencies in long-term care has not been delineated from basic geropsychology competencies. Such an examination sponsored by PLTC is now in process and may set the stage for psychologists without formal long-term care training to recognize their strengths and weaknesses so that continuing education credits or supervised consultation can target and remedy deficits. In this way, geropsychologists will be able to deliver state of the art assessment and intervention services to this most vulnerable population.

Definition

The construct of successful aging has found a number of definitional efforts. In the most established ones, high physical and mental functioning, low risk for disease and functional loss, high engagement with life, and high well-being are emphasized.

Successful Aging and Psychological Aging: Historical Context

The vision to develop successfully lies at the heart of lifespan developmental psychology and

developmental science at large. Successful development in early life and across the first half of life, particularly early adulthood, has been a major target of theory construction and empirical research in developmental psychology. However, the issue of successful development entered psychological aging research rather late, although the concept of successful aging has been treated since the beginning of the 1960s by scholars such as Robert Havighurst (1961). Indeed, Havighurst argued that both the disengagement theory and the activity theory may be seen as opposing explanations for successful aging. It is also remarkable that even earlier lifespan-oriented ideas such as those expressed in Carl Gustav Jung's radio essay "Die Lebenswende" (Life Transition) held in 1930 and those in the widely acknowledged life-stage model of human development suggested by Erik H. Erikson (1950) were optimistic in that developmental and personality growth and thus successful aging can happen through the very end of life. Gerontology's view of old age in the 1950s and 1960s was dominated by deficit-oriented perspectives, and geropsychology was no exception. For example, research related to cognitive performance, sensory functioning, social relations, health occurrences, and the influence of "pressing" environments – as well as some of the findings related to the aging self and "remaining" coping modes in old age – saw major loss components accompanying the psychological experience of old age. Emerging research on advanced old age since the middle of the 1980s (and what some have called the "fourth age") further strengthened more negative views of psychological aging and the pronounced limits of the human condition in very late adulthood, hence possibly undermining any "successful" developmental pathway connected with growth (Baltes and Smith 1999).

At the same time, it also became apparent that interindividual variability in all major psychological systems is large in old and very old age; calendar age is among the less important predictors of key development outcomes such as well-being. In other words, considerable portions of old as well as very old individuals are able to preserve psychological functioning to a major extent until

death. Furthermore – what now has found its place in psychological aging research as the paradox of well-being – even very severe threats to human development, such as chronic health impairments and interpersonal losses, are not able to durably undermine a given degree of well-being as people age (Kunzmann et al. 2000). Also, rates of major depression in those 65 years and older are lower as compared to younger ages (Zarit 2009). Most importantly, it also became clear that old age is accompanied by considerable developmental reserve capacity and thus plasticity, although it could be that many older adults are not in a position to fully unfold their latent developmental reserves due to persisting age-unfriendly environments, disengagement-provoking ecologies, and negative age stereotypes (Baltes and Baltes 1990; Miche et al. 2015). Finally, the reserve capacity argument found additional support by relying on and cultivating ideas of individuals as producers of their own development (Lerner and Busch-Rossnagel 1981). A major area has been illness prevention, for which longitudinal data revealed that even very serious negative outcomes such as cancer, disability, and dementia-related disorders are to a significant extent dependent on controllable behavioral factors across the lifespan (Fries et al. 2011). Hence, resources as well as lifespan-long behavioral options to shape aging for the better seem available; thus, successful development through very old age increasingly moved from being a vision to an empirical reality. However, controversies about successful aging, what is meant with this term, and whether it can be achieved by a majority of older adults or is the privilege of an elite group of older adults remained until present.

The aim of this entry is to offer in a rather balanced way a number of perspectives on successful aging, some of which may not be commensurable with others. Indeed, the array of successful aging is full of ambiguities, but nevertheless important to consider in geropsychology. First, a number of fundamental ideas and issues related to successful aging as well as its definitions and theoretical avenues are highlighted. Then a differentiation between outcomes and processes is used to address key issues related to

successful aging, such as variants of well-being research (outcome oriented) and models of developmental regulation (process oriented). Next also specific subgroups (e.g., minority groups) are addressed by asking for the relevance, potential, and risk of applying the concept of successful aging to such populations. This entry ends with recommendations such as better following a pluralistic understanding of successful aging instead of being too narrow from the start.

Fundamental Issues Related to Successful Aging as a Psychological Concept

To begin with, one may question the usefulness of the term “success” at large for the behavioral sciences. Success generally seems to be quite an ambiguous term in science as well as in everyday contexts (Baltes and Baltes 1990). Even in sports, success is not always clearly defined and is a relative qualification in many areas, such as career, income, educational pathways, social relationships, or what is called “life success.” Such ambiguity notwithstanding, success is (at least in Western societies) also generally accepted to indicate unusually positive development and often also a “better than others” qualification in whatever area considered. “Successful” may also be (and is most frequently) applied not solely to individuals but also to characterize groups or entities (e.g., the baby boomers may be characterized as more successful agers as compared to previous cohorts; societies may be qualified as more or less successful in dealing with their demographic aging challenges).

In psychology, terms such as successful coping or “successfully” coming to a solution in a cognitively framed experiment can be found, but it seems that reservations exist in using the term too frequently and too broadly. A major reason for being cautious with the term “success” in psychology is the difficulty in relying on generally accepted criteria for success while avoiding being extensively normative. On the other hand, psychology also made strong cases in regard to value judgments – for instance, in positive

psychology, which stresses the role of virtues such as altruism or mindfulness as criteria for a “good life.”

In light of psychology’s caution to restrict the use of the term “successful,” it is an interesting observation that it found extensive use particularly in geropsychology, given the prevailing existence of negative stereotypes of old age. However, Baltes and Baltes (1990), as well as Rowe and Kahn (1997) – both important promoters of the idea of successful aging – have argued that it may be important to use a strong term such as “successful” to efficiently counteract negative views of aging. Going further, both of these author teams also made it very clear that the distinction between “normal” and “successful” aging is a critical one. According to these scholars, normal aging is what one sees in the majority of older adults in terms of well-being, autonomy, how they view their own aging process, how long they live on average, how their physical and mental health and multimorbidity unfold, and how they die. Think of well-being and the robust and paradoxical finding that older adults report high well-being to a large extent (Kunzmann et al. 2000). In addition, a considerable number of older adults also describe their subjective health as good – even in the face of serious disease and functional loss – which seems to be a key source for maintaining well-being (Baltes and Smith 1999). In some contrast, successful aging means that available reserve potentials in various areas (e.g., cognitive function, health, functional ability) are used as much as possible. As is further assumed, this in turn leads to increased longevity, less and shorter late-life health occurrences, and less and shorter periods of dependency on others. This discussion brings one to the important question of which criteria one might use for successful aging.

Successful Aging: Definitional and Criteria Issues

In terms of content, a number of definitions of successful aging have been suggested, though researchers continue arguing which of the concepts describes “aging successfully” best

(Cosco et al. 2014). An influential definition has been proposed by Rowe and Kahn (1997), a geriatrician and a social psychologist. Their concept is based on three components: 1. low risk of disease and related disability, 2. high cognitive and physical functioning, and 3. continued active engagement in life. Despite its conceptual impetus, impact on previous definitions, and linkage with empirical insights – particularly, the MacArthur Studies of Aging – critical voices are constantly accumulating. For example, Villar criticizes that defining criteria of successful aging in such conceptions are seen as supposedly universal and objective, which renders only a small privileged group to meet the required standards of aging successfully (Villar 2012). According to this critique, solely relying on “hard” criteria of successful aging may make the group of successful agers a surprisingly small population in empirical reality (e.g., Hank 2011); in particular, this approach runs the risk of excluding major parts of the population, such as the very old, the socially disadvantaged, or those with severe functional impairment, many of whom enjoy their lives despite their aging under challenging conditions (see also below). That is, omitting subjective criteria in defining successful aging may neglect a person’s perceptions and evaluations of their lives. Furthermore, only relying on hard criteria may ignore the “agentic” nature of individuals and their ability to cope and adapt and by this means produce their own desired development (see again Lerner and Busch-Rossnagel 1981).

In line with Baltes and Baltes’ (1990) now classic chapter on successful aging, we argue that a multiple-criteria approach is needed that encompasses objective and subjective criteria. Objective criteria frequently addressed as indicating successful aging include length of life, biological health, mental health, and cognitive efficacy, whereas subjective criteria cover cognitive and affective well-being, control and mastery, and fulfillment in terms of social relations. There are also criteria that fall in between the objective and subjective realm, such as productivity and

engagement for others. Although consensus on the range and content of such criteria has been achieved to a large extent including the need to consider objective as well as subjective criteria, no consensus has been achieved on the relative weight and importance of these criteria. Seen in the light of Baltes and Baltes’ view (1990), models such as the Rowe and Kahn (1997) approach may be seen as containing only a subset of the realm of criteria related with successful aging and should therefore be treated with caution, when used as stand-alone models of successful aging.

Additional views on successful aging include the question whether geropsychology should rely on circumscribed normative or ideal state-oriented value judgments or should prefer a more general understanding that addresses successful aging rather content free (e.g., no defined single outcomes or goals) in terms of the adaptational efficiency. A classic example for the first position would be the already-mentioned theory of lifelong personality development by Erikson (1950), according to which generativity, ego integrity, and wisdom are the ultimate goals of late human development (e.g., Erikson et al. 1986). Now classic views for the second position are established models of human development, such as the model of selective optimization with compensation (Baltes and Baltes 1990; see also below). Both the normative and the general adaptation-oriented views also argue that “successful” must always include the planning and optimization of environments of aging; thus, development-enriching contexts able to unfold a maximum of reserve capacity of late human development are important for any consideration of successful aging.

Finally, studying laypersons’ perspectives underlines that the understanding of successful aging by older adults themselves is facet rich (Bowling and Dieppe 2005; Phelan et al. 2004). Jopp et al. (2015) found that, compared to existing psychological theories, laypersons’ view on successful aging indeed reveals more subdimensions, encompassing health, activities, social relations,

finances and psychological resources (such as well-being), and attitudes and life management skills.

Outcome Perspective of Successful Aging: Promises and Limits of Well-Being-Related Constructs

Even though the conceptualization of successful aging proposed by Rowe and Kahn (1997) covers two inarguably basic elements, i.e., good health and activity at large the question remains who decides whether someone is living a good life and, therefore, is “aging successfully”? The answer to this question may not the least come from the older person her- or himself, hence how she or he experiences aging. Therefore, a central aspect in the ongoing discussion on successful aging has been the suggestion that an important complementary (psychological) view to models such as the Rowe and Kahn one (1997) would be the consideration of a subjective well-being judgment.

There are various conceptions of subjective well-being. A well-established differentiation is the one between a cognitive and an affective component, which divides well-being into (cognitive) judgments about a person’s satisfaction with life (and life domains) and an affective balance, which is described by high levels of positive affect and low levels of negative affect (Diener 2000). Well-being has also been separated into hedonic and eudaimonic well-being (Deci and Ryan 2008). While hedonic well-being is affect oriented, eudaimonic well-being is about “living well,” hence the actualization of one’s potentials and the achievement of personal happiness by referring to generally accepted virtues. The concept of eudaimonic well-being obviously adds much to the concept of successful aging, particularly shown by Carol Ryff’s multidimensional model of psychological well-being (Ryff and Singer 2008). Ryff’s six dimensions of psychological well-being – self-acceptance, autonomy, personal growth, purpose in life, environment mastery,

and positive relationships – offer important differentiations to understanding successful aging in more subjective terms (e.g., Ryff 1989). One may argue that Ryff’s conceptualization lacks a definite description explaining how successful aging can be achieved in accordance with the six dimensions. Nevertheless, Ryff’s model appears as rather comprehensive, in terms of psychological understanding of successful aging, while mostly operating at an “advanced” descriptive level of successful aging.

In conclusion, a comprehensive theoretical and empirical psychological approach to the concept of successful aging underscores the importance of defining respective outcomes in terms of a multidimensional understanding of well-being. Although it continues to be important to reconcile the hedonic versus eudaimonic view of well-being to infuse psychological models of successful aging, there is a clear need that mostly objective medical views (Rowe and Kahn 1997) should be extended by the older adults’ subjective evaluations of what successful aging means for them.

Process Perspective of Successful Aging: Promises and Limits of Emphasizing Adaptational Dynamics

Instead of an optimal state characterized by specific criteria (or outcomes), some scholars view successful aging as a dynamic process, emphasizing the importance of adaption and self-regulation across the lifespan (see Baltes and Baltes 1990). A fundamental issue in this regard is that human development implies the constant interplay of losses and gains; however, as one ages, one’s balance changes with losses and threats becoming more pronounced (Baltes 1987). Given this inevitable double-track, defining successful aging merely as an attainment of gains or absence of illness may be a too narrow view. In order to do justice to the complexity involved, four of the most prominent lifespan theories are briefly addressed that describe optimal human development in light of the gain-loss balance.

Within the framework of selective optimization with compensation (SOC model, Baltes and Baltes 1990), successful development is conceptualized as minimizing losses while maximizing gains across one's lifetime via selecting areas of functioning, optimizing the use of available and selected resources, and compensating deficiencies with alternative means to maintain functioning. As is also argued, selection can be *elective* (if guided by individual preferences) or *loss based* (if goals are given up or are reorganized due to losses or resource restrictions). From the vantage point of the SOC model, successful aging therefore means the optimal orchestration of all three processes according to remaining resources and possible constraints imposed by external forces or the experience of critical life events.

How the perception of a shrinking time horizon contributes to successful aging has been addressed by Carstensen's socio-emotional selectivity theory (SST, e.g., Carstensen 2006). SST maintains that when future time perspective becomes shorter, people invest more time and energy in emotionally meaningful goals and activities to satisfy their needs. In particular, older adults become more selective in choosing close relationships (over knowledge-related goals) and in optimizing positive emotional experiences at large by wise selection of respective ecologies able to support such searched experiences. Although the shortened time horizon is a given in human development, SST assumes that developing individuals are proactively and flexibly shaping their search for the positive in life and thus their successful aging process.

Dealing with goals also lies at the heart of two other well-established lifespan developmental theories: the dual-process model of assimilative and accommodative coping (Brandtstädter and Renner 1990) and the motivational theory of lifespan development (Heckhausen et al. 2010). The dual-process theory, (Brandtstödter and Renner 1990) posits two mainly antagonistic coping modes that enable aging individuals to maintain a positive identity across the lifespan. Assimilation reflects persistent efforts to actively modify life circumstances to one's preferences and goals

("changing the world"), whereas accommodation involves a flexible adjustment of personal values and aims to situational constraints or limitations ("changing the self"). A major means to age successfully according to this model is the tendency to increasingly engage in accommodation modalities as people age.

The motivational theory of lifespan development views the maximizing of primary control as the key to successful aging (Schulz and Heckhausen 1996). The model distinguishes between two control-enhancing strategies: primary control (targeting the external world and changing the environment to fit one's particular needs) and secondary control (focusing on the self and changes within the individual). If goals are increasingly blocked due to the experience of aging, switching to secondary control is a major means to secure successful aging. Thus, successful aging in this process predominantly appears as the "art" of giving up or altering goals no longer attainable at the right point in time, but to continue to maintain goal striving wherever possible and feasible, thus stabilizing the lifelong striving for primary control.

Though these shortly reviewed lifespan theories differ in their specification of which adaptive mechanisms are relevant to successful aging, they converge in their assumption that successful aging is embedded in a lifelong process emphasizing agency and the possibility of the human choice potential (for a profound comparative review, see Boerner and Jopp 2007). Going further, according to these models, adaptive self-regulation is achieved through engagement in processes of goal setting and goal pursuit, disengagement of unattainable preferences, or reengagement in valued alternative goals. Although it seems helpful that lifespan adaptational models do not assume specified outcome criteria for successful aging and therefore have flexibility in their application to individual developmental trajectories, it is questionable whether they can operate without outcome criteria such as well-being or depression. Indeed, these and similar concepts are frequently used while empirically testing these models (e.g., Haase et al. 2013).

Successful Aging and Specific Groups of Older Adults: Examples

Minority Groups and Socioeconomically Disadvantaged Older Adults

There is high consensus that minority status has an important impact on various dimensions of living, but there continues to exist a lack of data on aging minority populations (see Federal Interagency Forum on Aging-Related Statistics 2004). Elders belonging to minority groups are described to have fewer psychological and social resources, which may result in higher vulnerabilities to life stressors (e.g., Thoits 1982). However, the evidence on health, physical activity, and subjective well-being of aging minority groups is mixed. For example, Kessler and Neighbors found in the 1980s that African American older individuals report more psychological distress than whites, when suffering from low income, but the gap was smaller when income increased (Kessler and Neighbors 1986). More recently, a study showed the opposite, i.e., African American older adults were significantly less distressed than their white counterparts in this study (Kubzansky et al. 2000). Most importantly, one may question whether established models of successful aging are equally applicable to minority groups and different cultures at large or whether a more differentiated and culturally informed perspective may be in place.

Being socioeconomically disadvantaged increases the risk for experiencing health problems and lowered well-being in old age (Britton et al. 2008). It is also an empirically well-established fact that although high income and education cannot buy happiness, having a certain level of both of these resources seems to infuse basic personal thriving, at least in Western society (e.g., Britton et al. 2008; Strawbridge et al. 1996). However, Palmore's classic (but now dated) study (1979) found neither intelligence nor years of education to influence successful aging, whereas social and physical activity revealed as highly predictive. More recently, McLaughlin, Connell, Heeringa, Li, and Roberts (2010) examined the prevalence of successful aging predominantly seen through the lenses of Rowe and Kahn's

approach in the USA and found that higher percentages of white as compared to African American and Hispanic older adults are classified as aging successfully. At the same time, increasing level of education and income considerably affected the percentage of adults aging successfully in all researched groups. Importantly, education and income remained noteworthy and significant predictors of successful aging, while the racial-ethnic disparities diminished, when taking both of these variables into account.

Can Older Adults with Dementia-Related Disorders Age Successfully?

Dementia is a chronically progressing brain disease that causes major decline in cognitive and behavioral abilities and has become one of the most feared diseases (Kessler et al. 2012). When asked how long one wishes to live after being diagnosed with dementia, the answer of older adults aged 70 years and older is expressed in days rather than even in weeks not to mention longer periods (Lawton et al. 1999). Obviously, dementia has a great impact on the quality of life of those affected, accompanied by increasing dependency, burdened social relationships, and possible transitions to long-term care institutions. All this seems to exclude the possibility of successful aging. On the other hand, it may be too strict to exclude dementia-related disorders by default solely relying on a set of hard criteria as described above. For example, although respective evidence is limited (e.g., Birks 2006; Sitzer et al. 2006), it may be argued that impacting the "natural" course of the disease by means of pharmacological and non-pharmacological intervention in terms of prolonging a phase of relative independence may be seen as successful aging for this specific group. Going further, studies indicate that people with dementia, at least to some extent, try to adapt to and cope with the experiences of changes caused by the illness and are not just pawns of the disease (Bahro et al. 1995; Clare 2003). Also, studies targeting the quality of life of individuals with dementia have found that meaningful social and other activities, spirituality, as well as a pleasurable daily routine may remain a

possibility even in the face of dementia, although this may only apply to subpopulations of the demented (e.g., Ettema et al. 2005; Kane 2001). Hence, although a lot of conceptual and ethical questions remain open, it may be that even in extreme cases and, as many would say, highly restricted conditions of human aging, the possibility of successful aging should be considered.

Outlook: Does Geropsychology Need the Concept of Successful Aging?

It has been the goal of this entry to address the complexity and ambiguities related to the concept of successful aging. For example, one may raise the question as to whether the term “successful” is a good term for the psychology of aging. It seems obvious that we are far from coming up with the final answer regarding which kind of role successful aging should play in future geropsychology. However, some recommendations may be in place as follows: First, a pluralistic approach to successful aging is advisable. In particular, a profound and facet-rich discussion on successful aging is an intellectually and practically enriching resource for geropsychology per se. Second, it is recommended that researchers referring to constructs such as successful aging should make – in light of various approaches described above – their own approach very clear and explicit. Third, it is of the utmost importance to consider the full multidimensionality of successful aging, including subjective and objective criteria, as well as lay people’s descriptions. Any conceptualization coming with proposals to reduce this set to a subset of dimensions in whatever direction must be challenged to make the rationale behind its selection as explicit as possible. Fourth, a visionary component of what is possible in late life is an important element of any concept of successful aging. Here, the idea of latent reserve capacities and forms of expression of aging are taking up, which need additional effort to become fully unfolded (see also Rowe and Kahn 1997). This idea also corresponds with Riley and Riley’s concept of structural lag and the

assumption that there may be forms of successful aging already appearing in older adults still not reflected in societal institutionalizations and policy (Riley and Riley 1994). At the individual level, successful aging explicitly addresses the possibility of developmental growth and potentially questions the assumption that growth is more the exception than the rule in old age (Baltes et al. 2006). Hence, the fundamental distinction between “normal” and “successful” may lose some of its importance in the future. Instead, it may become more critical, whether older adults, in whatever kind of situation, are using potentials still available or not. Consequently, as a fifth point, it is suggested that any conceptualization of successful aging must take major challenges of aging into consideration, such as aging as a member of a minority group or as a demented individual with pronounced care needs.

In conclusion, geropsychology should not abandon or even ban the construct of successful aging from its portfolio of key concepts due to all its ambiguities and possibly its tendency to further elite thinking in psychological aging research. However, a highly differentiated use of the concept of successful aging is essential and may indeed significantly infuse the conceptual and empirical future of geropsychology.

Definition

Psychological Theories on Health and Aging refer to approaches that explain how healthy aging can be promoted and how diseases can be prevented or delayed. They provide starting points for interventions to support adaptation to health-related changes that become more and more prevalent in later life.

Introduction

Since the mid-twentieth century, the world population has experienced a significant increase in life expectancy and in the proportion of older adults in the total population. Population aging is essentially driven by increasing longevity and reflects that more people will survive to the oldest ages (United Nations, Department of Economics and Social Affairs, Population Division 2013). A general and global increase in average life expectancy implies the question of whether these additional years will be spent in good health and highlights that the understanding of health in old age needs to be improved.

As people grow older and older, their health changes. There are obvious age-related physiological changes including changes in hearing, vision, lung function, bone density, digestion,

and a range of other physiological structures and functions (Aldwin and Gilmer 2013). From an epidemiological perspective, increasing age also indicates an increasing likelihood of having multiple illnesses. One of the most important questions is whether the increasing life expectancy in the total population is associated with a net gain of years in good health (compression of morbidity) or more years spent with increasing health problems (expansion of morbidity). Psychological theories on health and aging can help to explain how older adults experience, understand, and behave towards their health. With the help of these theories, an understanding can be gained of how health in older adults differs from younger adults, how subjective perceptions of aging and health interrelate, and whether there are factors that are specific to explaining and improving health and health behaviors in older age. This entry aims at describing some of these age-related phenomena in more detail, reviews key theories and frameworks of health and aging (for an overview of the selected theories and frameworks for this entry see Table 1), and shows how the potential for health promotion in old age can be tapped into using appropriate psychological theory and evidence.

Health in Old Age

The terms *health* and *illness* are often associated with medical classification systems, in particular the International Classification of Diseases and Related Health Problems (currently ICD-10). According to such classification systems, a person is ill if a physician diagnoses a disease and considered healthy otherwise. However, health is more than the absence (or nondiagnosis) of diseases, as acknowledged in the World Health Organization's (WHO) definition of health. Adopting a biopsychosocial understanding of health, health in old age is the result of an interaction of protective and risk factors on the biological, psychological, social, and the environmental level. This means that the consequences of and the reasons for a disease depend both on the physiological state and on psychosocial resources of the older individuals themselves as well as their personal

setting, access to medical care, and the societal context in which they live. The International Classification of Functioning, Disability and Health (ICF) of the WHO (2002) considers these dynamic and complex interactions between a health problem and the respective personal and environment-related factors. The ICF can be applied to examine functioning, disability, and health in all age-groups, but its range of meanings becomes more important in old age due to health changes that often accompany aging in later life. In the following, two major changes of health in later life will be introduced briefly before considering psychological indicators and predictors of healthy aging.

Multimorbidity as Particular Challenge in Old Age

One particularly relevant aspect of health in old age is an increase in the likelihood of suffering from multiple illnesses at the same time, and these can either be physical or mental illnesses or a combination of both. The majority of adults in the age-group of 65 and older have two or more chronic illnesses.

With multiple illnesses come multiple challenges. Older adults with multiple illnesses are more likely to experience further health deteriorations, face the burden of symptoms of different illnesses, are in particular need of being able to access health care, and often experience lower quality of life than people in the same age-group with fewer or single illnesses (for an overview, see Fortin et al. (2007)).

Is There a Decrease or Increase in Morbidity?

The high prevalence of illnesses and multimorbidity in old age together with increasing life expectancy has raised the question of how healthy people are in their final years of life. Are these additional years of life a net gain in lifetime that people remain active and in good health, or are these primarily years in which they face disabilities? The discussion about compression versus expansion of morbidity started in the late 1970s and is still alive and well. In broad terms, three scenarios dominate the discussion (for an overview, see Laditka and Laditka (2009)).

Psychological Theories on Health and Aging, Table 1 Theories and frameworks relating to health and aging

Main focus of theory (outcome or process)	Name of theory	Concepts and predictions	Authors	Specific to age?
I. Health and well-being	Ia. Successful aging framework	Successful aging = low probability of disease + high functional capacity + active engagement with life	Rowe and Kahn (1997)	Yes
	Ib. Response shift theory	Differential change processes – alpha change (change in health), beta change (<i>recalibration</i> of the underlying scale assessing health) or gamma change (<i>reconceptualization</i> of the meaning of health) – allow people to maintain similar levels of self-rated health despite objective changes in health	Schwartz and Sprangers (2000)	Yes
	Ic. Common-sense model of health and illness	People draw on subjective representations of illnesses and treatment when faced with a health threat – and these representations guide their response to illness in that e.g., being diagnosed with an illness that is perceived as more controllable will lead to less distress and more control efforts such as adherence to treatment	Leventhal et al. (1992)	No
II. Coping with developmental challenges	Iia. Life management strategy of selection, optimization, and compensation	Individuals manage their lives through three processes of developmental regulation: Selection focuses on setting goals, optimization refers to investment in goal-relevant means, while compensation includes alternative means to maintain a given level of functioning when primary goal-relevant means are no longer available	Baltes and Baltes (1990)	Yes
	Iib. Dual-process model of developmental regulation	In the face of diminishing resources, people can either increase goal pursuit (tenacious goal pursuit) or adjust goals to current resource level (flexible goal adjustment). If resources are sufficient, goal pursuit leads to more adaptive outcomes, if resources are scarce, goal adjustment	Brandtstädter and Renner (1990)	Yes
	Iic. Motivational theory of life-span development (MLD)	Key criterion for adaptive development is the extent to which individuals experience primary control of their environment in different life domains and across the life span. From midlife to old age, capacity of primary control declines. A large challenge for individuals is therefore to adapt to these changes and to choose due goals to engage with and to give up unattainable goals	Heckhausen et al. (2010)	Yes
	Iid. Lines of defense model	Based on the MLD, the model identifies specific health goals and functioning goals as well as control strategies, dependent on the level of disease. Three lines of defense are proposed: (1) maintain disease free status, (2) avoid chronic disease, and (3) maintain functioning in everyday life. According to the model, individuals strive at holding the respective line of defense as long as possible, and adjust when it cannot be maintained anymore	Heckhausen et al. (2013)	Yes

(continued)

Psychological Theories on Health and Aging, Table 1 (continued)

Main focus of theory (outcome or process)	Name of theory	Concepts and predictions	Authors	Specific to age?
III. Stress and resources	IIIa. Broaden and build theory	Positive affect leads to an increased repertoire of behaviors and social bonds which in turn improve health and well-being	Fredrickson (2006)	No
	IIIb. Conservation of resources theory	Resource loss and expected resource loss lead to stress. The theory proposes that resource losses have a primacy to resource gains, i.e., individuals are highly motivated to conserve their resources in the light of losses	Hobfoll (1989)	No
IV. Cognitions related to health and aging	Stereotype embodiment theory	Societal images of old age (age stereotypes) are implicitly internalized over the lifespan resulting in self-perceptions of aging. Both age stereotypes and self-perceptions of aging are predictive of various health outcomes, including physical health, physical functioning and mortality. Physiological, psychological and behavioral pathways are used to explain how these views on aging and old age can turn into self-fulfilling prophecies	Levy (2009)	Yes

A first scenario, *expansion of morbidity* (E. M. Gruenberg, M. Kramer) argues that due to medical advances, disease-related fatality rates decrease in contrast to incidence rates, which is why more and more people survive severe illnesses and accidents. A second scenario, *compression of morbidity*, was developed by J. F. Fries. Fries argued that health problems could be postponed due to primary and secondary prevention and the time of impairments to health could be compressed to a shorter time before death. Finally, a third and integrative scenario assumes a dynamic equilibrium (K. G. Manton), that is, an increase in the number of diseases together with a decrease in the severity of these diseases. Compression of morbidity would stress the importance of prevention for healthy aging (e.g., how health behaviors can be promoted up to old age), whereas the expansion of morbidity would draw more attention to the question how people cope with enduring health problems and limitations. Both health promotion and psychological adjustment in later life are important topics of geropsychology.

There are some good reasons to expect better health in later birth cohorts, for example, higher average educational attainment, improved living

standards, or advances in medicine and public health. The latter, however, could also point toward an expansion of morbidity as better medical care also implies earlier and more reliable diagnosis of diseases as well as higher survival rates in case of severe health problems. Better medical diagnostics can be associated with an increasing number of diseases *without* an increase in the subjective burden of disease, because the increase might just reflect better knowledge of the diseases and improved diagnostic tools. Higher survival rates in the face of severe health problems, however, are more likely to be associated with increasing burden of disease in terms of long-term disabilities and activity restrictions. For example, a series of recent studies published in *Lancet* in 2012 based on The Global Burden of Disease Study 2010 suggest an expansion of morbidity by showing slower increases in *healthy* life expectancy than *overall* life expectancy based on 187 countries (Salomon et al. 2012). However, conclusions about compression or expansion of morbidity largely depend on how these terms are defined. The study cited above defined expansion as an increase in the *absolute* number of years lost to disability while the authors report that the findings are less clear and consistent for different

countries if *relative* measures (e.g., ratio of healthy life expectancy to life expectancy) are used (Salomon et al. 2012).

This illustrates that an unambiguous answer on the question of compression or expansion of morbidity is difficult. Existing studies suggest that now and for the foreseeable future, multimorbidity and disability will remain an important challenge and will become even more important due to the increasing number of older people in many societies around the world. At the same time, socioeconomic variations in healthy life expectancy point to the malleability of health in old age and to the potential for prevention. However, the consequences of multimorbidity and disability for autonomy and quality of life do not only depend on health care but also on how society as a whole and each single individual is able to deal with it.

Theories on Psychological Adjustment Processes to Declining Health in Later Life

Apart from compression or expansion of morbidity, there are a range of closely related concepts that describe health in aging using terms such as “healthy aging,” “successful aging,” “optimal aging,” or “active aging.” Sometimes, these concepts are used interchangeably, as they all describe a state that includes good physical health, high functional and cognitive status, and active social participation. What these concepts have in common is a radical shift in the focus from deficit-oriented perspectives on health-related issues in old age, exemplified in the definition of *successful aging* by Rowe and Kahn (1997, p. 433): “We define successful ageing as including three main components: low probability of disease and disease-related disability, high cognitive and physical functional capacity, and active engagement with life.” (cf. Table 1, Ia).

Differences Between Being Healthy and Feeling Healthy

Both the age-related increase in (multi)morbidity and the increase in years spent with disabilities

(expansion of morbidity) pose the question of how these phenomena affect quality of life in old age. A psychological starting point that helps to explain the generally high levels of subjective quality of life in old age despite high prevalence of multiple illnesses is the concept of *self-rated health*. Most often, self-rated health (SRH) is measured with one single question asking individuals to rate their overall health on a scale from “excellent” to “very bad.” Studies have repeatedly shown that many people maintain good SRH up to old age despite worsening physical health. Correspondingly, the relationship of physical health indicators and SRH is closer in younger age-groups, while it diffuses in older age-groups (Pinquart 2001). In addition to the effects on health-related quality of life in old age, a large number of studies have shown that this single question on SRH is an independent predictor of mortality in later life, even after other health-related indicators such as medical or cognitive status and social status are controlled for (Idler and Benyamini 1997). This does not only mean that people with poor SRH are at higher risk for mortality, but also that those who maintain good SRH despite poor physical health may reduce their risk of mortality. Besides mortality, SRH has been shown to predict other health outcomes as well, for example, functional health, cognitive impairments, or recovery from diseases.

In the following, four approaches are presented to understand the high validity of SRH as a predictor for other health outcomes all of which are well evidenced by recent studies (Benyamini 2011): *First*, SRH is more inclusive than many other health indicators. It seems to reflect all possible states on the continuum from illness to wellness and therefore more than the existence (or absence) of a disease. This is also mirrored in the fact that SRH is correlated with physiological processes (e.g., inflammatory processes) that might indicate clinical or preclinical stages of a disease. *Second*, rating one’s health can be considered a dynamic evaluation process. People are able to maintain good SRH despite major health events which is explained by *response shift* theory (Schwartz and Sprangers 2000). Response shift encompasses a variety of cognitive processes

that lead to changes in the meaning of one's self-evaluation in SRH allowing stability in SRH despite declines in the objective health status. Such cognitive processes can include changes in internal standards of measurement (i.e., *recalibration* of what is considered good or poor health), changing importance of domains constituting SRH (e.g., higher *value* of positive affect or depressive symptoms for SRH in later life; (Spuling et al. 2015)), or a redefinition (*reconceptualization*) of SRH (cf. Table 1, Ib.). A *third* explanation for the validity of SRH lies in its relation to more preventive health behaviors, although this explanation is the least researched so far. *Finally*, SRH is related to a number of internal and external resources such as optimism, social support, or education. Better SRH could both be due to higher optimism or better education and could also lead to higher resources such as optimism or social support. The current state of knowledge suggests that SRH is a highly important health indicator that helps us to understand the potentials people have to adjust to adverse health outcomes and to live longer and better than their objective health status would give reason to expect. While concepts of healthy aging such as the successful aging framework focus more strongly on objective criteria such as physical and cognitive functional capacity, response shift theory is focused on the question how people adapt their subjective standards in order to maintain good self-rated health and quality of life.

Adaptation to Illness

Psychological theories to understand individual adaptation to illness such as the Common-Sense Model developed by Leventhal et al. (1992) are also based on lay models, that is, they examine health threats from the perspective of the affected person. The Common-Sense Model of Self-Regulation of Health and Illness (Common-Sense Model for short, cf. Table 1, Ic.) assumes that adherence to treatment is a function of how an individual manages to make sense of his or her illness based on subjective illness representations. If someone experiences symptoms such as a runny nose and elevated temperature, this might activate illness representations pertaining to influenza in

this person. These subjective influenza representations could then (based on the person's knowledge and background factors) evoke beliefs about an acute rather than chronic course of the illness or a virus as the cause of the illness – which in turn could suggest to the individual that antiviral medication is the treatment of choice. Another set of symptoms, for example, being short in breath when climbing the stairs might be attributed to one's increasing age rather than indicating an illness – whether accurate or not. Currently, this and similar theories of adaptation to illness explain individual reactions and coping attempts to *one* illness. However, as mentioned above, most older adults suffer from multiple illnesses at the same time, which means that theories and models need to be adapted and extended in order to be useful tools to understand how people make sense of multiple illnesses. While response shift theory is mainly used in epidemiological and quality of life research, the commonsense model is popular in health psychology because it facilitates understanding the subjective reasons for (health-related) behavior of individuals with a diagnosed illness.

Self-Regulation and Coping with Developmental Challenges

A number of theories on life-span development and aging also consider self-regulatory processes. Three prominent theories are the model of *selection, optimization, and compensation* (SOC, Baltes and Baltes (1990)); the *dual-process model of developmental regulation* (Brandtstädter and Renner 1990); and the *motivational theory of life-span development* (Heckhausen et al. 2010; see Table 1, IIa–c). These developmental theories are important tools to understand health in old age, because they focus on strategies for dealing with developmental losses such as the worsening of health. As all theories are described in more detail in other entries in this book, we will only focus on their commonalities. All three theories share the assumption that personal goals play a central role in development. Goals can refer to growth, maintenance, and recovery of already achieved goals, or the regulation of losses. While gain-related goals take center stage during the first

half of life, midlife marks a motivational shift from growth-related goals to an increasing focus on maintaining functioning and avoiding losses. Probably the most recent addition to these theories is the lines-of-defense model for managing health threats (Heckhausen et al. 2013) which is based on the motivational theory of life-span development. It identifies specific health goals and functioning goals as well as control strategies as a consequence of these goals, dependent on the severity or burden of disease. The model describes three lines of defense: (1) maintain disease-free status, (2) avoid chronic disease, and (3) maintain functioning in everyday life (cf. Table 1, II.d.). According to the model, individuals strive at holding the respective line of defense as long as possible and adjust when it cannot be maintained anymore. These approaches can improve our understanding how people face developmental challenges and how adaptive goal adjustments might look like.

Resource-Based Stress Theories

Resource-based stress theories such as the *Conservation of Resources Theory* developed by Hobfoll (2011; cf. Table 1, III.a.) argue in a similar vein but have not been developed with a specific life-span perspective in mind. According to Conservation of Resources Theory, stress experience occurs when resources are threatened or lost. Physiological changes associated with aging as well as the increasing likelihood of severe diseases undermine important resources but also warrant investment of psychological, social, or financial resources to protect against resource loss, to recover from losses, or to gain resources. The theory also assumes that people are more motivated to avoid resource losses than gain new resources. As aging is linked to losing resources, individuals who are well equipped with resources will cope better with the challenges of aging than individuals with lesser resources. Within these approaches, resources encompass both tangible (money, social support) and intangible (psychological). The *Broaden-and-Build* theory (Fredrickson 2006; cf. Table 1, III.b.) poses that psychological resources such as positive emotions widen repertoires of imagination and action by

allowing the individual to explore the world, to practice skills, and to strengthen social bonds. The theory assumes that positive emotions do not only indicate but also produce health and well-being.

Age Attributions and Self-Perceptions of Aging

Because irreversible losses become more and more likely with increasing age, the ability to accept inescapable losses and to give up unattainable goals becomes more and more important with age. However, aging itself is generally perceived as an unchangeable process that has to be accepted. Hence, if someone believes that physical losses are mainly caused by age, this might prevent the identification of symptoms as illness warnings and thus deplete motivation to avoid the losses feared. Several studies have addressed the propensity of older adults to attribute symptoms to “old age” and not to illnesses. These studies revealed that the attribution of symptoms to old age involves greater acceptance of illness symptoms, more passive coping, lower optimism, more detrimental health behavior, and higher mortality (Leventhal and Prohaska 1986; Prohaska et al. 1987; Stewart et al. 2011; Sarkisian et al. 2002). Similar findings exist for age stereotypes and self-perceptions of aging, suggesting that older adults with more negative views of old age in general and their own aging process in particular are less likely to invest in their health and face the risk of self-fulfilling prophecy (cf. Table 1, IV.). In recent years a number of longitudinal studies have shown that individuals with more positive self-perceptions of aging maintain better physical, functional, and self-rated health over time and also live longer than those with more negative self-perceptions of aging (Westerhof and Wurm 2015; Westerhof et al. 2014). These studies also show possible pathways explaining the impact of self-perceptions of aging on health and longevity; for example, a psychological pathway links personal control beliefs, will to live, and developmental regulation (SOC) to health, whereas physical activity has been shown to be an important behavioral pathway (Westerhof and Wurm 2015).

Applying Psychological Theories to Promote Health in Old Age

Having argued that health changes with age, it is reasonable to ask how detrimental changes in health can be prevented or whether and how health in old age can be improved. There is compelling evidence that physiological aspects of health are amenable to improvements even to old age, for example, via increases in physical activity for those who are able to increase activity, or activating care that targets improved participation in everyday life. At the same time, these two examples highlight that the goals of health promotion in old age change as well. In many cases, improving health is not a realistic option, whereas stabilizing health is. In health promotion, this would correspond to a gradual shift from primary prevention (where the goal is the prevention of new illness) toward secondary (prevention of worsening) or tertiary (prevention of recurring illness) prevention in older age (Scholz et al. 2015).

The theories and frameworks discussed above can be applied to health promotion in old age. For example, Rowe & Kahn's Successful Aging framework outlines indicators (low probability of disease and disease-related disability, high cognitive and physical functional capacity, and active engagement with life) that can be translated into health promotion goals by examining the determinants of these indicators. Theories of health behavior such as the Health Action Process Approach or the Theory of Planned Behavior (for an overview of health behavior theories, see, e.g., Conner and Norman (2015)) outline such modifiable determinants and suggest that in particular self-efficacy or goal setting are relevant for physical activity in older adults.

These determinants can then be applied to improve aspects of successful aging such as social participation – for example, a recent study found that low-threshold social-cognitive interventions based on the Health Action Process Approach can increase volunteering behavior in older adults (Warner et al. 2014). Thus, theories of health and aging not only improve our understanding of age-related changes in health and

health concepts but provide a framework for improving health in age as well.

Conclusions

Beginning with particular challenges for healthy aging such as multimorbidity and expansion of morbidity, this entry provided an overview of different psychological theories that can explain how older people are able to adapt to declining health. The discrepancy between physical and self-rated health (SRH) that increases with age may reflect a prominent ability of many older people. The ability to maintain good SRH in light of physical losses is able to predict future health outcomes, including longevity. However, more research is needed to better understand how people adjust their health assessment. For example, under which circumstances do people use the one or the other of the different types of response shift and how much is this related to health behavior? Moreover, how much does response shift depend on the socioeconomic and psychosocial resources and how much differ the adaptation processes not only by age but also between different birth cohorts?

Theories on adaptation to illness so far have focused on single illnesses. Thus, due to the increasing number of people with multiple illnesses our understanding of the lay models that people with multiple illnesses apply to their health status needs to improve. Do people, for example, view their illnesses separately or in their entirety, are they mostly concerned with one illness or with multiple illnesses, and do they perceive treatments and medications for multiple illnesses to complement, interact, or work against each other? Finally, how does this affect their overall health status?

The different psychological theories on healthy aging emphasize that there are multiple ways how people can adapt to health changes. As suggested by a number of theories, being ready to change the frame of reference and changing goals might be one of the most important adjustment tasks in old age, with health only being one of many domains where these principles can be applied.

However, finding one's own way and the right timing between goal engagement and giving up unattainable goals is a difficult balancing act in many cases. Current research suggests that positive emotions as well as positive self-perceptions of aging on health and longevity seem to be protective for health in later life. In contrast, the attribution of symptoms to old age seems to have detrimental effects, although this could also be considered a way of positive adaptation. More research is therefore needed to get better insight into how these different psychological mechanisms turn into health-relevant behaviors such as, for instance, exercise or health care utilization.

This entry outlined the relevant theories on health and aging originating from different psychological disciplines such as life-span developmental psychology, health psychology, or health-related quality of life research. The theories presented in this entry provide pathways to improve or stabilize health in old age by outlining determinants of health that can be targeted in interventions, and the entry has highlighted some examples of research where theories of health and aging have been successfully applied to improving health in old age.

Policy Advice: Definitional Issues

In Anglo-American political science, it is common to distinguish between politics, polity, and policy (in German language, there is no similar distinction). Politics refers to a procedural dimension, i.e., processes of consent formation and conflict resolution that may result in intentional political action as well as “nondecisions.” Policy refers to a contextual dimension, i.e., specific fields of politics and respective tasks, challenges, and aims to be reached by intentional political action. Polity refers to values and institutions as underlying circumstances of policies, e.g., constitution, laws, communities, or administrative units. This entry focuses primarily on the contents of politics, more precisely on the impact of geropsychological knowledge and perspectives on aging policy. Aging policy depends on policy-makers’ – politicians responsible for shaping aging policy – appraisal of the actual situation of older people and age-related changes in society, including both judgments on status quo and actual discrepancy. Perceptions of actual discrepancy do not only refer to existing design possibilities (including intergenerational relationships) but also to cost-benefit considerations and aspects of generational equity. Obviously, aging policy cannot be based on “subjective aging theories” and incidental more or less adequate reception of scientific knowledge. Instead, sustainable aging policy requires continuous and institutionalized processes of political advice.

Policy advice is applied in a wide range of domains in municipal, provincial, and federal

politics. If one looks for the uniform, i.e., a characteristic feature for all the tasks of policy advice, the involvement in the *preparation* of policy decisions needs to be mentioned, whereby these decisions (a) are related to a narrowly defined, *specific* area, (b) have to be carried out quickly as action is needed, (c) are related to a comprehensive area and (initially) express a general tendency or orientation, and (d) can be carried out late, because there is no immediate need for action. The *wide range of fields of responsibility* can be characterized as follows: (a) elucidation of a comprehensive area, a detailed, “in-depth” representation; (b) the answer to a specific political issue (here too, a detailed “in-depth” representation often proves to be necessary); (c) the answer to a specific political issue with a “pro and contra” structure (here, specific arguments are presented and analyzed in detail and evaluated); (d) the evaluation of political decisions, which have already been executed, with the aim of continuing the corresponding measures which resulted from these decisions; (e) participation in the preparation of a decision which relates to a specific measure, a more comprehensive measure, or a whole range of measures (e.g., establishment of a comprehensive infrastructure for older people); and (f) discussions with political decision-makers on a specific topic, whereby the focus is on elucidation (in this discussion, experts can try to promote certain policy measures or to warn against certain policies). This discussion should be *continuously* developed.

What Is Understood by Policy Advice?

Policy advice describes the process of (a) engaging an “expert” with the processing of a politically relevant issue, considering the aspects which are important for the political debate; (b) coordination between the principal and the “experts” in respect of those aspects of the subject to be discussed; (c) research on those aspects of the subject, the processing of which has been agreed by the principal and the expert; (d) analysis of the obtained data and collected findings from the research with the aim of reaching a theoretical, methodological, and empirical reasoned statement; (e) development

of recommendations as a basis for policy debate and – on this basis – the political decision; (f) discussion of the expertise statements and recommendations with political decision-makers (where appropriate, revision of said expertise); (g) additional expert advice to the political decision-makers (insofar as they are dependent on the advice) up until the decision; and (h) advising the political decision-makers (insofar as they are dependent on advice) in respect of the use or implementation of those statements that were made in the expertise.

Policy advice is *not* (or vice versa: the false understanding of policy advice is) (a) the attempt to have a *direct* influence on the policy decision (this would mean that fact and value levels would be integrated in an inadmissible way and objectivity significantly reduced); (b) the *value-orientated selection* of data and findings with the aim of wanting to have a direct influence on the political decision (this would significantly reduce the objectivity); (c) the unilateral *concentration* on political recommendations without a detailed explanation of the data, findings, and analysis from which these recommendations can be derived; (d) orientated on the (suspected or immediately exploitable) expectations which the principal has of the *content* design of the data, findings, and analyses (e.g., in terms of the selection of “certain” data and findings, as well as the undertaking of “particular” analyses), as well as of the statements on the *content* in the recommendations; (e) the design of the expertise in a style of thought and language which could not be understood by a layperson (in this case, it would not be a consultancy as such); (f) the formulation of policy recommendations which are, in their form and implementation, not adapted to the typical requirements that are characteristic of politics (keyword: unrealistic recommendations); and (g) the formulation of recommendations that basically have little or nothing to do with political decisions.

Which Questions Occupy the Psychology of Policy?

The psychology of policy advice is concerned with information processing in terms of political and policy-relevant content, whereby it assumes

the influences of motivation, values, beliefs, and attitudes on the information processing. Furthermore, it deals with the question of to what extent information processing and political discussions and decisions are influenced by prejudices and stereotypes. Finally, it studies the psychological processes in the communication between advisers and the political decision-makers.

Political psychology is concerned with the process of the genesis, maintenance, and change of political attitudes and beliefs and with the motivation behind the process. It is also concerned with the importance of more general, value-laden attitudes, beliefs, prejudices, and stereotypes for political decision-making and action, whereby psychology assumes that the motivation for taking certain decisions and actions is often not (to a full extent) understood.

Political psychology, and the psychology of policy advice, also delves into the question of how the politically significant or relevant information in hot processes (i.e., emotionally and affectively important and thus “loaded” situations) is received and processed.

What Aspects of Policy Advice Should Be Particularly Considered from a Psychological Perspective?

There are seven aspects that must be taken into account: (I) frequent high expectations of the experts with regard to the clarification of problems, expectations which can hardly be met. (II) These exaggerated expectations often have to do with the fact that policy-relevant statements and indeed also specific decision aids are expected of the experts. (III) Experts should make it clear from the outset how their expertise could be useful in the policy-making process; they should emphasize from the outset that they will not make direct political statements. (IV) Basically, no immediate recommendations in relation to specific policy decisions should be made as this can trigger reactance (postulate: do not diminish the freedom of the decision-maker). (V) Experts should be aware of their great responsibility especially when their statements do, in fact, not only serve as the basis for policy recommendations but could also quite possibly influence politicians’

decisions. (VI) Experts should be aware of the differences between value statements and factual statements; these two levels have to be considered in all phases of policy advice. (VII) Care should be taken not to overburden politicians with information as it can cause them to orientate themselves solely on value statements (and not on factual statements).

To What Extent Is Gerontopsychology a Special Field in Policy Advice?

Politicians often have only little knowledge of gerontology and yet, in this area, there is a great need for advice. Aging is a relatively new cultural phenomenon – for this reason there is uncertainty on the part of the politicians in respect of finding solutions to the demands posed by aging. Due to this uncertainty, many assumptions, positive or negative prejudices, and stereotypes prevail with regard to aging. Older people constitute *not quantitatively* but *expressively* a minority; thus there is the risk of discrimination in political decision-making (and thus also in the distribution of resources). It can be assumed that the establishment of seniors’ coordination centers in the future will increasingly become an alternative within districts or counties; however, these coordination centers will be confronted with a wide range of demands.

Policy Advice in the Context of a Value Judgment Dispute

This contribution touches upon a historical discussion, which has gone down in the history of science under the term, “value judgment controversy” (Turner and Factor 2014). In the period before the First World War, there was intensive debate in the *Verein für Socialpolitik* (Association for Social Policy) as to what the relationship between science and politics should be: may, or indeed can, science, in its own understanding, form the basis of political decisions by making *normative* statements? Can science, by its very nature, make value judgments that convey policy orientation? Or must science always refrain from any value judgments? In the *Verein für*

Socialpolitik, it was mainly Max Weber and Werner Sombart who represented the belief that science must, in principle, argue *free from value judgments* and must wholly refer to empirical findings. The counterpart was formed by scientists who, with a view to *questions of social justice*, felt that it was an important obligation of science to comment on social issues, thereby also making normative statements. After all, against a background of social inequality, science could and should be allowed to address societal issues and *not be value neutral*. Moreover, according to the counterpart, society was dependent on scientific disciplines for the resolution of social problems, disciplines which possessed the potential to contribute to the solution of these problems (Weber and Dreijmanis 2008).

The statement that science, in its own understanding, was not in a position to make any normative statements or value judgments was often misinterpreted in the sense that the values corpus basically defied systematic scientific debate. Following Max Weber, values are actually *not the result* of empirical research, but the research can and should systematically deal with the question of what influences the forming and changing of values and, above all, with the question of which paths should be taken to realize values and the related objectives. Other tasks of empirical research arise precisely in this context, such as evaluating the *appropriateness* of values and goals in the given situation at the time (do these appear to be at all realistic, and can they actually be realized?), as well as the answer to the question as to what extent existing values and objectives are *compatible or incompatible* and how far the values expressed are *traceable to even more fundamental values*, which are not articulated in public discourse and are not disclosed. In addition, it must not be overlooked that values are realized in the decision for a specific research topic: the distinction made in the theory of science between the discovery and the context of justification takes up this very point (Šešelja and Straßer 2014). The interest in a particular question (“context of discovery”) may well be connected to the values of a human being, but the empirical analysis of this question

(“context of justification”) needs to be free from values.

The findings of empirical research are essential for political objectives. National reports on aging do not only inform about situations of older people in the respective countries but also about possible antecedences and consequences of inequalities and expected effectiveness of alternative intervention measures. Moreover, scientific policy advice is regularly expected to give guidance on how specific policy aims might be reached. Here, however, scientists have to exercise restraint when it comes to *how their findings are used in politics*. Much like in the ethical discourse, it is necessary to distinguish between *is* and *ought*: while empirical research is directed at the formulation of “existence statements,” politics leans toward “ought statements,” in much the same way that ethics does. It frames its questions in terms of how the social world *ought* to be created and what might be meant by a *good life* from a social perspective. Such questions cannot be derived from empirical research. For instance, the question relevant to how the social world *ought* to be is not one that can be answered empirically.

However, scientists are then faced with a *potential conflict* of which they always need to be aware: they are not only scientists but also citizens. Accordingly, they do not just live in the *scientific* area but also in the *public* space, which is also a *political* space. The conflict is particularly exacerbated when scientific findings are misunderstood, overgeneralized, or even *instrumentalized*, i.e., used for policy objective definitions, such as in the case of taking empirical findings on the stability of specific personality traits in old age or increasing definiteness of narrative selves as alleged evidence for lack of psychotherapeutic treatability of older adults. Likewise, taking increased rigidity, shorter remaining lifetime, higher dependency, and vulnerability of older adults as evidence for decreasing benefits that older adults would receive from possible intervention measures (e.g., hip replacement surgery) is similarly unfounded. Findings on general satisfaction with the accessibility of health-care services might contribute to reducing

awareness of disadvantaged smaller groups (e.g., older people with constrained ability). The aforementioned examples illustrate that chronological age is often used to justify claims to rationalize services, whereas heterogeneity of aging processes and respective chances and limits of possible intervention measures are regularly neglected. Here, a clear limit needs to be drawn between research objectives and research statements on the one hand and policy objectives and policy statements on the other.

Two Basic Functions of Scientific Policy Advice

Firstly, policy advice has an *enlightening* function: it should explain to the political decision-makers, as well as to the administration, how a specific phenomenon is factually presented (“being statement”). It should also explain how the phenomenon is significant for defining and prioritizing potential policy aims and needs for political action, including the design of the public space and thus for political action (e.g., the fifth and sixth German National Report on Aging focused on potentials of old age for economy and society and images of old age and aging). Here, it must be questioned whether there is a need for “ought-to-be statements” to be that far removed from “being statements.” Otherwise, the idea of what the social world should be becomes unrealistic and results in political action being guided by illusions rather than implementable goals. This enlightening function can be used to define *realistic* objectives. However, this does not mean that the scientific (i.e., the being) statements stress more, primarily or exclusively, the *limits* of political action goals. No, scientific statements can also clarify *potentials* of political action by demonstrating how a social phenomenon *could* itself be presented, if its potentials were to be recognized and these potentials then promoted in the implementation thereof in the design of public spaces. To give an age-related example here: the physical, cognitive, emotional, and social plasticity of age – in the sense that a significant opportunity for designing the physical, cognitive,

emotional, and social development is present in old age (Cavanaugh and Blanchard-Fields 2014) – may reach their limits if the appropriate opportunity structures for the realization of physical, cognitive, emotional, and social plasticity are not even available. This may be due to the appropriate education and engagement opportunities are not politically “wanted,” or are not created politically, and/or because the reduction in social inequality in *all* age groups is not defined as a real political objective or else not enough is done for the realization of this objective or the measures introduced are inadequate (Vincent 2014). In other words, the possibilities and limits of plasticity are always *also* provided through the design of public space and thus politically.

In addition to this enlightening function, policy advice has a *critical* function. It is an *empirically checked and exposed* function. Empirical (i.e., “being) statements” are required to determine how far these normative statements are actually value judgments. Taking an age-related example, it has been argued by some that the possible effects of medical-rehabilitative or psychotherapeutic measures in older age have to be examined, because older people – especially the very old – no longer have the necessary physical, cognitive, and emotional plasticity (Gutchess 2014). Scientific expertise can and should unmask such a statement for what it is: a value judgment, an age-based statement which is motivated by “hidden” objectives such as age-related rationing, or a general devaluation (discrimination) of age (Anderson et al. 2013). By using scientific expertise to provide counterevidence to this statement, it fulfills a *critical* function and thus creates the basis for a significant extension of the policy planning, decision, and action spectrum.

This critical function of policy advice also comes into play when it questions whether certain political goals are *realistic* or not or whether these goals are a *contradiction* or not. Here, too, age-related examples are mentioned: for example, if retirement age is raised to 70, or even abolished, then there is the question (*to be empirically examined*) as to whether such a goal is even realistic (Vanhuysse and Goerres 2013). With regard to the resources, potentials, and skills in old age, it is

quite often assumed that *everyone is* able to continue their profession up to this age. Empirical research advises caution here – not only with regard to the heterogeneity of abilities and skills in old age but also, more specifically, by elucidating the challenging labor market circumstances for at-risk populations of older people, particularly displaced older workers; older workers with disabilities, prolonged or episodic illness, mental health issues, or injuries; low-skilled and low-literacy older workers; older workers with unpaid caregiving responsibilities; and recent older immigrants (National Seniors Council 2013). The (given or lack of) consistency of the objectives then constitutes an important issue if, on the one hand, intergenerational solidarity – considering the needs of all the generations – is described as a policy objective but, on the other hand, with reference to the freedom order, the discussion of the question is blocked as to what extent a stronger social commitment of those older people, who do have the necessary resources (keywords: work longer, redistribution of financial resources within the older generation), can relieve the social security systems to such an extent that their sustainability can actually be secured (Torp 2015). Moreover, changing labor market circumstances for older people also has an impact on younger generations. Provided that jobs are a finite resource, chances for older and younger workers have to be balanced. However, this does not mean that increasing labor market participation of older people restricts developmental possibilities of younger workers or even endangers generational equity. Instead, when usage of human capital in older people increases productivity and competitiveness, additional or longer employment of older workers can also contribute to improved job opportunities for younger workers.

An Example of Policy Advice: The International Plan of Action on Aging

First International Plan of Action on Aging

Demographic change needs to be understood as a global phenomenon. The time in which more old

than young people live on our earth is within reach and even emerging, and developing countries are not excluded from the aging population. Although the time horizons and intensities of these changes differ, we are dealing with a global development. Only gradually are international solutions sought globally for comparable problems, and only very rarely are joint strategies developed (Ezeh et al. 2012).

Exceptions are the approaches of the United Nations. As early as 1982, an almost pioneering action plan on the part of the international community was adopted at the World Assembly on Aging in Vienna (United Nations 1983). In this document, goals and policy recommendations are outlined in seven areas of concern to aging individuals, i.e., health and nutrition, protection of elderly consumers, housing and environment, family, social welfare, income security and employment, and education. The positions and guidelines formulated therein have, even from today's perspective, lost none of their relevance. For the early 1980s, the document included innovative ideas relevant to the global consequences of demographic change:

The trend towards the successive ageing of population structures is bound to be one of the main challenges to international and national planning efforts during the last decades of this century and well into the twenty-first. In addition to the general consideration outlined above on the status and predicaments of the elderly sections of societies, and the review of the needs and potentialities of the elderly, attention should be given to the vast and multifaceted impact which the ageing of populations will have on the structure, functioning and further development of all societies of the world [...]. (17, Para 33)

At this point in time, gerontology, with its study of aging processes, had already undergone a considerable development boost. However, beyond the universities, the sociopolitical impacts to date have only been taken up individually. The International Age Plan has thus been instrumental in the understanding and acceptance of the fact that the issues of aging are an immediate political task area. During the following period, the continuation of the systematic processing of the objectives and recommendations in the document

was unsuccessful. It was not possible to comply with the therein requested evaluation in a 4-year cycle. Only in the form of isolated initiatives does the subject of age and aging emerge on the agenda of the United Nations again.

Only in 2002 – after 20 years – was the importance of the International action plan recognized and adapted to the current situation, as part of the second world assembly. The signed agreement, also called the Madrid Plan, revealed the problems, objectives, and possible sociopolitical action areas. Among the key themes was an improvement in the living conditions particularly of older people by fighting poverty, sociopolitical participation, individual self-fulfillment, respect for human rights, and equality of men and women. At the same time, adjustments in the areas of employment, social security, health, and well-being were required (United Nations 2002). However, the action plan remained, as did its predecessor, without international legal liability. Building upon this, the efforts toward achieving regional implementation initially created the impression that supranational policies toward aging could succeed. First and foremost, the Economic Commission for Europe (UNECE) gave essential stimulus and guides for positive action. Retrospectively, however, it is sobering to note that, at the time, the chance of an international view of age was not consistently followed up and brought to life. Even in the immediate UN follow-up documents on the associated social policy topics, one looks in vain for a connection to the new International Age Plan.

Second International Plan of Action on Aging (Madrid Plan of Action)

The respective social and cultural contexts of a society and the associated images of age therein must be taken into account, particularly when it comes to the question of the use of potential resources of age for society. For this reason, the United Nations established a technical committee to prepare the Second International Plan of Action on Aging – which was adopted by the General Assembly of the United Nations in 2002 (United Nations 2002) – in which 15 scientists from five continents submitted proposals for the

development of strategies in the areas of education, labor, health, and social services, with the aim of creating “age-friendly environments.” (The first author (Andreas Kruse) had been a member of this committee.)

Similar to the First International Plan of Action on Aging adopted in 1982, the Second International Plan of Action on Aging also states that, within the international community, there are extremely large differences, both in prosperity and in the related prosperous living conditions, as well as in the design of the spatial, social, and infrastructural environment, whereby these differences become even more evident when comparing the living conditions and environments of older people to the living conditions and environments of people at earlier ages (Sidorenko and Mikhailova 2012).

Accordingly differentiated are the policy recommendations that have been developed in the two International Age Plans. In addition to the diversity of political strategies resulting from the aforementioned differences, similarities between countries in relation to the social issues of age can also be seen. These not only concern the provision of societal resources to reduce the health, social, and financial risks in old age but also the creation of an infrastructure for the social use of the resources of age. The technical committee has set forth five principles in its proposals for the development of strategies for the realization of the theme, “Society for All Ages” (Walker and Maltby 2012):

1. Life course development: Development potential is identifiable in every life phase. The process of the realization of these potentials is influenced by the typical social roles and social status in the specific life phases. Age-specific individual development potential can be used to benefit society.
2. Development and age: This principle combines the social and economic aspects of aging. Older people have an active part in development processes, benefit from these, and are quite possibly marginalized due to this.
3. Cultural/ethnic diversity: This principle depends on the ideal of basic human rights,

accentuates tolerance toward all ages, and points out the dangers which are connected with focusing exclusively on the respective dominant culture.

4. Gender: This principle refers to the fact that women are particularly affected by the negative aspects of aging and age. Accordingly, both preventative measures and measures which contribute to an immediate improvement in the living conditions in old age are required.
5. Intergenerational relations and social cohesion: This principle refers equally to the micro- and macro-levels. At the microlevel, family-related subjects are dealt with; at the macro-level, the focus is on solidarity, citizenship, and intergenerational justice. These reciprocity, solidarity, and development need to be supported equally.

National and International Expert Reports on Aging are regularly considered important and helpful because of informative, elucidating, and stimulating content. However, certain reports have had only little impact on aging policy. For example, in a resolution adopted by the United Nations General Assembly (United Nations 2010), it is recognized “that, in many parts of the world, awareness of the Madrid Plan of Action (Second International Plan of Action on Aging) remains limited or non-existent, which limits the scope of implementation efforts.” As a consequence, the aforementioned resolution explicates a total of 23 recommendations to further improve the implementation process; e.g., in recommendation (Anderson et al. 2013), the resolution “encourages Governments to pay greater attention to building capacity to eradicate poverty among older persons, in particular older women, by mainstreaming aging issues into poverty eradication strategies and national development plans, and to include both aging-specific policies and aging-mainstreaming efforts in their national strategies”; recommendation (Ardelt et al. 2013) “encourages Member States to strengthen their efforts to develop national capacity to address their national implementation priorities identified during the review and appraisal of the Madrid

Plan of Action, and invites Member States that have not done so to consider a step-by-step approach to developing capacity” (Turner and Factor 2014, p. 350).

“Age-Friendly Culture” as a Principal Aim of Aging Policy and Respective Guidance

The definition of an age-friendly culture emphasizes three aspects in particular. First, when society is spoken of, it is referring specifically to the elderly who form a significant and, in the future, an increasingly important part of society. Second, in the creation of framework conditions for the realization of potential, there must be recognition that older people, as active citizens, should be able to express their rights of participation. Finally, the same applies to vulnerability; older people should be able to show this without having to worry about being excluded from their participatory rights or opportunities in society as a consequence.

A profound reservation against old age in Western societies is reflected in the domain of employment (Finkelstein et al. 2015). Early retirement programs are still an often preferred solution for problems of productivity and competitiveness. Displaced older workers still regularly suffer from longer unemployment. Older workers still have particularly low rates of participation in extended vocational training. In addition, the aforementioned reservations toward age are clear in the current discussion of necessary reforms of the social security system. The risks of old age and the resulting financial burdens are unilaterally emphasized (Kruse 2013). With a view to civic engagement, it can be seen that the existing engagement of older people is just not acknowledged but, above all, that older people are only too rarely approached as jointly responsible citizens whose contribution is indispensable for society (Kruse and Schmitt 2015). The fact that people in old and very old age continue to develop and make a contribution to our society’s human capital (e.g., through their experience and knowledge) (Ardelt et al. 2013) is just not sufficiently recognized.

Drawing attention to existing potentials does not mean that an optimistic forecast in the aging processes in future cohorts, the development of the labor market and innovation capacity, or the sustainability of existing support systems has been made. The potentials of age refer much more to a twofold design option, which is to be understood in the sense of an opportunity and a challenge (for the individual and for society). From an individual perspective, on the basis of the stated potentials, and when compared to previous generations, there are now clearly significantly better possibilities for older people to fulfill their own life plans, goals, and values, as well as to participate in social development and to engage themselves for others and the community. From a societal perspective, the potentials of age refer firstly to the opportunity to contribute, by means of motivational, social, cultural, and institutional conditions, to the growing proportion of older people being able to lead an independent, self-, and jointly responsible life for as long as possible, whereby attention must be directed at the reduction in social inequality – not just in old and very old age but also in the preceding stages of life (Kruse and Schmitt 2015).

Moreover, the question arises as to what extent a society can also benefit from the experiences of older people when dealing with critical situations that are increasingly unavoidable, especially in old and very old age. At an advanced age, the increased experiencing of limitations – the “radicalization of the physically captured basic situation of the people” – also offers the chance of a qualitatively new fulfillment of individuation in which the individual can experience his or her own life as “the coming into existence of the singular totality” or as a “will to himself or herself” (Rentsch 2014).

A major social issue that is addressed with the potential and the vulnerability in old and very old age relates to intragenerational justice, which has consequences for the design of intergenerational relations. Potentials of age can and should be used in a socially responsible manner, i.e., this society should be in a position to effectively support those older people who find themselves in distress, be this health, social, and/or financial distress.

How can the term *age-friendly culture* be defined?

- (I) First of all, age-friendly refers to the involvement of older people in the social, political, and cultural discourse, as well as in social and cultural progress. Only too frequently in public discourse, there is the tendency to talk *about* the elderly, but not *with* them. This is an expression of the neglect of older people, if not hidden discrimination. Talking *about* the elderly, but not talking *to* them, suggests the assumption that older people are not perceived as active, co-responsible parts of society and that their potentials are not being taken seriously. In an age-friendly culture, elderly women and men are equally heard and are treated with as much respect as younger people. An age-friendly culture does not make generalization about the group of “older people” but respects the “uniqueness of being” of older women and men.
- (II) Related to the first-mentioned feature of an age-friendly culture, but with a slightly different emphasis, is the intergenerational perspective which forms the second feature of an age-friendly culture. We elucidated that age must be integrated into an intergenerational perspective, whereby it must be explicitly stated – and empirical findings support this statement – that there is an active exchange of ideas, knowledge, experience, assistance, and sympathy between the generations. This being embedded in a generation sequence is an important expression of participation, more so for the elderly than for the young. Moreover, the generativity and transcendence motivations, which are so important in old age, can be realized. Prominent examples of this intergenerational perspective are generation tandems and mentoring opportunities in the workplace, as well as sponsorships of older people in civic matters.
- (III) An age-friendly culture articulates the vital interest in the potentials of age (which can, of course, vary considerably from person to

- person) and creates conditions and public spaces that are conducive to the realization of such potentials – to be mentioned here is the introduction of the flexible retirement age in the world of work (which is not to be construed as a relinquishment of legally defined age limits), as well as the removal of all age limits in the field of civic engagement. Also important are the opportunity structures, such as community centers, where the generations can meet, enrich, and support each other: an important incentive to realizing potentials in old age.
- (IV) An age-friendly culture encounters older women and men, in whom vulnerability is clearly expressed, with respect and sensitivity. It provides socio-spatial contexts that promote independence and self-responsibility and secure participation – to mention are places to meet in the living quarters and to mention too are differentiated, target-group-specific service systems, as well as barrier-free environments, all of which have a positive impact on the maintenance or recovery of independence and mobility (Sharratt, M., Menec, V., *Age-Friendly Communities*, this Volume).
- (V) In the case of severe physical and cognitive losses in an older person, an age-friendly culture respects the individual's uniqueness, expresses their respect for the dignity of this individual, avoids trying to externally determine the quality of life of this person, and neither denies the individual the fundamental right of participation nor expert and ethically sound medical care. A "grading" of human dignity is avoided, as is an age-determined "downgrading" of the extent and quality of the medical and other care. Decisive for this provision is the diagnosis made by an expert alone, not the age of the individual concerned. We elucidated that continuous and institutionalized policy advice is particularly important because aging policy cannot be based on subjective aging theories and policy-makers' incidental reception of scientific knowledge.
- (VI) An age-friendly culture is determined to reduce social inequality among the group of older people and to ensure that every person – regardless of education, income, or social class – receives the social and medical services which are known to be necessary for his or her specific life situation (Liou-Johnson, V., Moorleghem, K., Mills, B., O'hara, R., *Ageing, in Equalities and Health*, this Volume). Apparently, social inequalities do not decrease with age. We elucidated this point particularly by referring to at-risk groups of older people in the labor market.
- (VII) An age-friendly culture does not deny the rights, claims, or needs of younger people, rather it endeavors to identify and recognize the rights, claims, and needs of all the generations, whereby no single generation is preferred or disadvantaged. We elucidated this point referring to the labor market where sometimes chances of older and younger workers have to be balanced and sometimes increasing opportunities for older workers go hand in hand with vital interests of younger workers.

Conclusion

Building an intervention-friendly society for all ages depends on policy-makers' appreciation of resources and malleability of lifelong development. Policy-makers' deliberations and decisions not uncommonly reflect unacknowledged preferences and value judgments, elucidating both the informative and critical functions of science in general and scientific counseling in particular. This entry provided basic reflections on the role of policy advice in the context of the philosophical value judgment dispute and discussed the aforementioned functions of scientific policy advice in more detail. The explicated understanding of age-friendly culture should be regarded as a desirable vision of society development that might function as a background for appraisal of the status quo, actual discrepancy, and priority goals of aging policy.

Psychology of Longevity

Boo Johansson and Pär Bjälkebring
Department of Psychology, University of
Gothenburg, Gothenburg, Sweden

Synonyms

Later life; Old age; Survival

Definition

Longevity denotes especially long-lived members of a population. It is separated from life expectancy which focuses on the likely mean age of death within a population.

Introduction

There is no overarching theory of aging and longevity or a specific psychological theory targeting longevity as the main outcome. Survival into

advanced ages is determined by multiple influences of genes interacting with environmental conditions over the entire life span. Already from embryonic life, individual experiences and behavior influence health, functioning, and the likelihood for longevity. To capture all these dimensions in a single theory seems impossible.

Biological theories focus on evolutionary aspects and underlying mechanisms for life and typically define longevity as the potential life span under ideal conditions. Foci in social theories are contextual influences related to survival, especially the socioeconomic environment that humankind has designed in the format of roles, institutions, and principles for age stratification over the life course. From a psychological perspective, longevity can be considered in relation to cognitive abilities, personality, and various aspects of well-being. The interactions of these psychological domains are expressed in our adaptation to everyday environmental demands and in later life to age-related biological changes, which in turn produce differential conditions for survival. In this respect, the psychology of longevity represents a nondeterministic approach in the crossroad of biological and social influences with a focus on biological constraints and socioeconomic prerequisites for cognition, personality, and affective components. There are several theoretical accounts proposed in biobehavioral and social sciences of relevance also for our understanding of the psychology of longevity. However, these theories and models do not typically focus on longevity as the main outcome.

The manifestation of a survival advantage becomes visible when an individual lives longer than the average person, from the same birth cohort. Thus, longevity needs to be related to the actual life expectancy in a certain population. A substantial gap between the average life span and a long-lived person directs our attention to factors that may contribute to the observed differences. To conduct such a search, we have to compare mortality rates within an older population and examine whether we can identify shared psychological characteristics and behaviors among those who live the longest.

Early ideas about longevity were typically based on the assumption that genetic influences and age-related biological changes produced unavoidable neurobiological changes and thereby changes in behavior. Later research gradually acknowledged that psychological characteristics and behavior are formed and expressed differently in various environmental contexts. Life-course influences, coping strategies relative to environmental demands, and more general lifestyles are therefore currently considered for their relevance to longevity. In this less deterministic view of longevity, psychological factors may have a more significant role.

A general psychological stress model of aging provides a broad theoretical framework for the psychology of longevity. Coping strategies in the broadest sense can here be seen as the psychological mechanisms we employ to fit our own perceived resources to demands and challenges in the external environment and changes due to our own age-related bodily change. Unlike a stochastic theory that views aging and death as a result of stressors that cause wear and tear on cells and disrupt function, a stress model emphasizes that both external and internal psychological stressors can cross the mind-body barrier with effects on overall health, survival, and longevity.

In the first section, we review empirical studies that illustrate the significance of cognitive “”functioning, personality, various aspects of self-perceived health and well-being in aging, as well as social connectedness. The focus is restricted to the potential role of these psychological factors as predictors of differences in survival rates in aging. At the end of the chapter, we synthesize these findings and suggest an overall theoretical account and model for the role of psychological factors in producing variance in survival and especially psychological predictors of longevity.

Cognition and Longevity

Cognition or the ability to think, learn, and remember is the basis for how we reason, judge, concentrate, and plan our daily lives. In geropsychology, cognitive health refers more specifically to cognitive test performance, self-perceptions, and others’

evaluations of memory and other cognitive abilities in everyday life.

An increasing body of empirical studies provides support for an association between higher cognitive abilities, already early in life, and a lower risk for subsequent mortality, less morbidity, and overall better health. These findings suggest a general life-course perspective in which cognitive abilities are viewed as significant for longevity. Among potential accounts, Deary (2012) proposed that this association may even be ascribed to a general body system integrity in which better performance on cognitive tests also reflects the vitality of other bodily systems that make individuals adapt better to their environment. However, this assumption is not new, and 2400 years ago Hippocrates even assumed that good cognition and appetite have prognostic value for survival. Two millennia later, St. John and Montgomery (2014) confirmed these thoughts. Using brief data from the Manitoba Study of Health and Aging, they compared individuals with normal cognition and good appetite with those with either poor cognition or poor appetite. They found that these two factors also were able to significantly predict death in a modern population.

Cognitive ability is a strong predictor of survival across the entire life span, and in cases with more severely compromised cognition, an elevated mortality risk can be observed (e.g., Johansson and Zarit 1995). The most convincing evidence of an association between cognitive ability and later survival is provided by studies applying a distance from death time metric in the analysis. These longitudinal analyses can, however, only be conducted in samples followed until death. Studies of the terminal decline hypothesis, originally proposed by Kleemeier (1965) in the 1960s, are largely based on the idea that cognitive change is a more informative marker of the likelihood for subsequent survival or death compared with information about chronological age or time from birth. According to this hypothesis, also referred to as terminal change or terminal drop, one can also expect an acceleration of cognitive decline in the years prior to death.

The first generation of studies on terminal decline typically focused on levels of cognitive

performance in relation to the likelihood of later survival (e.g., Bosworth and Siegler 2002). Cognitive test performance was generally found to be associated with subsequent survival in between-person analyses. In later studies, analyses are more often conducted using a within-person perspective, focusing on intraindividual change trajectories in relation to survival.

Using longitudinal data from the H70 study in Gothenburg, Sweden, in which 70-year-olds were followed until death, Thorvaldsson et al. (2008) examined the time of onset and rate of change in terminal decline in tests of verbal ability, spatial ability, and perceptual speed. The sample comprised 288 individuals without dementia. Change-point analysis was performed to identify inflection points, and a profile likelihood method was used to identify change points for each of the three cognitive abilities. The results demonstrate that the onset of terminal decline was identified more than 6 years prior to death for verbal ability, close to 8 years for spatial ability, and as early as almost 15 years for perceptual speed. Thus, both the time of onset and rate of terminal decline can vary considerably for various cognitive abilities.

The lesson to be learned from an increasing number of studies based on the terminal decline paradigm is that cognitive change is related to survival, although fluid abilities are more prone to show change than crystallized or verbal abilities that are more robust to change.

The findings of an association between cognitive functioning and survival also extend into the range of compromised cognition and subsequent dementia. Data from two Swedish population-based longitudinal studies was used to more specifically examine change trajectories in different abilities before a clinical diagnosis of dementia. The analyses revealed an onset of accelerated decline in the fluid domain of speed and memory approximately 10 years before dementia. The corresponding interval was about 5 years before diagnosis in tests of verbal or crystallized ability. An early onset of change in fluid abilities can predict subsequent onset of dementia as well as indicate an elevated mortality risk almost a decade in advance. These changes are, however, more difficult to detect due to substantial normal

age-related decline, compared with the more aging robust crystallized abilities (Thorvaldsson et al. 2011). Evidence is currently accumulating that shows that terminal decline is more universal and can account for change also in other domains of cognitive functioning (e.g., Wilson et al. 2012).

Since the early days of the so-called “use-it or lose-it” hypothesis, the assumption was that cognitively stimulating activities could preserve cognition and perhaps even have a neuroprotective role. Although an appealing assumption, the empirical evidence for this hypothesis is less convincing. For example, a coordinated analysis based on data from four major longitudinal aging studies, in which cognitive outcomes were studied for more than 20 years, showed that baseline cognitive activity and engagement at earlier ages did not predict the rate of decline later in life. Change in cognitive engagement, however, was associated with change in cognitive performance, suggesting that cognitive activity from a previous level has at least a transitory association with cognitive performance measured at the same point in time (Mitchell et al. 2012).

A theoretical approach related to the use-it or lose-it (or disuse) hypothesis is that of a greater cognitive reserve among individuals who have experienced more complex mental activity over the life span. Crystallized abilities are per definition associated with practice, training, education, and other influences that promote cognitive functioning. As repeatedly shown, these abilities are less prone to age-related change. In older ages, however, cognitive performance tends to become more dependent on preserved brain integrity and the amount of neuropathology that has accumulated over the years. After a certain inflection point, a cognitive ability might start to decline, but the decline is likely to start later and with a faster rate for those with a higher cognitive reserve (Stern 2012). The empirical evidence for a more universal and protective role of an assumed cognitive reserve, however, is still weak.

In sum, cognitive abilities are highly associated with survival and longevity, but the evidence for modifiability for the sake of an increasing life-span is less convincing.

Personality and Longevity

In the five-factor model of personality, the following core dimensions are distinguished: (1) extraversion with characteristics such as sociability, talkativeness, excitability, assertiveness, and high amounts of emotional expressiveness; (2) neuroticism expressed in emotional instability, anxiety and depressive mood, and irritability; (3) agreeableness, including attributes of trust, altruism, and various forms of prosocial behavior; (4) openness, shown as imagination and insight and in a broad range of interests; and (5) conscientiousness, which includes thoughtfulness, impulse-personal control, and goal-directed behaviors with the awareness of details in a broader context (e.g., Costa and McCrae 1992).

Among these personality characteristics, conscientiousness is typically found to be the most significant dimension associated with longevity. In addition, conscientiousness is also a predictor of more healthy behaviors and overall physical health (e.g., Friedman et al. 2014).

An interesting study on the role of conscientiousness for longevity was reported by Friedman et al. (1993). In using data of mortality in Terman's study from the 1920s, they found that conscientiousness in childhood was significantly related to survival decades later. Kern and colleagues (2009) also examined conscientiousness measured in young life, as well as later career success and the mortality risk over a 65-year period. They found that personality moderated the success-longevity link and that conscientiousness was the best predictor for survival among the least career successful individuals. This finding was confirmed by Terracciano and colleagues (2008) in their analyses of individuals followed for nearly 50 years in the Baltimore Longitudinal Study of Aging. Interestingly, they found that the association between personality traits and longevity was largely independent from health risk factors like smoking and obesity.

Along the lines of a life-span developmental inquiry, Eaton and colleagues (2012) proposed a more detailed investigation of personality as a nexus for connecting genetics, environment, and health outcomes, including longevity. The general idea is that personality reflects psychological

mechanisms that predispose individuals to engage in various health or unhealthy behavior across the life span, which in turn affects the likelihood for later survival.

Hill et al. (2011) designed a study to better understand the conscientious and longevity link. Using a 10-year longitudinal sample, they tested whether physical health and cognitive functioning mediated the association in the Health and Retirement Study of aging adults. Their measures included, in addition to conscientiousness, self-reported health conditions and measures of cognitive functioning (word recall, delayed recall, and vocabulary). Conscientiousness directly predicted greater longevity, even when the two mediators were included. They also found that cognitive functioning partially mediated the relationship.

Although personality largely remains stable over the life span, certain changes have been linked to longevity. Higher neuroticism is associated with more negative emotions and lower capacity in regulating emotional stressors, and increased neuroticism within a person has been linked to physical health problems as well as increased mortality (Mroczek and Spiro 2007).

Another aspect of personality linked to mortality is extroversion, higher extroversion with decreased mortality (Wilson et al. 2004). The link between extraversion and mortality is typically accompanied with greater social embeddedness. Our personality hence influences how we relate to others; trust, a subfacet of agreeableness, has been shown to be especially important. Barefoot et al. (1998) used scores on Rotter's Interpersonal Trust Scale to predict subsequent survival in a sample followed for mortality over 14 years from baseline. The analysis revealed a weak, but significant, association, suggesting that trust is a psychological dimension worth considering in relation to personality and longevity.

In sum, among the personality dimensions discerned in the five-factor model, conscientiousness is repeatedly found to be the dimension most strongly associated with longevity. However, behavior promoting longevity always reflects an interaction between underlying personality dimensions, situational and broader contextual variables that may prevent or allow the expression of core personality.

Subjective Aging and Longevity

Individuals typically have reference points that guide our perception of experienced age: some feel older than their chronological age, and some feel younger. In addition to being an alternative marker of development, subjective age is theorized to be a possible personal dimension that can be used to explore individual behavior and functioning (Montepare 2009).

Focusing on subjective life expectancy within a biopsychosocial framework, Griffin et al. (2013) found that individuals' ideas of their likely age at death were significantly related to biomedical and genetic factors (age, health diagnoses, parental longevity), health behaviors (exercise, smoking, alcohol use, diet), and psychosocial factors (optimism, distress, social connectedness), but not to socioeconomic factors (income, education). The findings show that individuals have the ability to construct an understanding of personal life expectancy that is largely based on significant predictors actually proven to be associated with actual life expectancy.

A study that specifically highlighted this psychological aspect of knowing how long one will survive was conducted by Levy and collaborators (2002). They used data from a sample of more than 600 individuals aged 50 and older who participated the Ohio Longitudinal Study of Aging and Retirement. Based on a survival analysis, they showed that older adults with more positive self-perceptions of aging in fact survived longer, on average more than 7 years, than those with less positive self-perceptions. The finding remained even after controlling covariates age, gender, socioeconomic status, loneliness, and functional health. Interestingly, the effect was partially mediated by the will to live.

Kotter et al. (2009) examined whether, and how, self-perceptions of aging change with age and whether such change is associated with distance from death. Using data from the Berlin Aging Study, they found that it seemed to be experiences of more favorable change patterns, not only better overall satisfaction with aging and subjective age that contributes to lower mortality hazards.

The effect of subjective aging, or how individuals perceive their own aging in relation to longevity, was analyzed in a meta-analysis by Westerhof and colleagues (2014). Based on a systematic literature search, they identified longitudinal studies reporting effects of subjective aging on health, health behaviors, and longevity. Their meta-analysis resulted in an overall significant effect of subjective aging. The associations were stronger in studies with a shorter follow-up, for health compared with actual survival, and in studies of younger participants. The average age in the studies varied between 57 and 85 years, with a median age of 63 years. Notably, the effects were stronger in studies based in a context where welfare systems and state provisions were minimal. The authors concluded that subjective aging has a small but significant effect on health, health behaviors, and survival.

Offspring's optimism about longevity was found to correlate with parental longevity in two community-dwelling cohorts (Rius-Ottenheim et al. 2012), suggesting that optimism in forecasting may be partly determined by ideas of genetic influences on longevity. Interestingly, such an effect should be evaluated against evidence for heritability estimates of longevity, which have been found to be as low as about 25% (Finch and Tanzi 1997).

Hill and Turino (2014) found beneficial effects on survival among individuals who claimed that they had a purposeful perspective on their life. Using data from the longitudinal Midlife in the United States (MIDUS) study, they showed that purposeful individuals, independent of age, lived longer than their counterparts during a 14-year observation period after the baseline assessment, even after controlling for other markers of psychological and affective well-being. The authors concluded that a purpose in life might buffer against mortality risk across the adult years.

In sum, significant information about the likelihood for survival can be drawn from self-perceptions of aging and subjective life expectancy, which in turn provides evidence for our ability to forecast longevity. In addition, feeling a purpose in life can increase survival.

Well-Being and Longevity

Subjective well-being (SWB) refers to how individuals evaluate their own life, including the emotional experiences of pleasure and what is considered to be a good life. SWB is commonly measured as positive affect which refers to experiences of pleasant emotion and mood, such as happiness and excitement, and low negative affect including the experiences of unpleasant distressing emotions and moods, such as sadness and anger. The balance between positive and negative affect has been used as an overall measure of SWB. In addition, life satisfaction is a construct closely connected to the affective dimensions of SWB, although it relates more to the cognitive evaluation of one's own life at present and how it has unfolded over previous years in terms of an overall satisfaction (i.e., "in most ways my life is close to my ideal and I am satisfied with my life").

Although we tend to strive for well-being over the entire life span, the socioemotional selectivity theory proposed by Carstensen (2006) assumes that the types of emotional states that are viewed as the most positive and preferable tend to change with age and the accompanying sense of a more restricted future time horizon. To feel satisfied with one's life becomes more of a priority than other goals that might have been viewed as important earlier in life. According to the theory, motivational shifts also influence cognitive processing in that older adults tend to show a preference for positive over negative information. This positivity effect may also be reflected in the preference for present emotion-related states over knowledge-related goals.

The sparse knowledge of the relative importance of cognitive and emotional facets of SWB for mortality led Wiest and collaborators (2011) to analyze the differential effects of life satisfaction, positive affect, and negative affect on mortality using data from more than 3000 German adults aged 40–85 years. Using Cox proportional hazards models, they found that no SWB indicator predicted mortality in middle-aged individuals when controlling for covariates. Life satisfaction and positive affect were, however, associated with lower mortality rates in adults older than 65, though self-rated health and physical activity attenuated the effect.

Another longitudinal study that examined components of subjective well-being was reported by Xu and Roberts (2010). They analyzed the relative role of the four well-being components suggested by Diener (2000), that is, global life satisfaction, satisfaction with important life domains, positive and negative affect, in data over 28 years drawn from a sample of nearly 7000 participants in the Alameda County Study. The outcome measure was longevity, evaluated by risks of all-cause, natural-cause, and unnatural-cause mortality. They found that higher well-being predicted a lower risk of all-cause and natural-cause mortality even after an initial control for age, gender, marital status, social contacts and affiliations, baseline health variables in terms of self-reports of chronic medical conditions and functional disabilities, and subjective health. With the exception of negative affect, they concluded that all other variables for subjective well-being significantly predicted longevity.

Lyrra and colleagues (2006) studied the relationship between scores on the Life Satisfaction Index Z scale and subsequent mortality among individuals aged 80 and older. Those in the lowest quartile of satisfaction with present life had an almost twofold risk of mortality compared with those in the highest quartile, even after adjusting for multiple confounders. Satisfaction with past life, however, showed no association with mortality, while current life satisfaction was highly related to survival over the next 10-year period.

Using data from the Longitudinal Study of Aging Danish Twins (LSADT), Sadler et al. (2011) confirmed that SWB predicted longevity in a study sample of 3966 twins aged 70 or older, followed for a median time period of 9 years. Notably, the effects were also revealed in within-pair analyses among 400 fraternal and 274 identical twin pairs which demonstrate that subjective well-being is associated with increased longevity independent of genetic and shared environmental influences.

In sum, positive dimensions of well-being are significantly associated with better survival. Life satisfaction and positive affect are not only markers of happy life, but also important predictors of longevity.

Subjective Health and Longevity

Subjective health, how we perceive our own health status, is likely to also affect how we define our subjective age. However, they are two different factors that both have a relationship to longevity. According to Jyhlä (2009), subjective health, or self-rated health, lies at the crossroads of culture and biology, requiring collaborative and multidisciplinary efforts between several disciplines. She proposed a model of self-rated health, which represents the global statement about multiple aspects of health and in which both subjective and objective dimensions need to be considered.

Several studies have demonstrated that a global self-rating of health is indicative of subsequent survival (Idler and Benyamini 1997; Jyhlä 2009). As suggested by several researchers, self-rated health is a more inclusive measure than most other health indicators typically employed in studies of unselected samples. Jyhlä (2009) emphasizes that even if self-rated health is a significant predictor of mortality, it cannot be given a role as a determinant for the underlying biological devitalization that precedes death. Experienced overall health may only be a condensed evaluation of bodily conditions involved in vital biological processes. Hence, the predictive power of self-rated health becomes weaker in studies controlling for objectively measured health especially among individuals more knowledgeable and better informed about their own health status (Jyhlä 2009).

There is also an association between self-rated health and other dimensions of well-being. In a sample of individuals aged 80 and older, Berg et al. (2006) showed that there is a significant association with life satisfaction. In a follow-up study, she examined the association with 25 common medical diagnoses in old age and found that only stroke, sleep problems, and incontinence were significantly associated with life satisfaction.

The associations between self-rated health, various objective measures of health, and longevity are far from perfect. In a study by Benyamini et al. (2011), they specifically addressed the question: For whom does poor self-rated health not

predict mortality? Using data from a study of individuals aged 75 and older in Israel, they found that engagement in meaningful activities was an indicator of better health and longer survival even among those with poor self-rated health.

Feng et al. (2014) compared self-rated health and interview-rated health in the Chinese Longitudinal Health Longevity Survey and found that disability, cognitive function, chronic disease conditions, psychological well-being, and health behaviors influenced both self-rated health and interview-rated health. In addition to a focus on hard measures of health such as diagnoses, blood pressure, and BMI, it is also important to ask the question: "How would you rate your own overall health?"

In sum, self-rated health is a statistical predictor and an indicator of a self-evaluation of overall health and vitality and findings underscore a significant association between self-rated health and longevity.

Social Connectedness and Longevity

The ability to establish and maintain a social network is partly a reflection of an individual's psychological competency as connectedness, and social embeddedness means that we are mutually attractive for social relationships.

In a meta-analysis, based on more than 90 reports with data on about 400,000 people, Shor and Roelfs (2015) specifically examined the relationship between social contact frequencies and longevity. Although they found a significant overall effect on mortality, subgroup analyses revealed no association among men or for the magnitude of interactions among family members. They concluded that contact frequency seems to be less beneficial than previously assumed for health and survival and that the quality of the social contact should be considered. In the Longitudinal Aging Study Amsterdam (LASA), Ellwardt and collaborators (2015) also examined the mortality risk in participants aged 54–85 at baseline, in relation to functional and structural characteristics of the personal network,

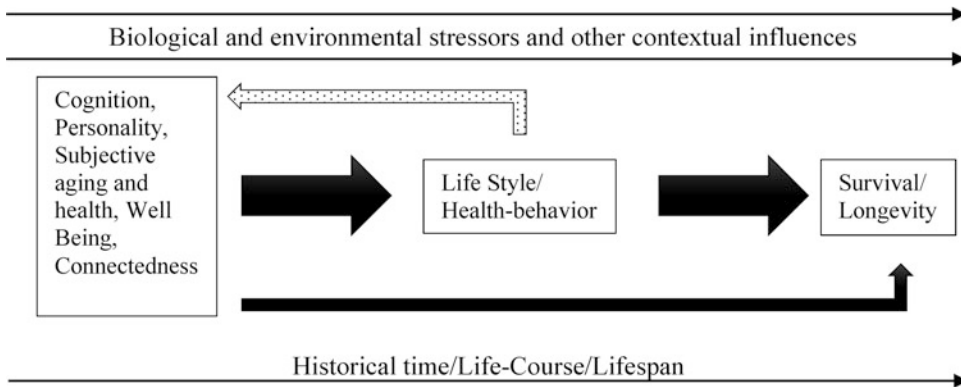

adjusting for mental, cognitive, and physical health. Almost 3000 individuals were followed for mortality over a 20-year time span. The four functional characteristics were emotional loneliness, social loneliness, emotional support, and instrumental support, whereas the structural characteristics were living arrangement, frequency and number of contacts, and various social roles. The lowest mortality risk was observed among those embedded in large and diverse networks.

Another extensive meta-analysis by Holt-Lunstad and colleagues (2010) examined the evidence of social relationships in relation to mortality in 148 studies with more than 300,000 participants. They reviewed the literature more specifically for the specific aspects of social relationships that seem to be most predictive for later survival. Individual characteristics were examined, including cause of mortality, initial health status, and health history. The time period for follow-up and specific rating of social relationships were also taken into account. The main outcome of the analysis was that of a 50% increased likelihood of survival among participants with stronger social relationships. Notably, the results were consistent across age, sex, initial health status, cause of death, and follow-up period. The analysis also revealed that the associations were stronger for more complex measures of social integration and lower for binary indicators like living alone versus with others. The authors emphasize that the observed effects are comparable with nonsmoking versus smoking and even exceed many other well-known risk factors.

In sum, social connectedness is related to longevity, but the association is stronger for closer and more emotionally rewarding social relationship, compared with contact frequencies.

Psychological Dimensions of Longevity: From Empirical Observations to Theoretical Synthesis

The human life span is ultimately determined by biological criteria for survival. A unique feature of humankind, however, is the capability to redesign

Psychology of Longevity, Fig. 1 Overview model of psychological factors contributing to longevity via lifestyle and health behavior

the environment and to adapt one's own behavior to reduce risks for morbidity, disability, and mortality, thereby increasing longevity. The outcome of such efforts is seen in the dramatically reduced infant mortality and among adults in the rectangularization of the survival curve. An extended life expectancy also in older ages demonstrates that the boundaries for life are not entirely fixed and deterministic. Longevity differs considerably between nations and reflects the overall living conditions in various regions of the world. In a review by Christensen et al. (2009), it was estimated that the majority of babies born in the year 2000, in countries with already long life expectancies, are likely to celebrate their 100th birthday.

Compared with earlier birth cohorts, later cohorts tend to show better overall health and cognition at the same chronological age. A possible explanation to this is influences from an extended education and lifelong intellectual stimulation that have made us better adapted to cope with challenges and environmental change. In the everyday context, general knowledge and specific cognitive abilities are crucial for adjustment and engagement with life in the broadest sense, as well as for specific health-related behaviors. Personality dimensions and the way we perceive ourselves as aging individuals are also important driving forces for the adjustment. Stochastic variables, however, tend to become more important with age in determining subsequent

longevity, independent of psychological characteristics and functioning. Studies of very old survivors therefore tend to find it difficult to identify clustered psychological characteristics that may have contributed to longevity. To better understand the prerequisites for longevity, we therefore need to adopt a life-course or life-span developmental perspective.

In this chapter, we have highlighted empirical studies demonstrating an essential role of psychological characteristics in human longevity. Cognitive health and cognitive ability, conscientiousness, well-being and positive emotions, subjective aging and health, the forecasting of purpose and meaning of remaining life, and social connectedness are all found to be associated with longevity (Fig. 1).

Although psychological variables are associated with differences in average survival, certain interaction patterns among these variables are likely. In various constellations, they are likely to affect lifestyle and various health-related behaviors which in turn affect the likelihood for maintenance of vitality, health, and thereby survival and longevity. This complexity is nicely illustrated in a longitudinal study by Wilson and collaborators (2015) which suggests that conscientiousness has a neuroprotective effect. They show that higher conscientiousness was related to a slower terminal decline trajectory, even after an adjustment for neuropathological burden.

According to our proposed model, there might be more direct relationships between individual psychological characteristics and longevity, but the model emphasizes that lifestyle and health-related behavior mediate these influences. A better understanding of the prerequisites for longevity therefore requires that we adopt a general life-course and life-span developmental perspective. We also need to localize the life-span development in the historical and environmental context. The general framework is not only important for a better understanding of observed outcomes but also important for public health interventions aimed at a longer and healthier life span.

To ensure healthy longevity in future generations, we need to consider interactions among multiple factors related to birth cohort and generation, living and socioeconomic conditions, and the interplay between genetic and environmental influences which in concert foster psychological functioning and characteristics as well as certain lifestyles and health-related behaviors. Future research needs to examine the direct and interactive relationships among dimensions of cognition, personality, and psychological well-being but especially the role of lifestyles and health-related behaviors as mediators determining longevity. To contextualize how we feel, think, and act within a broad biopsychosocial paradigm is therefore essential for a better understanding of observed gradients of late life survival and the psychology of longevity.

Life experience; Prudence; Sagacity

Definitions of Wisdom

As the number of wisdom researchers grows, so does the number of definitions and operationalizations of wisdom. While some issues are still under debate, researchers agree on the following aspects concerning the definition of wisdom (cf. Jeste et al. 2010): Wisdom is a highly desirable but rare quality; it is unlikely that an “ideally wise” person exists at all. Wisdom concerns the existential issues of human life – such as our awareness of our own mortality, fundamental ethical questions, or the balance of autonomy versus intimacy in relationships. Wisdom is a complex construct that combines cognitive components, such as broad and deep knowledge, and noncognitive components such as emotion regulation competencies and openness to new ideas and experiences. Wisdom involves critical self-reflection and awareness of the inherent uncertainty and unpredictability of the human existence – wise people are aware of how much they do not, and cannot, know. Wisdom is acquired through life experience, but it does not necessarily come with age. Wisdom involves good intentions – for others as well as for oneself. Therefore, it often manifests itself in guidance provided to others, though not necessarily in direct advice giving.

The most important point of current controversy concerns the degree to which wisdom is a quality that involves the whole self of an individual and immanently linked to his or her personal development. Some researchers focus more on the cognitive aspects of wisdom and define it more as

a quality of a person’s thinking about problems, including problems of fictitious individuals and larger societal entities. Other researchers argue that true wisdom goes far beyond thinking and is based on an extraordinary development of the self through the reflection and integration of life experiences. These two perspectives on wisdom have been labeled “general wisdom” and “personal wisdom” (e.g., Staudinger and Glück 2011). It is not yet clear, however, whether personal and general wisdom are really two empirically distinct constructs or if they should be considered as different methodological approaches to essentially the same construct. The most prominent definitions of general and personal wisdom are the following.

The Berlin Wisdom Model

The most classical psychological conception of wisdom is the Berlin Wisdom Model, developed by Paul Baltes and colleagues from the 1980s on (overview in Baltes and Staudinger 2000). It defines wisdom as expertise in the fundamental pragmatics of life. This kind of expertise manifests itself as wisdom-related knowledge, which is characterized by five criteria: Factual knowledge concerns the nature and variability of personalities, developmental pathways, and interpersonal relationships. Procedural knowledge concerns strategies and heuristics for dealing with difficult life problems. Life-span contextualism is awareness and consideration of the fact that situational and developmental contexts have strong influences on people’s thinking and behavior. Value relativism is acceptance and tolerance of individual and cultural differences in value orientations. Recognition and management of uncertainty mean that wise individuals are aware of and able to deal with the inherent unpredictability of human life.

Wisdom as Self-Distanced Reasoning

In a more recent approach to investigating general wisdom, Igor Grossmann and colleagues define wise reasoning as “the use of certain types of pragmatic reasoning to navigate important challenges of social life” (Grossmann et al. 2010, p. 7246). The relevant types of pragmatic

reasoning are based on dialectical thinking and intellectual humility. They manifest themselves in the ability to take different viewpoints, recognize the limitations of knowledge and the likelihood of change, make flexible predictions, and search for conflict resolution and compromise.

The Balance Theory of Wisdom

Robert J. Sternberg (1998) conceptualizes (general) wisdom as the application of tacit knowledge to life problems that involve conflicts between individuals and life domains. Tacit knowledge, according to Sternberg, is procedural, domain-specific knowledge about how to reach a goal within a system. With wisdom-requiring problems, the goal is to achieve a common good, i.e., to optimize the outcome across the different interests involved; ethical values play an important role in achieving this goal. A wise solution is balanced in that it considers and balances conflicting intrapersonal, interpersonal, and extrapersonal interests as well as short-term and long-term perspectives into account. It is also balanced in how it deals with the situational context: individuals may either adapt to the context, actively change it, or select a different context.

The Three-Dimensional Wisdom Theory

The best-known conception of personal wisdom is probably Monika Ardelt's three-dimensional wisdom theory (Ardelt 2003), which defines wisdom as a personality characteristic that entails three dimensions. The cognitive dimension develops through the motivation and ability to understand the human condition, which leads the individual to acquire rich and deep factual and procedural knowledge. The reflective dimension is based on a general willingness to look at phenomena from different sides and take multiple perspectives. Wise individuals also try to look at themselves from different perspectives, which leads to self-insight and self-growth. The affective dimension is an empathetic, caring attitude toward others that extends beyond friends and family to include humankind and the world at large.

Wisdom as Self-Transcendence

Michael R. Levenson et al. (2005) argues that the most central aspect of wisdom is self-transcendence. As self-transcendent individuals do not depend on external self-definitions, self-enhancement, or self-confirmation, they are able to perceive people and things as they really are. Based on philosophical work on culturally universal characteristics of wisdom, Levenson has proposed three stages through which self-transcendence develops. Self-knowledge is a clear awareness of the internal and external sources of one's self. Detachment is awareness of the transient nature of external sources of self. Integration is the acceptance and integration of all aspects of the self, overcoming self-illusions and accepting one's weaknesses. Individuals who are able to integrate all sides of their self will be independent of external self-enhancement and able to develop self-transcendent, and thus truly caring, relations to others and the world.

The different conceptions presented above may seem to some readers like the proverbial blind men "investigating" an elephant: they focus on quite different aspects – expertise, balancing, and self-transcendence do not immediately fit together. But they may all be facets of a certain way of dealing with life and the challenges that it entails, which is characterized by being reflective of one's own experiences, open to the perspectives of others, and motivated to understand, learn, and grow toward living a life that is good for oneself and others.

Psychological Wisdom Research

Lay Conceptions of Wisdom

In the first phase of psychological wisdom research, several studies looked at laypeople's conceptions of wisdom to get a first understanding of this somewhat elusive construct (overview in Bluck and Glück 2005). Lay conceptions were also labeled "implicit theories" of wisdom (Sternberg 1985) although they are usually assessed by rather explicit methods such as ratings of how central certain characteristics are for wisdom. The core components of wisdom that

were identified in studies of lay conceptions have clearly also shaped psychologists' theories. For example, a seminal lay-conception study by Clayton and Birren (1980) identified cognitive, reflective, and affective components of wisdom, which became an important basis for psychological wisdom theories (Ardelt 2003).

Later, lay-conception research focused more on individual differences in wisdom conceptions, e.g., between cultures and age groups. Cross-cultural research shows that "Western" conceptions tend to emphasize cognitive aspects of wisdom, while "Eastern" conceptions give equal weight to noncognitive aspects such as humility, empathy, and emotion regulation (Takahashi and Overton 2005) – a distinction that somehow parallels that of general and personal wisdom. In addition to differences between cultures, however, there are marked individual differences within cultures. For example, the perceived centrality of affective aspects of wisdom increases with age, suggesting that life experience may make people more conscious of the importance of caring about others.

Measuring Wisdom

With complex constructs like wisdom, measurement is a nontrivial issue. As explained earlier, wisdom combines certain attitudes, such as a motivation to question the obvious, personality components such as openness to new ideas and experiences, and competencies such as factual and procedural knowledge about life problems or emotion regulation skills. As discussed earlier, some researchers have focused more on the personality-type components of wisdom, while others have focused on the competencies. Accordingly, two general classes of measures of wisdom have been developed – self-report scales and performance tasks.

While attitudes and personality components are usually measured by self-report, assessing competencies by self-report has obvious limitations because people are not particularly good at judging their own abilities. Even with respect to attitudes and personality, however, people do not always describe themselves veridically in self-report measures, either because they want to

present themselves or because they actually perceive themselves in an unrealistic way. This is an issue with all self-report measures, but it is particularly problematic with a construct like wisdom that entails critical self-reflection: in fact, truly wise individuals are likely to view themselves less positively than people with strong self-illusions. Thus, the validity of self-report measures of wisdom may be somewhat limited especially when the items refer to characteristics that are clearly positive. Authors of self-report wisdom scales have used different approaches to avoid this problem, such as the use of reverse-coded items.

Competencies, on the other hand, are generally measured by means of performance tasks, often, e.g., in the case of intelligence, using closed-response tasks where the participant selects the correct response from a set of alternatives. Wisdom is almost impossible to measure with such closed-response tasks, however, because most people are very well able to recognize a wise response to a problem even if they would be completely unable to actively produce a response nearly as wise. Therefore, most competence measures of wisdom consist of open-ended tasks in which participants produce spoken or written responses that are then evaluated according to predefined criteria. Obviously, these approaches require much more time and effort than the administration of a self-report scale. Also, people who are highly intelligent, but not particularly wise, may well be able to produce highly convincing responses to open-ended wisdom tasks. If they were faced with the same problem in real life, however, their lack of the noncognitive qualities of wisdom might render them unable to utilize their wisdom-related knowledge. Currently, several researchers are working on new measures of wisdom, some of which are intended to increase participants' personal involvement.

Several self-report scales and performance measures of wisdom have been developed and validated. As each measure is based on a specific conception of wisdom, researchers who want to use a particular measure should always consider whether its theoretical background is consistent with their research question.

Self-Report Scales

The most prominent self-report wisdom scales include the 39-item Three-Dimensional Wisdom Scale (3D-WS; Ardel [2003](#)), which measures Ardel's cognitive, reflective, and affective dimensions. The Self-Assessed Wisdom Scale (SAWS; Webster [2007](#)) consists of 40 items measuring openness, emotional regulation, humor, critical life experience, and reminiscence and reflectiveness. The Adult Self-Transcendence Inventory (ASTI; Levenson et al. [2005](#)) measures wisdom as self-transcendence. The most recent version consists of 34 items, 10 measuring alienation and 24 measuring self-transcendence. The 20-item Brief Wisdom Screening Scale (Glück et al. [2013](#)) was empirically derived by selecting those items from the 3D-WS, ASTI, and SAWS that had the highest loadings on a common factor.

Performance Measures

The "classical" performance measure of general wisdom is the Berlin Wisdom Paradigm (BWP; overview in Baltes and Staudinger [2000](#)). Participants are asked to think aloud about brief descriptions of difficult life problems. Responses are transcribed and rated with respect to five criteria: factual knowledge, procedural knowledge, life-span contextualism, value relativism, and recognition and management of uncertainty. Mickler and Staudinger ([2008](#)) built on the Berlin wisdom paradigm to develop a parallel measure of personal wisdom. Their Bremen Wisdom Paradigm measures participants' wisdom with respect to their own self and life experiences. Participants are asked to think aloud about questions concerning themselves as a friend. Responses are transcribed and rated with respect to five personal-wisdom criteria: rich self-knowledge, heuristics of growth and self-regulation, interrelation of the self, self-relativism, and tolerance of ambiguity.

Grossmann et al. ([2010](#)) developed a new paradigm for measuring wise reasoning. Participants are presented with stories about conflicts between social groups in foreign countries, such as ethnic tensions or the assimilation of immigrants. They are interviewed about what they think will happen in those countries and why. Response transcripts

are coded for perspective shifting to take different viewpoints, recognition of the likelihood of change, flexibility of predictions, recognition of uncertainty and the limits of knowledge, search for conflict resolution, and search for compromise.

Correlates of Wisdom

Wisdom is conceptually and empirically related to at least six groups of psychological variables: intelligence, personality, affect and well-being, identity development, value orientations and moral development, and religiosity and spirituality.

Correlations between wisdom and **intelligence** are relatively low. Correlations with intelligence tests are between zero and 0.20 for self-report measures and somewhat higher, in the 0.20–0.30 range, for performance measures of wisdom. As wisdom is often considered as a kind of expertise, one would expect to find positive correlations with crystallized intelligence and zero or even negative correlations with fluid intelligence, but empirical findings show no consistent picture. While the SAWS and Grossmann's measure of wise reasoning show the expected pattern of correlations, the 3D-WS is positively related to fluid intelligence, and the BWP and BrWP are positively related to both fluid and crystallized intelligence. Linear correlations may not be the optimal indicator for the relations of wisdom to other variables, however. For example, wisdom might require a certain minimum level of intelligence, but beyond that level, there might be essentially a zero relationship.

The **personality** dimension that is most consistently related to wisdom is openness to experience. In fact, Webster ([2007](#)) considers openness a component of wisdom. People high in openness are more likely to learn and grow from new ideas, experiences, and contexts throughout their life. Apart from openness, self-report measures of wisdom tend to be correlated to other personality dimensions (e.g., agreeableness, extraversion, and negatively related to neuroticism) as well, whereas performance measures are mostly uncorrelated to personality. This is probably partly due to shared method variance among

self-report scales and partly due to the fact that most self-report measures are based on conceptions of wisdom that include personality aspects.

The relationship between wisdom and **well-being** is still under debate. Some authors are convinced that wisdom causes higher levels of life satisfaction and positive affect, but others believe that wisdom entails an awareness of the negative sides of the human existence that may prohibit high levels of happiness. Conceptually and empirically, wisdom is clearly more closely related to eudaimonic well-being, the awareness of meaning in one's own life, than to hedonic well-being, the simple enjoyment of a pleasurable life.

With respect to **identity development**, the evidence consistently suggests low positive correlations across different wisdom measures. Wisdom goes along with higher levels of ego development, integrity, and generativity and an orientation toward personal growth and learning from life. Correlations between wisdom and life experiences per se, on the other hand, tend to be low to insignificant. These findings are consistent with the idea that wisdom does not develop through any particular experiences but through the way individuals deal with and reflect upon them.

There is surprisingly little research on the question whether wisdom is related to **ethical and moral constructs** such as value orientations or levels of moral development. Definitions of wisdom as well as empirical findings suggest that wisdom is positively related to universalistic, altruistic, and growth-oriented and negatively related to authoritarian and hedonistic value orientations. Independent of which values an individual endorses, wisdom-related knowledge is also related to an advanced level of moral reasoning in the Kohlbergian sense, i.e., moral judgment based on general ethical principles.

A growing body of research suggests relationships between wisdom and **spirituality** and intrinsic **religiosity** but not extrinsic (i.e., externally motivated) religiousness. Spirituality may be particularly related to the self-transcendent aspects of wisdom. Both wisdom and religiosity could play important roles in helping individuals deal with existential challenges.

Wisdom and Age

Wisdom does not necessarily come with age. While the individuals that laypeople nominate as particularly wise are usually at least in their sixties, laypeople do not endorse the idea that every older person is wise. Research also suggests that most older people live largely satisfactory, happy lives but few have developed high levels of wisdom. Empirically, relations to age differ between measures of wisdom, with zero correlations for the Berlin wisdom paradigm and the adult self-transcendence inventory, a positive relation for Grossmann's measure of wise reasoning, negative relations for the Bremen personal-wisdom paradigm and the three-dimensional wisdom scale, and even an inverse U-shaped relation for the self-assessed wisdom scale (as nonlinear patterns have not been explored for the other measures, more complex relationships might actually be more frequent). This diversity is probably due to the fact that different measures emphasize different aspects of wisdom. Some aspects, such as accumulated life experience, relativistic thinking, or emotion regulation competencies, may increase with age, while others, such as self-concept complexity or fluid intelligence, decrease. However, highly wise individuals may be able to maintain high levels of functioning even in aspects that generally decrease with age because of their lifelong accumulation of expertise: someone who has been thinking and advising others about difficult life situations for many years may be able to grasp the essentials of a complex situation more fully at age 80 than someone else does at age 40 by using acquired strategies and heuristics that can overcome the cognitive limitations of old age.

In addition to individual developmental processes, there are several reasons to assume that the experience of old age itself can be conducive to wisdom. Aging may change the way people think about life, as it introduces new perspectives about control and remaining lifetime. Relatively typical experiences of old age, such as health-related events and loss of professional roles, may shift the focus from active problem-solving toward an increasing awareness of the limitations of personal control. Awareness of one's limited

remaining lifetime can foster adaptive emotion regulation and self-transcendence. Similarly, Erik Erikson (1959) has argued that integrity, the positive resolution of the last crisis of identity development, involves the acceptance of one's life as it was lived. Thus, experiences that are relatively typical of old age may be conducive to growth in wisdom – at least in those people who have sufficient psychological and psychosocial resources to deal with them constructively.

The Development of Wisdom

Why do a few people become very wise in the course of their lives, while so many others go through similar experiences but do not seem to learn or grow from them? The uncommonness of high levels of wisdom suggests that wisdom requires extraordinary constellations of resources and experiences to develop. In the context of the Berlin Wisdom Model, Baltes and Staudinger (2000) suggested that there are many different paths to wisdom, but they all involve characteristics of the individual such as intelligence, creativity, openness, expertise-relevant factors such as the presence of mentors or a motivation to learn and grow, and relevant experiential contexts such as parenthood, certain professional roles, or old age.

The MORE Life Experience Model (Glück and Bluck 2013) proposes that wisdom develops through an interaction of psychological resources with challenging life experiences. The four central resources – as sense of mastery, openness, reflectivity, and emotion regulation/empathy – influence which life challenges people encounter, how they appraise them and deal with them, and how they integrate past challenges in their life story. Individuals with higher levels of the resources are more easily able to deal with life-changing experiences in ways that foster learning and growth toward wisdom.

Fostering Wisdom

The question whether it is possible to teach or train wisdom has obvious societal relevance. Indeed, experimental research by the Berlin wisdom group and by Igor Grossmann's lab has identified short-term interventions that had significant positive effects on general wisdom. All these

interventions have in common that they somehow prompted participants to transcend their own viewpoints: by imagining to discuss a wisdom task with a close other person, by reflecting about the variability of life contexts and values, or by taking a distanced, as opposed to self-immersed, perspective. An instruction to “try to give a wise response,” however, increased levels of wisdom-related knowledge only in participants who already were quite wise. No experimental intervention research has yet been published with respect to personal wisdom.

Longer-term interventions for fostering wisdom have mostly been discussed with respect to education: could schools or universities teach wisdom or at least wisdom-relevant knowledge and skills? Little empirical research has been published as yet, but it seems likely that some aspects of wisdom, especially cognitive facets such as relativistic thinking or critical self-reflection, can (and should) be trained in educational settings.

Applied Wisdom Research: Wisdom and Leadership

Wisdom and leadership seem to be strongly associated in the minds of most people. When laypersons are asked to nominate wise figures, they often come up with societal leaders such as Mahatma Gandhi, Jesus Christ, Martin Luther King, or Nelson Mandela (Paulhus et al. 2002), who inspired millions of followers and fundamentally improved the lives of many. Currently, leadership research seems to be more and more interested in going beyond conceptions of leadership as mostly strategic, technocratic, and unconcerned with ethical issues and in integrating aspects such as wisdom. In a seminal paper, McKenna et al. (2009) built on the psychological wisdom literature as well as on Aristotle's writings on practical wisdom to derive five propositions about wise leadership: (1) Wise leaders use careful observation and logical reasoning to establish facts and to derive explanations and conclusions. (2) They are also aware of the relevance of nonrational and subjective aspects in decision-making. (3) Wise leaders value tolerance and humane and virtuous outcomes. (4) While their actions may be based on more general

considerations, they are always practical and real life oriented. (5) Wise leaders are aware of the personal and social rewards of contributing to the good lives of themselves and others. Along similar lines, Yang (2008) proposed three components of wise leadership: integration (of perspectives, interests, or ways of thinking), embodiment of ideas through concrete actions, and positive effects for the self as well as for others.

While wisdom research clearly has promising implications for leadership in many fields, such as politics, law, education, or medicine, it is also important to mention that structural constraints may often stand against the manifestation of wisdom in such contexts. In politics, for example, voters may tend to prefer leaders who strongly advocate simple, convincing visions to wiser individuals who are aware of the whole complexity of a situation and the diversity of values and perspectives. Also, temporal, organizational, and administrative constraints may make it very difficult and exhausting for a wise leader to try to attain major changes. For these reasons, wise individuals may not feel particularly attracted to fields that would require high levels of wisdom such as politics. In addition to calling for wise leaders, it may seem worthwhile to think about how societal structures could be changed to allow for more wisdom in their decision-making machineries.

Current Developments and Open Questions

The field of psychological wisdom research is growing fast; researchers are both developing new approaches to studying wisdom and applying concepts and measures of wisdom in new areas. New, more ecologically valid and less laborious methods for measuring wisdom are being developed, short-term and long-term wisdom interventions are being studied, and new methods of data analysis are being applied. A large number of important questions are still open. A long time ago, creativity research profited enormously from the suggestion to investigate at least four “Ps”: not just creative persons but also creative products, creative processes, and external presses. For example, what distinguishes presidential addresses that laypeople consider wise from those they consider less wise? Through which

cognitive and noncognitive processes do some people arrive at wiser solutions to difficult real-life problems? How do situational constraints in professional contexts limit people’s ability to make wise decisions? Another important issue concerns the fact that the large majority of current wisdom studies have been carried out in modern Western individualistic societies – to what extent are our conceptions of wisdom universal rather than shaped by our cultural, historical, and societal context? Our world is faced with many, and more and more global, challenges. Wisdom research will hopefully contribute to the identification and implementation of wise solutions.

Psychosocial Well-Being

Richard A. Burns

Centre for Research on Ageing Health and Wellbeing, Research School of Population Health, The Australian National University, Canberra, ACT, Australia

Synonyms

Eudaimonia; Hedonia; Psychological well-being; Subjective wellbeing

Definition

Psychological well-being refers to inter- and intraindividual levels of positive functioning that can include one's relatedness with others and self-referent attitudes that include one's sense of mastery and personal growth. Subjective well-being reflects dimensions of affect judgments of life satisfaction.

Introduction

The concept of well-being has received considerable interest in recent years, both in the scientific and lay literature. As such, well-being is frequently cited as a national priority for government policy around the world (Beddington et al. 2008). However, depending upon one's professional and personal perspective, the notion of well-being can have quite different connotations. For instance, economists may interpret well-being in terms of economic capacity and prosperity, the growth in both individual and national economic wealth. Population health researchers may focus on issues of health promotion and disease eradication. Social policy advocates may phrase issues of well-being in terms of health-care provision, education access, and issues of justice and equality. For behavioral scientists, the notion of well-being is most frequently framed in terms of individuals'

own level of experience, reflecting their personal, experiential, and phenomenological sense of happiness and engagement with their families, work, and community.

Consequently, different well-being definitions may lead to quite different understandings of how well-being is related to age and aging processes. Even within the behavioral sciences, where the operationalization of concepts is integral to model development and applied research, a lack of rigor in operational definition has made understanding the disparate findings related to well-being and developmental trajectories in late life difficult to reconcile. The psychosocial well-being literature is awash with various terms and models; the same term can reflect different concepts for different researchers, while different terms can mean the same thing for others. Over recent decades, considerable effort has been made to reconcile these different approaches. Most frequently, within the behavioral sciences, well-being research is described as reflecting two broad approaches or traditions. The first approach is frequently referred to as the hedonic or subjective well-being (SWB) tradition. With roots in the third and fourth century BC, the philosophy of Aristippus and Epicurus and by the work of fellow *Cyrenaics* – one of the earliest Socratic schools – SWB is based on hedonic principles in which pleasure and happiness are of primary concern to the individual, irrespective of the virtuous nature of that pleasure fulfillment. Such principles were echoed centuries later by Priestley and Bentham’s “greatest happiness principle” that a good society is built on individuals’ attempts to maximize pleasure and self-interest. The term *hedonia* itself is derived from the Greek word for “pleasure.” The second approach is the eudaemonic or psychological well-being (PWB) tradition. Similar to *hedonia*, *eudaimonia* has its foundations in antiquity, most notably reflected in Aristotle’s treatise *Nicomachean Ethics* which was one of the first secular texts to expound on what it is to live a good life. As with *hedonia*, the term *eudaimonia* derives from the Ancient Greek *eu* for goodness or well-being and *daimon* for spirit. Hence, *eudaimonia* can be interpreted as the focus on living the good life or with a good

spirit. Numerous reviews have sought to summarize and collate different well-being models within these broader contexts (Ryan and Deci 2001; Huppert et al. 2004, 2009).

Hedonia: Subjective Well-being

SWB research emerged during the 1960/1970s as an attempt to measure quality of life and to monitor the impact of social policy on social change. These initial SWB studies emphasized the importance of life satisfaction and happiness as indicators of well-being and life quality. As a hedonic approach, SWB models typically relate well-being to subjective happiness and relate to the attainment of goals or valued outcomes with a focus on “what makes experiences and life pleasant and unpleasant” (Kahnemann et al. 1999). SWB therefore represents individuals’ subjective evaluations about different aspects of their lives, incorporating an assessment of the range of emotions they are experiencing. These evaluations comprise cognitive and affective interpretations and, unlike objective measures of psychological and physical health, reflect an individual’s personal assessment of their own life. SWB is commonly defined by three components: life satisfaction, the presence of positive mood, and the absence of negative mood (Kahnemann et al. 1999; Diener et al. 1999). Accordingly, by clearly defining well-being in terms of satisfaction and positive and negative valence, research into the area has been able to clearly differentiate between constructs and has led to a voluminous amount of research into the causes and consequences of SWB. In addition, renewed attention in the “positive” psychology field at the turn of the century has strengthened the well-being literature base, arguing that for too long, well-being research was driven by clinical definitions of mental health and by the notion that the absence of mental ill-health is too narrow and constricting a definition to be useful as an indicator of wellness. However, even a focus on SWB, and in particular on notions of happiness and positive affective states, overlooks other important constructs of well-being such as personal growth and

development that are said to reflect a *eudaemonic* approach to well-being. Finally, it is important to note that while much of the SWB literature is focused on a positive and negative affect dichotomy, Russell and colleagues (Posner et al. 2005) have proposed a circumplex model of affect, for which there is an increasing evidence base, which highlights the need to discriminate between low- and high-arousal positive and negative affect. For instance, feeling sad (low negative arousal) contrasts with feeling nervous (high negative arousal).

Eudaimonia: Psychological Well-being

PWB has its foundations on *eudaemonic* assumptions that suggest that well-being is related to whether individuals live their lives according to their true nature or spirit (*daimon*), reflected in earlier psychological theories such as Maslow’s theory of self-actualization. However, unlike SWB concepts which have been clearly defined, much of the PWB literature has struggled to develop well-validated models of PWB. This is in part due to the vagueness of PWB operationalizations of wellness and what it means to be living the good life, unlike SWB constructs.

There are two widely cited measurement models of PWB. The first is that encapsulated by Carol Ryff’s model of PWB, from which the psychological well-being scales were derived (Ryff 1989a, b; Ryff and Keyes 1995). Ryff’s PWB scales drew from gerontological and life-span research and reflect one construct-oriented approach to PWB. Their theoretical underpinnings stemmed from a wide range of influences including Allport’s concept of the mature personality, Rogers’ fully functioning individual, and Maslow’s notion of self-actualization. Through interviews with young, middle-aged, and older members of the general population, Ryff argued that six key dimensions were consistently identified as indicative of the good life and well-being (Table 1). The PWB scales therefore reflect a multidimensional approach to the measurement of PWB that tap six distinct areas and include autonomy, personal growth, self-acceptance, purpose in life, environmental mastery, and positive

Psychosocial Well-Being, Table 1 Summary of PWB variables and their definitions

PWB variable	Definition
Environmental mastery	Feelings of competence and capacity to manage and meet the responsibilities of everyday life
Personal growth	Capacity for continued development, potential, and openness to experience
Purpose in life	Feelings of purpose and having a sense of life direction and that past and present experiences are meaningful
Self-acceptance	The capacity for accepting and acknowledging one’s strengths and virtues as well as recognizing one’s weaknesses
Positive relations with others	The sense that one has warm, satisfying, and trusting relationships and are socially concerned
Autonomy	The extent to which one views oneself as self-determining and independent, resisting pressure to meet social expectations

relatedness with others. *Self-acceptance* is a significant construct within theories that define self-actualization and fully functioning individuals and emphasizes an ability to develop warm trusting *relationships with others* and being empathetic and affectionate toward others. However, these individuals remain *autonomous*, resisting societal expectations to change and conform. *Environmental mastery* reflects an ability of self to manipulate and function within constraints, while *purpose in life* reflects the capacity for goal selection and developing a sense of life direction which contribute to meaning in one’s life. *Personal growth* reflects individuals’ capacity to grow and realize one’s own inner potential. Following Ryff’s theory, these PWB concepts are all fundamental to the individuals’ capacity to actualize and maintain a fully functioning self.

While the conceptual model has intuitive appeal, support for the PWB scales themselves has been mixed (Ryff and Keyes 1995; Abbott et al. 2006; Burns and Machin 2009; Clarke et al. 2001). It has been noted (Burns and Machin 2009) that a number of validation studies (1) utilized a short or a very short form of the PWB

scales or (2) implemented questionable factor analytical methods for the data in question (e.g., principal component analysis with varimax rotation). Indeed, in addressing these issues, two independent studies, using multiple national samples (Abbott et al. 2006; Burns and Machin 2009), have consistently demonstrated that at least the environmental mastery, personal growth, purpose in life, and self-acceptance items are unable to discriminate between their parent factors. This should not be surprising; Clarke, Ryff, and colleagues reported themselves a high degree of correlation between these four PWB factors (Clarke et al. 2001). However, despite the weaknesses related to aspects of the scale's initial construction and the analytical limitations of some subsequent validation studies, considerable evidence does relate various PWB dimensions to a range of outcomes including biological health, successful transitions in later life, and better therapeutic outcomes (Huppert et al. 2004; Abbott et al. 2006; Fava and Ruini 2003).

Often described as a theoretical framework of motivational drives, a second widely cited model that has embraced the concept of eudaimonia as a central aspect of well-being is Ryan and Deci's self-determination theory (SDT) (Ryan and Deci 2000, 2001). SDT delineates between three basic psychological and social needs which include autonomy, competence, and relatedness. Much of the research within this framework focuses on identifying the mechanisms by which internal and external drivers of individual motivation realize these three needs. Burns has noted (Burns and Machin 2009) the commonality with autonomy and relatedness from the SDT and Ryff PWB models and further suggested that the SDT competence factor may be related to the superordinate PWB factor that reflected the scales (environmental mastery, personal growth, purpose in life, and self-acceptance) which Burns and Abbott separately identified (Abbott et al. 2006; Burns and Machin 2009). According to SDT, the fulfillment of these three needs is essential for psychological growth and psychological health. Much SDT research has focused on identifying and examining the pathways by which social and cultural factors facilitate or

inhibit the fulfillment of these needs. At its heart, SDT posits that individuals (1) are proactive agents in their lives, with the capacity to master their own drives and emotions; (2) are inherently growth oriented; and (3) need a nurturing social environment to strive for optimal development. Within a life-span perspective, the capacity to satisfy these needs will vary with other age-related declines such as with changes in social status (e.g., retired), relationships (e.g., widowed), physical health (development of age-related diseases like dementia), and proximity to death. Thus, the satisfaction of these needs is purported to vary in different degrees of importance as a consequence of different developmental periods. However, it is generally considered that failure to strive for these needs results in negative psychological consequences. While well validated and cited in other areas of the behavioral sciences, SDT has had only limited influence in the geropsychology sphere.

Reconciling Different Well-being Traditions

PWB proponents have typically challenged SWB models as being limited in describing long-term positive functioning on the premise that SWB dimensions are often fallible indicators of healthy living given a focus on affective states and generalized evaluations of satisfaction, which generally change little over time, but which are highly reactive in shorter temporal contexts. However, PWB proponents do not dismiss the importance of satisfaction or emotion; simply, they place less emphasis on the promotion of positive emotions or for that matter reducing negative experiences. Rather, they are concerned more with the appropriateness of the emotional experience. For example, as a consequence of experiencing a negative life event, such as the death of a loved one, it is only natural for an individual to experience a degree of negative affect and/or lowered positive affect. Emotion, for researchers within the PWB perspective, is therefore contextual. The end goal of experiencing emotions is to contribute to the promotion of personal growth in the long term.

Despite their conceptual differences, PWB and SWB share a number of commonalities. While decades of research have related notions of positive mental and physical health with the absence of such adverse states as depression, anxiety, and physical illness, a number of researchers have proposed that well-being is not necessarily an antithesis to ill-being (Beddington et al. 2008; Ryan and Deci 2001; Huppert et al. 2004, 2009; Kahnemann et al. 1999; Diener et al. 1999; Ryff 1989a, b; Abbott et al. 2006; Burns et al. 2014a). There have also been attempts to reconcile SWB and PWB, and there is an increasing literature providing substantial evidence from factorial analysis studies for items to discriminate between SWB and PWB domains (Burns and Machin 2009; Gallagher et al. 2009). A recent collaboration of well-being researchers (Huppert et al. 2009) has sought to consolidate these different well-being traditions into a coherent measure of well-being that

...systematically assesses key wellbeing variables for representative samples, including positive and negative emotions, engagement, purpose and meaning, optimism and trust, and life satisfaction, as well as satisfaction with specific domains of life.

The European Social Survey (ESS) Well-being Module (Huppert et al. 2009) reflects a systematic attempt to reconcile both SWB and PWB approaches and also extends a focus on intrapersonal factors by incorporating dimensions of social and interpersonal well-being. The ESS Well-being Module (see Table 2) comprises two domains, the inter- and intrapersonal domains within which well-being can be conceptualized in terms of psychological feeling and functioning, reflecting the SWB and PWB traditions, respectively. Huppert et al. (2009) argue that the module’s development provides an

opportunity for a richly textured description of how the citizens of Europe experience their lives. It complements more objective data on economic, social and environmental influences on well-being, which can be derived from other items within the ESS and from other data sources. We believe that the Well-being Module will provide invaluable information for behavioural and social scientists, and contribute to the development of policies and practices for enhancing well-being across Europe.

Psychosocial Well-Being, Table 2 Conceptual framework for the ESS well-being module and constructs assessed within the four domains (Huppert et al. 2009)

	Intrapersonal	Interpersonal
Feeling (SWB)	Satisfaction	Belonging
	Positive affect	Social support
	Negative affect	Social recognition
	Optimism	
	Vitality	
	Self-esteem	
Functioning (PWB)	Autonomy	Social engagement
	Competence	Caring
	Interest in learning	Altruism
	Goal orientation	
	Sense of purpose	
	Resilience	

It is clear that the model attempts to encapsulate leading well-being theories and models and importantly focuses on both the individual and their relatedness to their social contexts. There is a considerable literature base on the role of these different well-being dimensions on outcomes across the life-span and into older adulthood. Importantly, their utility in providing additional and complementary information to traditional clinical measures of psychological distress and mental health is clear. For example, Burns and colleagues have recently and consistently demonstrated the additional utility of well-being measures over and above measures of psychological distress in promoting health outcomes including falls likelihood, self-rated health, and mortality (Burns et al. 2012, 2014a, b, 2015) in older adults. Further, in trying to place well-being and mental health constructs within some theoretical context, Burns and colleagues (2011) explored the associations between measures of SWB or “feeling” (operationalized by positive and negative affect) and PWB or “functioning” (operationalized by mastery/competence and resilience), with measures of depression and anxiety. They identified strong support for a model whereby SWB mediated the effects of PWB on depression and anxiety. That is, perceptions of mastery and resilience

drove positive and negative affect which in turn predicted depression and anxiety outcomes. It is increasingly evident that well-being and mental health are related and that well-being outcomes are worthy of study as much as the clinical focus on dimensions of mental health.

Relating Well-being and Age

In relation to changes in well-being with age, there has been a paradox of sorts. Despite consistent findings relating to decreased physiological and cognitive capacity in later life, older adults are generally satisfied with their lives. However, the capacity to describe and explain well-being trajectories across later adulthood is impacted by a number of factors. Issues of operational definition have previously been identified as factors that may moderate our understanding of well-being processes in late life. Other issues relate to study design and whether data are drawn from cross-sectional or longitudinal panel data. While some cross-sectional studies indicate few age-related differences in well-being, analyses of longitudinal studies often identify some individuals as reporting considerable well-being decline (Burns et al. 2015). This is compounded by current estimates that suggest over half of the variance in various well-being dimensions are within person. Hence, in order to appreciate the exact processes in which well-being may fluctuate in later life, it is important to understand the extent to which well-being varies within individuals and the drivers of this variation. However, even where designs and operational definitions are consistent, disparate findings can be found. For example, Clark and colleagues (2012) have suggested that the association between life satisfaction and age is best described as an inverted U shape whereby both young and older adults report the highest levels of well-being (compared to adults in mid-life). In contrast, Baird and colleagues (2010) reviewed over 20 years of longitudinal data from the German Socio-Economic Panel and British Household Panel Studies and found stable life satisfaction in the German population until age

70, while the British population reported increases in mid-life and with substantial declines in late life. In Australia, Headey and Warren (2008) identified life satisfaction as lowest in mid-life. These findings indicate the large differences in life satisfaction across seemingly similar countries and further highlight that although some differences between studies can be attributed to differences in operational definition, even where constructs are comparable, it may be that a particular construct, such as with life satisfaction in this case, is not necessarily a valid or sensitive indicator of age-related changes.

A further issue that may influence our understanding of well-being in later life relates to increasing evidence that changes in well-being are less a context of aging, but rather exposure to other confounding factors that may in turn drive well-being changes. These include changes in physical health and mortality. For example, Gerstorf and colleagues (2008, 2010) have demonstrated that changes in well-being are more strongly related to mortality and time to death than increasing age per se, providing evidence for both a terminal decline (a gradual decline) and terminal drop (a gradual decline prior to a precipitous drop in the years preceding death) in well-being. Extending Gerstorf et al.'s findings, Burns and colleagues (2014a) replicated the terminal decline but importantly were able to demonstrate how within-person change in physical health attenuated these terminal declines in well-being. Similarly, within a mixture modeling analysis framework, Burns and colleagues (2015) identified that despite an overall population-level terminal decline in well-being, mixture analysis revealed several classes for whom most reported stable well-being trajectories, with only 10–20% of the population actually reporting decline. Analysis indicated that participants in these classes comprised individuals with the worst and/or worsening health status. Other evidences for the confounding role of physical health have been reported. Windsor et al. (2013) extended focus on positive and affective dimensions of SWB to incorporate the role of arousal states and the role physical health plays in moderating age

differences. In line with other findings (Kessler and Staudinger 2009), Windsor et al. (2013) identified older adults as reporting higher levels of low-arousal positive affect and lower levels of high arousal, but that age-related declines in physical functioning were significant drivers of the lower levels of high arousal.

Improving Well-being Outcomes

There is a growing body of evidence for the efficacy of psychological interventions to elicit changes in well-being in both clinical and community populations (Fava and Ruini 2003; Lyubomirsky et al. 2011; Sin and Lyubomirsky 2009). Within a clinical context, Fava and colleagues have utilized well-being therapy (WBT), in conjunction with cognitive behavioral therapy (CBT), that focuses on building dimensions of psychological functioning (e.g., mastery, purpose, self-acceptance). Their clinical findings indicate substantial reduction in relapse rates in the WBT group (relapse rate = 40%) in comparison with the CBT-only group (relapse rate = 90%). Their methods have been utilized as part of health and social development classes in schools with great impact in reducing psychological distress and improving a sense of well-being in students. A recent meta-analysis (Sin and Lyubomirsky 2009) identified medium effect sizes for the efficacy of positive psychology programs for increasing well-being ($r = 0.29$, 95%; CI: 0.21, 0.37) and for decreasing depression symptoms ($r = 0.31$, 95%; CI: 0.17, 0.43). Engagement in these activities elicited both positive functioning and feeling in adults, the benefits of which included improved health outcomes, community engagement, and increased workforce participation.

Conclusion

Well-being is an important concept across a wide variety of scientific and health domains and is increasingly impacting on government policy. Within the behavioral sciences, approaches to

well-being can be described as ascribing to one of two broad traditions, hedonia (SWB) and eudaimonia (PWB). While SWB proponents focus on hedonic factors that include judgments of satisfaction and affect, PWB researchers seek to identify those characteristics that may describe how well individuals are living their lives and relate to perceptions of personal growth, a sense of life purpose, and self-acceptance. There is considerable conceptual and statistical evidence to support the delineation of these two related yet separate traditions. However, failures to recognize different operational definitions and to disentangle age effects between cross-sectional and longitudinal studies have highlighted limitations in our capacity to accurately describe well-being changes in later adulthood. It is increasingly recognized that much of the well-being literature has failed to identify the extent to which well-being variation is a consequence of true age-related differences as opposed to natural daily variation and changing individual contexts such as decline in physical health or cognitive capacities. Overall, there is increasing evidence for the utility in examining well-being in late life in concert with clinical measures of psychological health and distress, with evidence to suggest that well-being is a sensitive indicator of lives being lived well within the context of age-related physical, health, social, and economic declines.

Assault; Combat; Posttraumatic stress disorder;
Threat; Traumatic event; Violence

Definition

The newest version of the *Diagnostic and Statistical Manual of Mental Disorders* classifies posttraumatic stress disorder (PTSD) as a cluster of symptoms that develop after a traumatic experience (American Psychiatric Association 2013). The stressor may include direct exposure to actual or threatened death, serious injury or sexual violence, witnessing such an event, or repeated exposure to aversive details of an event. Learning that a close relative or friend has experienced a trauma, such as finding out a parent or child has died suddenly of accidental or violent causes, can also qualify as a trauma. As a result of experiencing one of these stressors, the individual must respond with intrusion symptoms such as intrusive memories, nightmares, or flashbacks; avoidance of trauma reminders and/or thoughts and feelings associated with the event; changes in cognitions and mood such as persistent feelings of guilt or anger; and increased arousal that often takes the form of irritability, aggression, or sleep disturbances. Symptoms must result in functional impairment and last for at least 1 month.

Introduction

Given that the number of older adults within the US population is growing more quickly than other

age-groups (US Census Bureau 2010), examining PTSD and its treatment within the older adult population is a critical endeavor. PTSD, and trauma more broadly, can have a significant impact on older adults (Hyer and Sohnle 2001). This entry will cover the epidemiology, course, risk factors, assessment, and treatment of PTSD in older adults. Much of the current PTSD literature in older adults is based on research examining the impact of the Holocaust, military experiences such as combat and prisoner-of-war status, or large-scale disasters (e.g., natural disasters). Little is known about the effects of other types of trauma, such as interpersonal trauma or the effects of traumatization during older adulthood (Cook and Niederehe 2007; Thorp et al. 2011). Furthermore, research on this topic is complicated by the fact that “older adult” has been defined in various ways in the literature, sometimes including subjects as young as 55. While future research in these neglected areas is critical to our understanding of PTSD in older adults, the current state of the literature allows some conclusions regarding how PTSD and its assessment and treatment may differ in older populations.

Epidemiology

There are a few studies that have examined the prevalence of PTSD in older adults – most epidemiological studies either do not include older adults or do not incorporate enough older adults to draw any reliable conclusions (Cook and Niederehe 2007; Thorp et al. 2011). Additionally, longitudinal research in this area has been limited, partially due to the fact that PTSD was not included in the DSM until 1980 (DSM-III) and changes to PTSD diagnostic criteria have occurred with every successive DSM since that time. Estimates of the lifetime prevalence of any traumatic event range from 70% to 90% in the older population compared to about 55% in the general population (Thorp et al. 2011). However, studies have found that the lifetime prevalence of full PTSD in older adults is approximately 2.5–3.5%, compared to approximately 7% in the general population. Nonetheless, prevalence rates

for PTSD over 50% have been reported among older adults who were combat veterans, former prisoners of war, or Holocaust survivors (Averill and Beck 2000; Thorp et al. 2011). It has also been suggested that older adults who do not meet criteria for the full PTSD diagnosis may still be suffering substantially from PTSD symptoms. Prevalence estimates of subsyndromal or partial PTSD, when an individual is only one or two symptoms short of the diagnosis, have been estimated at 13.5% for older adults (Averill and Beck 2000). This wide range of prevalence estimates can be explained by differences in diagnostic criteria, populations studied, diagnostic criteria used, and assessment format (e.g., clinical interview vs. self-report questionnaire).

Course

Studies that examine the long-term effects of early and midlife trauma into older adulthood have found that PTSD that is chronic (lasting at least 3 months) typically persists when left untreated and that individuals can continue to exhibit symptoms or meet criteria for PTSD several decades following the initial trauma (Cook and Niederehe 2007). Some research indicates that older adults who have been traumatized at a younger age are more likely to have longer courses (Averill and Beck 2000). It has been hypothesized that symptoms surge immediately following the trauma, dissipate for a period of time later on, and resurge later in an ongoing cyclic fashion, though there are few empirical longitudinal studies (Cook and Niederehe 2007). Some authors posit that decreased cognitive functioning, social isolation, and health issues in older adults may be related to relative increases in PTSD symptoms later in life (Averill and Beck 2000; Cook and Niederehe 2007).

When an individual first develops PTSD at least 6 months after the traumatic event, they are classified as having delayed-onset PTSD. There have been case study evaluations of delayed-onset PTSD in older adults, specifically in Vietnam combat veterans (Averill and Beck 2000). In some cases, full PTSD did not emerge until

many years after the traumatic event. There are many hypothesized theories regarding the emergence of full PTSD in later life, including reduced psychological resilience and resources to cope with the changes associated with aging, increased chance of experiencing an event that resembles the initial trauma over time, and more time available to reflect on past life events due to retirement and other major changes (Averill and Beck 2000). Some authors suggest that, instead of a late-life emergence, symptoms most likely remained unnoticed until later in life or intensified once the distractions of work and family declined (Andrews et al. 2008; Thorp et al. 2011). It is important to note that delayed-onset PTSD is relatively uncommon, and thus little is known about how delayed-onset PTSD may differ from standard PTSD (onset within 6 months of the traumatic event).

Comorbidities

Many individuals with PTSD have comorbid psychiatric conditions (Fields 1996), and older adults with PTSD are more likely to have major depression, anxiety disorders, somatic disorders, cognitive difficulties, or substance or alcohol use disorders than individuals without PTSD (Averill and Beck 2000). Individuals with PTSD are also more likely to have comorbid physical problems when compared to those without PTSD, including gastrointestinal, arterial, dermatological, and musculoskeletal diagnoses (Cook and Niederehe 2007; Rodgers et al. 2005). Of note, the vast majority of this research has been done with male combat veterans; little is known about comorbid conditions in females, minorities, and individuals with noncombat trauma histories. Furthermore, among older adults, it is typically not reported whether these comorbid conditions predate the trauma or if they form later in life. Many traumatic events reported by older adults occurred early in life (e.g., late teens or early 20s), so it is possible that the PTSD preceded the other physical and mental health problems.

There are a variety of potential risk factors for PTSD, including history of psychiatric illness,

child abuse, and family adversity, though these have not been examined in a population of older adults separate from other populations. There is also some evidence that individuals who have several significant life stressors, a substance use disorder, or an exaggerated physiological response to the trauma itself are more likely to have poorer PTSD outcomes (Thorp et al. 2011). There is some evidence that individuals may be vulnerable to PTSD in older adulthood given the transitions and negative life events that are associated with advanced age, such as widowhood, loss of identity, loss of income, or decreased mobility (Cook and Niederehe 2007). Additionally, individuals' previously successful avoidance strategies, which can include activities like working long hours or avoidance of family and friends, may no longer be possible in older adulthood. Thus, vulnerability to PTSD and the course of the disorder would be affected by the unique circumstances that can occur in late life (Averill and Beck 2000; Thorp et al. 2011).

Assessment

The comprehensive assessment of PTSD is a critical part of determining an individual's unique needs and how to best address them. As with all populations, it is important to assess a variety of domains including medical, psychiatric, and substance use history. However, there are some unique factors that should be considered when working with older populations. For example, self-report items may be easier to read when printed in large, bold fonts with high contrast, and providers should sit facing patients who have hearing difficulties to enhance communication (Cook and Niederehe 2007). Clinicians should also consider obtaining collateral information from family members, friends, and caregivers. Utilizing a combination of observational methodologies, self-report, and interviews is optimal (Thorp et al. 2011). Utilizing more than one method of assessment often provides a more comprehensive understanding of the patient's experiences and current symptoms.

Although there are limited data on the assessment of PTSD in older adults in comparison to other age-groups, clinicians may consider adjusting their standard procedures when working with older adults (Thorp et al. 2011). Providers sometimes address immediate concerns with appetite, sleep, mood, or anxiety without assessing for past traumatic history. Optimally, clinicians will comprehensively assess a patient's history to examine different periods of that individual's life as well as to adequately cover the various types of trauma that could occur. Clinicians can invite discussion by specifically asking about experiences of sexual assault, combat, childhood sexual trauma, accidents, and other potential traumas. Assessors should carefully document age of onset, duration, and course of symptoms across psychiatric conditions. There are often time constraints during assessments, but the clinician should be careful not to rush the historical portion of the interview with older adults. This history may uncover critical past traumas, treatment experiences, or treatment expectations. The information can help a clinician educate the patient and normalize responses. It may be helpful to consider creating a visual timeline of all traumas, symptoms, treatments, medication, and medical and psychiatric conditions to share with the individual, to ensure that the assessor, treatment team, and patient (and patient's family if patient is willing) are all in agreement regarding the historical pattern of symptoms (Thorp et al. 2011).

There are other considerations that should be taken into account when assessing PTSD in older adults. For example, older adults may experience hyperarousal and anxiety symptoms differently than younger populations, differentially express symptoms of a foreshortened future, or have medical comorbidities and medications that change the expression of symptoms and complicate the assessment process (Thorp et al. 2011). Further, older adults grew up in a generation when mental health issues were discussed less openly; therefore, older adults may have increased stigma around mental health symptoms. They may be less likely to report psychological distress compared to physical health complaints.

Assessment Instruments

Several PTSD and trauma-related assessment tools have been validated in older adult populations or are commonly used in these populations.

Clinician-Administered PTSD Scale (CAPS). The CAPS is a 45-min, 30-item clinician-administered interview that assesses PTSD severity and can aid in diagnostic decision-making. The CAPS is one of the most commonly used PTSD assessment tools across populations, but clinicians must be trained in utilizing the measure to ensure accuracy (Foa et al. 2009; Keane et al. 2007). The CAPS-4 has been validated in older adults and has been shown to have high validity and internal consistency in this population (Cook and O'Donnell 2005; Thorp et al. 2011). The CAPS-5 has been updated to reflect DSM-5 diagnostic criteria, but norms specifically for older adults are not yet published.

PTSD Checklist (PCL). The PCL is a 20-item self-report questionnaire that assesses a variety of PTSD symptoms. Scores range from 0 to 80, with higher scores indicating greater levels of symptomology. Although an interview should confirm the presence of a qualifying traumatic event, the PCL can be a critical component of a PTSD assessment (Foa et al. 2009; Keane et al. 2007). The PCL has been validated in older adult populations (Cook and O'Donnell 2005; Thorp et al. 2011). The PCL has been updated for DSM-5 (PCL-5), but norms specifically for older adults are not yet published.

PTSD Symptom Scale – Interview (PSS-I). The PSS-I is a 20-min, 17-item semistructured interview that assesses symptom severity and can aid in diagnostic decision-making (Foa et al. 2009; Keane et al. 2007). The PSS-I does not require any training but has not been validated specifically in older populations.

PTSD Diagnostic Scale (PDS). The PDS is a 49-item self-report measure that assesses PTSD symptom severity over the past month in regard to a patient-selected trauma. Unlike many other self-report measures, the PDS includes a section that asks the individual to describe their traumatic event in some detail (Foa et al. 2009).

The PDS has not been validated specifically in older adults.

Impact of Event Scale, Revised Version (IES-R). The IES-R is a 22-item self-report measure that asks individuals to pick a traumatic event and then rate the impact of several PTSD-related symptoms on his or her past week. The revised IES has three subscales – intrusion symptoms, avoidance symptoms, and hyperarousal symptoms – but is not considered a diagnostic measure (Keane et al. 2007). The IES-R has been validated in older populations (Cook and O'Donnell 2005; Thorp et al. 2011), but there are no norms for DSM-5 published specifically for older adults.

Mississippi Scale for Combat-Related PTSD (M-PTSD). The M-PTSD is a 35-item self-report scale that was specifically designed to assess combat-related PTSD. Items were adapted from the DSM-III (Keane et al. 2007; Thorp et al. 2011). The M-PTSD has been validated in older populations (Cook and O'Donnell 2005; Thorp et al. 2011).

Minnesota Multiphasic Personality Inventory (MMPI). The MMPI is a lengthy self-report questionnaire that contains over 500 true/false questions in total and can take up to 2 h to complete. Despite its length, the simple true/false response format can facilitate administration with older adults. The MMPI contains a PTSD scale that can provide helpful information regarding potential trauma-related symptoms but is not diagnostic. Although the MMPI can be time consuming, it provides several other scales that cover personality characteristics, depression, anxiety, and schizophrenia and can give information regarding validity including over-reporting or downplaying of symptoms. The MMPI has been validated in several populations, including older adults (Cook and O'Donnell 2005; Thorp et al. 2011).

Posttraumatic Cognitions Inventory (PTCI). The PTCI is a 36-item self-report measure (only 33 items are scored) that was developed to assess trauma-related cognitions that may contribute to the development of PTSD or maintenance of PTSD symptoms in an individual. Although this

is not a diagnostic measure, it can be very helpful in guiding treatment or providing motivation to obtain treatment (Orsillo 2001). The PTCI has been used across several demographic groups, but the psychometric properties have not been specifically examined in the older adult population.

SCL 90-Revised (SCL-90-R). The SCL-90-R is a 90-item self-report scale that takes about 15 min to complete. Like the MMPI, the SCL-90-R provides information regarding other psychiatric symptoms via additional subscales that include somatization, interpersonal sensitivity, depression, hostility, and paranoid ideation scales. This measure has been validated in older adults (Cook and O'Donnell 2005; Thorp et al. 2011).

Treatment

There are some important considerations that should be taken into account during the psychological or pharmacological treatment of PTSD in older adults. In regard to pharmacotherapy, older adults may be more prone to side effects, reduced metabolic capabilities, cognitive changes, medical conditions, age-related pharmacokinetic and pharmacodynamic changes, and polypharmacy (Thorp et al. 2011). When working with older adults, prescribers often choose to start with a low dose of medication and to titrate as necessary (“start low and go slow”) (Cook and Niederehe 2007). Additionally, because older adults are often prescribed several medications at once, prescribers should consider possible interactions between medications. They should also be careful to closely monitor both common and uncommon adverse reactions to each medication.

Data on the efficacy of pharmacotherapy in older adults with PTSD are limited (Cook and Niederehe 2007). However, prazosin and quetiapine have been shown to reduce PTSD symptom severity (Thorp et al. 2011). Selective serotonin reuptake inhibitors (SSRIs) are often prescribed as the first-line treatment for PTSD across age-groups. There is substantial evidence that SSRIs reduce hyperarousal, avoidance, and

re-experiencing symptoms in older adults, and they also have been shown to improve symptoms of anxiety and depression, which often accompany PTSD. Although the SSRIs have noteworthy side effects that may include sexual dysfunction, insomnia, or gastrointestinal problems, they are typically better tolerated than other classes of psychotropic medications. While some prescribers choose to use tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors (MAOIs), there is some evidence that these classes of medications only reduce re-experiencing symptoms and they carry greater risks of side effects (Thorp et al. 2011). Therefore, they are often considered a second line of treatment to SSRIs.

Although many types of psychotherapy have been applied to PTSD, few have been tested empirically with older adults. It is recommended that providers use existing evidence-based treatments for PTSD in the general population, such as prolonged exposure (PE), cognitive processing therapy (CPT), and eye movement desensitization and reprocessing (EMDR) when treating older adults (Foa et al. 2009).

PE is a type of cognitive behavioral therapy that has been specifically designed to treat PTSD. PE's core components are psychoeducation, breathing retraining, imaginal exposure, and in vivo exposure. PE has been shown to be highly efficacious in the treatment of a variety of traumas. In vivo exposure involves repeatedly engaging in previously avoided behaviors, and imaginal exposure requires a repeated, detailed oral narrative of the trauma memory. Going to a crowded grocery store, visiting a part of town that reminds you of the traumatic event, or calling an avoided friend or family member are just some examples of possible in vivo exposures. Sessions last approximately 90 min, and treatment can take 12–15 sessions (Foa et al. 2009). Originally developed for survivors of sexual trauma, PE has been repeatedly shown to be effective for sexual trauma, childhood sexual trauma, military-related trauma, physical assault, accidents, and mixed traumas (Foa et al. 2009). There have been no published randomized controlled trials (RCTs)

that examine the efficacy of PE specifically in an older adult population. However, there are two studies that have compared exposure to other conditions, and these studies and case studies have indicated the efficacy of exposure in the older population.

CPT is a type of cognitive behavioral therapy that was developed for individuals with PTSD. CPT focuses on identifying how an individual's thoughts and beliefs about themselves, others, and the world have been impacted by the trauma. Many individuals with PTSD report thinking that the world is more dangerous than he/she used to believe, that he/she is incompetent, or that people are not to be trusted. Next, the clinician helps the patient challenge their maladaptive thoughts and modify those thoughts and beliefs in accordance with information obtained via Socratic questioning (Resick and Schnicke 1993). In the full protocol of CPT, patients are asked to write a trauma narrative that describes the traumatic event in detail. However, research has also shown that CPT-C (CPT without the trauma narrative) is also efficacious for the treatment of PTSD. Therefore, research is mixed regarding whether the trauma account is a necessary part of treatment or whether some individuals may benefit more from CPT or CPT-C. The clinician and patient discuss themes of safety, trust, esteem, intimacy, power, and control. CPT can be delivered in both group and individual formats and is typically done in 12 weekly 60-min sessions (Resick and Schnicke 1993). There have been no RCTs to date examining the efficacy of CPT specifically in older adults.

EMDR was developed with the goal of helping an individual process their trauma while engaging in bilateral eye movements. The patient is asked to focus on the trauma for brief periods of time while performing these eye movements. While there is significant evidence that the eye-movement portion of EMDR does not add efficacy to the exposure portions of the treatment, research indicates that EMDR is an effective treatment for PTSD (Cook and O'Donnell 2005). There have been no RCTs examining EMDR specifically in older adults, though some case studies have shown

efficacy in this population (Cook and O'Donnell 2005; Thorp et al. 2011).

Some researchers have proposed that exposure therapies may be contraindicated for older adults because of increased autonomic arousal that may exacerbate physical conditions. Further, some individuals have suggested that older adults with cognitive impairments may struggle with cognitive behavioral therapies because they are learning based (Thorp et al. 2011). However, there are no empirical data to suggest that older adults do not respond well to exposure-based or cognitive therapies. Although there are no published randomized controlled trials (RCTs) of PTSD therapy in older adults, RCTs across other age-groups support the efficacy of PE, CPT, and EMDR for the treatment of PTSD (Foa et al. 2009; Thorp et al. 2011). There have been three trials and case studies supporting the use of general exposure therapies with older adults with PTSD and case studies suggesting that EMDR can be helpful with this population.

Most of the information available regarding the treatment of PTSD in older adults comes from single case studies or severely underpowered, uncontrolled, nonrandomized studies. More research is needed to determine (a) whether current gold standard treatments are effective in older populations and (b) whether any modifications are needed to improve treatment outcomes in older populations. Clinicians should take reasonable steps to ensure that treatments are enhanced for each patient based on their individual needs. Potential modifications may include involving caregivers for a patient who cannot care for himself or herself or printing in bigger fonts for individuals who have vision difficulties.

There is little research available on whether it is necessary to modify psychotherapy for PTSD in older adult populations and if so, how treatment should be modified (Koder 2007; Thorp et al. 2011). However, some considerations have been suggested, including increasing the structure of treatment and each individual session (e.g., overview of course of treatment, agendas for each meeting); progressing more slowly; simplifying material; adding modules that address loss,

dependency, and survivor guilt; addressing the individual using proper titles (e.g., “Mr. Smith”); discussing physical ailments; utilizing memory aids; and incorporating family members and/or caregivers (Koder 2007). It is important to note that research has not indicated that any of these modifications are necessary to enhance the efficacy of current evidence-based treatments for PTSD in older populations, but clinicians may choose to include some of these approaches.

Summary

PTSD is a major mental health concern among all populations. Given that PTSD can become a chronic problem if left untreated and affects a large number of older adults, more research is needed regarding the phenomenology, course, assessment, and treatment of trauma-related symptoms in this population. Furthermore, specific research is needed on older women, minorities, and older survivors of noncombat traumas, including sexual assault, other crime victimization, and car accidents. As the proportion of older adults continues to climb over the next several decades, developing a better understanding of the proper assessment and treatment of PTSD in this group will shift from an important area for future research to an imperative health issue.

Synonyms

Meaning in life; Psychological well-being; Purpose in life; Well-being in retirement

Definition

The workplace often provides a prominent context in which one derives a sense of purpose or meaning to life. Research has begun to consider the role of aging and retirement on constructs like purpose and meaning, though clear directions remain for future research.

Introduction

When considering the prominent changes that occur during the adult years, many of those that immediately come to mind likely occur with respect to one's work and career. Across adulthood, not only do individuals typically experience multiple changes in their specific occupations and workplaces, but also the functions that work serves tend to differ over time. For instance, the key normative tasks that confront individuals differ in the workplace during young, middle, and older adulthood (Hutteman et al. 2014). Broadly speaking, the early adult years are typically spent "getting started," with respect to obtaining occupational qualifications and building a foundation for future success within one's domain of interest. Middle adulthood brings an opportunity to build toward higher levels of job success (promotion,

recognition, etc.), while still focusing on maintenance in terms of consistent job responsibilities. Finally, a primary task confronting older adults is navigating the transition out of one's job responsibilities into retirement.

As the workplace often provides a primary context for individuals daily lives, one would expect that the normative changes in work roles would provide developmental "presses" that shape individual dispositions and personal characteristics. Indeed, research looking at personality change during young adulthood consistently has shown that individuals tend to increase on those traits seemingly important for occupational success, such as being conscientious, emotionally stable, and agreeable (Roberts et al. 2006). Furthermore, meta-analytic work suggests that commitment and success in the workplace is positively linked to these dispositional characteristics (Lodi-Smith and Roberts 2007). These dispositional effects have been found to be lasting, such that people do not appear to decline on these characteristics once they lose their work status through retirement (Roberts et al. 2006). While broad personality dimensions may remain largely intact, other individual difference variables may be more influenced by the work transitions later in life. The goal of the current entry is to discuss how constructs such as sense of purpose and meaning may be influenced during older adulthood and retirement.

Given that the personal significance or intrinsic value of work may change throughout the life span, it is valuable to consider whether work transitions influence the extent to which individuals perceive a sense of purpose or meaning to their lives. Prior to investigating such claims, the current entry first consider some important definitional issues, given that several labels are used in the literature for similar though not synonymous constructs. One consideration of central importance to the current entry is the potential for distinguishing purpose (and purposefulness) from meaning (or meaningfulness). In addition, it is worth understanding how researchers have assessed and couched these constructs specifically within the context of the workplace.

Purpose and Meaning in Life and Work

A sense of purpose refers to the perception that one has life goals in place that serve to organize one's sense of self, direct daily activities, and thus chart a direction to take in life (McKnight and Kashdan 2009; Ryff 1989). Alternatively, researchers note that the process of finding meaning in life typically is more retrospective in nature and involves establishing a sense of connectedness and coherence that provides personal significance (Steger et al. 2006). Though it is theorized that engagement in purposeful activity can increase one's sense of meaning, researchers suggest that following one's purpose is but one of four avenues toward a sense of meaning, with other promoters of meaning including having set values and justification, a belief in one's self-efficacy and self-worth, and the sense that one is perceived by others as a worthwhile individual (Crescioni and Baumeister 2013). Therefore, while purpose and meaning are interrelated constructs, they are distinctive in ways that can prove valuable for understanding the potential for differing trajectories for levels of purpose and meaning during older adulthood.

To help elucidate the potential distinction between these constructs, it is valuable to consider how the terms "purposefulness" and "meaningfulness" are used within the psychology and organizational behavior literature. Purposefulness has previously been conceived as a personality trait reflecting a lower-order component of conscientiousness (Hofstee et al. 1992), and thus the phrase "purposeful activity" tends to reflect premeditated, goal-directed action, from which it is difficult to distract the actor. Meaningfulness though tends to come from the realization that something or someone has significance in one's life, and thus is a particularly positive experience. In this respect, one can determine that something has a meaning or definition, and yet not view that event or action as meaningful (see, e.g., Rosso et al. 2010; Wrzesniewski 2003). As an example, one can determine that the meaning of going to work is to accrue wealth, but still not define this activity as *meaningful* in nature. Despite the potential value

of distinguishing purpose from purposefulness, and meaning from meaningfulness, researchers more commonly employ these terms interchangeably. Throughout, this entry employs the same terminology as the original researchers used when describing their findings, though these labels may not fully reflect the distinction between purposefulness and meaningfulness described here.

That said, work from the industrial-organizational psychology and organizational behavior literature typically has focused more on how individuals derive meaningfulness rather than levels of felt meaning in work. Two frequently examined and related constructs on this front are meaningful work and a sense of calling. Meaningful work refers to the amount and type of purpose and significance work holds for an individual (Rosso et al. 2010). Sense of calling is conceptualized as an approach to work that aligns with a sense of personal meaning, is motivated by prosocial values, and arises in response to a transcendent summons (Dik and Duffy 2009). For example, a teacher may feel called by societal need to use her personal talents to improve the lives of underserved youth. Callings are considered unique to each individual – something people believe they must do to fulfill their unique purpose in life or to be living in line with their deepest self. While sense of calling has been linked to meaningful work (Wrzesniewski 2003), one need not have a sense of calling to experience work as meaningful. Meaningful work has also been linked to specific job characteristics, such as the individual's identification with the task, sense of autonomy, and perceived task significance (Fried and Ferris 1987). Meaningful work also has been linked to a sense of belonging, whether one perceives alignment or coherence between one's behavior and the "true" self (i.e., authenticity), and a belief in one's ability and power to produce an intended effect or make a difference (i.e., self-efficacy [see Rosso et al. 2010 for a review]). Thus, like purpose and meaning in life, sense of calling and meaningful work are interrelated, yet distinct, constructs that provide unique insights into how people attach purpose and significance to their work.

Considering Change in Levels of Purpose and Meaning in Life as Related to Work

With these definitions in place, one can consider how and why the work transitions facing older adults may influence their levels of purpose and meaning in life. Given that purpose is defined with respect to having long-term goals that organize one's daily activities, purposeful activities often may involve engagement in one's work and vocation. Choosing a career path is clearly a prominent method by which individuals can organize and define their daily activities to be in line with their ultimate long-term goals. For instance, most individuals likely have experienced how engaging in work-related activities allows one to feel more purposeful and driven; similarly, reflection upon task completion may provide one a sense of personal significance or meaningfulness.

In line with this belief, multiple studies have now pointed to the close link between a sense of purpose in life and occupational activities and aims. For instance, when asked to identify life goals most personally important, adults commonly endorse goals related to occupational success and achievement (Hill et al. 2010a; Roberts et al. 2004). Moreover, one study found that individuals who reported increasing importance of occupational goals during the transition to adulthood tended also to report higher levels of purpose in life in middle adulthood (Hill et al. 2011). The belief that work is a central arena in which purposeful activities occur is likely instilled even before individuals begin initial engagement within the workplace. For instance, when adolescents (a group either yet to begin or just beginning to take part in work) are asked to define what it means to have a purpose, one study found that around one-quarter of participants explicitly mentioned themes of occupational or financial success (Hill et al. 2010b).

Given the strong connection between purpose and work, retirement may portend negative consequences in the form of reducing a sense of purpose, because individuals have lost a prominent context for purposeful activity. Indeed, meta-analytic work confirms the predicted relationships between levels of purpose in life and both age and

work status (Pinquart 2002). Older and retired adults do tend to score lower on a sense of purpose than their counterparts. Researchers have suggested a curvilinear trend for sense of purpose in life during adulthood, insofar that participants tend to report higher levels on the construct from young to middle adulthood, with declines thereafter (Ryff and Keyes 1995). Though these effect sizes are modest in nature, this age trend conforms to the age-graded work tasks described above. Middle adulthood is a period primarily of maintenance and successive achievement in the workplace, which – if work commitment and progress does play a role in purpose – should allow one to feel more purposeful in this stage than during initial efforts to find a job or during later efforts to deal with the loss of occupation through retirement.

An interesting question then is whether these trajectories also hold for levels of meaning in life. Though living a purposeful life is one route to meaningfulness, one could predict an attenuated decline among older adults, in part because meaningfulness can be derived from other sources as well (e.g., relationships, community, self- and social worth [see for a review, Crescioni and Baumeister 2013; Rosso et al. 2010]). There even are reasons to predict that a sense of meaning could *increase* during older adulthood, given that a primary goal during this developmental period is a focus on being generative toward future cohorts and having a sense of integrity (Erikson 1959). Retirement could provide an opportunity to reflect upon past achievements in the workplace for deriving greater self-worth and a sense that one's life has significance, as well as provide greater opportunities for generative activities. Cross-sectional research appears to support this later prediction (Steger et al. 2009). Specifically, participants aged 65 and older reported a greater presence of meaning in their lives than their young and middle adult counterparts.

In addition to considering the role of retirement as a predictor of purpose and meaning levels, it is worth considering whether and how purpose and meaning predict retirement. The cross-sectional findings above also can be interpreted as evidence that individuals who report a greater sense of

purpose in life may be less likely to retire. Indeed, the perception that one's work is meaningful could provide one reason why older adults continue to work well after the age necessary for financial stability after retirement (e.g., Smyer and Pitt-Catsouphes 2007). As such, there likely exists a bidirectional relationship, to an extent, between the decision to retire and levels of purpose and meaning in life, which merits further consideration in future research.

With regard to meaningful work and calling, it is logical to predict that both may experience declines following retirement, given their conceptual coupling within the workplace. However, there is evidence that a sense of calling and meaningful work may continue past retirement. Research has demonstrated that individuals are quite adept at choosing leisure, volunteer, and community activities that align with their perceived calling in life (Berg et al. 2010). Additionally, retirees with a strong sense of purpose may begin "encore careers" – purpose-driven postretirement careers that make a difference in personal and communal well-being (Freedman 2007). These postretirement careers, which vary in their degree of formality, often are motivated by personal values and goals, and align career goals with work and leisure activities in retirement. In turn, there is ample reason to expect that older adults should be better able to maintain a sense of purpose and meaningfulness post retirement when they are able to organize their daily lives and activities in ways that conform to their sense of calling and/or provide new avenues for work meaningfulness. In line with this prediction, the next section will identify potential avenues for promoting greater purposefulness and meaningfulness in old age.

Promoting Purposefulness and Meaningfulness in Old Age

Two strategies that may help to promote purposefulness and meaningfulness in old age are role engagement and activity engagement. Role engagement may prove a valuable pathway for mitigating the general declines in purposefulness

and meaningfulness in older adulthood and post retirement. For example, helping retired individuals find roles and responsibilities that promote their sense of self-efficacy, personal worth, connection, and contribution may allow individuals to experience a sense of purpose, as well as maintain continuity with some of the sources of meaningfulness provided in a work context (Froidevaux and Hirschi 2015). This should be particularly true when such roles and responsibilities are similar to what individuals experienced in the workplace (e.g., a retired professor providing workshops to fellow retirement community members; a retired mechanical engineer with a passion for fishing designing and making fishing reels to give to friends and sell online). In line with continuity theory (Wang and Shultz 2010), which suggests that retirees are likely to benefit from maintaining activities comparable to those they experienced prior to retirement, one method for helping older adults maintain their levels of purposefulness and meaningfulness may be through providing them clearly prescribed roles within their communities (or retirement communities). This could involve connecting them with volunteer, community, religious, or leisure pursuits that allow them to experience continuity with some of the sources of meaningfulness provided in a work context (Froidevaux and Hirschi 2015). These pursuits can help individuals apply their talents to activities that are interesting and challenging, making a contribution that goes beyond the self, and acting in accordance with their values and beliefs.

In addition to the benefits of more circumscribed role engagement, multiple studies have demonstrated the benefits of promoting activity engagement for healthy aging later in life. Several of these studies have focused on cognitive activity engagement, given the susceptibility for older adults to decline on their levels of cognitive functioning. Interestingly, experimental work suggests that regular engagement in cognitive activities may motivate individuals toward seemingly adaptive personality changes, such as greater openness to experience (Jackson et al. 2012). This type of activity engagement could prove particularly valuable given the strong

relationship between openness to experience and sense of purpose among older adults (Hill et al. 2015). When work no longer provides a context in which to experience new events and situations, older adults may be more vulnerable to declines in purposefulness if they do not possess a natural disposition toward seeking out new activities. As such, interventions to promote openness may encourage older adults toward greater activity engagement and personal agency, both of which are conceptual and empirical hallmarks of having a purpose in life.

Future Directions for Research

Future research is needed to foster a better understanding of how to reduce the vulnerability of older (and retired) adults to feeling less purposeful, as well as potentially losing their sense of meaningfulness and/or calling. Several areas of research could help accomplish this aim. First, research is needed to develop measures that better distinguish and couch the constructs of purpose and meaning in life, meaningful work, and calling within the context of older adulthood. Most measures of these constructs are intentionally agnostic with respect to developmental stage, in order to facilitate comparisons across age-groups. However, such a measurement approach may fail to account for how older adults in particular would define what it means to be purposeful or have a meaningful life, as well as consider how meaningful work can occur outside of the “traditional” workplace.

Second, more research on these topics is needed that employs older adult and retired samples. For good reason, existing research on a sense of calling and meaningful work typically samples individuals currently involved in the workplace, often focusing on young or middle adult samples. One limitation of this work, however, is that it complicates the ability to make strong conclusions with respect to whether older and retired adults do report significantly lower levels on these constructs, or if older adults naturally reinterpret the items with respect to their current

activities outside of work, a point with clear measurement ramifications. Accordingly, research is needed to examine whether existing inventories allow older adults to reliably report their levels of meaningful work and calling when retired or in more reduced work roles, such as bridge employment or encore careers.

Third, longitudinal research is needed in order to better investigate mean- and individual-level trajectories for sense of purpose, meaningful life, meaningful work, and calling across adulthood. Only recently has purpose in life inventories been included in prominent large-scale studies of adult development (e.g., the Health and Retirement Study of U.S. Adults), and fewer still are long-term studies that include measures of the other constructs mentioned herein. As such, most developmental research with these constructs has relied on cross-sectional studies that sample broad age ranges. While useful, this approach does not allow researchers to consider individual-level fluctuations in purpose, meaningfulness and sense of calling, or which variables may predict such fluctuations over time. Understanding such relationships is particularly valuable to inform the development of interventions that target those older adults potentially at greater risk for declines in purposefulness and meaningfulness with old age and retirement. Moreover, longitudinal research would be valuable for verifying the cross-sectional finding that a sense of meaning in life increases in older adulthood (Steger et al. 2009), in order to gauge the relative need for purpose-focused relative than meaning-focused interventions with older adults.

Conclusion

Given that the significance and function of paid work changes throughout the life span, and evidence that purpose and meaningfulness are tied to work, it is important to consider how and why one’s sense of purpose and meaningfulness may be affected by retirement, as well as how these can be maintained in old age. This chapter has outlined the characteristics of purpose and

meaningfulness in work and life, and considered how purpose and meaningfulness might change in relationship a transition from work. Moreover, this chapter has suggested strategies for promoting purposefulness and meaningfulness in old age, and outlined potentially fruitful areas for future research in this area.

Q

Quality of Life in Older People

Robert A. Cummins
Deakin University, Melbourne, VIC, Australia

Synonyms

Aged; Happiness; Old age; Subjective life quality;
Subjective wellbeing

Definitions

Both of the terms in this chapter title require definition. A simple and comprehensive definition of “quality of life” (QOL) comes from the Australian Centre on Quality of Life, as: “Quality of life is both objective and subjective. Each of these two axes comprise several domains which, together, define the total construct. Objective domains are measured through culturally relevant indices of objective wellbeing. Subjective domains are measured through questions of satisfaction.”

While this definition will be elaborated as the chapter unfolds, two points can be noted. First, the objective and subjective dimensions must be measured separately. Second, the subjective dimension is commonly referred to as subjective wellbeing (SWB).

“Older people” are defined in agreement with the general literature and with the convention

adopted for this volume, as referring to people 65 years of age and older.

Overview

The life quality of older people has always been in jeopardy. As people age beyond their capacity to offer effective instrumental support, their very survival has been traditionally dependent on family generosity. This chancy proposition has continued into in recent times, at least in terms of social dependence, as extended families have given way to nuclear families, often requiring the older person to be housed separately. In response to this transition, charitable institutions have offered some support and some governments offer basic forms of assistance. In general, however, older people have become increasingly at risk of disconnection from their familiar support networks, at a time when increasing infirmity is making them more vulnerable. Even more alarming, the proportion of such people in the population is increasing.

Recognition of aging populations as a serious issue for public policy began during the 1950s. Of special concern at that time was the belief that occupational retirement results in frustration, bitterness, isolation, and general psychological malaise. Indeed, some writers, such as Dorfman (1954), even asserted that retired workers would create such a seed-bed of discontent that they might alter the basic structure of the society.

The disconfirmation of this myth required the creation of theory and appropriate social statistics, both of which were slow to develop. In the meantime, the life quality of aging populations was inferred through traditional objective statistics concerning such variables as wealth, health, and social structures.

Of special interest to developed countries has been quality of life issues associated with aging and health. This is because the provision of optimal medical care to older people has the potential to bankrupt most governments. So, some form of health-care rationing is necessary, and underpinning all such schemes is a consideration of life quality. So, measuring life quality in medicine has been an important scientific responsibility.

Before the 1990s, objective indices were used for this purpose. Health was measured as physical health and high life quality was inferred through longevity. While this changed with the subsequent development of Health Related Quality Of Life scales, such measures over-emphasize the life domain of health in estimating overall life quality (Cummins et al. 2004). A more balanced view of subjective quality of life has gradually emerged from within the social sciences.

The earliest efforts to measure the subjective side of life quality go back to the 1940s, with various pioneers devising scales of "morale" and "happiness." Progress in developing and applying such measures over the next three decades was very slow, with both researchers and administrators expressing concern that such data were unreliable. Then, in the mid 1970s, two extraordinary publications (Andrews and Withey 1976; Campbell et al. 1976) changed the way quality of life is understood.

At the heart of this new understanding is the appreciation, previously mentioned, that the quality of life construct comprises two very different universes of measurement. The traditional measures of objective life quality are matched by new measures comprising subjective perceptions of life quality: how satisfied people feel with their health, with their financial situation, and so on. Crucial for understanding is that these two kinds of measurement, objective and subjective life quality, are so different that they cannot be

substituted for one another. Just because an older person is physically frail and widowed does not mean that they feel bad about themselves; they probably feel just fine. So in order to get a full picture of someone's life quality, both dimensions need to be measured and separately considered.

The remainder of this article concerns the subjective side of life quality, especially as it has evolved within the social sciences. A prerequisite to such discussion, however, is to clarify the vexed issue of terminology.

Issues of Nomenclature

The science concerning subjective wellbeing (SWB) is plagued by ill-defined and confusing terminology. For example, while researchers contributing to this literature often refer to "happiness," this term has two quite different meanings. In common language, happiness is a feeling generated by a nice event. It is transitory and what psychologists refer to as an emotional state. However, there is another kind of happiness that is not an emotion. This different form of happiness is not generated in reaction to something that has happened, but rather it is a mood, in the form of a trait. Mood happiness is genetically driven, unchanging, and normally forms a constant background to our thoughts. It is a gentle, mildly activated form of positive affect and its role is to make us feel good about ourselves.

Mood happiness is the major component of SWB measured by scales such as the Personal Wellbeing Index (PWI: International Wellbeing Group 2013). However, in the early days of research into the subjective life quality of older people, no such understanding was available, and one of the earliest forms of measurement was termed "morale." Several different kinds of items would be used to create morale scales including satisfaction with life and other positive feelings, together with depression and other forms of negative feelings. The latter would be reverse-scored and the numbers combined to provide an average level of morale. While these measures lacked the sophistication of contemporary instruments, they tend to produce rather similar results.

For this reason, these various measures will be considered together as representing SWB.

Issues of Theory

Once researchers started to apply SWB measures to population samples, it became evident that contrary to earlier fears, the data were surprisingly reliable. So these measures started to be employed to measure the chronic life quality of individuals and groups. These psychologically “positive” measures were seen as representing a desirable side of subjective life. So the combination of reliability and desirability started to attract researchers to investigate the relationship between SWB and other variables. These included both objective variables such as age and income, as well as subjective variables, such as perceived adjustment and depression.

Of special interest to the early 1960s researchers was the SWB of older people. This group was getting the attention of demographers, as has been described, and it was assumed they would exhibit low SWB. After all, they commonly had reduced financial resources, were in poor physical health, and feeling uncertain of their role following the departure of the children or retirement. It was therefore a great surprise to find that empirical measures indicated no universal decrement in morale after 65 years. So theory was needed to account for this unexpected finding. The first of these was “activity theory.”

Activity Theory and Disengagement Theory

Some of the first scientific observations concerning the life quality of older people were their reduced scope of activities. This was assumed to have implications for their life quality, since relationship interaction is such a crucial human need.

The first effort to account for this phenomenon was proposed almost 70 years ago by the sociologist Ruth Cavan and colleagues (Cavan et al. 1949) in the form of activity theory. Then,

about a decade later, a far more elaborate account of social withdrawal was proposed in the form of disengagement theory (Cumming and Henry 1961).

Both theories generated much interest among researchers at that time, and both theories failed to survive the welter of critique that was heaped upon them. Nevertheless, it is instructive to consider what they both proposed and why they were discredited.

While each theory assumes a decrease in “activity” beyond 65 years of age, they differ in the form of activity under consideration. For activity theory, it was measured using the Chicago Inventory of Activity and Attitudes (Cavan et al. 1949). This activity scale comprises a set of very broad measures, which include leisure-time activities, religious activities, intimate social activities, economic activities, and health. Items vary from estimates of social interaction to reading the Bible. In other words, an “activity” is regarded as almost anything that the person does physically. For disengagement theory, the dependent variable is “engagement” measured through the number of social roles, the variation of those roles, and the frequency of interaction.

The first observation relating to both theories is that the supposed phenomenon of a universal reduction in “activity” after 65 years of age has not been empirically supported. This is true of both general activity (e.g., Palmore 1968) and social engagement (e.g., Zborowski 1962). However, older people do show substantial heterogeneity in both the level and type of maintained activities. So this opens the question of whether more refined measures of activity might reveal connections to SWB.

Activity theory makes no such refinement. It simply asserts that reduced activity equates to low SWB. The benchmark for judging “reduced” is the average activity levels of middle-age people. It is then assumed that these levels are also needed in old age because the basic psychological and social needs of such people remain unchanged. Thus, the way to maintain SWB in old age is to remain active.

The proposal from disengagement theory is quite different. It asserts a process of

disengagement exists as a natural and inevitable outcome of old age. In this context, the maintenance of SWB depends on the person matching their levels of engagement to the levels dictated by this developmental imperative. If the reduction in activity exceeds the level that is developmentally appropriate, then SWB will decrease.

Neither of these propositions has withstood scrutiny. First, the definition of “activity” is so broad, covering virtually any form of human activity, that it cannot be effectively measured in normally functioning people. Second, the developmental imperative to reduced engagement, coupled with the requirement to match this by actual behavior, is both unlikely and without empirical support. It also fails to adequately consider the differences between different forms of social contact. For example, Lowenthal and Haven (1968) found that among community-dwelling older people, the probability of depression depends on the absence of a confidant, not on the level of social interaction.

With the advantage of hindsight, these pioneer theories did a good job with the information available at that time. But they were trying to solve a problem for which the available tools and concepts were inadequate. Importantly, both relied on objective measures of activity, whereas the key link to SWB comes from subjective measures of engagement and interaction. So neither theory was able to account for the mixture of results that were reported. This caused confusion, even among the theories’ authors. For example, Cumming and Henry (1961) report that their measure of morale “is somewhat higher among women whose children have left home, as indeed it is among older men who have retired” (p. 100). Yet they also report that their measure of disengagement is not related to morale (p. 91). Other authors add to the confusion using various angles of reasoning, which include psychological processes that support denial of the claimed losses, denial that SWB is maintained, and the power of Zen transcendence. However, none of these can adequately explain how SWB can remain at normal levels into old age even after evident reduction in key objective variables such as money,

health, and relationships. A contemporary explanation comes from homeostasis theory.

Subjective Wellbeing Homeostasis

Using the seven-item Personal Wellbeing Index (International Wellbeing Group 2013) we have been monitoring the subjective wellbeing (SWB) of the Australian population over the past 15 years. Respondents use a 0–10, end-defined response scale, anchored by “no satisfaction” and “complete satisfaction.” The data are converted to a standard 0–100 point format, as described in the manual. When the mean scores from our 30 independent surveys are used as data, the grand mean is 75.3 percentage points and the standard deviation 0.72. This yields a normative range of 73.8–76.7 points. In other words, the mean score of a random survey of people in Australia can be predicted, with 95% certainty, to lie within a 2.9% point range.

A reason for this extraordinary level of stability is provided by the theory of SWB homeostasis. This proposes that, in a manner analogous to the homeostatic maintenance of body temperature, the essence of SWB is actively controlled and maintained by a set of psychological devices (for an extended description, see Cummins 2013a). The purpose of this homeostatic system is to protect the central positive and activated trait mood called homeostatically protected mood (HPMood).

HPMood normally perfuses all items forming the Personal Wellbeing Index, as well as other semiabstract thoughts about the self (Lai and Cummins 2013). This includes responses to the classic single question to measure SWB “How satisfied are you with your life as a whole?” Given the extraordinary generality of this question and the impossibility of answering through cognition, the response that people give reflects their level of HPMood. That is, respondents are using mood as information (see, Schwarz and Clore 1996).

The stability of population mean scores comes about because each person has a genetically determined set-point for their own level of HPMood. These set-points form a normal distribution between 70 and 90 percentage points (Cummins

et al. 2014) and around each set-point is a range of 8–9 percentage points, within which homeostasis normally maintains the affective experience of each person.

Contrary to views expressed by some authors (Headey et al. 2014), set-point theory does not carry an assumption of immutability in the measured variable. There are three reasons. First, returning to the example of body temperature, a thermometer does not measure the temperature set-point. It measures whatever temperature the body happened to be at the time of measurement. This principle also applies to measures of SWB and HPMood. Second, as explained by Cannon (1932), the measured variable can move within its set-point-range. Third, homeostasis can be defeated and, when this occurs, the measured variable moves outside its set-point-range as it comes under the control of the challenging agent. Thus, prolonged exposure to a sufficiently persistent hot or cold thermal challenge will cause measured body temperature to rise or fall. This does not represent a change in set-point. It is a defeat of homeostasis and a change in the *measured* variable. Once the source of thermal challenge is removed, core body temperature will normally revert to its set-point under the influence of homeostasis.

The measurement of HPMood (or its proxy, SWB) shows analogous properties. While its level normally lies within 8–9% points of its set-point, the experience of strong emotion causes homeostasis to fail. When this occurs, attention switches to the emotion generated by the challenging agent and away from HPMood. This emotion then influences responses to all semiabstract questions regarding the felt-level of SWB. However, over time, external and internal resources will be directed to the restoration of homeostasis. These will normally reduce the perceived challenge to a level allowing homeostatic control to be restored, and then reported SWB returns to lie within its set-point range.

Homeostatic Resources

The first line of homeostatic defense is formed by the three primary “external resources” of money, relationships, and meaningful activity. Money is

the most flexible resource. It can be used not only to purchase positive experience but also to avoid negative experience, such as by paying someone to clean the house. Relationships, when positive and intimate, allow much of daily life experience to occur within known contexts of positive interaction. Achieving something personally important each day enhances positive feelings and a sense of purpose, while also building financial or social capital.

Interestingly, more of each resource is not necessarily better. The positive influence of money on SWB, as an Australian average, rises up to a gross household income of around AU\$150,000, and then its influence plateaus. The reason for this ceiling is that all reasonable purchasable defensive resources have been deployed. In a similar vein, more than one intimate relationship is not normally a better defensive resource than one and may indeed be worse due to a diffusion or responsibility. Finally, too much attention to a single aspect of personal achievement, such as making money, will detract from developing other important life areas.

Recovering Homeostatic Control

No matter how well developed are the combined external resources, strong emotional episodes will still be experienced from time to time. When this occurs, homeostasis is defeated, SWB moves below (or above) its set-point-range, and the imperative on such occasions is homeostatic recovery.

When the challenge is negative, brief and not too strong, we recover homeostatic control fast. This is achieved through a number of automatic psychological processes: (a) Behavior: we disengage from the source of the challenge; (b) Habituation: decreasing responsiveness to a repeated stimulus; (c) Adaptation: people judge the strength of their current positive or negative experience against a level of “affective neutrality,” which can be raised or lowered by past experience. This concerns the processes of allostasis (McEwen 1998).

When the challenge is negative, prolonged, and strong, recovering homeostatic control is a slower process. This is achieved through the use

of both the external resources that have been described, together with a different set of internal resources. These are collectively called secondary control (Rothbaum et al. 1982) and have the aim of changing the self to accommodate an uncontrollable new situation. For example, people can find meaning in the event “God is testing me.” The purpose of secondary control is to minimize the impact of the negative event by introducing the prospect of a positive future outcome.

If the combined power of the external and internal resources fails to return homeostatic control, then the consequence is a period of sadness and negative self-reflection. If the condition of homeostatic failure persists, the probability of depression is much enhanced (Cummins 2010).

Depression and Resilience

The specter of depression is the worst outcome of homeostatic failure. It represents the collective failure of all the resources described above, so the strength of these resources together may be conceptualized as constituting the strength of homeostatic resilience. The normal maintenance of SWB is, thus, a balance between the strength of homeostatic resilience versus the strength of emotional challenge.

A substantial focus of applied research in QOL has been to identify general population subgroups where the resilience of homeostasis is overwhelmed by the strength of emotional challenge people experience each day. Some such groups have been well described and are more commonly found among the older generation. They include people recently divorced or separated, retrenched from their job, or having become widowed. Some groups, however, are not so obvious, and one of the most poignant are informal carers; family members caring for a relative with a disability at home.

In 2014, Hammond et al. (2014) reported a study of over 4,000 informal carers, conducted in collaboration with Carers Australia. Using the Personal Wellbeing Index, the group as a whole had the lowest mean level of SWB we have recorded (58 points, as against a normal range for the population of 73–76 points). As confirmation of the link between low SWB and depression,

the median SWB of the carers corresponded to being moderately depressed, using the depression, anxiety and stress scale (Lovibond and Lovibond 1995). The reason for this dreadful situation is straight forward. Despite a strong social security system in Australia, these families typically have a low household income. Additionally, the primary carer commonly has no employment due to the demands of their caring role, parents are often separated, their friends have evaporated, and for those caring for their child with a disability, their role as carer is likely to continue throughout the remainder of their lifetime. In short, SWB homeostasis has failed due to inadequate support from money, relationships, personal achievement, and an overwhelmed system of secondary control.

Summary

The failure of activity theory can be understood when considered in terms of homeostatic resources. The crucial issue for maintained levels of SWB is not the level of “activity” but the strength of homeostatic resilience. This understanding is important at all ages, but especially in old age since the level of homeostatic challenges is likely rising, thereby requiring more defensive resources to be deployed. Supportive evidence comes from (Lowenthal and Boler 1965) who followed-up a sample aged 60+ years over 3 years. While they found no overall evidence of voluntary social withdrawal (contrary to disengagement theory), they did find that when social withdrawal occurred, the potentially negative effects on SWB could be offset by calling on the resources of money or intimate relationships. Thus, to a reasonable extent, the three primary external resources can substitute for one another.

The Application of Homeostasis Theory to Old Age

In considering the application of the homeostasis theory that has been described, there are three broad issues to be kept in mind. The first is that old age is not simply a time of resource loss. Not only can resource advantages be identified in key

areas, such as accumulated wealth, but also the defensive power of secondary control is likely at its highest level in old age. Second is the crucial understanding, absent from activity theory, that objective and subjective variables form two different kinds of measurement, and that measures of one cannot be used to infer levels of the other. Third is that the various forms of external resource can reasonably substitute for one another.

Thus, if an older person is living alone, with no family contact, and in poor medical health, this does not mean they have low SWB. They may have an intimate, noncohabiting partner, adequate income, and engagement in a solitary activity such as painting. These issues will now be examined in the context of the specific key external resources. The source of the cited results and tables, unless otherwise specified, is based on the accumulated data from 30 surveys using the Australian Unity Wellbeing Index. Detailed results are available from Cummins et al. (2013).

Income

The power of income as a defensive resource can be demonstrated in two ways. The most obvious is that when the population is separated into income groupings, there is a consistent rise in SWB with each income increment, up to a threshold. The reason for this threshold has been stated, as representing an income, which allows the purchase of most reasonable forms of homeostatic defense. In Australia, this corresponds to a gross, before tax, household income of around \$150,000 per annum. The second demonstration comes from regressing the seven domains of the Personal Wellbeing Index (PWI) against the single global item of General Life Satisfaction (“life as a whole”). This regression shows that, of the 51% of variance accounted for, over half (58%) is shared variance, caused by HPMood. This leaves the 42% unique variance contributed by individual PWI domains (Cummins et al. 2013, Table A2.17.1). Within this unique variance, the three highest contributing domains are: standard of living (18%), achieving in life (13%), and relationships (8%). Thus, in general population samples, which mainly comprise people younger than 65 years of age, income

is the single most important influence on SWB in Australia.

Interestingly, this strong connection between SWB and income is much reduced in old age. From the lowest income (<\$15,000pa) to one of the highest (\$251,000–500,000pa), the SWB of young adults aged 25–36 years of age moves from 64.2 points to 78.4 points, an increase of 14.2 points. For the group aged 76 and older, the shift is from 76.9 to 79.4, an increase of just 2.5 points (Cummins et al. 2013, Table A3.10). Clearly, the connection between money and SWB is much weaker in old age. This may be due to a host of factors, some of which may not generalize to other nations. Australia’s social security system ensures that people living on an old-age pension have a level of income sufficient for simple living and, importantly, that this income is secure. They also receive subsidized medical care and can access numerous forms of support to assist living in their home, including subsidized meal delivery, home cleaning, and nursing care. Thus, their need for money is reduced.

Relationships

Unbeknown to the early researchers on aging, the power of human interaction is only weakly measured by quantity. They had assumed that the more social contacts someone has, and the more diverse these contacts are, the more likely is the person to have high morale. However, as has been stated, reliance on objective data to infer SWB is invalid. One strong, intimate, reciprocal relationship is a more powerful homeostatic defense than a thousand Facebook friends. It is the subjective side of reciprocal relationships that is such a powerful resource for SWB.

The defensive power of a confidant continues into old age, and this understanding allows a many of the early results to be better understood. For example, the literature is consistent in showing that divorce, separation, and widowhood are a severe threat to SWB maintenance at all ages, but especially among older people. The most likely active element causing such results is the loss of an intimate relationship, rather than simply decreased social contact. This has strong implications for remediation. If someone in a broken

relationship has an intimate other partner, their SWB may well be fine. However, again, money provides a caveat. If relationship loss means the survivor is without income then, of course, the negative effect on their SWB is severe. Notably, however, even with a modest income, widows in Australia aged 66 years and over have normal-range SWB (Cummins et al. 2013, Fig. 5.12).

A Role in Life

Having the sense of something important to do each day is assessed by the PWI domain “How satisfied are you with what you are achieving in life?” Purpose in life is the third corner of the triumvirate “Golden Triangle” of external resources supporting homeostasis, and it is a risk area for many people as they retire or after the children leave home. The central construct describing this life domain is perceived control (Rothbaum et al. 1982). If people feel they are in control, either because they can control some relevant aspect of their environment or control their own feelings about the things that change, they are likely to be homeostatically intact. If, however, they lose this capacity and enter a state of learned helplessness, depression is a likely outcome. Cumming and Henry (1961) asked their older sample “What are the worst things about the age you are now?” The first was “health,” the second was “not being listened to,” indicative of a sense of role loss.

Again, however, there are counterbalancing positives in old age. Cumming and Henry (1961) also asked their older cohort “What are the best things about the age you are now?” They report that nearly a quarter of the older men and nearly a third of the women felt freedom from their instrumental roles to be a great advantage. In truth, many paid jobs are hard and unrewarding, while many women experience relief when their children become independent. Moreover, in contemporary society, a valued role as a volunteer is generally available to anyone who seeks life purpose through such position. Confirmation that a strong sense of life purpose is generally retained into old age comes from a national sample of over 60,000 respondents in Australia (Cummins et al. 2013). These data show that satisfaction

with achieving in life falls significantly from 18–25 years of age to 46–55 years of age, then starts to rise again. At 76 years and over, it is at its highest level of any age (Cummins et al. 2013, Table A 5.11.4), an actual increase in the sense of life purpose from younger ages.

Health

As people age, their bodies accumulate structural damage and metabolic dysfunction. Moreover, as in the example above from Cumming and Henry (1961), health is usually a front-of-mind topic for people who are old. So, as expected, satisfaction with health shows a regular decrease with increasing age. So why does SWB go against this trend and generally increase after 65 years of age or so? There are two reasons. The first is that the relationship between SWB and physical health is generally weak due to:

1. Homeostasis causing a disjunction between objective health and SWB. For example, people normally adapt to reduced levels of physical mobility and, when they do, there is little or no relationship between measures of physical capacity and SWB.
2. A whole raft of conditional factors which include the following:
 - 2.1 Whether the medical condition has an associated psychological discomfort that is consciously perceived. If the person perceives severe pain, then this may well result in homeostatic failure. If, however, a severe medical condition such as high blood pressure is properly treated, the person will be generally unaware of their condition and it will weakly impact SWB.
 - 2.2 Whether the medical condition is chronic or acute. If the condition has a slow onset and development, then it is likely the person will adapt to the imposed circumstances and maintain homeostatic control of SWB. If, however, the onset is sudden, such as with injury, adaptation requires the passage of sufficient time to become maximally effective.
 - 2.3 Whether surgery or prostheses can ameliorate the disability.

- 2.4 Whether the person has the support that they need. There are two separate categories to consider. One is instrumental support and the other is social and intimacy support.
- 2.5 Personal resilience. This can be conceptualized in homeostatic terms as command over resources and a review is available (Cummins and Wooden 2014). As has been described, the resources may be either external or internal through cognitive devices such as secondary control.

The second reason for the general increase in SWB in older age is that, of the 7 PWI domains, health is the only domain to decrease beyond 65 years of age. Of the others, safety shows no reliable change, while all of the other five domains increase. Thus, when the seven domains are combined to yield SWB, they present as an increased level in older-age (Cummins et al. 2013, Tables A5.11.2 to A5.11.8).

From the above it is evident that only way to determine whether a medical condition is associated with subjective life quality is to measure SWB directly.

Conclusions and Outlook

The theory of subjective wellbeing homeostasis provides a coherent description of the relationship between subjective wellbeing (SWB) and the various sources of challenge that people face in old age. As far as is known, the results of published studies are consistent with predictions made by this theory. However, of course, whether it will accommodate future findings is unknown. More certain is that the theory is set for further development, most particularly in terms of understanding differences in homeostatic resilience between people, especially people from economically undeveloped countries. Most of the results that form the empirical support for homeostatic theory come from either North America or Australia. Much greater challenges are experienced by older people in developing countries. Whether the predictions of homeostasis hold fast under

conditions of different resource availability remains uncertain.

Baby boomers; Hiring; Labor demand; Mature aged workers; Workers aged over 50

Definition

Recruitment refers to seeking, selecting, and hiring people for employment.

Older workers are people aged over 50 years who participate in the labor market.

Introduction

In recent decades there has been a shift in labor market public policy from a culture of early retirement to one centered on hiring older workers, i.e., those aged over 50. The culture of early exit flourished in most major industrialized economies until the 1990s. Previously, older workers who left the workforce prematurely were regarded to be early retirees rather than unemployed. Their joblessness ended not with their reentering the

workforce but transferring to pensions (Casey and Laczko 1989). Subsequently, there has been a policy shift towards prolonging working lives that has been generated by population aging in general as well as the aging of workforces in specific industry sectors, such as nursing and teaching.

Despite there being a business case for retaining older workers and legislation protecting them from discrimination, age-related biases continue to limit opportunities for those nearing retirement. However, there is some limited evidence that employer's attitudes and behaviors may be shifting in response to workforce aging (Taylor et al. 2013). Notably, biases in selection processes restrict an older worker's mobility within the labor market.

Age barriers in the labor market refer to discriminatory practices based on age-related characteristics and beliefs that are exercised by employers and recruiters, managers, and coworkers. Such judgments rely on age without taking into account an individual's actual knowledge, skills, and abilities. This can result in unlawful age discrimination (Posthuma et al. 2012). This entry explores age barriers experienced by older workers and considers these in the context of recruitment.

Age-Related Bias in Recruitment Practices

Attitudes to older workers have shifted to become more positive at the public policy level, but the question arises as to whether and how attitudes

may have also shifted at the employer level. It is long established that age-related norms are important in recruitment. Recruitment practices, such as short listing and interviewing, may discriminate against older workers, particularly when education, qualification, and experience are specified (Taylor and Walker 1994). While age-related biases and unlawful discrimination are evident in recruitment practices, they are far less obvious than in workforce exit (Anderson et al. 2013). This subtlety stems from a combination of factors including a manager's priorities, personnel shortages, and other organizational factors as well as the applicant's age and other attributes upon which the hiring of older workers depends (Karpinska et al. 2011).

Research indicates that the significance of age norms in recruitment should not be underestimated, although individuals who violate age norms do not automatically receive negative evaluations. One of the most interesting and elegant studies to consider these issues found that recruiters rated candidates lower when they were considered older than the normative age for their career level whereas the opposite was the case when the candidate was younger. Candidates who were younger than the normative age for their career level were seen as on the "fast track," whereas older workers were seen as being behind schedule (Perry et al. 1996). The implications of these findings are that a younger person who applies for the kind of job typically reserved for an older person might be considered incongruent but this would be offset by the positive perception that the individual is aspirational. Older and younger workers who applied for jobs considered age normative would be considered congruent.

Moreover, while age is not indicative of personal work-related traits, research in simulated hiring situations demonstrates that it is a significant factor in shaping recruiter perceptions and expectations about the probable or possible duration of an older applicant's remaining working life (Craft et al. 1979). Another study found recruiters who evaluated hypothetical job applicants preferred mid-age candidates. While both the oldest and youngest jobseekers were less likely to be selected, applicants aged over 54 years were the least likely to be offered a job (Richardson

et al. 2013). It does appear that stereotypical assumptions underpin the types of jobs that might be considered suitable for older workers.

Labor Shortages Make Hiring Older Workers Attractive

Economic imperatives may induce employers to seek new sources of labor. Employers who face labor shortages seek to engage workers who have not traditionally formed the core of their organizations' workforces. Such workers include primarily women and migrant workers but also older workers (Henkens et al. 2008). Research indicates that the selection of older workers forms part of a multifaceted strategy to respond to labor shortages and workforce aging. Experiences of recruitment difficulties, such as being unable to fill vacant positions quickly, attracting insufficient candidates for selection, and inadequate quality of candidates, may also contribute to employers hiring older workers, even if they hold negative stereotype-based attitudes about them (Taylor et al. 2013). However, recruiting older workers may be a secondary or less preferred option to other sources of labor supply (Loretto and White 2006).

Hiring probabilities decline with age. The older an older worker is, the more difficult they find it to secure work. This may be due in part to the uncertainty employers may perceive about the level of productivity of older jobseekers compared to younger ones. Nevertheless, older managers and managers of older workforces more readily hire older workers, which increases the hiring probability of older jobseekers in an aging population (Heyma et al. 2014). Even in an aging workforce, older workers are more likely to be selected when employers face a constrained choice of recruits and they are able to demonstrate that their skills are up to date. Moreover, older workers who strategically reskill or upskill themselves are more successful as they are able to find employment in industries experiencing labor shortages (Patrickson and Ranzijn 2003).

While older workers may be valued in meeting labor shortages in aging populations, age barriers still exist and they may restrict career development

as well as take a toll on mental health and emotional well-being. It is important to recognize that not all employment offers have a positive effect on an older worker's well-being. Permanent work that overcomes financial hardship or uncertainty experienced during a period of unemployment has a much more positive influence on well-being than temporary work and self-employment (Strandh 2000).

Employer Attitudes to Hiring Older Workers

Recruiters assess an applicant's potentiality for performance. Older workers with years of accrued experience may be viewed by employers as lacking an appropriate "fit" in an organizational context of rapid change and dynamism where portability and flexibility are highly valued (Sennett 2006, 2008). However, expert performance seems to be unaffected by one's age. On most tasks, the benefits older employees have accrued through practice are much greater, in both absolute and relative terms, than the losses that their increasing ages may have brought about. Nevertheless, during the selection process, there is evidence that employers not only make use of actual information concerning applicants but also draw on their perceptions gleaned from biases related to age or other factors (Perry et al. 1996).

Research indicates that employers view older workers' potentiality and organizational fit in stereotypical terms as being reliable, resistant to change, and difficult to reskill, particularly as a contrast to highly desired attributes, such as flexibility, creativity, and innovation, which they are perceived to lack. Older workers are likely to experience diminishing prospects when their accumulated experience is regarded unfavorably to indicate a lack of potentiality (Taylor et al. 2010). Older jobseekers report being offered low-skilled and poorly remunerated jobs that are not in line with their experience nor their skills (Riach and Loretto 2009).

It also seems that recruiters are likely to consider older job applicants to have a fairly stable set of attributes that would be unresponsive to remedial actions, such as training or work redesign.

There is further evidence from simulated hiring situations that when recruiters were presented with a scenario under which they were facing high levels of cost pressure, they reverted to age-related biases about capacity to learn and consequently were less likely to recommend training when the hypothetical employee was older than when they were younger (Erber and Danker 1995). Recruiters were also found to be more likely to attribute poor performance by hypothetical older subordinates to stable, permanent, factors than was the case for younger subordinates. Additionally, job simplification rather than training was felt to be more appropriate for older workers (Dedrick and Dobbins 1991). Employer uncertainty about the knowledge and skill performance of older workers may be compounded by their perceptions of an older worker's potentiality in terms of injury risk. Employer attitudes vary; some may consign aging employees to less productive roles, and others may redesign the workplace to accommodate older workers within productive roles (Brooke et al. 2013). Recruiters would not be as likely to make such an assumption about younger applicants.

Studies of simulated hiring situations have consistently found that individuals playing the role of recruiter express bias against older workers in applicant evaluations. Such biases may center on the perceived "fit" of an older worker in an organization. In one study it was found that employers were more likely to hire an older worker when their workforce had a high age norm coupled with a labor shortage and the applicants met their expectations about physical appearance and relevant experience (Karpinska et al. 2013). Additional research concludes that issues of gender and race further complicate hiring conditions for older workers. Age discrimination is reported to be as pervasive as other forms of discrimination in recruitment (Lahey 2008).

Judging the Perceived Value of Older Workers

Stereotyping plays a role in employer and recruiter attitudes to employees of all ages. Older workers are valued for a set of perceived attributes

identified by employers and recruiters. These attributes are often evaluated in contrast to the perceived attributes of younger workers. Common stereotypes about older workers suggest they are less employable than younger workers, which places them in a precarious situation regarding the risk of job loss and future opportunities for reemployment (Klehe et al. 2012). Yet, it is possible that there are no performance differences between older and younger workers and that older workers may indeed outperform young workers. In this case, the negative attitudes that have been evident among employers must be understood to stem from unconscious bias and hidden workplace agism (Malinen and Johnston 2013).

Age stereotyping has been found to be influential in shaping employer attitudes about older workers even when they are targeted in recruitment. Advocates have promoted an approach that replaces negative stereotyping with more positive alternatives to minimize biases against older workers, which although benevolent does not challenge a reliance on universalizing characteristics and narrow modes of behavior (Riach 2007). Moving beyond common stereotypes provides a more positive and more differentiated understanding of older workers (Kunze et al. 2013).

However, it is not only employer attitudes that influence how older workers are treated in the workforce. It is also important to consider the attitudes of other workers towards older employees. Research indicates that attitudes to older workers in the workforce are largely positive, with older workers' attitudes being more positive than those of younger workers. Older workers do not feel more discriminated against than their younger colleagues, although they perceive some human resource practices preference younger workers (Kluge and Krings 2008).

Combating Age Discrimination in Hiring

A decision to target older workers for recruitment is more likely in organizations with a high age profile and an organizational climate oriented towards

diversity (Goldberg et al. 2013). Once an organization decides to target older workers, employers need to consider which recruitment sources, recruiter characteristics, and impression management tactics are most effective for attracting older jobseekers (Lievens et al. 2012). But, as older workers are not all alike, to view them as an equity group in their own right is highly problematical and potentially lends itself to age stereotyping rather than evaluation of individual capabilities. To be effective, employer policies need to be not simply directed at older workers but should adopt an "age-aware" rather than "age-free" approach (Brooke and Taylor 2005).

Equal opportunity legislation proscribing age discrimination in the labor market is a feature of most developed economies. However, there is very little evidence that stronger age discrimination protections help older workers cope with labor market disruption and workforce stresses relative to younger workers. Stronger age discrimination protections may in fact deter hiring of older workers during times of uncertainty (Neumark and Button 2014).

Another common approach has been wage subsidies to encourage employers to hire older workers. Job creation programs in Europe throughout the 1970s and 1980s relied on policies of full or partial wage subsidies, particularly for older and younger unemployed workers (Bekemans 1985). Their use has persisted, despite mixed evidence concerning their efficacy. Some evaluations conclude that such policies are successful by improving the employability of older workers and by enabling unemployed older workers to reenter the workforce, while their negative side effects of deadweight loss, crowding out, creaming, and displacement effects seem to be limited (Conen 2013). Other evaluations, however, while being positive in their overall assessment, report results that may give cause to doubt the effectiveness of wage subsidies and also stress the need for careful design of such schemes (Jaenichen and Stephan 2011). Added to this are possible stigmatizing effects. Such measures are, by their very nature, agist and may further erode self-confidence by categorizing people as "difficult to employ." The signal that might be received by employers is that older workers have such work-limiting issues that only government compensation could make them

attractive, with the risk of deepening age prejudice and institutionalizing age discrimination.

An alternative approach has been awareness-raising campaigns among employers. These have been tried in a number of industrialized countries, although their impact appears to have been limited. For instance, following consultation the British Government's Code of Practice on Age Diversity in Employment was launched in 1999 with an accompanying media campaign. An important part of government policy on age and employment, it was disseminated widely (Education and Employment Committee 2001a, b). Although it set out principles of nonage-biased employment practices and provided examples of best practice, research indicated that the Code had a limited impact (Goldstone and Jones 2001). Over three waves of an evaluation survey, awareness of it increased from 23% to 37% of employers. However, a very small number – 9% at wave 3 – had seen a copy. More representatives of larger organizations had seen a copy – 1 in 5 larger compared to 1 in 12 smaller organizations. A very small number of employers – 2% at wave 3 – stated that they had changed policies as a result of the Code. Thus, it may be difficult to persuade employers of the merits of implementing age-aware human resource management policies.

On the other hand, pressures on labor supply may change employer behavior without the need for substantial government intervention. Concerns about workforce aging and its influences and about labor shortages appear to be influencing the adoption of measures favoring older workers, with the implication that they may persist even in the situation of an economic downturn (Taylor et al. 2013).

Future Directions

The mechanisms underlying recruiter bias towards older workers appear to be well understood, although much of the research has been based on hypothetical scenarios. More “real-world” research is needed to confirm this understanding that older jobseekers are evaluated unfairly on the basis of age-related biases about their potentiality as well as from actual

information about their workforce experience in a way that younger workers may not be.

While internationally public policy is being aimed at the prolongation of working lives, there is mixed evidence concerning the efficacy of current practical approaches to influencing recruiter behavior regarding older workers. These have emerged rapidly in recent years, but systematic research into their utility is lacking. Comparative research considering the extent of their impact and value for money would be valuable.

In considering employer hiring strategies, there is also a need to consider what jobs older workers are being selected for and on what terms. While employers may become more favorably disposed to older labor, if it is relegated to roles on the periphery of organizations without opportunities for advancement and growth, this may not be conducive to the worker's well-being and, consequently, to a successful transition from work to retirement.

In this regard, flexible working is much promoted as a strategy for retaining older workers. However, it must be stressed that flexibility, if this means part-time work, may not be a solution. Not every older worker desires to work part-time. Taking an approach that offers one strategy for all older workers is neither equitable nor realistic. For those who do seek flexible working options, flexibility and job quality need to go hand in hand.

Amid labor shortages generated by workforce aging and other industry-specific factors, recruiters will need to design recruitment strategies so that they can deal with greater workforce diversity. Otherwise, they will face persistent skill and labor shortages and also risk losing valuable knowledge and experience, and concomitantly, competitive advantage.

Autobiographical memories; Episodic memory; life review

Definition

Reminiscence is the intentional or spontaneous process of retrieving episodes personally lived in the past. This retrieval of autobiographical memories may or may not have a logic or sequence in terms of the topics recalled. Understanding and evaluation are not an integral part of reminiscence, which tends to be highly spontaneous and mostly unstructured. On one hand, reminiscence can be regarded as a spontaneous phenomenon emerging in different settings, which forms part of many social and family events, providing people with the opportunity to relate episodes and/or tell their life history. On the other hand, especially in older adults, reminiscence can be used as a therapeutic intervention strategy in different fields, such as a prevention strategy for mental disorders or a way to promote mental health. Reminiscing past events can help a person feel more confident and self-assured when dealing with the changes related to old age. It can also have positive effects in different psychological and psychiatric pathologies.

Reminiscence and Autobiographical Memory in Aging

As people age, the tendency to remember the past and reinterpret it positively increases naturally. Individuals remember positive events that made them happy more frequently than negative ones. However, this does not mean that negative events are forgotten; these are often reinterpreted and/or changed in their affective valence or perhaps make change in order to provide more positive feelings.

Autobiographical memory (AM) is a memory system consisting of specific episodes recollected from a person's life. It emerges as a re-living of actions, events, and situations remembered by an individual. This memory generally contains information on places, actions, persons, objects, thoughts, and affections and plays a central role in the construction of identity or of the self, in emotional experience, and in all the attributes that define a person. Reminiscence (RM) is the way

individuals access such information for its use. It is the voluntary or involuntary action of recollecting memories from one's past. This recollection can reinforce the memory itself and reinterpret it, giving it meaning and emotion according to affective state. Specifically, the socioemotional selectivity theory (Carstensen et al. 2003) argues that as a person ages, they focus on stimuli of positive emotional valence. These cognitive strategies can have considerable advantages since they help to regulate emotion, maximize coping efforts, and increase subjective satisfaction with the present and the past. However, not all memories are linked to positive emotions. The past generates emotions ranging from resignation, serenity, pride, and satisfaction to complete bitterness and vengeful anger, emotions determined by thoughts of the past (Latorre et al. 2008).

Although there is still little experimental and clinical research on autobiographical memory and aging, deficits in episodic memory (and more specifically in details of the context) are a major problem in old age. Some authors consider this lack of the capacity to recall information related to context could be a result of a deficit in the ability to control sources, in other words, the ability to remember the source or origin of thoughts and memories. There are numerous studies in this regard, which confirm that the memory of episodic contextual details deteriorates in older adults (Berna et al. 2012; Friedman and Johnson 2014; Latorre et al. 2012). Older adults tend to choose personally significant memories maintained by frequent repetition. Since these memories have been repeated many times, they are highly accessible and retain their realism and original details. Although in younger people a strong emotion generated by a dramatic or stressful event is enough to produce long-lasting, vivid memories, in older people the retention of detailed memories depends almost exclusively on repetition.

In order to understand the decline in AM's specificity in older adults, one theory can be enunciated – that proposed by Conway and

Pleydell-Pearce (2000) regarding how AM functions and how it is organized. In summary, the theory holds that AM is highly organized and comprises three levels of hierarchically organized autobiographical knowledge: (1) The highest level of the hierarchy corresponds to *lifetime periods*, categorized as segments of life measured in years or decades. (2) The middle level includes *general events*, episodes which by virtue of having occurred on more than one occasion are classified as general memories. They are events which last days, weeks, or months. (3) The lowest level corresponds to *specific events*. These are concrete, individual events, which are measured in seconds, minutes, or hours. When people tell life stories, these three elements tend to be intertwined, yet in terms of access to memory, they are ordered hierarchically. This structure helps to explain the differences in latency time in the access to each memory type; the more specific the memory, the greater the latency time. Life periods help to locate knowledge of general and specific events. They provide the skeleton framework for autobiographical memories. General events appear to be the natural points of access to our autobiographical memories, and, arguably, they hold this privileged position due to the benefits of repetition. Furthermore, they retain a large part of the distinctive flavor of a person's past and are easily accessible because they have been reinforced through repetition.

In the last decade, a large number of studies have focused on analyzing differences in access to autobiographical memories between control groups and groups with different pathologies. These studies show that when a cue word is presented (e.g., *happy* or *sad*), depressed persons retrieve fewer specific and more general memories than nondepressed persons. This phenomenon is known as overgeneral autobiographical memory (OGM) (Williams et al. 2007). Research on OGM shows that older adults generate fewer specific memories than younger adults (Ros et al. 2010). The OGM effect is also found in older adults with depression (Serrano et al. 2007). However, the effect size (the magnitude,

or size, of an effect) is smaller than in samples of younger adults. In contrast to the case of younger adults, in samples of older adults, the effect size is larger for positive cue words than for negative ones (Latorre et al. 2012). Furthermore, younger adults are able to generate a larger number of specific memories in response to a series of cue words. This is possibly explained by the decrease in executive capacity of working memory in old age (Ros et al. 2010).

Taxonomy and Functions of Reminiscence Styles

The different taxonomies and functions of reminiscence emerge from the fact that it is a multidimensional, multidisciplinary, and multi-generational process. On some occasions this process is intrapersonal, encouraging introspection and self-reflection, and on others it is interpersonal, promoting sociability and connections with others.

Several authors have attempted to classify the types and functions of reminiscence using qualitative coding of narratives and quantitative analysis of data collected from questionnaires. Here we present some of these taxonomies, in order, mainly, to illustrate what function is associated with the process of reminiscence and how this process can be directed in the search for well-being in the aging process. According to Coleman (1974), there are two types of reminiscence: simple reminiscence and informative reminiscence. Simple reminiscence is the spontaneous retrieval of past events; the event is viewed as a significant element of a person's life and can be a resource for the balance of the self. Informative reminiscence is the application of past experiences to the present as a way to teach others. LoGerfo (1981), on the other hand, describes three types of reminiscence: informative, evaluative, and obsessive. Informative reminiscence entails a pleasurable recollection of past events, which can lead to mood enhancement. Evaluative reminiscence involves attempts to reconcile with past conflicts

and failures. Obsessive reminiscence describes the persistent and unproductive recollection of remorseful memories.

Merriam (1980) identifies three types of reminiscence: therapeutic, informative, and enjoyment. Therapeutic reminiscence describes reminiscence as a mechanism to cope with life's problems and to understand oneself. It also refers to life review as a form of acceptance and integration of the self. Informative reminiscence entails the storytelling function of reminiscence, the transmission of cultural and educational values and teachings from the past: it involves the pleasure of entertaining and retelling personal achievements to others. The third type refers to the enjoyment produced by reminiscence and entails passing the time and the pleasure that telling stories from the past generates. Finally, Kovach (1990) considers that reminiscing often entails explicit or implicit interpretation of past events. This author identifies two types of reminiscence: *validating* and *lamenting*. Validating themes include joys, past to present comparisons, and self-appraisals. Lamenting themes include difficulties, regrets, and lacking choice.

In an effort to make a qualitative leap forward, Watt and Wong (1991) proposed one of the most commonly cited taxonomy in the field of reminiscence research. The authors identify six types of reminiscence: *integrative*, *instrumental*, *transmissive*, *narrative*, *escapist*, and *obsessive*, stressing that only the first two are related to measures of successful aging. *Integrative reminiscence* is a process involving acceptance of the self and others, conflict solving and reconciliation, a sense and meaning of personal value, and integration of the past and present. The functions of *instrumental reminiscence* are recollecting past plans and the attainment of goals, drawing from past experiences to solve present problems, and remembering past attempts to overcome difficulties. *Transmissive reminiscence* resembles storytelling in that it attempts to teach and entertain listeners. This type of reminiscence involves an audience, generally comprising younger people who can benefit from the experiences transmitted.

Moral instruction is usually included. *Escapist reminiscence* is generally considered to be defensive. It tends to glorify the past and deprecate the present. It expresses a wish to return to the past. This type of reminiscence can help protect one's self and self-esteem as it gives pleasure and provides relief from present stress. However, this type of reminiscence can be damaging if it interferes with present functioning. The key characteristic of *obsessive reminiscence* is persistent rumination on negative past events. This type of reminiscence is evidenced by feelings of guilt, shame, resentment, and despair. It reflects a failure to integrate problematic past experiences in positive aspects of life. Obsessive reminiscence is often associated with mental health disorders. However, for two reasons, it can also have an adaptive function: it highlights an unresolved conflict and can lead to its solution, and it can serve as preparation for problem solving. *Narrative reminiscing* is descriptive rather than interpretive or evaluative. It is a nonevaluative narrative of a life episode.

The Reminiscence Function Scale (RFS)

The taxonomy presented by Webster (1993) is currently one of the most widely accepted. Webster's reminiscence function scale (RFS) is a 43-item questionnaire in which, using a 6-point Likert-type scale, participants are required to quantify the extent to which they use reminiscence for one of the given functions. It permits a quantitative approach and facilitates research through the use of a test, which has proven to be psychometrically consistent in terms of reliability, validity, and factorial structure. The RFS identifies eight functions or uses for reminiscence: (i) *boredom reduction*, which emerges in non-stimulating environments as a way to pass the time, when memories are used to fill a void of stimulation or interest; (ii) *death preparation*, where memories are used to help review life, to deal with thoughts of life coming to an end, and to find tranquility when death is close; (iii) *identity*, that makes use of personal memories in the search for coherence, worth, and meaning in

one's life and to consolidate a sense of self; (iv) *problem solving*, where reminiscence is used as a way to recover techniques used in the past to solve problems and apply them to current challenges or situations; (v) *conversation* that includes the recollection of past events as a duty and form of social engagement; (vi) *intimacy maintenance*, which consists of retrieving memories of intimate social relations that are no longer part of one's life; (vii) *bitterness revival*, characterized by the rehashing and ruminating on memories of difficult life circumstances, misfortunes, and lost opportunities; and (viii) *teach/inform*, where reminiscing is a way to transmit life lessons or share personal ideologies.

The access to AM through RM serves a wide range of functions varying in importance across individuals and the life cycle. These can be divided structurally into three main functions (Webster et al. 2010). Interpersonal functions emerge when memory occurs in a social setting. These include *social interaction* (AM is used as material for conversation; exchanging experiences serves to maintain interest and allows individuals to take part in a group), *self-disclosure* (sharing AM as a way to establish relations and develop intimacy and friendship), and *empathy* (AM provides a basis to interpret behavior, infer emotions and opinions, and guide answers). Intrapersonal functions emerge when memory forms part of private reminiscence. These include *mood regulation* (used to regulate mood state) and *formation of the self-concept* (used to construct, preserve, or modify the self-concept; it also provides a means to deal with unresolved conflicts or decrease discrepancies between the ideal and current self). Knowledge-based functions refer to semantic memory and include *general knowledge* (the accumulation of general knowledge occurs when general event knowledge representations are constructed by processes of abstraction or inductive inference from specific autobiographical memories) and *problem solving* (AM provides experiences of past problems that can offer possible solutions for current problems and guide plans for future actions). There is evidence that the

Reminisce Interventions in Elderly People, Table 1 Types of intervention reminiscence based

Type of reminiscence intervention	Description
Simple reminiscence	An unstructured autobiographic narrative that emerges spontaneously in a social, relational setting. This type of intervention can be used in groups at residential centers or care homes for older people as a way to establish social relationships and improve social well-being in the short term. This intervention is supported by the socioemotional selectivity theory, which encompasses the positive effects of reminiscence on mental health, regarding emotion regulation and the processing of information oriented toward pleasurable stimuli
Structured reminiscence or life review	In contrast to simple reminiscence, life review reminiscence is much more structured, focusing on the integration of positive and negative life events. It can be classified as evaluative. This type of intervention is suitable for persons with mild psychological disorder, who need support to cope with their current situation or life events. This intervention is supported by Erikson’s psychosocial theory of development, which describes eight developmental stages. This intervention identifies continuity between the past and present and obtains a vision of how participants have developed across the life cycle and how they feel in the present moment (Butler, 1963). This type of intervention is commonly used in the prevention of mental health problems and is usually conducted individually
Life review therapy	This is an eminently therapeutic intervention. It needs to meet all the requirements of this type of intervention regarding the technical knowledge of the therapist and the consent and confidentiality of the therapeutic process. It is highly structured and is designed for use with persons with mental problems or pathologies such as depression, anxiety, schizophrenia, posttraumatic stress disorder, etc. Life review therapy can modify identity and create a new outlook on life, producing changes in identity and mood state. It is usually combined with cognitive and problem-solving therapy, narrative therapy, and cognitive training

relative importance of these three functions varies with age. In middle age, memory is mainly used for problem solving while in old age intrapersonal functions dominate. There is a rapid increase in life review as “death preparation.”

Reminiscence Therapy

The application of reminiscence as a therapeutic intervention strategy should be carefully planned and make use of validated assessment protocols from research results and scientific theory. Health professionals and therapists must be aware that reminiscence may, in some cases, have adverse effects such as depression or anxiety (Westerhof et al. 2010).

Different types of material have been used in reminiscence interventions to facilitate the retrieval of autobiographical memories. This

material takes various forms, such as stimuli for reminiscence stimuli, visual aids, personal artifacts or objects, personal photo albums, memorable events or tangible past memories, etc. Given the subjectivity and importance of this type of memories or personal material, the process must be conducted with the informed consent of the participant and respecting the confidentiality of the data and intervention. Table 1 presents three basic types of reminiscence intervention: simple or unstructured reminiscence, structured reminiscence or life review, and life review therapy (Westerhof et al. 2010).

Reminiscence as an Intervention Strategy in Depression in Older Adults

Reminiscence is a psychological intervention proven to reduce depressive symptoms in old

age. It has been the subject of various studies (Bohlmeijer et al. 2005). In overall, there are two trends in the application of reminiscence treatment in the symptoms of old age. On one hand, there are interventions based on the training of specific positive autobiographical memories. On the other hand, there are interventions based on promoting integrative and instrumental reminiscence styles. The effectiveness of reminiscence based on specific positive memories can be explained by its potential to counteract two tendencies in depressive persons: the tendency to remember negative events and the tendency of depressive older adults toward over-generality when recalling autobiographical events (Serrano et al. 2007). So, the stimulation and retrieval of specific positive autobiographical memories counteract tendencies associated with depressive symptoms, thus reducing these symptoms. Secondly, interventions promoting integrative and instrumental reminiscence of autobiographical memories include cognitive processes and content related to depression, such as self-appraisal, causal attributions, and evaluation of personal resources and selection of coping strategies. Instrumental reminiscence requires individuals to recall coping with situations, the strategies they developed to solve difficult situations, and situations in which they achieved highly evaluated aims or helped others to achieve theirs. This type of memories permits the identification and recognition of important coping resources that have been useful for adaptive coping in life. The recall of problematic situations successfully coped with promotes self-appraisal and can motivate the individual to apply the strategies identified to current problematic situations. The ultimate aim of integrative reminiscence is to find continuity between different events and to discover that life, as lived, is of value. Using this type of reminiscence, individuals attempt to accept events, resolve past conflicts, and resolve the possible discrepancy between the ideal and reality. This reminiscence style provides the opportunity to review causes and consequences of different autobiographical events, by reviewing attributions formed and contextualizing events.

Reminiscence-Based Interventions for Persons with Neurocognitive Disorders

Reminiscence-based interventions for persons with neurocognitive disorders consist in stimulating a person to retrieve and speak about past events and experiences with a person or group. For persons with this clinical condition, it is common to use material such as photos, images, videos, objects, and/or recordings to trigger autobiographical memories. The use of reminiscence therapy seems to have an impact on cognition, mood state, social relations, identity, problematic behaviors, functionality, and relations with their carers. However, there is little robust evidence of this therapeutic intervention's effectiveness, and studies on the impact of this therapy tend not to be rigorous and are based on small-size samples (Woods et al. 2005).

Reminiscence as a Strategy to Promote Well-being in Old Age

Reminiscence can be used to foster skills of self-understanding, conflict resolution, acceptance of life as lived, and the understanding that life is finite, which all together can promote well-being in old age. One of the reminiscence-based techniques used to achieve this is to construct an autobiography in which the participant builds his/her life story using the memory of autobiographical events. It is a planned activity, which, apart from reminiscing, involves a structure uniting the participant's main life events. It can also include evaluation of the events (Webster and Haight 1995). Analysis of the effects of building an autobiography suggests it stimulates AM, facilitates the sense of continuity of self, increases self-confidence and the capacity to adapt, and improves self-understanding as well as interpersonal relations (Birren and Deutchman 1991). Reminiscence can even be used as a strategy for intergenerational community development. Changes in visual memory functions and attention have been observed in older adults taking part in structured autobiographical writing workshops (de Medeiros et al. 2007).

Conclusions and Future Research

Reminiscence is an important process in old age that promotes a sense of identity across the life cycle and allows a person to cope with change and loss. As an intervention strategy, it has great therapeutic potential for geropsychologists in the reduction of depressive symptoms and in the promotion of well-being in old age. Despite available evidence of its impact, more research is required on how and in whom these interventions work the best (Westerhof and Bohlmeijer 2014). Evidence in those individuals suffering from a neurocognitive disorder is not as clear as in the case of persons with depressive symptoms.

Presently there is an increasing interest in the impact of reminiscence interventions and there are signs of emerging conceptual clarification. More sophisticated designs with control groups and clinical trials are being applied which provide more robust results on the use of this technique with therapeutic goals. More advanced techniques such as confirmatory factor analysis are being used, and psychometric instruments are being perfected. The organization and characteristics of reminiscence interventions are highly heterogeneous. The use of multimedia technology as an aid to record the autobiographical events recalled constitutes a challenge for the development of new formats of reminiscence intervention.

interest in their environment (Keane and O’Toole 2003). The National Remotivation Therapy Organization (NRTO) defines remotivation therapy (RT) as a small-group therapeutic modality, designed to help clients by promoting self-esteem, awareness, and socialization (National Remotivation Therapy Organization 2003). As the concept itself suggests, remotivation relates to the creation of interest in life, i.e., in a person’s daily activities, talents, hobbies, and social relationships with family and friends.

Remotivation therapy is a form of intervention focused on the capabilities and potential of individuals. It aims at helping to value personal strengths and to recognize specific features, roles, and unique traits of the patient. Although not originally conceived for older people, it has been used with this population as a way of promoting interest in the world. This is accomplished through the process of discussing small things in life that are not related to their problems. This is done by helping participants to think and talk about real-world issues and by aiding them in relating and communicating with other group members (Herlihy-Chevalier 2005). RT contributes to the improvement or maintenance of cognitive and physical skills, promotion of self-esteem, and increased hope and courage (Vandevender 2005; Vickery and Allison 2005).

All of these RT goals are achieved through stimulating activities combined with meaningful discussions and supportive interactions. It integrates features of several other therapeutic intervention modalities: first, *reality orientation* by asking the individual questions about time and space, as well as information about himself/herself; second, *reminiscence* by asking them to share their life experiences, memories, and personal belongings; third, *validation* by the therapist through their receptivity, neutrality, and impartiality; and finally, *sensory stimulation* through visual aids, pictures, music, and songs.

This entry provides an overview of the RT from its emergence in the 1950s onward, emphasizing its evidence-based contribution in promoting elders’ social skills, self-esteem, hope, and meaning in life.

Remotivation refers to a variety of group therapy techniques used with chronically mentally ill patients in inpatient settings to stimulate their communication, vocational, and social skills and

Origin and Development of Remotivation Therapy

Dorothy H. Smith, a retired English teacher who was a volunteer at the Northampton, Massachusetts, Veterans Administration Hospital, started the practice of remotivation in 1950. She started to use poetry, specifically reading poems and asking questions about the poem, with a group of seven men, most of them catatonic and considered to be mute since they had not spoken in years (Meixsell 2005). The initiative was considered a success since several members of this group answered the questions that she asked about the poem and one had even asked for the poem to be read again (Meixsell 2005).

Following these initial findings, in 1956 Smith began to develop training classes at Philadelphia State Hospital, which was then considered the national training center for remotivation. This practice attracted the attention of the American Psychiatric Association (APA) that, along with Smith, Kline, and French laboratories, promulgated remotivation groups in several hospitals and long-term care facilities around the United States (Sullivan et al. 2001). Reports from 1965 refer to the existence of 241 remotivation programs in 45 US states and over 15,000 trained remotivators (Meixsell 2005). In 1971, the National Remotivation Therapy Organization was formed. This organization, still active, provides seminars, classes, and Web access training for professionals who wish to use remotivation techniques with their patients, aiming to provide the standards for RT and to promote its practice.

After 15 years of exponential success, a decline in RT dissemination and practice occurred. According to Meixsell (2005), RT became confined to only a few activities due to the deinstitutionalization movement of the 1970s. With the closing of many psychiatric facilities, remotivation programs didn't move into the new treatment settings, and so these practices became less popular. The same disinvestment of RT also happened within academic and research fields. Between 1971 and 1977, five doctoral dissertations on RT were completed providing useful empirical data in what regards this therapeutic

approach in several areas including the effects of intensive remotivation techniques on institutional geriatric mental patients in a state mental hospital (Bovey 1971), reactions of nursing home residents to a specific remotivation technique (Arje 1973), and the effects of remotivation technique on patients, staff attitudes, and staff care of the patient (Pruitt 1976). Others also examined the benefits of RT in the treatment with domiciled geriatric combat veterans (Vandevender 2005) and the effect of RT on activity level and life satisfaction with institutionalized elderly populations. After this first effort in researching and establishing the impact of RT, no further research about this intervention occurred. A systematic literature review in PubMed and ISI Web of Knowledge databases using the term "remotivation therapy" revealed only 13 articles (Table 1).

The articles were published between 1973 and 2011, but the majority ($n = 8$) dates back to the 1970s. No abstract or full texts were available for six of the 13 identified manuscripts. Even so, when analyzing the titles and journals and, when available, the abstracts and manuscripts, it appears that the first publications were more broad and conceptual, presenting the definitions and procedures of RT. Some of the researches presented the benefits for specific target populations (e.g., Huntington's and schizophrenic diseases, Sullivan et al. 2001), but the majority discusses remotivation with older individuals, suggesting the interest of its use in this population. As for the scientific scope of journals where the research on RT was published, it encompasses several disciplines, including psychiatry (e.g., *Perspectives in Psychiatric Care*), geriatrics (*Journal of the American Geriatrics Society*), nursing (e.g., *Journal of Gerontological Nursing*), and health and social policy (e.g., *Journal of Health & Social Policy*).

Using "remotivation" as the keyword (title, keywords, and/or abstracts), in an electronic search in PubMed, expands the results to 63 relevant manuscripts. This includes articles in which remotivation techniques were used within other interventions, such as the 3R mental stimulation program that incorporates remotivation with

reminiscence and reality orientation (Koh et al. 1994) and the use of remotivation assumptions in intergenerational programs (West and Hutchinson 1992).

Practices of Remotivation Therapy

Remotivation therapy is usually developed as a group treatment but can also be conducted individually, at the bedside for those who are too ill to integrate group sessions or for those who show disruptive behaviors or are not able to participate in a group for other reasons. Group interventions usually embody twelve sessions, conducted once or twice a week, lasting from thirty minutes to an hour. Groups are comprised on average with six persons (Herlihy-Chevalier 2005). In order to promote attendance, trust, and goal's attainment, the sessions should be held consistently and by the

same therapist. The remotivation program must have a certified remotivation therapist, commonly entitled “remotivator.” To become a certified remotivator, a clinician must have the National Remotivation Therapy Organization's training, with class time followed by a practicum in which the professional must conduct a therapy session with clients (National Remotivation Therapy Organization 2003). Professionals who specialize in RT include psychologists, nurses, recreational therapists, social workers, occupational therapists, psychiatrists (Meixsell 2005), and other professionals, including gerontologists.

According to Meixsell (2005) remotivation programs can be developed considering different topics and following specific steps. There may be remotivation in (i) self-care groups, directed to several hygiene tasks that a person performs on a daily basis; (ii) exercise groups, in which a conversation about the benefits of exercise and some

Remotivation Therapy, Table 2 ProTR – a program of remotivation therapy

Session	Topic	Discussion (examples)
1	Living in our city	How can we describe our city? What memories do you have about some places of our city?
2	Saint Valentine's day	What kind of values is associated to this day? How was dating when you were young?
3	Going outside	What are the most well-known places to visit in our country/town? How do you feel during a tour?
4	Cooking	What are the typical dishes of our region? What is your favorite dish, the one that you used to cook?
5	Professions	What professions are most valued nowadays? How was your profession like? What specific tasks did you perform?
6	Successful aging	What must a person have or do to be "successfully aged"? What are your strategies for having good aging experiences?
7	Songs	What style of music is that (while listening to music)? What is your favorite music and how do you feel when listening to it?
8	The happiest days of our lives	What is associated with happiness (while seeing images)? What was the happiest day of your life?
9	Family	What are the characteristics and main differences of families from the present and the past (e.g., composition, (co)habitation)?
10	Easter	What are the typical traditions and customs of Easter time? What memories (visual, auditory, and smell information) do you have about this celebration?

physical activities could be promoted; (iii) patient education groups, focusing on a specific medical diagnosis and its functional implications to participants that experience similar conditions; (iv) media and craft groups, used to teach how to perform leisure activities; and (v) instrumental activities of daily living groups, with discussions and tasks about activities such as money management and homemaking (Meixsell 2005).

Vickery and Allison (2005) propose that remotivation sessions could approach more basic and objective topics, namely *what I did for a living, memories of early school years, my home when I was a child*, or more advanced and subjective ones. The advanced remotivation assumes a more differentiated and deep level of intervention and could explore topics such as *attention* (being alert, discovering the world around), *compassion* (caring and being cared for), *forgiveness* (feeling the healing balm of being forgiven), or *hospitality* (allowing people into your heart) (Vickery and Allison 2005). In the program presented by Cummings (2003), themes for the ten weekly sessions include personal continuity, hidden strengths and talents, functional adaptation, emotional adaptation, coping mechanisms, social skills, dealing

with loss, and caring for self and others. Table 2 exemplifies an example of themes/topics and questions for debate to be considered in a group intervention (Araújo et al. 2011).

Independently of the theme/topic to be covered, each remotivation session must include five distinct steps (Herlihy-Chevalier 2005): climate of acceptance, bridge to the real world, appreciation for the work of the world, sharing the world we live in, and climate of appreciation. Each of the steps must be followed in this order. These steps establish a set of microlevel goals that the remotivator must accomplish. Planning and resource management are important to remotivation's success. The topics must be of interest to the group members, which could be confirmed through prior conversations with them but also with their families and staff members. The use of tools can compensate sensory losses and enhance attention. The use of texts from magazines and newspapers, music and songs, and pictures and photographs instead of poetry (as initially defined by Dorothy Smith) works best with participants with regressing mental abilities and lower education levels (Araújo et al. 2011). To give each person a hands-on

project relating to the subject, using props (e.g., flowers in a session about seasons, dolls and toys in a session about traditional games) is essential to promote participation and facilitate the understanding of the topics (Vandevender 2005). Here is a detailed description of the five steps essential to a remotivation:

Step 1. *Climate of acceptance*

The remotivator introduces himself/herself and welcomes each person on his or her arrival in a warm, friendly manner and assists in finding a seat or wheelchair space in the circle. Acknowledging members by name and giving attention to any aspect of their uniqueness (such as the clothing or haircut) must be guaranteed. It could also allude to aspects related with the weather or other trivial but relevant subjects in order to establish contact with participants. These observations must be pleasant and objective and serve to create an atmosphere free of formality and tension.

Step 2. *Bridge to the real world*

The remotivator introduces a general topic that would be relevant to the group. In the original technique, the linkages with reality were promoted through the lecture of poetry about objective themes, following the assumptions of bibliotherapy. Also texts from magazines and newspapers as well as citations can be used. The texts must be simple, rhythmic, and related to the topic under exploration. Along with reading and analyzing a text, visual aids, pictures, and other objects that are related to the topic can be used. It is important to ensure that all participants have contact with the materials.

Step 3. *Appreciation for the work of the world*

The remotivator develops the topic through planned, open-ended, factual, and objective questions, promoting discussion and interaction between participants. In order to keep the debate alive and to avoid dispersion, questions must be successively placed. In line with the previous step, also at this one materials appealing to the group members should be used.

Step 4. *Sharing the world we live in*

The remotivator must stimulate the group members to think about the topic in relation to themselves and their realities. Here, the questions must call for subjective aspects of the topic, such as the participants' past experiences and reminiscences, personal opinions, and points of view.

Step 5. *Climate of appreciation*

The remotivator provides a brief summary of the session emphasizing the most important ideas exchanged between participants. It is also time to express appreciation for the participants' attendance and contributions. The remotivator ends with information on the following session, inviting the group members, and transmitting a sense of continuity.

During the sessions the remotivator must not assume the role of a lecturer. Instead, the remotivator must speak in a nonthreatening and nonjudgmental manner, regardless of the participants' response to the presented topic. An individual acknowledgement of each group member's contribution must take place (Sullivan et al. 2001). Along with the use of open-ended questions, the remotivator seeks active listening, verbalizing appropriately in discussions, attentiveness to the activity, ability to remain on task, responding to reality cues, accepting redirection, making an effort to communicate with other group members, and demonstrating or expressing positive feelings in group (Erwin 2013).

Remotivation Therapy with Specific Groups and Its Outcomes

What started out as a group therapy in a psychiatric setting has been expanded into a modality developed in geriatric settings, especially in nursing homes, day care, and social clubs and in home for deinstitutionalized persons. Remotivation can therefore be used as a tool to intervene with individuals of different ages (adults and older adults), with different characteristics and needs, from functionally independent individuals to those with dementia and high sensory, cognitive, and physical constraints.

The first studies about the effect of RT were with mentally ill persons. Long (1965) reported the first experimental studies that were published, in which he concluded that remotivation significantly contributed to improve patients' behaviors by increasing communication and interest in other activities. The author pointed out remotivation as a suitable technique for preparing patients for other activities and treatments since it increases their willingness to do so.

The effects of a remotivation program, held twice a week over 21 weeks, with nursing home residents were explored within the Project Share (Arje 1973). The results showed that the remotivation group's outputs were significantly higher than the controls in socialization, mental status, morale, interest, appreciation, and relations with other members of the group, suggesting that the remotivation program had a positive effect in several social and psychological features. More recently, a study on the benefits of a remotivation program for the institutionalized elderly (ProTR) in terms of depressive symptoms, morale, and participation revealed the potential of RT as an intervention with older adults with global emotional distress, which is very common in this type of settings (Araújo et al. 2011). The program used ten sessions, planned in accordance with the participant's needs, capacities, interests, and cultural background, in which several questions were explored with the patients (see Table 2). The results revealed that the experimental group has experienced a reduction in terms of depressive symptoms and an increase in morale after the intervention. Remotivation also showed to be effective in persons who were isolated and unmotivated, living in single-family homes and who were unwilling to travel or to visit others (Harris and Bodden 1978). After receiving one-on-one weekly remotivation sessions during a time of six weeks, these individuals showed a significant improvement in the levels of motivation, trust, extroversion, independence, and anxiety.

Case studies about the use of remotivation programs for patients with Huntington's and Alzheimer's diseases have also been reported. Sullivan and colleagues incorporated RT in a treatment program designed to provide an

enriched environment for institutionalized Huntington's disease patients (Sullivan et al. 2001). The results pointed to the benefits of remotivation on these patients: it promoted a positive exchange of experiences, interaction with other patients, increase of interest, better frustration tolerance, and improved attention, abilities that can be constrained in Huntington's disease. With Alzheimer's and other dementia-related disorders, the sessions should be shorter and more frequent (daily) in order to achieve the benefits of remotivation therapy (Farmer 2005). Since these patients have diminished attention and cognitive constraints, the session should be adapted through some techniques such as placing the patients around a table with the remotivator, using songs and music instead of poetry, giving each person a hands-on project (e.g., sorting of buttons, arranging flowers), and maintaining the same structure during all sessions (Farmer 2005). With these recommendations, remotivation could be appropriate for dementia since it does not require advanced group therapy skills and is not psychologically intrusive. Furthermore, it demands the use of the available cognitive skills and promotes patient's strengths, avoiding dwelling on negative and symptoms of deficits.

Future Directions

The emergence of RT dates back to 1950, in a group setting, applied to help withdrawn patients in mental care facilities regain communication, vocational, or social skills, along with (re)discovering interest in their surroundings. It reached its peak in the 1970s with the National Remotivation Therapy Organization establishing remotivation as a new approach to group intervention. The 1980s and 1990s brought RT into new settings, including long-term care facilities for older adults. Since then, RT has faced several challenges relating to waning popularity resulting in few opportunities for training and networking among professionals. The scarcity of research is also a challenge with few empirical publications on the topic (Stotts 2005). Nevertheless, the benefits of RT include promoting restoration of self-worth,

rekindling social skills, increasing reality awareness, and improving communication and verbalization (Sullivan et al. 2001). These benefits highlight the need to reinvest in this treatment modality. Further research is needed to determine RT's efficacy as compared with other treatment options, particularly for cognitively impaired older adults in a long-term care setting who may have few options.

Resilience and Aging

Ursula M. Staudinger¹ and Werner Greve²

¹Columbia Aging Center, Columbia University, New York, NY, USA

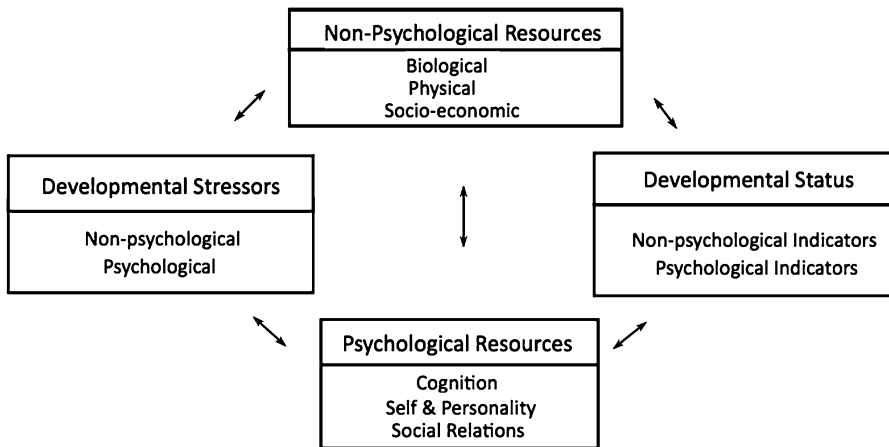

²Hildesheim University, Hildesheim, Germany

Synonyms

Maintain well-being despite stressor; Reduced vulnerability for detrimental life constellations; Type of plasticity

Definition

Resilience is a constellation of risk factors and resources that predict developmental outcomes. It aims to maintain or recover subjective

Resilience and Aging, Fig. 1 Resilience as a constellation of psychological and nonpsychological resources

well-being and/or functioning in the face of developmental stressors.

Origins and Challenges of the Concept

Resilience is most often used to convey the idea that individuals can avoid negative outcomes despite the presence of significant risk factors in their lives. It also includes the idea that individuals can regain normal levels of functioning after developmental setbacks, both with and without the help of external interventions (e.g., Garmezy 1991; Rutter 1985). When defining resilience more precisely, however, there is the challenge of not succumbing to a circular logic (Rutter 1985; Leipold and Greve 2009). Is resilience the outcome, the antecedent, or the process? Is it possible to assess resilience independently of risk and protector factors? Is it indeed a person characteristic, as notions of hardiness (Kobasa 1979), or ego resilience (Block and Block 1980) suggest?

We have proposed that it is useful to define resilience as a relational construct rather than a personality characteristic (Staudinger et al. 1995; Greve and Staudinger 2006), that is, a constellation of risk factors or stressors on the one hand and of available protective factors that are both of a psychological and nonpsychological nature, on

the other (see Fig. 1). This constellation then results in a developmental outcome such as (the maintenance of) subjective well-being or a given level of performance. According to this model of resilience, certain characteristics or mechanisms are not necessarily once and for all to be considered a resource. Rather, it may vary between individuals and even within one person across time what is a resource depending on the respective constellation at hand. Of course, it is crucial to define and assess each element of the constellation independently in order to avoid circularity.

Given this conceptualization, there is overlap between resilience and coping. Coping models provide a useful framing for one type of psychological resource in the sense of mediating mechanisms connecting risks on the one and developmental outcomes on the other side (Greve and Staudinger 2006).

A LifeSpan Perspective on Resilience

It may come as a surprise, but it was not before the 1990s that the notion of “resilience” has been considered in the context of theorizing and research on aging (Staudinger et al. 1995; Ryff et al. 1998). There are at least three reasons for this: First, the concept of resilience was originally introduced for the study of child development

and, more precisely even, for the study of the psychopathology of child development rather than the investigation of normal development (e.g., Rutter 1985; Masten and Garmezy 1985; Luthar 2006). Second, the study of aging only gained in prominence in these years when longitudinal studies started to reach these higher ages. Thirdly, stereotypic conceptions of late life and the process of aging have tended to see late life as a time of uniformly negative changes and losses, in other words, a period of the life span not characterized by much resilience.

Managing threats and losses in late adulthood and age can be discussed from two angles. First, it is a question of specific events and conditions to be managed in old age. Decades of research have shown that adverse problem situations begin to accumulate in later adulthood. Physical and mental performance tend to decline, serious illness and disabilities occur with a higher probability than in younger years, the remaining years of life decrease, career goals disappear due to retirement, and important friends and relatives die (Baltes et al. 2006). The repeatedly replicated finding that indicators of well-being and psychological health do not decrease until very old age demonstrates, however, that older adults are able to cope with these adversities (e.g., Staudinger and Pasupathi 2000; Staudinger and Kessler 2009; Staudinger and Bowen 2010). The fact that problems associated with old age are characterized by a decreasing level of subjectively perceived control leads us to the second aspect: the means of coping in old age change. Adaptive reactions and processes that do not actively solve but “dissolve” the problem, i.e., reframe it, become increasingly promising and probable (Staudinger et al. 1995; Staudinger and Kessler 2009; Staudinger and Bowen 2010; Brandtstädter and Greve 1994).

From a lifespan perspective, the basic characteristic of human development and aging is its modifiability. This modifiability has been called the plasticity of human development, which is dependent on the risks and resources present in a person’s internal and external developmental contexts (Staudinger et al. 1995; Lerner 1984). The modifiability of human development is a neutral characteristic denoting the positive as well as the

negative deviation from typically observed developmental trajectories (Staudinger 2015). Resilience refers to those types of plasticity that concern the maintenance or recovery of functioning under conditions of stress. Whereas, when a typical developmental trajectory is exceeded (with or without the presence of stressors), this is called growth or thriving (Staudinger et al. 1995; Carver 1998). There is empirical evidence that resilience and growth are qualitatively different phenomena that ought to be studied separately (e.g., Staudinger and Kunzmann 2005). Two types of positive development have been distinguished to capture this difference: adjustment and growth. The former is linked with mastering the developmental tasks and challenges as they arise across the life span as well as the day-to-day hassles and maintaining one’s well-being. The latter is linked with pursuing the advancement of the greater good even if that implies jeopardizing one’s own well-being.

Empirical Evidence for Resilience in Later Adulthood and Old Age

Resilience as the maintenance or recovery of prior levels of functioning after the occurrence of a stressor may be further differentiated as to whether it occurs as an *endogenous* (i.e., without external intervention) part of adult development and aging or whether it requires *exogenous* (i.e., intervention-based) conditions and support (Greve and Staudinger 2006; Staudinger and Greve 2001). In the following, we will present empirical examples for both types of resilience from two different areas of psychological functioning, that is, cognition and self and personality.

Cognition

Following Fig. 1, we first need to establish the stressor, which requires a resilience constellation to unfold. The stressor in this case is the age-related decline in brain functioning such as the number of neurons, their connectivity, and the brain physiology, which is reflected in decreased performance in indicators of the mechanics of the mind such as the speed of information processing

(e.g., Baltes et al. 2006). Surprisingly, under normal conditions, this decline, which starts already around age 25–30, does not play out negatively in everyday performance and when familiar circumstances are concerned. The decline only becomes visible under conditions of time pressure and in highly novel environments. How is that possible? Research has shown that this type of *endogenous* resilience of the cognitive system is based on the knowledge and experience that we accumulate as we move through life, be it in the context of work or life in general. For instance, Salthouse (1984) demonstrated in a classical study that expertise in typing compensates for age-related changes in performance. Due to years of typing experience, older expert typists read further ahead than their younger counterparts and thereby were able to compensate for the decline in the mechanics of the brain as they concern, for instance, the speed of eye-hand coordination. Or it was shown for the expertise in chess that older chess experts compensated for age-related decline in speed of information processing by forming larger chunks of information than younger chess experts and were thus able to maintain their chess performance (Charness and Bosman 1990).

Research on *exogenous resilience* of the cognitive system has demonstrated that it is possible to recover earlier levels of performance in the mechanics of the mind if certain types of training were provided. Decades of cognitive training research have shown that it is possible to regain earlier levels of intellectual functioning through massed practice (e.g., Consensus 2014; Hertzog et al. 2008). This work has also shown, however, that the increase in cognitive performance based on massed practice or explicit strategy training is achieved through strategy acquisition, that is, acquired knowledge (i.e., cognitive pragmatics) compensates for performance losses. No reactivation of brain areas and mechanisms that have undergone age-related decline are observed, and therefore, such performance increases generally do not generalize across different kinds of cognitive tasks (Nyberg et al. 2003). In recent years, long-term intervention studies (e.g., 12 months) that investigated the effect of aerobic exercise on cognition in old age found that

performance in the cognitive mechanics was improved across a wide range of tasks and that this improvement was associated with a reactivation of brain functioning in brain areas that previously had undergone pronounced age-related decline (e.g., Voelcker-Rehage et al. 2011). Thus, it seems that there is also cognitive resilience that is based on biological reactivation and not only based on knowledge-based compensation. Currently, there is work that examines how continuous cognitive challenges in everyday life such as at work or during leisure time may also help to stimulate exogenous resilience (e.g., Bowen et al. 2010). Of course, there are many more types of exogenous resilience to be mentioned and studied such as the compensatory distribution of cognitive tasks within a long-term couple or the use of external storage devices to support memory functioning to just mention two.

Self and Personality

A number of studies indicate a high – and increasing – stability and predictability of self and personality across adulthood (Roberts and Caspi 2003). Though some approaches claim that this is indicative of the absence of personality development during adulthood (e.g., McCrae and Costa 1996), the lifespan perspective on human development argues that there is highly functional self-regulatory dynamics that supports such stability and resilience constellations (Greve and Staudinger 2006; Staudinger and Pasupathi 2000; Staudinger and Kessler 2009).

Personality change. The pattern of personality change during adulthood can be described as follows: emotional stability, conscientiousness, and agreeableness increase (Staudinger 2005). This pattern has been described as an increase in social mastery and adjustment and as such is an important component of the age-related increase in resilience in the face of developmental tasks. Similarly, using measures rooted in the personality change rather than stability literature, it has been demonstrated that environmental mastery, self-acceptance, and positive social relations increase, as we get older (Keyes and Ryff 1999). At the same time, openness to new experiences

and purpose in life and personal growth tend to decline with age in current cohorts, which is indicative of a decrease in personality growth (cf. Staudinger and Kessler 2009; Staudinger 2005). This latter finding is in line with the fact that wisdom-related insight and judgment as an indicator of psychological growth, in contrast to biological growth or maturation, does not automatically increase as we get older but resilience does (Staudinger and Glück 2011).

Self-regulatory processes. The tension between stability and change, just mentioned, extends to evaluative perspectives of (and on) the person. We tend to evaluate ourselves in an impressively stable manner (Staudinger and Pasupathi 2000); even though the balance of gains and losses tends to get worse in the second half of life and, we are indeed able to also perceive this decline quite clearly (e.g., Heckhausen et al. 1989). This pattern of results, at first glance almost “paradoxical” (Staudinger and Pasupathi 2000), highlights likewise the power of resilience constellations in reconciling stability and change in late adulthood and age.

Maintenance of one’s self can be achieved by strategic (planned) reactions as well as by automatic processes the person cannot control (as a rule, he or she is not even aware of them). Strategies of self-regulation (Brandtstädter 2006) include increased efforts of goal pursuit and attempts to receive social support. Such active forms of coping with life challenges are characterized by adherence to the standards and goal orientations under pressure. However, these problem-oriented reactions (“primary control”; Heckhausen et al. 2010) are only possible as long as appropriate problem-solving competence (e.g., social skills, physical resources) is available.

Once attempts to solve a given problem or to alleviate a stressor fail, self-regulatory adjustments can maintain or regain the individual’s sense of coherence and well-being. Adjustments of personal values and preferences, reinterpretations of stressful problem situations, changes in perspective, and deliberate (downward) comparisons are typical examples of processes that contribute to resolving the perceived problem, thereby reducing its adverse effect on well-being

and life satisfaction (Brandtstädter 2006). Although a person might be able to facilitate his or her detachment from a formerly important goal (by, say, a long journey that redirects one’s thoughts), the process of actually replacing a goal (degrading the old one, upgrading a new one) is certainly beyond the individual’s control (for instance, usually we have a hard time to let go of unreciprocated love). Nevertheless, the modification of one’s level of aspiration or the setting of a different goal altogether makes it possible to exercise control over such newly set goals, thus regaining a level of “primary” control which had been impossible before (Brandtstädter 2006; Baltes and Baltes 1990). For instance, when faced in old age with strong physical constraints, it may be highly adaptive to give up independence, that is, move into an assisted living facility or have permanent help move in. By choosing dependence in one domain, we may free up energy that we can use for keeping up independence in others such as maintaining friendships or for pursuing other interests (Staudinger et al. 1995). The reduction of aspiration levels can be interpreted in a similar fashion. Being irreversibly unable to fulfill a specific criterion of physical fitness due to aging – for example, climbing several flights of stairs with ease – may be alleviated by a more age-appropriate criterion such as climbing one flight. Such adjustments, however, presuppose that alternate evaluations and interpretations are available and require the cognitive flexibility to revise initially preferred interpretations and assessments (Brandtstädter 2006). The availability and integration of cumulated life experiences and adjustments in emotion regulation (i.e., mastery; Staudinger and Kessler 2009) seem to facilitate these adaptive processes, as increasing resilience has been observed across the life span.

In the past two and a half decades, several developmental theories of self-regulation have been developed to describe and explain this interplay of tenacious strategies and adjusting processes (Brandtstädter 2006; Heckhausen et al. 2010; Baltes and Baltes 1990; Freund et al. 1999). Whereas they differ, with respect to the scope of adaptive adjustment (from goal pursuit to

cognitive functioning) and with respect to the methodological approaches applied, they converge in the assumption that resilience emerges from the interplay of processes in a given constellation of stressors and resources (Staudinger et al. 1995).

Resilience constellations in old age do, of course, have their limits (Baltes and Smith 1999). Health problems of later life are often not curable and are not easily reframed. Not least in very old age, there is an increasing probability of deficits and losses that no longer appear “manageable.” Permanent eyesight restrictions or the loss of a long-term partner, for example, can only be compensated to a certain degree, and their emotional alleviation might prove difficult. And yet, constellations of resilience remain possible. For instance, focusing on reachable goals (e.g., being a valuable grandmother) and embracing transcendental values (e.g., prospect and hope of a reunion with the lost spouse in heaven) might contribute to a stabilization of one’s quality of life, one’s experience of meaning. Further, even though it seems intuitive, negative emotional reactions are not always to be evaluated as dysfunctional or a lack of resilience (Freund and Staudinger 2015). This is likely to be the case if they persist, but recognizing grief and desperation as steps in a healthy regulation process has become state of the art of resilience. It has been found that resources supporting short-term resilience can differ from mid- and long-term resources. Similarly, what has been identified a resource in dealing with a life-threatening illness may not be effective or even be dysfunctional in dealing with a marriage crisis. Also, resources supporting the maintenance of cognitive functioning differ from those that support resilience in the personality realm, not withstanding that fact that there seem to be some wildcard resources such as internal control beliefs or physical activity (Staudinger et al. 1995).

Resilience as Integrative Concept: Theoretical and Empirical Perspectives

Besides signifying an important developmental phenomenon, the concept of resilience has a

huge potential for theoretical integration of several (hitherto separately discussed) fields and issues such as self-regulation and self-stabilization, coping research, personality development, and successful aging. For instance, the focus on stability as a developmental outcome facilitates the insight that personality (i.e., the stability of the self) is, to a remarkable degree, the product of self-regulatory processes, which are not only producers, but at the same time products of developmental processes (Leipold and Greve 2009). In the following, we will outline three examples of how the concept of resilience serves this integrative function.

Resilience Constellations as an Attribute of Developmental Systems

The conceptualization of resilience as constellation is firmly grounded in lifespan psychology (Baltes et al. 2006) and converges with earlier approaches of “developmental systems” (e.g., Ford and Lerner 1992; see Masten 2014). Without going into more detail, it is important to emphasize the common claim that one particular phenomenon (e.g., developmental stability) can result from various (i.e., heterogeneous) functionally equivalent constellations. This is exactly the decisive point of the conceptualization of resilience put forward here: The fact that a certain person is able to regain the level of functioning under conditions of threat is certainly not to be explained by one and the exact same process, or condition, or constellation in each case. Rather, the specific interplay of various conditions and processes will result in resilience in different constellations (see Fig. 1). For instance, the maintenance of a sense of meaningfulness of life after retirement might be achieved by, say, continuation of working for your company (e.g., as an advisor), by offering your professional expertise to a different institution (e.g., as a volunteer in a charity organization), by refocusing your interests on your partnership or your grandchildren, or by retrospectively downgrading the work experience (“I’m so happy that this is over!”). Accordingly, competencies or attributes that prove to be a resource in one constellation may turn out to be detrimental in others. For instance, a relatively

high degree of self-esteem has been shown to be a buffer (and, thus, a resource) against stressful life conditions, but, at the same time, it poses a risk factor for antisocial behavior in adolescence (Greve and Staudinger 2006). Additionally, a certain developmental state or trajectory might be evaluated either as “crisis” or as “success” – depending on one’s personal perspective and framing (Greve 2015). In other words, resilience constellations are highly specific such that, e.g., the resources identified when using subjective well-being as an outcome have been found to differ from resources found to avoid depression as a developmental outcome (e.g., Staudinger et al. 1999).

The Ubiquity of Resilience

The often-replicated finding that the majority of people prove able to maintain well-being and quality of life throughout late adulthood and (old) age asks for an explanation given that objective circumstances in old age lead us to expect otherwise (Staudinger et al. 1995). Even under very harsh developmental conditions more often than not, and with increasing age even more so, individuals prove able to maintain or regain quality of life and adequate levels of functioning (Staudinger and Pasupathi 2000). The fact that resilience is the rule rather than exception can be explained by the substitutability of protecting and stabilizing conditions (i.e., the functional equivalence of various resources, as mentioned above). In other words, the ubiquity of resilience redirects theoretical attention on developmental processes of stabilization (over and above of processes governing change). Based on extant evidence, there is no reason to assume that mastering adversities would require special person-specific skills or conditions that are only available to certain individuals. Rather, we can assume that they are different constellations of resources that make up resilience for different persons but even for one person across time or across different domains of functioning.

The Neurophysiology of Resilience

As in many fields of psychological inquiry, during recent decades, investigations of resilience have

been expanded beyond the behavioral level to also include its (neuro)physiology (e.g., Staudinger and Pasupathi 2000; Reuter-Lorenz and Park 2010; Ryff and Singer 2000; Schindler and Staudinger 2005). For instance, there is a close association between low and variable heart rate as well as a relatively stronger resting activation of the left prefrontal cortex and a person being less inhibited, more sociable, and approach oriented and having a tendency toward positive affectivity (e.g., Schindler and Staudinger 2005). All of which can be considered resources in a resilience constellation. Furthermore, mechanisms that support flexible HPA axis deactivation have been discussed as a neurobiological wild card resource when buffering stress (Kalisch et al. 2015). The advances in understanding the neurophysiology of stress and its interindividual variability hold the potential to add further precision when deciphering resilience constellations; however, they also hold the danger of reductionism (e.g., Freund and Staudinger 2015; Kalisch et al. 2015; McEwen 2007). A person’s resilience constellation is not preempted by early or even intrauterine experiences or by genetic makeup; rather, it is dynamic and in constant flux (Schindler and Staudinger 2005; Shanahan and Hofer 2011).

Future Directions

Although theories of resilience in late adulthood and old age are embedded in the lifespan perspective on human development (Baltes et al. 2006), they have rarely been connected with approaches on resilience in childhood and youth (Luthar 2006). Both for theoretical and for practical reasons, it might prove important to learn to which degree and how processes that underlie resilience constellations in old age develop earlier in life (Thomsen and Greve 2013): Aging starts early. It may be helpful to try to predict interindividual differences in resources of resilience by focusing on early developmental trajectories. In particular, a deeper understanding of the early developmental conditions of adaptive competencies may finally make truly primary prevention possible: The seeds for the resources of resilience which

are useful or even necessary in later life have probably been planted in earlier phases of development.

The better we understand the developmental conditions for resilience resources, the more effective we will be able to intervene and overcome risks and vulnerabilities in time. Although studies show that exogenous improvement of resources is possible (see above; Voelcker-Rehage et al. 2011), a systematic approach to strengthening resilience resources throughout the life span is still lacking. Certainly, at different stages of life, different interventions are appropriate or necessary (and differently so for different people). However, several “polyvalent” resources might prove useful throughout the life span (e.g., sense of control, adaptability of one’s goal system, the individual’s capacity to reframe, etc.). Building and replenishing resilience resources throughout the life span by incorporating biological, psychological, and social-cultural features as well as their interactions represent a major contribution to modern public health.

Synonyms

Buoyant; Elastic; Hardy; Strong; Supple

Definition

Resilience is the ability to spring back or recover from a physical, emotional, financial, or social challenge.

Resilience as a Key Factor in Health

The word “resilience” comes from the Latin word “salire,” which means to spring up, and the word “resilire” which means to spring back. Resilience is defined as the ability to spring back or recover from a physical, emotional, financial, or social challenge. Being resilient means that the individual has the ability to adjust or deal with trauma, adversity, hardship, and ongoing significant life stressors. Resilient individuals are able to respond appropriately to changes and challenges encountered and adapt and adjust their behavior. Most importantly, individuals who are resilient are able to move beyond the challenge, regain equilibrium, and gain knowledge, experience, and a stronger or better sense of well-being following the challenge (van Kessel 2013; Wild et al. 2013). Resilient individuals will also be less likely to succumb to illness, including both mental and physical illnesses.

There are some individuals who respond to illness with negative emotions such as depression and anxiety, while others are more optimistic and establish a more positive perception of health status and recovery, regardless of the disease. The World Health Organization defined health as a general sense of well-being, including physical well-being, mental, social, and functional improvement (World Health Organization 2002). Thus maintaining health requires that individuals address many challenges throughout their lifetimes and adapt to changes as they occur. It is possible that healthy aging and longevity are associated with personal resilience, while individuals who are less resilient tend to succumb to illnesses and experience excessive morbidity.

Health Resilience

There are many types of resilience and individuals vary in terms of their resilience across these different domains. Most commonly, resilience has been differentiated into health resilience (Sanders et al. 2008), psychological resilience (Boardman et al. 2008), emotional resilience (Chow et al. 2007), and dispositional resilience (Rossi et al. 2007). Health resilience is the capacity to

maintain good health in the face of significant adversity. Evidence of health resilience is the ability to maintain good health in the face of challenges, with good health including both physical and mental health. The specific health challenge encountered by an individual might be physical, psychological, or social. For example, those without health insurance and less access to health-care resources would be challenged to maintain health if they had to pay for health-promoting activities (e.g., immunizations) out of pocket. Likewise, it might be challenging to maintain good psychological health without any social supports such as what occurs in older age when one has outlived family and friends.

Factors That Influence Resilience

Resilience is believed to be a component of the individual's personality although it develops and changes over time through ongoing interactions with the physical and social environment and the challenges that one encounters throughout the life course (Hughes 2012). From a physiologic perspective, resilience has been associated with the individual's flexibility in his or her neurochemical stress response systems and the neural circuitry involved in stress responses. Prior research has shown that being exposed to stress, whether this is chronic or acute stress, can result in depression, anxiety, or other types of negative psychological and physical outcomes (Taliaz et al. 2011). Stress can cause alterations in brain structures associated with cognition, mood, and behavior within the hypothalamic pituitary-adrenocortical (HPA) axis (Bowes and Jaffee 2013). In addition, the response to stress impacts neurotransmitters, neuropeptides, and hormones, and some individuals respond with resilience, while others decompensate when exposed to the same type and level of stress.

Serotonin has been the most commonly studied neurotransmitter, and the serotonin gene, solute carrier family 6 neurotransmitter transporter (*SLC6A4*), is the gene most commonly associated with resilience at least among older adults (O'Hara et al. 2012; Feder et al. 2009; Resnick

et al. 2015). Some additional genes that are believed to be involved with prefrontal cortex reactivity associated with fear and other stressors have also been associated with resilience. These genes include brain-derived neurotrophic factor (*BDNF*), corticotropin-releasing hormone receptor 1 (*CRHR1*), peptidyl-prolyl cis-trans isomerase (*FKBP5*), glutamate receptor metabotropic 1 (*GRM1*), solute carrier family 6 member 15 (*SLC6A15*), and catechol-*O*-methyltransferase (*COMT*).

Some additional genes have been associated with response to stress and subsequent depression in animal models and/or humans and consequently are anticipated to be associated with resilience. These genes include neuropeptide Y (*NPY*), neurotrophic tyrosine receptor kinase 1 and 2 (*NTRK-1*, *NTRK-2*), and guanine nucleotide-binding protein beta polypeptide 3 (*GNB3*) (Taliaz et al. 2011). Overall the genetic aspects of resilience provide support for the personality component of this characteristic.

Genetics is not the only factor, however, to influence resilience. Resilience is known to be a dynamic process that is influenced over the course of one's life by significant life events and challenges. Resilience related to health is an accumulation of learned experiences as well and ways in which the individual has coped with health challenges over time. In older age, for example, if one has never had to deal with health challenges, the normal changes that occur associated with aging can become overwhelming. Conversely, chronically ill individuals tend to cope with age-associated changes and common illness associated with aging such as degenerative joint disease easily.

Many factors or qualities within individuals have been associated with resilience (Table 1). These include such things as positive interpersonal relationships and building social connectedness with a willingness to work with others, strong self-efficacy, and positive self-esteem, establishing a sense of purpose, using humor and creativity, accepting and even embracing changes encountered such as those associated with aging, being self-determined, having an optimistic or positive perspective about life, keeping things in

Resilience and Health, Table 1 Resilient qualities or traits commonly noted in older adults

Resilient qualities
Positive interpersonal relationships
Strong self-efficacy
Positive self-esteem
A sense of purpose
Spirituality
Ability to use humor
Creativity
Acceptance of changes (physical and mental)
Maintaining a positive attitude
Ability to identify and utilize resources
Self-determination
Optimism
Keeping things in perspective
Taking care of oneself – physical and emotional care
Avoid seeing crises and insurmountable problems
Setting goals and working toward them
Taking decisive action

perspective, setting goals and working toward them, and taking decisive action (Bonanno et al. 2007; Charney 2004; Lamond et al. 2008; Ong et al. 2006).

Positive Interpersonal Relationships

Interpersonal relationships include interactions with family, friends, colleagues, and other acquaintances that the individual may interact with for physical, social, or psychological purposes. With regard to health resilience, relevant interpersonal relationships include interactions with health-care providers encountered through any variety of health-care situations. Interpersonal interactions and activities, whether receiving help from others or providing support or help of some kind to others, serve as a psychological buffer against physical and emotional stress, anxiety, or depression. Interpersonal activities also help individuals cope with losses. When one individual is helping another individual with physical tasks and specific services (e.g., providing a ride to an appointment) or providing social support and friendship, it generally results in a sense of belonging and purpose and strengthens self-esteem and self-efficacy. Thus individuals who volunteer to do such things as work with children

in reading programs, deliver the mail in continuing care retirement communities, or serve on committees or boards tend to be more resilient than those who are not willing to engage with others in this manner.

Strong Internal Resources: Self-Efficacy, Self-Esteem, Determination, and Problem Solving

Self-efficacy is the belief in one's ability to organize and execute a course of action to achieve a specific outcome (Bandura 1997) and as such impacts one's resilience. Different than self-efficacy, self-esteem is reflective of one's appraisal of his or her self-worth. Individuals who have a positive sense of self-worth, accept and like themselves, and refrain from being "too hard on themselves" are more likely to be resilient and maintain their psychological health.

Determination, or hardiness, is another important component of resilience. There are just some individuals who are determined and this is noted to be a central aspect of their personality. Determined individuals tend to be more confident in their ability to cope with health challenges such as the diagnosis of a malignancy or the ability to access resources to maintain health. These individuals are also more likely to seek out and find necessary resources to achieve their health-related goals.

Optimism, Positivism, and Keeping Things in Perspective

Optimism is one of the most commonly considered components of resilience or of a trait associated with resilience. Optimism has even been used as a proxy measure of resilience (Ronaldson et al. 2015). Repeatedly it has been noted that having the ability to stay focused on positive outcomes in the face of challenges and avoid focusing on negative facts is critical to resilience. As with resilience overall, optimism is learned throughout life based on experiences and interactions with others. At any point in time, optimism can serve as a buffer to becoming psychologically or physically unhealthy (Chung et al. 2015). Interestingly, optimism does not need to be rooted in truth to positively impact resilience and optimal coping. That is, unrealistic optimism may serve as

Resilience and Health, Table 2 General intervention strategies to strengthen resilience

Developing dispositional attributes	Improving socialization practices	Strengthening self-efficacy, self-esteem, and motivation	Creative engagement
The use of humor to facilitate a sense of optimism and vigor	Facilitate social interactions such as dinner dates and bridge games	Reinforce successful completion of activities (e.g., making a dinner date)	Encourage participation in art classes
Help individuals keep challenges in perspective	Encourage participation in exercise classes	Verbally encourage to engage in specific activities	Encourage journaling
Review prior successes and strengths	Encourage volunteering within communities or settings of care	Expose to role models of others doing specific activities of interest	Encourage enrollment in a foreign language class or class to learn how to play an instrument
Help maintain a sense of hope		Decrease the unpleasant sensations around performing a specific activity (decrease anxiety around setting a dinner date)	
Help set realistic and achievable goals		Eliminate negative self-talk	

an important buffer that can help individuals remain resilience in the face of challenges that might otherwise result in negative outcomes such as subsequent worsening of health, depression, or anxiety.

Spirituality

Spirituality, considered broadly, includes a sense of self and purpose, creativity, humor, and a curiosity and willingness to learn and experience new things. Spirituality is not the same as religion. Rather it is a process of personal transformation, in accordance with traditional religious beliefs or based on subjective experiences and psychological growth independent of any specific religious context. Spirituality is a resource that is used to support the individual through challenges and can optimize and influence resilience in the face of health challenges such as the diagnosis of a malignancy.

Interventions to Strengthen Resilience

Although some individuals may be more likely than others to be genetically predetermined to be resilient (Feder et al. 2009), interventions can be

implemented to strengthen resilience among all individuals. Examples of established approaches to helping individuals who are experiencing health challenges become more resilient are shown in Table 2. These interventions generally address four areas: (1) developing disposition attributes of the individual such as vigor, optimism, and physical robustness; (2) improving socialization practices; (3) strengthening self-efficacy, self-esteem, and motivation through interpersonal interactions as well as experiences; and (4) creative engagement. Two additional areas will also be highlighted including the use of general lifestyle interventions and technology.

Developing Dispositional Attributes

Developing positive attributes such as vigor, optimism, and a sense of physical robustness can be done by using a variety of techniques. Humor, for example, may be helpful in accepting changes in function and ability and help turn negative thoughts to more positive acceptance. Laughing about the physical changes that normally occur in aging, for example, is a useful approach to adjusting to these changes rather than becoming depressed or responding to such changes negatively by no longer being willing to go out in

public. Trying to keep challenges from becoming insurmountable and unresolvable problems can also help keep the challenge in perspective and maintain optimism. Likewise, reviewing prior and current strengths and trying to see oneself in a positive light can help build optimism. Encouraging hope, whether or not that hope is realistic in nature, can also build an optimistic attitude. Believing one will walk following an acute neurological event, for example, can be extremely useful in terms of helping the individual be resilient and continue to engage in what may be difficult therapy sessions. Motivational interventions such as developing realistic and achievable goals related to the challenge being encountered can also help to build a sense of success, robustness, and ability to recover.

Improving Socialization Practices

Throughout life there are losses that occur within one's social network including losses among family members, friends, and colleagues. Maintaining and assuring adequate social resources, however, are critical to building resilience. Therefore, helping individuals reach out and make connections with others and develop relationships can be an extremely effective way to strengthen resilience. Specifically, offering concrete ways in which to engage socially provides a framework for individuals to initiate social activities. Examples might include such things as making lunch or dinner dates, setting up bridge games, starting walking groups, attending exercise classes, or participating in volunteer activities. All of these activities can help build relationships that can grow into social supports. One particularly important skill to help older adults develop following a challenging event is to reach out and ask others for help. This also should be encouraged as an important development in building socialization practices.

Strengthening Self-Efficacy and Self-Esteem

Self-efficacy is generally behavior specific and is strengthened using four sources of information including (1) successful performance of an activity, (2) verbal encouragement to perform an activity, (3) seeing similar others perform, and (4) elimination of unpleasant sensations

associated with an activity and strengthening or highlighting the pleasant experiences that result from the same activity (Bandura 1997). Generalized self-efficacy has been noted to be more comprehensive and more likely to be associated with an individual's beliefs about personal abilities in general. General self-efficacy is defined as an individual's belief in their capability to manage or perform tasks across a wide variety of situations and is associated with self-esteem. Building self-efficacy is best done by helping individuals feel successful in their ability to complete a task. Facilitating success can be done by breaking a task down to small achievable goals, providing consistent positive reinforcement toward task completion and showing the individual how others similar to him or her have successfully completed the task and being sure that the positive rewards and sensations associated with the activity are appreciated by the individual.

Self-esteem refers to a person's positive evaluations of himself or herself. Self-esteem has been associated with an overall sense of well-being, mental health, and positive engagement in recovery as well as routine activities. Interventions that have been shown to be effective in strengthening self-esteem include such things as engaging in structured life reviews or successfully participating in an exercise class, eliminating negative self-talk, recognizing one's self-worth, and being able to accept mistakes and rejection.

Creative Engagement

Exploring creative endeavors is particularly helpful for individuals during times of crises. Creative interventions have been shown to positively affect mental and physiological health. This might include journaling, painting or other types of art classes, dance and movement classes, and trying new activities such as learning to play an instrument or speak a foreign language. It is not unusual, however, for individuals to perceive themselves as not being creative and thus reluctant to engage in such activities. Innovative ways to encourage creativity, particularly for older adults, include encouraging individuals to complete focused projects such as having them write their life stories for grandchildren.

General Lifestyle Interventions

Lifestyle changes can also help to improve health-associated resilience and enhance individuals' sense of well-being (Southwick and Charney 2012). Lifestyle interventions include such things as nutrition, exercise, complementary and alternative medicine approaches, and meditation. Nutritional intake can certainly influence health and decrease the risk of heart disease and inflammation. Diets high in fruits and vegetables and those that focus overall on caloric restriction while maintaining nutritional balance are important to maintaining optimal health and possibly extending life. Along with nutrition, exercise has clearly been associated with maintaining a sense of overall health and well-being and can therefore facilitate resilience. Exercise has the benefit of improving both physical and psychological health and helping to prevent physical diseases such as cardiovascular illness and psychological problems particularly depression.

The use of complementary and alternative medicine for some is useful to optimize mood and strengthen one's resilience to interpret health status as good regardless of the underlying disease (Charney 2004; Chan et al. 2006). Interventions include such things as the use of vitamins and supplements (e.g., omega-3 fatty acids, ginseng), acupuncture, yoga, meditation, and pastoral care or other types of spiritual interventions.

Technology-Based Interventions

The use of technology to provide telehealth, behavioral monitoring, optimize safety or build independence, and provide psychological and social support is a new and important way in which to strengthen resilience. Participating in self-help communities online can help build confidence and provide the critically important social support to continue to adhere to health behaviors or help adjust to new diagnoses. Further, social interactions via the Internet can help prevent loneliness and depression in times of crisis and alleviate stress-related diseases.

Conclusion

Health resilience is central to successful aging and adjustment to the many changes that occur throughout the life span. Some individuals may be genetically predisposed to be resilient. Others may develop resilience through life experiences or via focused interventions. Interventions to strengthen resilience include such things as strengthening general self-efficacy and self-esteem, engaging in social activities and interactions, using humor and maintaining an optimistic attitude, accepting change, and looking for ways in which to make the change a growth experience, among many others. Deliberately trying to strengthen one's resilience can result in significant health benefits with regard to physical health as well as psychological health and may even buffer the impact of disease and decrease morbidity and mortality.

Adult day services; Caregiver intervention; Community-based long-term care; Home care; In-home help; Long-term services and supports

Definition

Respite care refers to support for family/unpaid caregivers through the provision of short-term, intermittent relief from care responsibilities that is delivered in a home, community, or institutional setting (Mason et al. 2007; Nottoli 2008). Respite care is not disease or age specific. This paid or unpaid service may be provided to caregivers by health-care professionals, community agencies, or untrained personnel including volunteers, friends, and family members. The length of respite care service utilization tends to vary. For example, respite care may be used for short breaks from caregiving duties during the day or may provide more extended relief (e.g., overnight respite, where older persons can receive 24-h care for several days that allows a family member to take a vacation or attend to other responsibilities; see <http://helpguide.org>).

The overall goal of respite care is to offer rest and recovery for the informal caregiver in order to enhance caregiving relationships and support the in-home care provided by a family member (Nottoli 2008). A secondary goal is to improve health or quality of life of older care recipients or at least to maintain function and independence on the part of the older person. In-home care may

take the form of unpaid support from family or friends, companionship through volunteerism, or skilled care provided by health-care professionals. Some of the services provided by in-home respite care include assistance with meal preparation, daily activities such as toileting and feeding, and other specific health-care needs. Respite care provided outside of the home may occur in adult day service programs, respite camps, or more formal health-care and long-term care settings such as hospitals or nursing homes (<http://helpguide.org>).

Respite Care and Population Aging

The population of older adults continues to increase worldwide. As life expectancy lengthens, more older adults will require care. About 25% of households in the USA contain a caregiver (Nottoli 2008) or a person who provides help and assistance to another due to a health need. Many informal (or unpaid) primary caregivers also have additional non-caregiving responsibilities, such as paid work. Smaller family size and more women in the workforce pose challenges to providing adequate family care, as caregivers are most likely to be women (Genet et al. 2011). A generation of caregivers in the UK, known as the “pivot generation,” simultaneously manages the care of their children or grandchildren while also caring for a parent, other older family member, or a friend. These duties can contribute to adverse emotional, psychological, social, and financial stress, which may lead to negative health behaviors such as smoking (Hoffman and Rodrigues 2010). One option that is believed to help support family caregivers with multiple role responsibilities is respite; it is thought that the provision of time off from care responsibilities can provide relief to family caregivers, thus allowing these family members to remain in their caregiving roles for longer periods of time and potentially delay other costly health transitions for disabled older adults (e.g., residential long-term care admission).

In 2012, 4,800 adult day service programs served 273,200 clients in the USA (Harris-Kojetin

et al. 2013). Adult day programs are designed to not only provide family caregivers with respite but to also offer a range of therapeutic activities and services to help maintain the independence and function of clients (many of whom are older adults). In 2011, approximately 4.7 million individuals received services from home health agencies in the USA; however, it is not clear the extent to which these services were utilized as a source of respite for family caregivers (Harris-Kojetin et al. 2013). As of 2004 it was estimated that approximately 40% of caregivers in the UK received respite; one-third of these respondents felt that the availability of respite services was insufficient (Mason et al. 2007). Policies supporting respite exist in most European countries; for example, Germany offers publically financed respite care for up to 4 weeks, while in Luxembourg respite support is provided over a 3-week period. The 2006 Act on Family Caregiving in Finland provides 3 days of respite a month for “continuous” caregivers. In Denmark, respite care is offered at the municipal level and is fully funded from public sources, although in Spain, the UK, and northern European countries municipal organization and financing of respite care lead to wide disparities in availability across communities. In some European countries, such support does not extend to in-home respite care (e.g., Austria, Finland, and Hungary) (Colombo et al. 2011, pp. 128).

The use of respite care is often believed to decrease the perceived financial, social, and emotional hardships associated with caregiving responsibilities. For example, respite holds the potential to decrease caregiver stress and in turn reduce the need for transitioning an elderly relative to a nursing home (Gaugler et al. 2006). Despite these benefits, barriers to respite care include challenges in access, cost, lack of knowledge of available respite, and fear of potential disruption to the care recipient’s routine (Hoffman and Rodrigues 2010; Colombo et al. 2011). Moreover, conclusions of efficacy/effectiveness must be made with caution due to the varying quality of evidence (i.e., randomized controlled trials) available.

Research on Respite Care

Evaluation research on respite care emerged in the 1970s (Gaugler et al. 2011). Current research on respite takes place largely in Canada, the UK, and the USA (Mason et al. 2007; Gaugler et al. 2011; Gaugler and Zarit 2001; Fields et al. 2014). Published studies on respite care vary widely in terms of their study design (e.g., since the early 1980s there have been few randomized controlled evaluations of various types of respite such as adult day services; see Gaugler and Zarit 2001; Fields et al. 2014), outcome measures, data collection, analysis, and conclusions (Gaugler et al. 2006). For example, research on respite care tends to feature a range of study designs, including ethnographic/observational methods, correlational studies, quasi-experimental designs, more advanced controlled experiments, and much less frequently randomized controlled evaluations (Mason et al. 2007; Pinquart and Sörensen 2006). Each study design has distinct strengths that contribute valuable insights into respite care, although a lack of randomized controlled evaluations makes conclusions of efficacy difficult to interpret. Meta-analyses that have attempted to pool empirical data or even systematic reviews are often hampered by this heterogeneous design quality as well as variations in outcome measures (Mason et al. 2007; Gaugler et al. 2006; Pinquart and Sörensen 2006; Shaw et al. 2009). There are a host of measures commonly investigated in respite care research. These include but are not limited to care recipients' activities of daily living and self-care abilities, cognitive status, emotions, physical functioning, and behaviors. Additionally, evaluations of respite care sometimes aim to determine if respite care delays nursing home placement among older care recipients in addition to whether respite care reduces emotional and psychological distress of family caregivers. The scope of respite care research is also diverse due in part to a lack of standardized terminology and definition of respite care as well as the duration of respite use and the samples included. As a result of heterogeneous study methodology, it is perhaps not surprising that individual research studies have yielded different conclusions

regarding the efficacy and effectiveness of respite care (Gaugler et al. 2006).

Systematic reviews and meta-analyses of respite generally indicate that these services are either unable to demonstrate evidence in support of benefits for family caregivers or older persons or that respite care is only marginally beneficial (Mason et al. 2007; Gaugler et al. 2006, 2011; Fields et al. 2014; Pinquart and Sörensen 2006; Shaw et al. 2009). Existing studies do indicate that respite care is not harmful, nor does utilization of respite result in adverse events for older users or their family caregivers (Mason et al. 2007). Caregivers typically perceived respite care as valuable and were highly satisfactory with these services; as noted above, survey data from the UK suggests that many families desire much more respite care for their own situations (Mason et al. 2007; Gaugler et al. 2011).

To date, the potential efficacy of respite care remains unclear, although slightly more robust evidence seems to suggest its effectiveness. One meta-analysis conducted by Shaw and colleagues found tentative conclusions on the effects of respite care on the caregiver. This analysis suggested that caregiver burden was reduced at 2–6 months' follow-up in single-sample studies but not in randomized control trials or quasi-experimental studies. Shaw et al. also revealed that caregiver depression was reduced in home care and randomized control trials in the short-term but not with the use of adult day services. However, these effects were tentative and were not significant in more rigorous, randomized controlled designs (Shaw et al. 2009). A more recent consideration of descriptive and quasi-experimental research on adult day services suggests the potential links between adult day service use and improvement in the psychosocial well-being of family caregivers and their relatives who attend such programs, implying some degree of effectiveness (Fields et al. 2014). Shaw et al. did not find any effect of respite on caregiver anxiety, although respite care did have positive effects on caregiver morale, anger, and hostility. Additionally, it has been suggested that respite care improves caregiver stress levels, provides a break for caregivers, preserves the relationship

of caregivers with care recipients, and fosters quality provision of family care in the home.

Syntheses of extant literature imply potentially undesirable outcomes. For example, single group studies indicated that caregiver quality of life was reduced after respite use and care recipients sometimes increased their rates of institutionalization following a family member's respite use (Mason et al. 2007; Shaw et al. 2009). However, this does not indicate a causal relationship; instead, such findings may be a result of using respite relatively late in the trajectory of family caregiving (Mason et al. 2007; Gaugler and Zarit 2001). Indeed, descriptive, longitudinal studies suggest that earlier use of home- and community-based services by dementia caregivers could result in delayed institutionalization of care recipients, although still other reviews suggest that respite care has no significant effect on institutionalization (Pinquart and Sörensen 2006; Gaugler et al. 2005).

In summary, respite care appears to exert benefits for caregivers and to a lesser extent older care recipients in some studies, but overall the scientific evidence is mixed. This is particularly evident when randomized controlled trials are taken into account (Mason et al. 2007; Gaugler et al. 2011; Shaw et al. 2009). A current gap in the existing scientific literature is a lack of understanding of the process/mechanisms of respite whereby such services may (or may not) exert benefits. Much of the existing evaluations of respite tend to treat these services as "black boxes" where the main objective is to ascertain *whether* respite provides relief to caregivers and reduces health service utilization on the part of older adults; *how* respite is able to achieve such benefits remains largely misunderstood. This is perhaps why a disconnect exists between scientific findings and the anecdotal reports of providers and families themselves, who often view respite and its benefits quite positively during the course of caring for a disabled elderly relative (Gaugler 2014).

Another area of clinically valuable research is the cost-effectiveness of different models of respite care. A review of prior evidence suggests that adult day service use was associated with similar or higher costs and either similar or

slightly increased benefits relative to usual care (Mason et al. 2007). However, limited economic data on respite care makes it difficult to assess for whom and what type of respite care is particularly cost-effective on an individual basis. Only slightly more than one-third of respite care studies included economic evaluations (Mason et al. 2007).

Although research on respite care is varied in terms of its type and evidence-based rigor, it has yielded some recommendations related to quality indicators. Shaw et al. state that respite must provide a "mental break" for the caregiver in addition to providing a temporal one (Shaw et al. 2009). This can be accomplished by respite providing active information about services, support early in the caregiving career, access to a variety of services with flexible offerings, reliable transportation, continuity of care, appropriate environments, care that yields benefits for care recipients, and appropriate activities for care recipients' abilities and interests. In light of this extensive list, quality respite care for diverse individuals can be achieved by offering a range of respite types, providing flexibility in terms of when respite is provided, and programmatic receptivity to change in both caregiver and care recipient preferences and needs over time (Shaw et al. 2009). As noted above, however, the extent to which current respite services feature such elements is currently unknown.

Available research has attempted to identify caregiver and care recipient characteristics that influence respite service use. Respite use is positively influenced by more positive caregiver attitudes toward respite provision, greater knowledge of and availability of services, a perceived positive impact of respite care on care recipients, accessibility of respite services, perceived higher quality of available respite care, and flexibility of service provision (Shaw et al. 2009). Further, caregivers helping individuals with severe cognitive and functional deficits are more likely to utilize respite care than other caregivers (Gaugler et al. 2006). Nonetheless, it has been found that 22–50% of dementia caregivers refuse respite care despite the absence of concerns related to cost on the part of families (Gaugler et al. 2006). Reasons

for this finding are unclear. Existing evidence suggests that some families delay respite use and do not use it for long periods of time, possibly because families are uncomfortable with someone else providing care or because the care recipient is too impaired to benefit. More research that identifies those factors that promote or inhibit respite use could help programs tailor their services for certain types of caregivers, thus making respite more attractive and beneficial to caregivers in need and allowing these services to be utilized earlier (thereby potentially increasing their chances of exerting benefits over time).

Future Research on Respite Care

Research on respite care is difficult due to the diversity of the “treatment.” There are various forms of respite care available (Gaugler et al. 2011). Such variation limits any synthesis of overall efficacy or effectiveness of respite care. Further, lack of evidence from existing studies in support of respite care may be due to low respite service use, liberal targeting (i.e., inclusion of family caregivers or older adults who may not benefit from the service that respite provides), short-term evaluations, inappropriate or poorly targeted outcome measures, a failure to account for heterogeneity in study populations, and control/comparison groups seeking out respite care themselves in addition to respite treatment conditions (Gaugler et al. 2006).

Because of the need to better understand the process of respite for older adults and their family caregiver (see above), several other considerations are required when researching the effects of respite. First, development work that quantifies caregiver needs and preferences should be carried out to better match families with appropriate respite care services (Shaw et al. 2009; Kane et al. 2006). Additionally, care recipient outcomes must be defined and validated based on caregiver expectations and on the aims and processes of the intervention (Gaugler et al. 2006). Further, the boundaries between different forms of respite care must be clarified (Mason et al. 2007). Then, more high-quality trials of a substantial size

should be conducted that utilize randomization and appropriate comparison groups (whether “usual care” or perhaps comparative effectiveness designs that evaluate one type of respite care against another) (Mason et al. 2007; Shaw et al. 2009; Institute of Medicine 2009). Trials must also include economic evaluations and should consider both short- and long-term outcomes (Shaw et al. 2009). Additional studies are needed to determine the optimal time for provision of respite to provide maximal caregiver relief (e.g., earlier during the course of caregiving) (Gaugler et al. 2005) and to evaluate interventions that break down barriers to respite implementation or utilization. Greater attention to how respite is perceived and utilized across various ethnic groups could also enhance understanding of the potential benefits of respite care or lack thereof for diverse and underrepresented older adults and their caregiving families (Shaw et al. 2009).

Practice and Policy Implications of Respite Care

A variety of resources provide information for families when selecting the appropriate type of respite care. For example, respite locators are available in the USA to help assist families identify a respite care provider in their area. These services also provide families with suggested criteria for selecting an appropriate respite care service to meet their needs or the needs of their relatives who are care recipients (<http://archrespite.org/respitelocator>). When considering the various forms and providers of respite care, caregivers should assess the geographical location, availability, varying costs, and special needs or preferences of their families and relatives who will receive respite (Nottoli 2008). Respite programs such as adult day services may employ a range of professional or paraprofessional care providers, including social workers, case managers, nursing staff, and physical, occupational, or speech therapists to meet the needs of their clients (Gaugler et al. 2011). When evaluating respite care programs, it is recommended that families actively inquire about emergency procedures as

well as staff training, background, and screening (<http://nadsa.org>; <http://Helpguide.org>). Visiting a respite care provider can also assist families during their selection process. Additional information is provided regarding the screening of respite care providers at the National Respite Network or similar resources in the USA (e.g., <http://archrespite.org/>).

The funding for and costs of respite services in Europe vary considerably across countries due in part to diverse funding mechanisms (e.g., municipally based programs) and accessibility (Tarricone and Tsouros 2008). For example, with the exception of Hungary, Norway, and Poland, and European countries in the Organisation for Economic Co-operation and Development, all European countries offer respite services, but as described above accessibility, availability, and funding mechanisms vary not only across but within countries (Colombo et al. 2011). In the USA, some states offer Medicaid waiver programs or state funding as a part of the National Family Caregiver Support Program through the Older Americans Act Amendments of 2000 (Nottoli 2008). Other sources of funding for families include veterans' benefits, foundation grants, insurance and long-term care policies, disability coverage associated with supplemental security income, or specific state agencies.

Health-care professionals are in a key position to provide referral and education to family caregivers regarding respite care services. However, research has found that health-care professionals often have negative attitudes themselves regarding the use of respite or simply do not view such services as preferred referral options for older adults or their caregiving families (Kane et al. 2006). Therefore, ongoing education for health-care professionals regarding the needs of family caregivers and the benefits of respite care is desirable. Health-care professionals require the appropriate training and education to adequately assess family caregivers in order to give meaningful referrals to respite programs that are individualized to fit each caregiver's situation (Gaugler et al. 2011, 2014).

Due to the lack of evidence regarding the effectiveness and cost-effectiveness of respite care,

informing policy development and clinical practice is challenging (Mason et al. 2007). The National Adult Day Services Association (NADSA) highlights a public policy agenda for adult day services. NADSA focuses on facilitating access to adult day services. NADSA also advocates for modernizing Medicare to allow caregivers to take advantage of cost-effective nursing services, physical therapy, occupational therapy, and social work services offered by many adult day services.

As noted by several researchers, community-based long-term care services including respite may actually serve to increase long-term care expenditures, rather than reducing them due to delayed residential long-term care admission. As Grabowski and colleagues suggest (Grabowski et al. 2010), ongoing support for community-based long-term care programs may still be necessary even in the absence of cost savings because (1) many older adults in the USA and in other developing countries do not wish to leave their homes in favor of residential long-term care, and in the USA at least older adults actively fear this proposition, and, (2) while respite may not result in cost savings, cost-effectiveness is still possible given the degree to which families value such programs. For these reasons, continuing to advance the current state of the science from efficacy to effectiveness would likely better demonstrate the value of respite services for caregiving families in need as well as their disabled elderly relatives (Gaugler 2015).

The Future of Respite Care

A balance is required between families' desire and perceived need for respite care services with evidence-based determinants of service quality and patterns of utilization (Gaugler et al. 2011). The use of respite services on the part of families may be attenuated due to high costs, lack of knowledge of available respite resources, and a concern that respite care may be too disruptive to the care recipient (Hoffman and Rodrigues 2010). An emerging development for respite care services has been consumer-directed care options,

where older persons themselves can choose to use public funds to pay family members to provide help and assistance. Evaluations of these approaches have suggested at least moderate benefits for older adults and their caregivers (Hoffman and Rodrigues 2010; Gaugler 2015). Consumer-directed approaches are able to tailor services to individual clients' needs and allow for increased flexibility. Ongoing concerns include lack of regulation, coverage of costs, and barriers related to payment streams and funding control (Genet et al. 2011). In addition, it is not clear if the use of consumer-oriented options would work effectively in instances where older adults are decisionally impaired. Whether the use of consumer-oriented options in instances where families are paid directly for care actually results in providing relief or respite to families also remains unclear; such approaches may incentivize family care provision and thus may place some family caregivers at risk for overload, exhaustion, or other psychosocial stressors.

Technology has the potential to improve respite care. Advancements in technology ranging from online information, assistance, and consumer ratings to remote health monitoring systems may ease the burden of caregiving, resulting in more time for informal caregivers to remain active in their community and other life responsibilities (Tarricone and Tsouros 2008; Gaugler 2015). A challenge to implementing such advances, however, is the low level of computer literacy among many older adults and their caregivers as well as costs related to purchasing and utilizing various technologies.

Retirement and Cognitive Functioning, A Tricky Association

Aging; Cognitive functioning; Dementia;
Retirement

Definition

Retirement can be defined in various ways. One common definition of retirement is to consider individuals to be fully retired if they left the workforce and are not working for pay (Maestas 2010). Over the past half century, the time spent in retirement has increased considerably (i.e., 8 years on average in 1960 as opposed to 20 years nowadays). This extension results mainly from growing life expectancy, decreasing birth rates, and promotion of early retirement in most developed countries. In this regard, the crisis of the 70s and the emergence of mass unemployment have led many European countries to promote early retirement and to redistribute work to the young. This demographic change presents a major

socioeconomic issue and raises many questions: Was it useful to open up the job market to young people? Will it remain financially viable? How much will the health care cost? How will pensions be financed?

To date, the possible implications of these policies have been mostly discussed from the economic perspective and less in terms of cognitive health. Yet, a better understanding of factors related to cognitive aging seems especially relevant due to growing interest in dementia and Alzheimer's disease.

This entry first provides an overview of scholarships that studied the association between retirement and cognitive functioning of older adults. After covering this relationship, the causality issue will be discussed. Third, the effect of deferred retirement on dementia and, in particular, on Alzheimer's disease will be discussed. This will be followed by key findings that should be drawn from empirical data and an outlook for future directions.

Activity-Retirement and Cognition of Older Adults

Recent evidence shows that activity (Schooler and Mulatu 2001) is associated with better subsequent cognitive functioning. This falls in line with the theoretical concept of the cognitive reserve developed by Stern (2002). In particular, the concept of cognitive reserve postulates that all activities conducted in life will allow individuals to build a sort of *reserve* that will help them to compensate for the age-related or pathological detrimental effects. Thus, several factors have been identified as contributing to the development of the cognitive reserve including educational attainment (Le Carret et al. 2003), leisure activities (Newson and Kemps 2005), and occupational activity (Andel et al. 2007; Schooler et al. 1999). However, many scholars that study the effect of activity have focused on what individuals undertook earlier in life and how these activities may affect subsequent cognitive functioning rather than wondering whether engagement in such activities in late adulthood (no matter past

Catherine Grotz is supported by the Fund for Scientific Research (F. R. S.–FNRS, mandat Aspirant), Belgium (www.frs-fnrs.be)

activities) has a positive impact on cognitive health. In other words, the question that remains is whether individuals who engage in activities could still have some control over their cognitive aging beyond the age of 60 for instance.

It is within this context that Adam and colleagues (2013) investigated whether engagement in different activities over the age of 60 (i.e., professional activities, nonprofessional activities, physical activities, and other factors), regardless of past activities, is associated with cognitive functioning (measured by semantic fluency, episodic memory test, global cognitive assessment). To do so, data from the first wave of SHARE, a European survey of more than 55,000 individuals aged 50 and over, were analyzed using a measurement approach known as stochastic frontier analysis that tests the effect of potential factors simultaneously. The analyses revealed that all types of activities considered were associated with cognitive performances. For instance, a 60-year-old individual delays his/her cognitive aging by 1.75 years if he/she engages in charity/voluntary work, by 1.38 years if he/she continues employment, or by 3.08 years if he/she attends an educational course. The first conclusion that can be drawn here is that not all is played during childhood or adulthood: people aged over 60 years old can still have some control over their cognitive functioning through the maintenance or development of activities.

However, the cross-sectional nature of these data does not address the causality issue between activity and cognitive functioning. In that sense, does being active predict cognitive functioning or do cognitive deficits causes decrease in activity? As suggested by Schooler and Mulatu (2001), there may be a reciprocal relationship between these parameters. Nevertheless, while there is strong evidence that cognitive deficits have detrimental effects on daily life activities, the reverse causality is less evident. One possible way of dealing with the thorny question of the causality is through retirement transition. Indeed, retirement has the main advantages of: (1) being precisely dated and (2) varying across both individuals and countries. Consequently, given that countries have different retirement policies

(the age of retirement is not set based on the level of cognitive functioning of the population), the potential consequences of these policies on cognitive functioning can be grasped.

The Causality Issue

The work setting offers opportunities for social interaction and intellectually demanding activities. One could therefore argue that leaving the workforce is likely to affect engagement in stimulating activities, which helped to maintain a high level of functioning. Therefore, once the stimulation previously provided by the workplace ends, one could expect a decrease in cognitive efficiency during retirement. This outcome was observed in most (Mazzonna and Peracchi 2012; Rohwedder and Willis 2010) but not all studies (Coe et al. 2012). For example, Rohwedder and Willis's (2010) results suggest that early retirement has a significantly negative effect on cognitive performance (retirement causes a drop close to 40% in average cognitive score).

Moreover, a group of authors provided arguments in favor of a causal effect of retirement on cognitive functioning using two large surveys: the American Health and Retirement Study (HRS) and the European SHARE. The first argument comes from the use of cross-country differences in the age-pattern of retirement (Adam et al. 2013). Indeed, given that countries do not set the eligibility age for retirement based on the cognitive functioning of individuals, the authors argue that the reverse causality is unlikely. The cross-country analysis revealed that cognitive scores of older adults were better in countries in which the eligibility age for retirement benefits tends to be higher (e.g., 65 years old in Sweden) as compared to those where it is lower (e.g., 60 years old in France). Figure 1 highlights the strong association between the relative decrease in cognitive score (measured by a ten-word recall test) between 50–55 years old and 60–65 years old (see Fig. 1, vertical axis) and the relative decrease in employment rate (see horizontal axis) between those age categories.

Retirement and Cognitive Functioning, A Tricky Association, Fig. 1 Employment rate and memory score. Notes: Relative difference between individuals aged 60–65 and 50–55 years. Survey of Health, Ageing, and Retirement in Europe 2004–2006. Health Retirement

Study 2004 for the United States. The relative difference in employment rate/cognitive score is defined as $(Y_{60-65} - Y_{50-55})/Y_{50-55}$ for Y_i = the average employment rate/cognitive score for the age category i (Figure reproduced from Bonsang et al. (2010))

Longitudinal data (1998–2008) from the nationally representative HRS – an ongoing biennial US panel survey (14,710 American aged 51–75 at baseline) – were also used in order to test the causal relationship between retirement and cognitive functioning (Bonsang et al. 2012). Using the eligibility age for social security as an instrument for retirement, they demonstrated that cognitive performances slowly decreased with time, but interestingly, they also showed a significant drop in cognitive scores from 62 to 63 years old. No physiological reason can explain such abrupt cognitive change at those particular ages, but this does correspond to the minimum age at which social security benefits can be claimed and also to one of the peaks of retirement waves in the United States. Their analysis also pointed out that the effect of retirement on cognitive functioning is not instantaneous but occurs with a lag of about one year. Figure 2 illustrates that the curves of the rate of retirement and memory decline can be overlaid with a lag of about a year. While the rate of retirement in the United States is higher at 62, 65, and 66 years of age (Fig. 2a), a significant cognitive decline with a lag of about a year is observed at 63, 66, and 67 years old (Fig. 2b).

In general, these data suggest that retirement has a detrimental effect on cognitive functioning of older adults or conversely that people benefit from staying longer in employment. One step further would be to address whether retirement also influences the development of neurodegenerative disease such as Alzheimer's disease.

Retirement and Dementia: Caution Is Advised

To date, the issue of retirement in the context of pathological aging has received little attention. Only four studies have addressed this issue and found that later age at retirement is associated with both reduced risk of developing dementia (Dufouil et al. 2014; Grotz et al. 2015a) and delayed onset of Alzheimer's disease (Grotz et al. 2015b; Lupton et al. 2010). Nevertheless, one recent study calls for caution when studying the effect of retirement on a sample of patients with Alzheimer's disease (Grotz et al. 2015b).

In this respect, the first research in this area was a cross-sectional study of 382 men with Alzheimer's disease, which found that each

Retirement and Cognitive Functioning, A Tricky Association, Fig. 2 Changes in retirement probability and changes in cognitive scores by age. Notes: Health and Retirement Study 1998–2008. All respondents were

aged between 55 and 70. The figures show the coefficient estimates and the corresponding 95% confidence interval (vertical grey lines) (Figure reproduced from Bonsang et al. (2012))

additional year of employment delayed the onset of Alzheimer’s disease symptoms by 0.13 years (Lupton et al. 2010). However, this study has two main limitations (Grotz et al. 2015b). First, in Lupton et al., the selection of patients with Alzheimer’s disease who were diagnosed after retirement (to discard the possibility that cognitive impairments push them to retire) creates a selection bias that may lead to overestimate the effect of retirement on the onset of Alzheimer’s disease. Indeed, patients who retired later were necessarily those who were diagnosed at a later age. This is because all subjects had already been diagnosed with the disease at inclusion, and those who had been diagnosed before retirement were excluded from the analyses. For instance, a person who retired at 60 years of age could only be diagnosed after this age, whereas a person who retired later, e.g., 80, could only be diagnosed after the age of 80. Second, this selection strategy (i.e., considering only patients with Alzheimer’s disease and excluding those who retired after the disease

onset) does not completely resolve the causality issue. Given that the prodromal phase of Alzheimer’s disease could last more than a decade (Amieva et al. 2008), it is therefore not sufficient to exclude the possibility that patients may have encountered cognitive deficits that inclined them to retire long before the diagnosis of dementia was made.

Using a design similar to Lupton et al. (2010) (i.e., patients with Alzheimer’s disease who were diagnosed after retirement), Grotz et al. (2015b) replicated Lupton’s results by showing that each additional year of employment delayed the age of onset of symptoms by 0.30 years. They then showed that once the selection bias was considered, the association between retirement age and age of onset of the disease was still significant, but to a lesser degree (i.e., association reduced by half). Finally, they attempted to reduce the possibility of a reverse causality by excluding individuals who were diagnosed within 10 years after retirement (given that the prodromal phase of the

disease lasts more than a decade). In this case, the association between retirement and the onset of dementia was no longer significant – only a tendency was observed.

These initial results highlight the need to be cautious when studying such complex relationships that, as it will be discussed later, have major social and political stakes. In addition to the potential methodological biases brought to light, one should also consider the interpretation of these data. There is often a tendency to consider that retirement has a direct impact on the brain, yet, this relationship is not as simple as it might seem.

Effect of Retirement on Cognition: Only a Brain Issue?

The most common explanation for the association between retirement and cognitive aging is that the effect of retirement on cognition is only a brain issue. The more individuals stay employed, the more it stimulates the brain in such a way as to compensate for the effect of age-related cognitive impairment and pathology.

However, a recent scholar showed that the beneficial effect of deferred retirement on the risk of dementia cannot be explained by more years spent at work but rather by the fact that retirement transition occurs later in life (Grotz et al. 2015a). Along the lines of the “use it or lose it” hypothesis (Katzman 1995), work life and especially occupational settings are a great source of social and intellectual stimulation, which may support brain function further into older adulthood. Individuals who stayed in employment longer can function at a higher level for a longer time. An analogy with holidays can be drawn. The stimulation provided by the working life keeps individuals cognitively alert: people manage various activities and life is punctuated by work and weekdays. When people plan holidays, they look forward to indulging in a full complement of activities. However, once on holidays the plans often are discarded and people become cognitively relaxed. After a few days, they no longer even know what day of the week

it is. If their cognitive performances were to be tested before and after holidays, there would certainly be a difference, and this can be explained by the cognitive relaxation. Nevertheless, if people were to be evaluated once they are back at work for some time, their performance would be similar to baseline. The effect of retirement could be similar to that of the holidays: once retired, the brain relaxes and this affects cognitive functioning.

On the other hand, the transition from work to retirement is not only an objective life event but is also a complex process. It entails major changes in social roles and status (George 1993), which are negatively perceived by many western countries. Older adults and retirees are the targets of negative stereotypes – a form of ageism with harmful effect on cognition. For instance, the simple fact of activating negative stereotypes associated with age (intellectual performance declines with age so older adults may perform more poorly than younger individuals) adversely affects cognitive performance of older subjects (Abrams et al. 2006). While the negative stereotypes conveyed by modern societies (e.g., less useful, lack of productivity, burden to society) may affect the perception that retirees have of themselves, it could be argued that the transition to retirement may be smoother for those who retire above the normative age of retirement. In that sense, leaving the workforce at a later age is a normal and socially accepted phenomenon.

Other psychosocial factors could also explain such results. For instance, people who retired at a later age probably had additional time to prepare for retirement (e.g., plan postretirement activities). The choice to remain in the workforce above the societally normative retirement age may provide them a sense of control, which is related to adjustment quality (Hershey and Henkens 2013). Nevertheless, while factors that are important for retirement adjustment quality have been identified (e.g., control over the departure from the workforce, financial status, marital status, and postretirement leisure activities) (Wang et al. 2011), only one study has considered various factors (job-related variables, retirement transition related variables, postretirement

variables) that are likely to influence cognitive functioning of retirees (Grotz).

Conclusion and Future Directions

Later retirement age is associated with both cognitive functioning of older adults and dementia. Nonetheless, it is becoming evident that the effect of retirement cannot be comprehended as blunt and forthright. The current evidence should not serve the economic interests to justify increasing retirement age. Therefore, one should not suggest that increasing the age of retirement would be beneficial for everyone's health based on those initial results. On the contrary, researches on retirement and cognition mostly underline the importance of activity in a general sense rather than just the professional ones.

Further studies should seek to specify the association by considering the different nature of various professional activities. In particular, the impact of retirement on cognitive functioning may be different depending on whether the occupation is intellectual or manual, including light or heavy workload, involving high or low social network, and stressful or not. The nature of the occupation may cover different realities. For example, one study found that retirement is beneficial for blue-collar workers (i.e., manual occupation) (Coe et al. 2012) whereas it could be argued that later departure for white-collar occupations may be beneficial. In addition, one recent scholar revealed that shift work has detrimental effect on cognitive functioning (Marquié et al. 2014). Therefore, one could imagine that later departure from the workforce for those occupations may even be more harmful to cognition.

Moreover, as discussed before, the retirement transition is a complex life event. It involves numerous factors that may also influence cognitive functioning. Consequently, the implications of retirement should be viewed in light of various psychological and social factors surrounding retirement (variables related to individuals, work, retirement transition, and postretirement). A better understanding of the factors related to retirement that are important for cognitive

vitality would lead to the development of health policies that are more tailored to the professional and psychological specific context of each individual.

To date, the only constructive element from a political perspective is to consider that if an individual who reaches the age of retirement wishes to continue working beyond the legal age of retirement, there is no reason to stop him/her. On the contrary, forcing him/her to stop working could have deleterious consequences for his/her health. Beyond the issue of employment, other solutions need to be considered. For instance, Adam and colleagues (2013) showed that being professionally active has a positive impact on cognition, but other activities such as volunteering and educational courses also have a beneficial effect. In addition, studies often suggest that it is important to promote activity among elders in all its forms. Nevertheless, a key issue that has to be addressed is: what constitutes a constructive activity for the well-being and quality of life of seniors? It is now important to gain a better understanding of the concept of activity: What does it mean to "be active" in aging; what type and amount of activity should be offered, etc.? This issue has to be examined in a very critical light, so that one does not end up engaging in a sort of activism and mandating that older adults remain permanently active. Above all, critical reflection on what constitutes a constructive activity for older adults and patients with dementia is required. For instance, it seems that not all activities are equally beneficial for cognitive health (Adam et al. 2013). Most importantly, clinicians and scientists should determine the kinds of activities that provide meaning to the individual's life and that promote well-being.

Retirement and Continuity Theory

Aging; Early retirement; External continuity;
Internal continuity; Work ability

Definition

Continuity theory helps describe the psychological development of middle-aged and older individuals, particularly with regard to retirement. The theoretical assumption of Continuity theory is that individuals are regularly guided by existing internal mental frameworks, which make them more likely to maintain similar patterns of behaviors or lifestyles across time, changing only slowly (Atchley 1999). Robert Atchley began the initial framework for the theory in 1968. He studied transitions into retirement and witnessed that older individuals were not in crisis as other existing theories posited (e.g., Disengagement theory or Role theory). Rather, most individuals in the study were effectively adapting to retirement. Atchley built upon the Continuity theory framework between 1975 and 1999 during the Ohio Longitudinal Study of Aging and Adaptation (OLSAA).

The OLSAA Study

The OLSAA provided a large proportion of empirical support for Continuity theory. The project was funded through the National Institute of Mental Health and surveyed individuals on their retirement adaptation. Participants were surveyed every 2 years, except when the project lost funding between 1981 and 1991. In 1991 the Ohio Long-Term Care Research Project took over funding of the OLSAA and data collection resumed. Atchley acquired data from over 700 initial participants in 1981, using both fixed-alternative and open-ended questions in interviews. Around this time, Atchley began to realize retirement had little to no effect on an individual's ability to effectively maintain satisfaction with their activities and lives. In 1995 the number of cohort participants had dropped to 273, but the data collected from the OLSAA was telling. Continuity theory ultimately extended Activity theory, which posits that individuals remain in good mental states and health if they continue to remain active (Rosow 1967). In contrast with this notion is Disengagement theory (Cumming and Henry 1961). Disengagement

theory states that a natural withdrawal from typical activities and social systems is normal as one ages. Therefore, Disengagement theory argues that people tend to make large changes in their older ages (by disengaging from their previous activities and roles), but Continuity theory argues that people remain relatively the same over time as they age. The OLSAA data collected by Atchley provided support for Activity theory and for the theoretical underpinnings and elements of Continuity theory.

Original Elements of Continuity Theory

Over time, Atchley further outlined Continuity theory as it is understood today. The premise of Continuity theory is built upon feedback systems. Older individuals follow internal frameworks, built from years of feedback and experience, to make decisions and maintain their satisfaction. Adults place value in these internal frameworks, or schemas, to guide them successfully through life. A certain level of continuity emerges as they age and as individuals repeatedly rely on these schemas. However, Continuity theory does not imply total lack of change. Continuity theory assumes a certain amount of change will occur, particularly in older individuals who experience life-altering experiences (i.e., unwanted retirement or physical decline accompanying aging). Rather, although Continuity theory emphasizes stability, it argues for a dynamic process and should not be considered to be mutually exclusive with change. Continuity implies that certain patterns or persistent themes will appear across time, but those slight changes are common.

Internal Versus External Continuity

Continuity theory further distinguishes between internal and external continuity (Atchley 1999). Within Continuity theory it is expected that individuals, despite age, will work to maintain similar internal and external patterns. Internal patterns are the relatively stable mental schemas created by an individual's thoughts, mental abilities, and memory.

They help people understand their environment and determine the ways that they interpret information and events in their world. These internal forces lead to concepts such as personal goals, philosophies of life, moral frameworks, values, and coping strategies. Furthermore, individuals tend to maintain these individual traits, skills, attitudes, or abilities as they age. Atchley referred to this as *internal continuity*. Data from the OLSAA supported the concept of internal continuity; a majority of participants showed moderate to high levels of continuity for their personality, ideas of the self, self-confidence, personal goals, and emotional resilience. Additionally, beliefs specifically about retirement were also enduring; in fact, the slight changes that occurred were due to individuals feeling *less* inclined to believe the negative stereotypes associated with retirement, which probably would help them adjust comfortably to retired life.

People's interests, personalities, ideas, and self-concepts are internal patterns or schemas, but equally important, external patterns in people's environment and their behaviors or activities in that environment tend to be stable according to Continuity theory. These are represented by mental schemas associated with their relationships, social roles, activities, environments, and geographic places. For example, if people were interested in attending or participating in music, sporting, or social events when they were younger, they will tend to be interested in the same activities when they are older. *External continuity* is tantamount to preserving external patterns. In general, Continuity theory states that these external factors will stay constant. External continuity is especially significant for older individuals, as it serves as a gauge for their own personal security and well-being. The OLSAA evaluated several dimensions of lifestyle, including household composition, lifestyle arrangements, marital status, modes of transportation, and income. The majority of dimensions remained consistent across time. The only real evidence of marginal discontinuity was with physical activity, but Atchley noted this can be attributed to physical aging rather than to people's preferences or inclinations to engage in physical activities. Further, many participants in the OLSAA tried to maintain their physical

activity patterns, but due to uncontrollable factors they usually had to reduce or stop their activities.

Alternate Theories

Activity and Disengagement theories were often directly contrasted with Continuity theory during the theory's development, but there are still other theories that describe development in older life. Two of the most common are Role theory (Mead 1934; Biddle 1979) and the life course perspective. Role theory argues that most daily behaviors can be categorized as positions within the social structure. Examples of specific roles include wife, grandfather, and retiree. Roles consist of expectations that one's self and others have regarding the behaviors and obligations for the person occupying a role in a social situation. Furthermore, roles are interconnected in role sets. A wife and a husband or the people in a workgroup might constitute a role set, for example, and each person in the role set has expectations that define the role of the others. Role theory posits that as individuals age they may experience a loss of some of these roles, which is more consistent with Disengagement theory than Continuity theory. For instance, role loss is expected to occur when a spouse dies (e.g., a wife transitions to a widow), when an individual takes a new job, or when an individual retires. Role theory contends that without roles to help define people, they struggle to adapt to older age. However, Role theory does not take into consideration the possibility that individuals may reenter into new roles at a later stage in life, the ability to learn or cope from experiences, or the widespread variation in how individuals adapt to role loss. The dynamic internal/external patterns explained by Continuity theory help to explain how individuals cope with role loss and how different variations in adaptation occur. If they tended to think, feel, and behave in certain ways in one role, they may continue to think, feel, and behave similarly in other parts of their life. So the person who acted as a leader in past roles gravitates toward leading in new social situations, just as the person who was the class clown in high school tends to offer comic entertainment in the workplace and also

later in his or her group of retiree peers. Furthermore, Continuity theory would expect that people do not just passively or randomly fall into new social sets; they would tend to choose new friends who resemble their former friends, making role continuity easier and more likely.

The life course perspective is another dynamic theory, surmising that themes or events from people's younger years influence how they proceed in older age (Elder 1985). This perspective is dominated by the influence of critical life incidents, cohort events, or turning points that lead to change in people's lives. As people proceed through life, they enter into social spheres that mold their development. Timing, context, and processes are key dimensions of the life course perspective of adult development. The life course perspective does not focus on the individual differences that may lead to varying forms of adaptation to aging or role loss, but rather it focuses on the impact of environmental influences. It emphasizes the impact of generational cohorts or social spheres leading up to any one specific point, rather than the specific mechanisms of individual adaptation. Often the life course perspective is used in conjunction with Role theory or Continuity theory to help explain individual aging and retirement.

Applications to Retirement

Since the OLSAA studies, Continuity theory has frequently been used to explain retirement decisions and the lifestyle adjustments of retirees. Retirement is typically characterized by a decrease in work hours, work-related income, and mental attachment to work. Traditionally, retirement has followed a specified age (65 in America), but in the last few decades, retirement options have expanded with advancements in modern medicine and a better understanding of individual health – and with labor laws banning mandatory retirement ages (in the USA). Increasing proportions of older individuals are deciding not to retire, or at least not to withdraw fully from the workforce, because they can still effectively maintain relationships, physical activities, and mental capacities. Moreover, a portion of retirees

would actually prefer to continue working beyond retirement (Gobeski and Beehr 2009). The decision to retire is multifaceted, consisting of many forms, and this has made understanding the antecedents and outcomes of retirement difficult.

The decision to retire can be divided into three phases (Feldman and Beehr 2011). In the first stage an individual begins to imagine what they would like their retirement to look like. Continuity theory is readily applicable to this stage, as individuals will probably focus on developing a retirement similar to the parts of their current lifestyle that they enjoy. The second stage requires the individual to make a decision on whether they want to retire (at a given time). It has been proposed that retirement decisions are driven by one's attitudes toward retirement, their perceived control over retirement, and the retirement norms they perceive in their social groups (Beehr et al. 2014). In the last stage of retirement, individuals actually take action on the decisions they have made. The most common retirement decisions are either full retirement or partial retirement. In partial retirement, often referred to as bridge work, an individual chooses to continue working after retiring. Consistent with Continuity theory, if retirees liked their former career job, they will try to obtain a bridge job that is similar to it (Gobeski and Beehr 2009; Wang 2007). In addition, there are some who opt for early retirement, either partial or full retirement. Of course, if there is no mandatory retirement age, the term "early" retirement loses some of its meaning.

In the last couple of decades, there has been a movement to distinguish different periods of aging. In particular, some have argued that there is a period in life referred to as the "third age," which is distinguished from the "fourth age" or onset of noticeable age-related physical declines (Laslett 1991). This concept of third age might help to explain early retirement. Individuals might retire early because they are still in good physical health and see retirement as an opportunity to live their remaining future freely before any physical health declines occur. Earlier retirement had become more popular over the last few decades, but has probably halted and might be reversing (Beehr et al. 2014). Furthermore, individuals no

longer place a negative stigma on retirement, but they see retirement as a normal transition in the aging process, which may also encourage early retirement if that is now a legitimate social status or role. Continuity theory would predict that these early retirees will try to maintain the same types of leisure activities they enjoyed before retiring.

When an individual decides to retire, a certain level of adjustment is expected. In regard to individual well-being after retirement, there are three mechanisms for adjusting including maintaining, recovering, and what has been referred to as the U-shaped pattern of adjustment (Wang 2007). The maintaining pattern of adjustment describes individuals who maintain their level of psychological well-being throughout the retirement transition. Recovering patterns posit that individuals may have a slight positive increase in their well-being, but that the increase will lessen over time. Finally, the U-shaped pattern of retirement adjustment argues that there will be a dip in psychological well-being, but then an increase after postretirement adjustment. It is expected that Continuity theory would help explain both the maintaining pattern and the U-shaped pattern as they both describe only slight changes in typical patterns. Furthermore, the majority of individuals exhibit the maintaining pattern, which most strongly supports continuity in retirement.

Bridge Work

In addition to full retirement, there is also the option of partial retirement or bridge work. Bridge work can be any type of work employees take after transitioning from their career to retirement (Gobeski and Beehr 2009). Working beyond retirement can be important for human needs (e.g., social, financial), and many individuals opt for this type of partial retirement. Bridge employment can be career-related or noncareer-related. Career-related bridge jobs refer to work that is similar to a person's prior career. For instance, an English professor who retires but still works part-time as an author would be doing career-related bridge work. Conversely, the type of work would be labeled noncareer-related if the

English professor retired and decided to work part-time as a barista. Noncareer-related bridge work is the more common form (Gobeski and Beehr 2009). Perhaps because of this, bridge work is often a lower status, lesser paying position, and may not offer as many fringe benefits as traditional career work. An individual is most likely to take bridge work immediately or at least soon after retiring rather than after a long delay (Pleau and Shauman 2012). Other aspects of bridge work, which have yet to be fully vetted, concern the potential differences in impact of steady or intermittent bridge work, or self- versus other-employed bridge jobs.

From a continuity perspective, both career and noncareer types of bridge work can be seen as a desire to maintain internal and external continuity. Continuity theory posits that as individuals age, they will try to maintain the social status and image they have created for themselves. Abandonment of the physical things and social relationships that one holds dear can be detrimental to that effort. Therefore, individuals will work hard to maintain or substitute for things in their life that are important to them. Career bridge employment provides an opportunity to continue daily life with probably fewer adjustments than full retirement does. Noncareer bridge work still demonstrates some continuity however, simply because the person has decided to continue working. Individuals still have a role as an employee and still get to engage in social activities at work, etc. Sometimes noncareer-related bridge work can be viewed as a reinvention of oneself or one's image (Davis 2003). However, few individuals are interested in picking up drastically new behaviors or changing their attitudes later in life. In fact, starting new activities in retirement is uncommon, but if done, it is usually done by women (Iso-Ahola et al. 1994).

Besides financial ability to retire, a wide variety of factors seem to influence the decision to retire or to take on bridge work. Two of the strongest predictors of retirement include age and health. Numerous studies have shown that as individuals age they are more likely to retire and less inclined to engage in bridge work (Beehr 1986; Shultz and Wang 2007; Cahill et al. 2006)

Physical health is also a key antecedent to retirement; as an individual's health declines, they are less likely to maintain the capacity to work in particular jobs and more likely to retire (Beehr 1986; Shultz and Wang 2007). Thus, many individuals retire to less strenuous types of bridge work (e.g., customer service). Age and physical health are significant contributors to discontinuity in adults, but the majority of older adults in the OLSAA study tried to maintain good health. Perceived work ability has also been shown to predict bridge employment among retirees and is relatively constant across time (von Bonsdorff and Ilmarinen 2012).

Other individual-level factors include the financial security and marital status of an individual. For example, individuals in higher status or higher-paying jobs may retire earlier than lower status or lower-wage positions because they may have the financial means to do so. There has also been some research suggesting gender differences in retirement based on the sex's preferences regarding retirement (Nicolaisen et al. 2012). Specifically, women who engage in certain types of leisurely activities (e.g., volunteering) may delay retirement, whereas men who partake in fishing and hunting may be more likely to retire earlier. Future research is still needed, however, to fully understand possible gender differences in retirement decisions.

Some specific work-related attitudes and the job itself also have an impact on the decision to retire and what to do after retiring (Gobeski and Beehr 2009). Individuals may be less likely to retire if they have high career attachment. Individuals with high attachment have the desire to continue their work and have positive affect toward their career. Similarly, higher job satisfaction has been linked to a higher likelihood of taking a career-related bridge job rather than a noncareer-related bridge job. Lower levels of job-related strain (an indicator of stress) also predicted taking a career-related bridge work position versus noncareer-related bridge work. Specific job-related characteristics predicted career-related bridge employment over noncareer-related bridge work, and even predicted bridge work versus full retirement. Individuals with higher goal

attainment and greater job-related skills were also more likely to partake in career-related bridge employment.

As the current research illustrates, predicting retirement and understanding retirement decisions are nebulous tasks. Yet continuity and the notion that individuals will choose to maintain similar patterns and avoid drastic changes help to understand the more common themes in retirement research. As both full-time and part-time retirement options become more prevalent across the globe, gerontology will become increasingly paramount to understanding retirement trends.

The Importance for Gerontology

There are growing concerns, among both Americans and people in other countries, about the outflow of baby boomers from the workforce and the resulting tax on nations' resources designed for retirees and older people (Eyster et al. 2012). Although working in older age is much more feasible due to improved healthcare, current birth rates are lower than previous generations, which could mean the proportion of available workers versus employees exiting the workforce will decline (Eyster et al. 2012). Conversely, the number of older individuals who plan on retiring early has actually decreased since 2000 (Eyster et al. 2012). Because of this, companies are preparing ways to manage the expected exit of older individuals and looking at options to retain employees as long as possible. In the context of Continuity theory, organizations should make adaptations to the work environment, which help older individuals remain successful in their current job tasks and work roles. For instance, companies may consider limiting the amount of physical activity a job contains as an individual ages, so that he or she can continue to perform the job well. Slight changes in the work context may encourage continuity in the workforce. Similarly, organizations might consider interventions or training programs specifically designed for retaining the aging workforce (Eyster et al. 2012).

Conversely, baby boomers departing from the workforce leave organizations at a potential disadvantage if the employer is not proactive. As these individuals leave their employing organization, there is a potential loss of tacit knowledge (Greller 2012). The majority of supervisors, managers, and CEOs are middle-aged or older-aged individuals, and organizations need to prepare for their imminent retirement (Greller 2012). Perhaps encouraging career-related bridge work, which would allow individuals to maintain internal and external continuity, could be mutually beneficial for the organization and the individual.

Conclusion

Currently, Continuity theory is one of the most useful theoretical constructs for explaining the transition from work to retirement. Today, retirement is no longer seen as a major life stressor, but rather is an expected life transition that is somewhat predictable and controllable for the employee. Most individuals will be likely to maintain their similar lifestyle patterns during this transition, but current research does not help to fully understand how one arrives at the decision to retire or what type of retirement to choose. Based on existing research and the almost certain increase in numbers of retirees, it is expected that bridge work will increase as the need to maintain the current workforce also increases. Retirement will continue to be an important issue within gerontology. Therefore, continued research regarding the antecedents, processes, and outcomes of retirement is warranted, and Continuity theory is a promising guide for those investigations.

Pensions; Social security; Superannuation; Withdrawal from work

Definition

Retirement, understood in terms of a period of pensioned rest or leisure at the end of working life, is a relatively recent development. It only became a widespread stage in life following the expansion of social security and pensions in the mid-twentieth century. The status of retirement has become more ambiguous in more recent decades as concerns about population aging and longevity have prompted policy debate about the social organization of work and retirement in later life.

Introduction

With population aging and increased longevity, the social organization of work and retirement is

now the site of continuing political negotiation and transformation. Historically, the passage from work to retirement has played an important role in shaping the experience of aging, serving as the boundary point for entry into old age. For much of the twentieth century, the conventional definition of old age as starting at around 60 or 65 years coincided with the age when people became eligible for pensions and were expected (often forced) to retire. The transition from work to retirement thus became an important element in the fashioning of an old age identity “separate from that associated with work and paid employment” (Phillipson 2013a). However, with a large cohort of baby boomers entering retirement, policy makers have become increasingly concerned about a potential pensions’ crisis from economies having too many pensioners to support and not enough workers. These anxieties have caused cultural expectations about the status of retirement as a period of “pensioned leisure available to the general population of workers” to become increasingly unsettled (Ekerdt 2010). Changes in the nature of work and careers and increased emphasis on the market provision of pensions are also leading retirement transitions to become more uneven for many groups.

The Shifting Policy Landscape

The concept of retirement as a period at the end of the life course free from the demands of work is a relatively recent phenomenon in historical terms. In the nineteenth and early twentieth centuries, work resembled a lifelong obligation for the majority of people. Only elite public servants covered by limited state pensions and the independently wealthy had the means to disengage from the world of work. For everyone else, the boundary between work and old age came at an uncertain point in the life course, whenever people “were simply no longer able to work” (Shultz and Wang 2011). The transition out of the workforce in later life was consequently experienced as a negative transition that was accompanied by deepening poverty and illness in old age.

It wasn't until the decades following the Second World War that most working people came to have any secure expectation of stopping work at a fixed age. This was partly driven by the expansion of social security regimes during the so-called era of "welfare capitalism" (1940s to early 1970s), as the political ethos of industrialized countries shifted in the direction of social democracy (Phillipson 2013a). In Europe, the provision of public or state pensions gave a degree of economic security following the end of people's working lives, as well as the expansion of publicly funded health insurance and health services, which helped to alleviate the risk of infirmity associated with aging. In the United States, social security was first introduced in 1935, although the program initially only covered workers in commerce and industry. The program was gradually extended from the 1950s to include workers in other industries such as hospitality, agriculture, and state and federal employees, while Medicare was also introduced in the mid-1960s to provide government-funded health insurance for older workers (Zickar 2013).

At the same time, a shortage of workers following the Second World War prompted companies to expand the proportion of employees who were covered by corporate or occupational pensions as a way of trying to attract and hold on to skilled workers. For example, in the United States, the number of employees covered by occupational pensions jumped from 3.7 million in 1940 to 19 million employees in 1958 (Zickar 2013). In the United Kingdom, almost half of all employees were members of occupational pension schemes by the end of the 1960s (Phillipson 2013a).

The expansion of public pensions and what Ekerdt (2010) calls "corporate welfare" during the postwar decades created the conditions for retirement to become a mass transition regulating the passage from work to the final stages of the life course (Kohli 1987). Underpinned by an intergenerational compact in which prime age workers pay for the pensions and healthcare of the retired in the expectation that other generations will do the same for them, retirement at the age of 60 or 65 became a *predictable* transition in the industrial "three box" life course of education,

followed by work, followed by retirement (Phillipson 2013b). As Phillipson (2013a) observes, for a brief period at least, the meaning of old age was temporarily resolved around "a vision whereby retirement and welfare were viewed as natural supports to the end of the human life cycle". With the increased availability of occupational and public pensions providing the material conditions for a phase of life beyond work, there was a cultural shift in attitudes towards retirement (Shultz and Olson 2013). Far from being considered an oppressive institution, Ekerdt (2010) notes that most people cooperated in their superannuation and indeed regarded retirement as "an aspirational status".

However, by the mid-1970s, various intermediary statuses between the end of employment and receipt of a state pension emerged and a predictable retirement transition unraveled as an increasing number of older people left the labor force before their formal retirement age (Phillipson 2013a; Guillemard 1997). The impetus for this change was the oil crisis of 1973, which plunged most industrialized countries into an extended period of recession. In the face of rising unemployment, and with a large cohort of young baby boomers looking to join the workforce, various measures were introduced within unemployment, disability, and associated social benefits, plus employer-controlled occupational pension arrangements, to enable older workers to leave the labor force (Guillemard 1997). These policies continued into the 1980s, rendering the point at which work ended and retirement began more ambiguous and contingent on personal biographies. The notion of a stable period of retirement was increasingly challenged "for a majority of workers through greater insecurity in the workplace; for a minority through the attractiveness of retirement given the safety net of an occupational pension" (Phillipson 2013a). In the view of several commentators, what happened over this period was a "dechronologization" of the life course and the emergence of a more "individualized" or fragmented experience of retirement (Kohli 1987; Guillemard 1997).

The 1990s saw an acceleration of such trends, as the policy environment surrounding work and

retirement has shifted from being “pro-retirement” to “pro-work” in almost all industrialized countries. The cause of this shift has been growing anxiety about population aging and the capacity of governments and businesses to cope with rising pension and other age-related costs. A new policy consensus has emerged around the extension of working lives, presented as a means of reducing pressures on social welfare systems (Taylor 2010). The reconfiguration of social security systems and working lives is now firmly on the policy agenda. Delaying retirement and indentifying pathways for older workers to remain in and return to work have eclipsed earlier attempts to foster early retirement/exit (Phillipson 2013b). Several member countries, including Britain, the United States, and Australia, are now in the process of gradually raising the age eligibility for receiving a full state or social security pension from 65 to 67 years of age (Taylor 2010). In the longer term, the state pension age in the United Kingdom will rise to 68 years of age, while Australia has proposed a pension eligibility age of 70 by 2035. Countries are also being encouraged to follow the United State’s lead and abolish mandatory retirement ages, as well as close off pathways to early exit in social security arrangements.

Along with longer working lives, building self-reliance through private pension provision is also now seen as a key part of the solution to the fiscal challenges posed by population aging. “Risks once carried by social institutions have now been displaced onto the shoulders of individuals and/or their families” (Phillipson 2013a). Intergovernmental organizations such as the Organization for Economic Cooperation and Development, the World Bank, and International Monetary Fund have been at the forefront of attempts to limit the scope of the welfare state by establishing an expanded role for private capitalized pension provision as a “second pillar” of retirement funding. Within the sphere of occupational or employer-provided pensions, traditional defined-benefit pensions have been progressively supplanted by defined-contribution pensions, “placing more risk on the individual” (Ekerdt 2010). Instead of receiving a guaranteed pension

based on salary and years of service for the duration of their retirement, a proportion of employees’ salary is now paid into an investment fund. Consequently, retirees must now bear the financial costs of their longevity and the risks of a stock market collapse.

Changing Perspectives on Aging and Retirement

The development of retirement as a distinct stage in the life course prompted gerontologists to explore questions about the meaning of retirement and the challenges and opportunities associated with a new phase of life beyond career employment.

Early Approaches: Continuity Versus Disengagement

The primary concern of researchers during the postwar decades was on how individuals could best adjust to the loss of the work role associated with transitioning to retirement. In the late 1940s and 1950s, gerontologists worried that the loss of work could lead to a major deterioration in well-being and health for older men if it was not successfully replaced with alternative activities and social roles (Phillipson 2013a; Lynott and Lynott 1996). Role, or activity theory as it later came to be described, emerged as the dominant perspective on aging and retirement during this period. It posited retirement and the cessation of paid work as the site of a potential identity crisis or breakdown, although as Ekerdt (2010) observes these expectations of retirement as a negative life event have not been borne out in the research literature. To maintain quality of life in old age and successfully adapt to being retired, role theorists argued that older adults needed to replace their previous work role with a large number and variety of other active social roles such as taking up new hobbies or leisure pursuits or joining church groups or voluntary associations (Lynott and Lynott 1996).

Following the publication of Cumming and Henry’s seminal work, *Growing Old: the Process of Disengagement*, in the early 1960s, the assumption that retirement adjustment was best achieved

by taking up new social roles became increasingly challenged. For disengagement theorists, later life constituted “a period in which the aging individual engages with society in a process of mutual separation” (Phillipson 2013a). Separation rather than the uptake of new social roles represented the criterion for successful aging. Social withdrawal by older adults was viewed positively by disengagement theorists, who argued that it was part of an adaptive process that helped to maintain morale and self-esteem in old age in the face of declining skills. It was also vital to generational succession, as older adults represented a “drag” on societal functioning: “whatever type of work they do, they do it less well as they age,” and they must withdraw from social roles to allow younger adults to take their place (Lynott and Lynott 1996).

The Political Economy of Retirement

From the late 1970s, gerontologists began to adopt a more critical stance towards retirement. In the context of social policy and company arrangements that were encouraging older workers to leave their jobs at earlier ages, the expectation that people should retire from employment at particular ages came under scrutiny from critical gerontologists influenced by neo-Marxist perspectives in political economy (Walker 1980; Townsend 1981). Political economists of aging, as this group of critical gerontologists came to be known, held concerns about the “close link between retirement and poverty” (Walker 1980) and the role of retirement in fostering what Townsend (1981) termed “the structured dependency of the elderly”. This approach marked a radical departure from previous understandings in focusing attention on how “aging” and “retirement” were socially constructed phenomena and therefore contestable. Political economists argued that retirement was something that had largely been imposed on older adults by “changes in the organization of work and in the kind of people wanted for work” (Townsend 1981). In particular, they argued that the expansion of early retirement during the 1970s reflected government interest in masking the reality of shrinking employment and companies’ desire to regulate the age-composition of their workforce

so as to prevent people from growing old in their jobs (Kohli 1987; Townsend 1981). Viewed from this perspective, retirement constituted a largely passive and unwelcome transition that amounted to little more than “a euphemism for unemployment” (Townsend 1981).

The “poverty” of retirement went beyond the diminished economic circumstances associated with no longer being gainfully employed. Retirement also represented a residual or marginal social status that implicitly devalued the work and social contributions of older people. By removing the individual “from an important source of self-esteem and social contract,” it was argued that the institutionalization of retirement stigmatized older people as dependent citizens who “can no longer contribute to society’s productive activity” (Walker 1980).

The Emergence of the Third Age

The political economy critique paved the way for more positive images of “old age” to emerge in the late 1980s and 1990s, when gerontologists began to emphasize the growing proportion of the population who were living longer and healthier lives. This prompted gerontologists to reflect on the individual and societal implications of a lengthy period of healthy retirement, and the sorts of opportunities available for continued growth and development in later life. Laslett (1989) popularized the concept of the “Third Age” to characterize this period between the end of employment and the onset of frailty and dependency in deep old age. It was argued that the improvements in health, education, and material living conditions that those approaching retirement in the 1990s had carried through their adult lives uniquely positioned them to engage in society in ways that were unavailable to earlier generations (Gilleard and Higgs 2000).

The emergence of the Third Age pointed towards a “blurring” of life-stages and even “the irrelevance of chronologically determined age-related statuses” (Featherstone and Hepworth 1989). In this vein, postmodern theorists of aging such as Gilleard and Higgs argued that “[i]t is increasingly meaningless to consider ‘age’ as conferring some common social identity or to treat

‘older people’ as a distinct social group acting out of shared concerns and common interests.” They argued instead for a vision of the Third Age as a “cultural field” of choice, autonomy and self-expression underpinned by greater engagement with contemporary “lifestyle culture” (Gilleard and Higgs 2000). This interpretation was associated with the aging of the postwar baby boomers and the “generational style” that they are carrying with them into retirement. This cohort was the first to grow up in a mass consumer society, where people’s social and personal identity was expressed through lifestyle as much as through occupation. A problem for the boomers was their tendency to define identity in contrast to preceding generations and as similar to younger age groups. Biggs et al. (2007) indicated that identity centered on finding a balance between “youthful” and “mature” points of reference. They also found that few boomers conformed to the stereotype of political activism. In this regard, the cultural field of the Third Age reflected the enhanced material circumstances enjoyed by baby boomers compared with previous generations.

Productive Aging

If the “Third Age” described a trajectory of consumerism in retirement, growing economic concerns, amplified by the Global Financial Crisis, emphasized continued working life. Gains in health and longevity had increased people’s potential “for remaining productive later in life” (Caro et al. 1993). This variant of Third Age gerontology emerged in part as a response to characterizations of older people as dependent and a drain on social resources (Biggs 2001). Concerned that such age prejudice should be avoided, Robert Butler coined the term “productive aging” to highlight the significant number of people over retirement age who were still capable of working and contributing to their communities (Butler 1985). Definitions varied, with some authors defining productive aging as the capacity of people “to serve in the paid workforce, to service in volunteer activities, to assist in the family, and to maintain [themselves] as independently as possible” (Butler and Schechter 1995).

Others defined “productive aging” more narrowly as activity that “contributes to producing goods and services or develops the capacity to produce them” (Caro et al. 1993). Freedman, another key figure in the “productive aging” movement, suggested “a new phase of work in mid and later life” whereby older adults would leave their career employment to embark upon new encore careers as nonprofit managers, patient advocates, teachers, and in other occupations “that are not only personally meaningful but that mean something beyond themselves” (Freedman 2006–2007). Some authors argued that legitimizing aging in terms of work created new forms of ageism that restrict personal development and alternative forms of social contribution (Biggs 2001).

Critical Perspectives on the Third Age

As concerns about the economic costs of population aging crystallized in the twenty-first century, approaches based on production and consumption became increasingly influential in policy circles, promising more older workers paying taxes and fewer pensions claimants. They also became the subject of renewed debate within social gerontology.

Critical gerontologists writing from a feminist perspective accused discourses about a new Third Age of healthy, active agers of failing to consider the impact of gender and other social inequalities on people’s experiences of retirement. Calasanti and King (2011), for example, claim that post-modern perspectives ignore the fact that, for women, retirement from the labor force rarely means the end of the responsibilities of the Second Age. For many women, work not only continues but can increase in later life, such as when they take on additional caring responsibilities towards grandchildren, or adult family members who become frail or elderly. Women generally retire with far fewer retirement savings than men as a consequence of discontinuous work histories, lower rates of pay over the course of their careers, and increased likelihood of part-time employment. Calasanti and King (2011) point to how differences in patterns of employment, income, and health accumulate over the life course putting

a Third Age of healthy, active retirement beyond the reach of many minority social groups. Polivka (2011) notes that most retirees in the United States still depend heavily on Social Security and Medicare, while the global recession and collapse of the housing and financial markets has “substantially increase[ed] the risk that the retirement security of the Baby Boomers will not match their parents’ experiences”.

A second criticism is that “productivist” and “consumerist” understandings ignore significant psychosocial development that occurs as one grows older, prompting a change in existential direction. Far from empowering and winning social recognition for older adults, such narratives of “positive aging” solve the problem of aging “by assuming that older people are no different from everyone else” (Biggs 2001). Further, they reduce “social, political, and public life generally to participation in the market and the citizen to just another consumer whose rights are determined by their power in the market, by their wealth or lack of it” (Polivka 2011).

This denial of difference conflicts with accounts that report changes in direction that emerge as people grow older to give later life “its very own meaning and character” (Tornstam 2005). Dittmann-Kohli (1990) suggests that the awareness that life’s time is running out prompts a fundamental reorganization of personal meaning system in mid and later life. This sense of finite brings about a rethinking of identity and a desire for authenticity that leads people to develop aspects of the self that have hitherto been hidden (Tornstam 2005; Biggs 1999). As Baars (2012) suggests, “When we realize that the times of our lives are limited, we become aware that we must *live* these short lives and face the challenges and opportunities that are most essential to us.” . . . “aging life may offer more opportunities and unexpected exciting challenges than are foreseen in a career-oriented planning of the life-course” (Baars 2012).

These criticisms draw attention both to the limited availability of a Third Age and to the danger that macroeconomic concerns can erase alternative contributions which emerge as life progresses.

Retirement Patterns in the Twenty-First Century

Expectations about work and retirement in later life have changed as institutional supports for retirement have ebbed and flowed. In the early twentieth century the expectation was that individuals would work until they were no longer physical able to do so, leading withdrawal from work in later life to be viewed as something reserved for the infirm elderly. However, as Shultz and Olson (2013) observe, the increased availability of occupational and public pensions in the 1950s and 1960s prompted a cultural shift in attitudes towards retirement, which came to be seen as “an earned rite of passage and something that individuals should look forward to after a long career toiling at paid labor”. The emphasis on viewing older workers as a reserve army of labor during subsequent decades resulted in the emergence, particularly in European countries, of an expectation of early retirement (Taylor 2010). However, the trend towards earlier retirement ages appears to have abated and even gradually reversed in recent decades: beginning from around the mid-1980s in the United States (Ekerdt 2010) and from the mid-1990s in Europe (Taylor 2010).

Shultz and Wang (2011) point to the “changing nature of work, careers, families, and the organization of work” as all impacting how retirement is enacted in the twenty-first century. For example, a life course perspective emphasizes the interdependency of different life spheres: experiences in one life sphere such as work shape and are influenced by experiences in other spheres such as marital or family life, suggesting that “the retirement experience is played out in a network of shifting social relations” (Kim and Moen 2001). In this context, studies of people’s adjustment to retirement suggest that people who have a strong and vibrant relationship with their partner are more likely to achieve better transition and adjustment outcomes in retirement, whereas others with poorer perceived marital relationships may continuing working to distract themselves from their adverse relationship (Shultz and Wang 2011; Shultz and Olson 2013). Similarly, divorce

and couples waiting longer to have children may encourage people to work longer. On the other hand, with people living longer, many older workers, particularly women, are caring for elderly family members, which may pull them away from work due to a shortage of flexible working arrangements and the subsequent difficulties that women experience juggling paid work with caring responsibilities (Shultz and Wang 2011; Shultz and Olson 2013).

Changes in the nature of jobs and organization of work over recent decades are likely to be another key influence on changing retirement patterns. Industrial change since the 1970s has resulted in an increase in part-time, temporary, and transitional employment “leaving employment less secure and less certain” (Ekerdt 2010). The traditional linear model of career progression that underpinned retirement in the 1950s and 1960s has been eclipsed by more disjointed career paths involving multiple job and career changes over the course of people’s working lives (Shultz and Wang 2011). For example, Evandrou and Falkingham (2006) observe that, in Britain, the proportion of baby boomer men born in the 1960s who had ever experienced unemployment by the age of 35 was “very much higher than for previous generations”. With the policy emphasis on the “individualization of risk” and associated shift towards greater private pension provision, individuals’ financial security and ability to retire in later life is now far more dependent on their earlier labor-market experiences. Hence older workers who have had interrupted or more disjointed work careers over the course of their working lives may have “to soldier on due to financial necessity” (Ekerdt 2010).

Another important structural change in the economy has been the shift away from manufacturing and production towards greater emphasis on knowledge-based and service sectors of the economy. As a consequence, jobs on the whole are becoming less physically demanding which coupled with higher levels of education and health among older workers should position them to work for longer. However, other workplace changes such as tighter deadlines, more frequent organizational restructuring, and higher

expectations to work long hours mean that many jobs have also become more stressful, potentially pushing people towards retirement (Shultz and Wang 2011).

Drawing on data from the Survey of Health, Aging, and Retirement in Europe, Siegrist and Wahrendorf (2013) observe a pattern of earlier labor force exit among retirees who experienced low control or low reward in their jobs compared with retirees who had greater autonomy in their jobs. This leads them to suggest that “retirement is experienced as a relief from the burden of work” by those who work in stressful psychosocial conditions such as having low control over task performance in the face of high workplace demands. This sense of retirement as a “relief from the burden of work” also emerges in qualitative studies of older workers’ attitudes towards working longer. These studies show that many older workers, particularly those whose careers are spent in professional or creative occupations, regard work as central to their identity and find the prospect of stopping paid work at the age of 60 or 65 illogical and even frightening. However, a significant minority of older workers, particularly those who have mainly worked in heavy manual, semiskilled, or elementary clerical jobs, look forward to retirement as a time when they can “leave the employment treadmill, relax and enjoy life” (Parry and Taylor 2007). These workers view retirement and “getting the pension” as forms of reward and the beginning of a period of relative freedom in their use of time, something that has been absent from their working lives. Hence policies to increase pension ages may too readily take for granted the desirability of working additional years and may be “especially unfair on working class groups” (Phillipson 2013b).

In this context, one of the major explanations for the reversal in retirement trends since the 1990s is the change in incentives for work in later life arising from reforms to social security and employer-provided pensions. Despite the increasing emphasis on private and occupational pensions as key pillars of retirement funding, social security and public pensions remain the majority source of income for a large proportion of retirees, especially those from lower

socioeconomic backgrounds (Ekerdt 2010). Compared with the 1970s and 1980s, social security systems now provide fewer and smaller disincentives to work after pension eligibility age (Burtless 2013). In the United States, for example, previous limits on what a person can earn before their social security benefits are affected have been relaxed, while penalties for claiming social security before full-pension eligibility age have been increased (Shultz and Olson 2013; Taylor 2010). Other OECD countries have similarly made it more lucrative for people to delay receipt of a pension by continuing to work while simultaneously closing off avenues to early retirement within social security arrangements (Taylor 2010).

The change in the structure of employer-sponsored retirement plans from defined-benefit arrangements to defined-contribution arrangements has also increased the financial pressures for people to work longer. Workers now have to bear much more economic risk with regard to funding their retirement as the amount of income they can expect to live on will be sensitive to the ebbs and flows of the stock market (Ekerdt 2010; Shultz and Wang 2011). For example, over the period September 2007 to March 2009, an estimated \$3.4 trillion or 40% was wiped off the value of retirement savings held in defined-contribution plans and individual retirement accounts (IRAs) in the United States (Ekerdt 2010). In the United Kingdom, the collapse in housing and share markets caused the value of private pensions to shrink from £552 billion to £391 over this same period (Phillipson 2013a). If it was hoped that retiring baby boomers would redefine aging as a form of consumer lifestyle choice, this appears to be severely challenged by such transfers of risk. In the United States, this transfer of risk also includes the elimination of many employer-funded retiree health plans which, Burtless (2013) suggests, has combined with increases in the cost of health insurance to make it “riskier for workers too young for Medicare to leave jobs that provide a health plan”.

Taken together these trends indicate that retirement has become an increasingly “blurred” rather than “crisp” transition, involving “moves in and

out of paid work” (Phillipson 2013b). Men and women in their 1950s and 1960s are increasingly exiting their primary career jobs only to seek second or third careers or transitioning to short-term or part-time employment in jobs that serve as “bridges” to retirement. The promotion of such flexible pathways from work to retirement is now a cornerstone of policy attempts to extend working lives and is presented as providing major advantages for governments, businesses, and older workers. For example, Shultz and Olson (2013) argue that bridge employment provides older workers with financial security and enables those who are not quite ready to begin life as a retiree with no work responsibilities “to continue to engage in meaningful, productive activities”. Viewed from this perspective, the uptake of more flexible pathways from work to retirement such as “bridge employment” represents a strategic reinvention of retirement by older adults who no longer want to work full time but are neither ready to finish work entirely.

While a more gradual retirement may be beneficial for individuals in easing the transition out of the workforce, studies suggest that the degree of choice that individuals have over how and when they retire is just, if not more, important in determining how well people adapt to retirement (Shultz and Wang 2011). From this perspective, Ekerdt raises concerns about the characterization of bridge employment as being about older workers taking strategic control of their conditions of work and the course of their late careers. Late career switches to short-time positions or part-time employment, he suggests, may equally be “the result of job displacement or poor prospects for retirement income” (Ekerdt 2010). Writing in the context of the United Kingdom, Phillipson (2013b) observes that many older workers, particularly those at the lower end of the socioeconomic scale, “move into ‘bridge employment’ out of ‘financial necessity’ and often into contingent or ‘non-core’ areas of the workforce.” Concerning the rise in part-time working among older European workers in the early 2000s, Taylor (2010) observes that there

was also an approximate doubling of older workers wishing to increase their working hours or work full time, findings that indicate “significant constraints on the choices of older workers”. These constraints are reflected in higher levels of long-term unemployment among older workers, who spend longer periods in unemployment after losing jobs than younger groups of workers (Ekerdt 2010; Phillipson 2013b).

Conclusion

While retirement constitutes a significant life transition, it emerges as one that is socially determined by the external policy environment. Changing constructions of retirement affect the perceived social value of later life and the values and attitudes that affect psychological adaptation. Not all social groups perceive retirement in the same way, and an overemphasis on work can eclipse alternative forms of personal development. There may also be reasons, arising from psychosocial research and retirement insecurity, that cast doubt on current policy directions. In particular, the individualization of retirement risk through the privatized market provision of pensions means that people’s experiences of retirement transitions and later life are increasingly sensitive to earlier experiences of working life. Declines in the real value of public pensions and an increased emphasis on private and occupational pensions point towards potentially more divided and unequal experiences of retirement in the future as earlier inequalities widen and accumulate with aging (Evandrou and Falkingham 2006).

Definition

Retirement is a process rather than a single event. It may be thought of as broadly progressing across three key stages: preretirement, transition, and adaptation. This entry provides a framework based on these stages to enable future researchers to interpret, design, and evaluate retirement research from different disciplines, theories, and research areas.

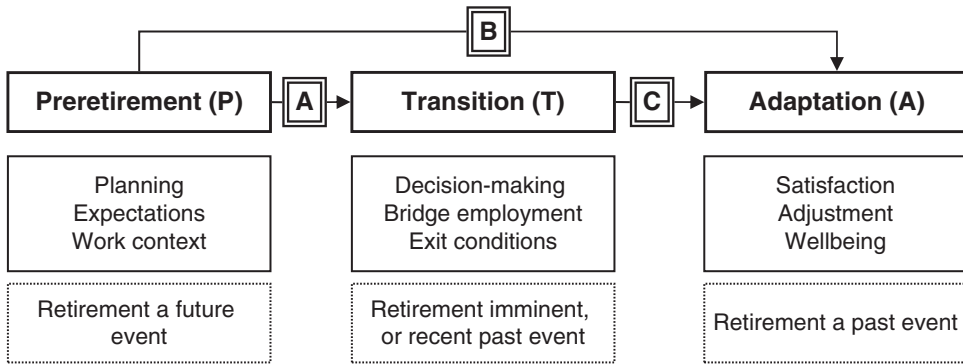

Understanding Retirement Adjustment Can Promote Benefits and Ameliorate Risks Associated with an Aging Population

Adjustment to retirement is a dynamic and ongoing process (Sterns and Subich 2004), potentially with multiple alternating periods of stability and readjustment. An individual who successfully negotiates the retirement process is at ease with retired life (Wang et al. 2011), and a variety of constructs have been used to measure this, including happiness, psychological well-being, retirement satisfaction, life satisfaction, and depression (Wang et al. 2011). Interest in the characteristics of successful retirement is growing pursuant to the increasing number of retirees (Wang et al. 2011; Beehr and Bennett 2007; Ekerdt 2010), forcing retirement onto the agenda of researchers, health professionals, and governments (Beehr and Bennett 2007).

This population can represent a remarkable reserve to society (e.g., via caregiving, volunteer work, and labor force reserve) or a burden (e.g., due to poor psychological or physical health and reliance on pensions) (McKelvey 2009). Accordingly, identifying and promoting the factors that lead to retirees being self-sufficient and well-adjusted will help society realize the benefits and manage the potential risks associated with an aging population.

A Conceptual Framework Will Help Researchers to Consolidate Insights About Retirement Adjustment

A range of variables including individual attributes, job and organizational factors, family

Retirement Planning and Adjustment, Fig. 1 Retirement phases that organize the existing (and future) literature into three broad research areas. The figure shows the three phases of retirement and the outcomes and temporal orientation to retirement typically observed in the corresponding literature. Note that the outcomes of interest at each stage can predict outcomes in later phases. Specifically, outcomes of preretirement can influence what happens during the transition (a) and adaptation (b) phases.

Outcomes of the transition phase can influence outcomes in the adaptation phase (c). Phases are not as clearly divided as is implied in the figure, but are expected to overlap. For example, after choosing gradual retirement, an individual may start adjusting to retirement as they reduce their work hours, yet still face decisions about when and how to retire completely (Taken from Earl et al. 2015)

factors, and socioeconomic contexts have been investigated within a number of different research frameworks (Wang and Shi 2014). The diversity in individuals’ retirement experiences has driven many distinct research approaches within and across disciplines as researchers attempt to identify those characteristics that are crucial to producing positive outcomes (Ekerdt 2010). Recent reviews offer excellent analysis and summaries of the many issues that inform retirement research (Wang et al. 2011; Wang and Shi 2014; Wang and Shultz 2010); however, integrating these ideas can be difficult. Using a framework to conceptually organize retirement literature can help researchers to connect the diverse investigations that belong to this field and promote the important scientific goal of consolidating knowledge (Shultz and Adams 2007). Therefore, rather than repeat the findings presented in previous review articles, the purpose of this entry is to provide the reader with a framework that will facilitate the integration of findings from retirement adjustment research and their implications. Accordingly, the present entry draws on a recently developed framework, the preretirement transition adaptation (PTA) framework, which facilitates the interpretation of studies across different disciplines,

theories, and research areas to aid interpretation and evaluation of retirement adjustment research.

The Preretirement Transition Adaptation (PTA) Framework Facilitates Interpretation of Adjustment Research

The PTA framework provides the means to interpret, design, and evaluate retirement research from different disciplines, theories, and research areas. Rather than focusing on summarizing what we know about retirement, the PTA framework highlights the conceptual detail that underpins this knowledge. Specifically, the PTA framework organizes retirement research according to three phases (preretirement, transition, and adaptation, shown in Fig. 1) and six elements (social context, selecting the population, defining retirement, experiences, theory, and stakeholders, shown in Fig. 2). The three phases organize the existing (and future) literature into three broad research areas, and the six elements define a research focus within each of these areas, described in more detail below.

The framework is broad enough to encompass studies from different disciplines, theories, and

Retirement Planning and Adjustment, Fig. 2 *The elements of a research focus.* The figure identifies the elements that underpin a precise retirement research focus

research areas. This breadth offers a particular advantage because many articles do not state their theoretical approach, which may prompt reviewers to organize the literature by empirical themes (Wang and Shultz 2010). As a result, studies are categorized according to whether a variable is treated as dependent or independent. Using the PTA framework, we can make a more meaningful distinction by organizing studies according to research area. For example, the characteristics of workforce exit may be a dependent or an independent variable. Applying the PTA framework, when exit is a dependent variable, the study focuses on the transition phase. When exit is an independent variable, the study focuses on the adaptation phase (refer to Fig. 1). This encourages researchers to think temporally about retirement research, appreciate retirement as a process, and identify the part of the process that their own research illuminates. With better understanding of the existing research on retirement, we can identify pertinent questions for future research, thereby linking new and old investigations. The framework is introduced below, along with findings from and implications for retirement adjustment research.

Three Phases Identify a Study's Research Area

A study's research area can be identified as preretirement, transition, or adaptation based on the variables being investigated and the temporal treatment of retirement. Using three phases highlights that circumstances earlier in the retirement process influence retirement adjustment and acknowledges the temporal nature of retirement variables. It is generally agreed that the individual is principally engaged in work (preretirement), begins a transition toward retirement that may

last any length of time and involve multiple changes in employment status (transition), and then is principally engaged in retirement (adaptation) (Richardson 1993). Wang and Shi (2014) refer to this as a temporal process model of retirement (Wang and Shi 2014). The PTA framework uses these phases as the foundation for interpreting research.

The respective focus of individuals, researchers, and practitioners changes at each phase as different issues become more or less relevant (Sterns and Subich 2004; Richardson 1993). This provides the means to prioritize the multitude of variables relevant to retirement when designing a research (Wang and Shultz 2010) as well as identify published studies with a particular phase based on the variables that form the basis of the investigation. For example, the adaptation phase concerns how individuals adjust to retirement. Adjustment is a dynamic and ongoing process (Sterns and Subich 2004), potentially with multiple alternating periods of stabilization and readjustment. In this phase, retirement is a past event, yet individuals may still be involved in paid work in the form of bridge employment (Wang et al. 2009). Of interest are the predictors of outcomes such as well-being, adjustment, and satisfaction over time. Second, action or inaction earlier in the process can affect outcomes in later phases (Sterns and Subich 2004; Richardson 1993). For example, retirement adjustment research focuses on outcomes in the adaptation phase but should acknowledge the potential influences of events from the preceding phases. Third, variables have temporal properties. Just as retirement may be a future, present, or past event, other variables may be viewed prospectively or retrospectively and individual concerns may change

with their proximity to the transition (Feldman and Beehr 2011; Topa et al. 2009). This means that comparisons between individuals at different stages of the process should be made with caution (Topa et al. 2009), because the same variable measured at preretirement or at adaptation may not be equivalent.

It is important to note that Fig. 1 is an abstract representation of the retirement experience. In reality, the individual may experience a nonlinear transition with multiple moves into and out of the workforce (Wang et al. 2009) that could mean a recycling through the phases. Viewed in this way, retirement is indisputably a process. Accordingly, existing studies that may use narrower definitions of retirement can be understood as providing insight into a particular phase of a broader progression.

Six Elements Define a Study's Research Focus

Using six elements to analyze research focus facilitates knowledge integration because within each research area, studies may, for example, use different populations, theoretical frameworks, and definitions of retirement. Accordingly, once a study is identified as addressing the preretirement, transition, or adaptation phase, its research focus can be precisely defined using the following six elements (Fig. 2). When designing research, prescribing elements for explanation rather than exhorting the use of a common definition of retirement offers a particular advantage. Specifically, definitions can be derived according to research purpose, leading to greater research precision (Wang and Shultz 2010).

Social context. Policies from broader societal structures, such as organizations, the government, and the economy, underpin retirement (Atchley 1993; Adams and Beehr 2003). To a large degree, an individual's work and retirement opportunities are determined by his or her position within these structures (McKelvey 2009). Policies are formulated in response to changes within societal structures such that changes in employment relationships, government resources, and the norms of a leisure lifestyle drive changes in retirement (McKelvey 2009; Wang and Shi 2014). For example, older workers may become a more attractive

labor pool in light of the growing strain on government resources, an extended lifespan, shrinking labor market, and anticipated skills shortage (Ekerdt 2010; Adams and Beehr 2003). Accordingly, contemporary government policy encourages individuals to retire at a later age (Ekerdt 2010).

This means that (a) individual circumstances are to some degree externally determined and researchers should not neglect these constraints when interpreting research findings, (b) retirement trends change over time and so the need for research is ongoing and comparisons between studies from different time periods should be thoughtfully made (Beehr and Bennett 2007), and (c) government policies and resource structures that dictate retirement serve broader social and economic requirements, which may not support the best possible outcome for the individual (Atchley 1993).

It is also important to note that countries regulate retirement differently. Some countries still enforce a mandatory retirement age, while in others, retirement is not yet institutionalized, such as in developing countries (Adams and Beehr 2003). Accordingly, researchers should carefully consider whether research contexts are comparable before consolidating findings. As changes take place in global economies and mandatory retirement ages are raised or abolished, there is an opportunity for shared learning to inform future public policy and government direction.

Defining retirement. The multifaceted nature of retirement makes a universal definition difficult (Adams and Beehr 2003; O'Rand and Henretta 1999). Different retirement definitions point to whether the whole retirement experience or just one portion is under investigation challenging whether studies have a comparable focus. Observed in Fig. 1, retirement in its entirety is most accurately depicted as a process. Alternative definitions capture some part of the experience, and these may be introduced when aligned to the researcher's purpose (Wang and Shi 2014). Examples of the various definitions used by researchers are briefly described below.

Retirement has traditionally been understood as the point of separation from work (Ekerdt 2010). This perspective emphasizes the loss of the work role and ensuing stress as well as attempts at finding satisfying substitutions (Topa et al. 2009). It may become increasingly challenging to apply event definitions in contemporary research. Such definitions have trouble accounting for the complexity of modern retirement (O’Rand and Henretta 1999) and suggest a distinction between work and retirement that may be too simple (Hedge et al. 2006). Note that studies that conceptualize retirement as a past event will likely provide insight into the adaptation phase.

Alternatively, researchers may define retirement as the period of time between two relatively stable and distinct life stages. This definition complements the conceptualization of retirement as a decision-making process (Wang and Shi 2014). From this perspective, retirement might be considered in the context of the life course with reference to age norms, how it affects multiple life domains, and reduced psychological commitment to work (Adams and Beehr 2003). This focuses on how the individual deals with change (i.e., as crisis, opportunity, or continuity) and accounts for diverse retirement pathways including gradual exit from work (Topa et al. 2009; Atchley 1993). Studies that focus on consequences of the transition for adjustment may provide insight into the adaptation phase.

As another option, researchers may focus on the construction and experience of a new lifestyle in retirement, which is directly relevant to understanding the adaptation phase. This perspective corresponds with investigations into the retirement role or retirement identity and how it is socially and individually constructed. Definitions based on this perspective refer to the duration of the stage, the shift to leisure and consumption, and the potential for freedom and development (Atchley 1993). With the increasing incidence of paid work, retirement may also be considered a career development stage (Wang and Shi 2014).

Finally, researchers may define retirement as a process, in line with contemporary consensus (Wang and Shi 2014). Process definitions acknowledge that the line between work and

retirement is blurred, that the process begins before the end of work and continues well into retirement, and that it can involve multiple work status changes (Adams and Beehr 2003). Using a process definition of retirement may be particularly appropriate if the elements of retirement, including planning, decision-making, and adjustment, are considered dynamic (Wang et al. 2011; Topa et al. 2009). Studies that focus on the outcome of this process will provide insight into the adaptation phase. Process definitions are particularly suitable to investigating retirement adjustment because retirement adjustment can itself be viewed as a process (Wang et al. 2011). Furthermore, using process definitions of retirement acknowledges the potential influence of earlier phases, for example, characteristics of the individual’s work or career that may influence attitudes or later adjustment (Wang and Shi 2014).

Selecting the population. Identifying “retirees” is complicated, mainly because definitions rely on arbitrary concepts such as aging and work transitions (Ekerdt 2010). Studies rely on a variety of different criteria to select participants. Economic criteria infer retiree status from employment status and whether the individual receives a pension (O’Rand and Henretta 1999). However, reliance on economic criteria may be increasingly impractical as participation in a variety of paid work in retirement is increasing (Adams and Beehr 2003). Furthermore, economic criteria may ignore cultural and social processes that underpin the retirement status of parties such as women and minority groups (Richardson 1993).

On the other hand, social phenomenological criteria allow for subjective and personal interpretations of retirement (Richardson 1993), but may make quantitative research difficult and challenge the extraction of general principles. Individuals may have personal reasons for identifying themselves as retired or not retired. For example, an individual may be reluctant to identify as retired due to negative associations with old age (Teuscher 2010) or may prefer to identify as retired because it is more positively perceived than being unemployed (Lamberg et al. 2010). With the former, this may mean that those who

are particularly negative in their view of retirement are excluded from research, clouding researchers' understanding of retirement adjustment and limiting support. With the latter, it may mean that the incidence of unemployment at older ages is underestimated.

These complications suggest the use of social criteria that incorporate subjective and objective elements (Richardson 1993), for example, using workforce status and whether or not the individual identifies as retired (Wang and Shi 2014). Given that contemporary retirement may include multiple work status changes as well as a change in roles or identity, using a combination of indicators seems particularly appropriate (Wang and Shi 2014). Researchers should be aware that the population selected for any study is determined by whether the study uses economic, identity, or a combination of indicators to infer retiree status (Ekerdt 2010), and this will have important implications for whether results may be generalized to all retirees or just a subset.

Experiences. Experiences refer to the individual characteristics or circumstances that indicate opportunities or constraints. For example, individual experience of retirement may vary according to demographics (such as age or gender), pathways into retirement, and the meaning attached to retirement. A study may seek to understand one dimension of experience, for example, early retirement, or to generally understand positive experiences. Depending on the variables included in a single study, predictors may be ascribed different importance. For example, including the dimensions of both control over workforce exit and a gradual workforce exit demonstrated that control was the more important dimension (de Vaus et al. 2007). If these dimensions were not included concurrently, their relative contribution could not have been compared. Wang and Shultz (2010) and Wang and Shi (2014) provide a comprehensive summary of retirement experiences that warrant investigation (Wang and Shi 2014; Wang and Shultz 2010). A brief summary of current understanding of key influences on retirement adjustment is provided here.

Accumulated evidence suggests that health, finances, social support, and leisure are important

predictors of adjustment (Adams and Beehr 2003). The way in which one exits the workforce stands to influence a variety of retirement outcomes including available income, satisfaction, and well-being (Wang and Shi 2014). Evidence consistently shows that individuals who have choice in how and when they retire report better outcomes (Adams and Beehr 2003).

It is also important to acknowledge the potential role of meaning in retirement adjustment. Meaning in life is central to well-being and includes an individual's understanding of the world, sense of purpose, ambition and achievement, and associated positive feelings (Ho et al. 2010). In reality, it seems likely that individuals attach multiple meanings to their retirement, both positive (e.g., opportunity to pursue pleasure) and negative (e.g., the start of old age). Indeed, there can be substantial stress in the retirement transition, but also the potential for growth, development, and freedom (Sterns and Subich 2004; Atchley 1993). Acknowledging the multiple meanings of retirement facilitates specific predictions and informs the design of targeted interventions.

Theory. The theoretical framework adopted by the researcher should be selected according to study focus (Wang and Shi 2014). It is incumbent upon researchers to consider whether the theoretical framework used in the study was tested completely and appropriately. Due to the many theories that have been applied to retirement research (Wang and Shi 2014), researchers may also evaluate whether the framework selected was the one best suited to explaining the phenomena under investigation. Theory may explain experiences of individuals or subsets of individuals within a particular phase or provide a more comprehensive explanation of the retirement process (Wang et al. 2011). Theory can be drawn from a variety of disciplines including economics, sociology, psychology, gerontology, and business (Shultz and Adams 2007).

As a result of the accumulation of diverse experience (O'Rand and Henretta 1999), life course differences exist in available resources and expectations between men and women, majority and minority groups, and white- and

blue-collar workers (O’Rand and Henretta 1999). Significantly, the variation both within and between groups is expected to increase as individuals age (O’Rand and Henretta 1999). In addition, late career transitions are variable and complex due to the number of options, multiple life roles an individual holds, and issues specific to the older worker, such as health concerns and age discrimination (Wang et al. 2009; O’Rand and Henretta 1999). Once retired, an individual’s circumstances may be affluent or disadvantaged and may change over time or be influenced by concurrent life events or societal trends (McKelvey 2009; Adams and Beehr 2003).

Despite this, theory and research have often failed to take account of diversity (O’Rand and Henretta 1999). Universalistic theories that suggest the experiences of group members are equivalent are still used (Kolb 2004), and differences within an older cohort are ignored or marginalized (Mein et al. 1998). An overreliance on cross-sectional research provides only a snapshot of a continuing process and confounds aging and age-cohort effects (Adams and Beehr 2003). These challenges have led researchers to question the value of theories that seek to prescribe a universal retirement experience and whether a single theory can account for the entire process for all individuals (Moody 1988). Indeed, certain theories may have greater utility in explaining certain phases (Wang and Shi 2014).

A life course perspective, role theory, continuity theory, and a resource perspective are prominent models in retirement research and may particularly apply to retirement adjustment (these theories are briefly described in Wang et al. 2011). The life course perspective draws attention to the multiple past, present, and interlinked contexts that influence retirement, such as those of society, family, organization, community, and the individual. Role theory posits that retirement constitutes a role transition as the individual may exit a worker, organizational member, or career role and reinvest in family and community roles. Adjustment may be a result of three dimensions that can change from old to new roles, specifically, the clarity of role identity, role investment, and role demands. According to continuity theory,

how well people transition depends on whether they can replicate preferences, preretirement and postretirement. Being able to maintain preferences, social relationships, and lifestyle patterns can help ease the transition. Resources represent the capacity an individual has to meet core needs and can be physical, cognitive, motivational, financial, social, and emotional (Wang and Shi 2014). Resource change predicts well-being, such that an increase, decrease, or stability in well-being after the retirement transition is a result of an improvement, depletion, or maintenance of resource level (Wang and Shi 2014). A resource perspective may be particularly useful in explaining retirement outcomes because it can explain multiple patterns of change in well-being after retirement, whereas life course, continuity, and role theory can each only account for a subset (Wang and Shi 2014). For more detail on theories applied within retirement research, refer to Wang et al. (2011) and Wang and Shi (2014).

Stakeholders. Stakeholders refer to bodies at the political, organizational, and individual level that have a vested interest in retirement (Beehr and Bennett 2007). Every stakeholder has an agenda and decisions made about retirement structures may be at the detriment or benefit of other stakeholders. For example, government policy changes to delay access to pensions may reduce government spending but force people to work beyond their physical or psychological limits (Adams and Beehr 2003). A study’s stakeholders indicate who will feel the benefit of recommendations based on results.

Retirement adjustment research focusing on outcomes for the individual may investigate factors that influence individual risk and may seek to understand changes that accompany retirement or older age including adjustment to new roles, social context, and time organization or improve well-being in retirement (Wang and Shi 2014). At the organizational level, research may focus on the implications of losing skilled workers and opportunities to retain these workers or to provide retirement programs (Adams and Beehr 2003). At the societal level, research may focus on fostering valuable activities such as volunteering, caring, and paid work to address skills shortages

(Adams and Beehr 2003). Encouraging unpaid activities is beneficial not only to the individual but to the broader community although these may be undervalued (McKelvey 2009).

Future Directions

The breadth of variables investigated with respect to retirement research needs to be expanded by including social and spousal resources, personality, motivation and self-regulatory processes, and socioeconomic context (Wang et al. 2011; Wang and Shi 2014). In addition, the potential moderating effects of variables warrant closer examination (Wang and Shultz 2010). The reasons behind particular decisions may be an important antecedent of adjustment (Wang and Shultz 2010). For example, the reason a person retires is expected to influence how they evaluate subsequent outcomes (Wang and Shultz 2010). Similarly, financially motivated bridge employment may indicate financial strain or dissatisfaction with retirement and hence poorer retirement outcomes (Wang and Shi 2014). Researchers should consider simultaneous investigation of factors from multiple levels such as individual, group, family, organizational, and social context (Adams and Beehr 2003) because retirement has important implications for all of these (Beehr and Bennett 2007). In addition, measuring multiple domains of a phenomenon can improve our understanding of its antecedents because predictors may only be associated with a particular outcome or may be differently related to outcomes (Wang et al. 2011).

A particularly important area of research at the societal level is whether policy will have the desired effect on the individuals it is designed to influence. Individuals may not be aware of policy, may not understand it, or may be unable to respond to its incentives (Ekerdt 2010; Powell et al. 2007). Individuals differ in their resources, knowledge, and life experiences, and these may be stronger drivers of retirement preparation than generic government policy that assumes individuals to be informed, responsible, and self-sufficient (Powell et al. 2007). Policies to promote work may be ineffective if other barriers to work, such as age

discrimination, poor health, caring responsibilities, career plateaus, and low self-efficacy, are not addressed (Ekerdt 2010; Wang and Shi 2014; Wang et al. 2009). Therefore, investigating individual understanding and response to retirement issues can help to inform effective policy (Ekerdt 2010; Wang and Shi 2014).

Future research also needs to consider that there are some groups whose experiences are argued to be markedly different from the majority (Wang and Shi 2014). For example, we would expect retirement plans and experiences to differ between individuals living in rural versus urban areas, between those who are self-employed versus part of an organization, and those who move to a new location versus those who seek to age in place. Losing a spouse can have a profound impact on the retirement experience (Wang and Shi 2014). Individuals with disabilities may not have a clear understanding of retirement and may benefit from additional tailored support (Wang and Shi 2014). Finally, migrants may be at risk due to a poorly formed social network, challenges of integrating into the new culture, and ineligibility for government support (McKelvey 2009). These different experiences increase the variability among older adults and could be studied systematically.

Future researchers may also explore whether differences exist between individuals who are partially and fully retired, who are facing their first or second retirement, and who are comfortable adopting the retiree identity and those who are not. For example, partial retirement or bridge employment may be a way to resolve ambivalence and facilitate adjustment toward full retirement (Wang and Shi 2014), and this population may be different from those who have fully retired. Distinguishing between participants who have retired once versus multiple times may also be important because multiple shifts into and out of the workforce are increasingly common over the retirement transition (Ekerdt 2010). Mentioned earlier, individuals may be reluctant to adopt the retiree identity due to negative associations or may adopt it in preference to identifying themselves as unemployed. Whether this indicates particular difficulty adjusting to retirement should be investigated.

The implications of retirement as a process are starting to permeate the literature demonstrated by the acknowledgement that planning, decision-making, adjustment, and bridge employment are themselves sequential and dynamic (Wang and Shultz 2010; Topa et al. 2009). Consequently, calls for longitudinal investigation to establish trajectories and their causes as well as dynamic theories to explain observed patterns are increasing (Wang et al. 2011; Adams and Beehr 2003). This opens opportunity for more complex data analytic techniques. Hierarchical linear modeling, latent growth curve modeling, time series analysis, spline regression, and logistic regression can answer questions on longitudinal data, discontinuous change, and dichotomous phenomena (Adams and Beehr 2003). The application of item response theory may enable the development of improved psychometric measures (Adams and Beehr 2003).

Additional frameworks, methodologies, and important concepts may be drawn from the fields of aging and careers in the future. Aging and retirement are concurrent processes respectively describing individual developmental and life course pathways (Schaie and Willis 2011). Therefore, successful adaptation to retirement and successful aging appear interdependent. Supporting this, recognizing the potential of the third age and plasticity in later life has encouraged individuals to demand more than inevitable decline from retirement (Beehr and Bennett 2007). Accordingly, concepts, theories, and methods that apply to adult development (Schaie and Willis 2011) may similarly lend insight into retirement adaptation, for example, selective optimization with compensation (discussed previously Baltes and Baltes 1990) and successful aging (Shultz and Adams 2007).

Careers and retirement are changing (Adams and Beehr 2003) such that career theory may help to explain retirement experiences in the future. The line between work and nonwork is blurring (Hedge et al. 2006) as is the temporal distinction of learning, work, and leisure across the life course (Ekerdt 2010). Self-management plays an increasing role in career and retirement (Adams and Beehr 2003). Hence, career perspectives that prescribe a personal capacity for flexibility,

resiliency, adaptability and self-assessment for career success, such as a protean career, may similarly secure favorable retirement (Wang and Shi 2014). Other career concepts, such as career adaptability, that indicate readiness and resources for coping with anticipated changes may be particularly useful constructs to apply to retirement (Savickas 2005). Finally, career counseling that helps individuals to navigate uncertainty and create meaning in their careers, for example, life design, may also help individuals overcome similar challenges in retirement (Savickas 2012).

Conclusion

The body of research relevant to retirement adjustment is complex because researchers investigate many different variables from diverse theoretical and disciplinary perspectives. To make use of this wealth of information, researchers can benefit from conceptual frameworks that facilitate knowledge integration. The PTA framework applied in this entry improves our understanding of adjustment research by making clear the contributions of theoretical, empirical, and review papers, facilitating knowledge consolidation.

Retirement Villages

Dimitry A. Crisp
Faculty of Health, University of Canberra,
Canberra, ACT, Australia

Synonyms

Continuing care retirement communities (CCRSs); Independent living community/units; Lifestyle communities/villages; Retirement communities

Definition

A managed purpose-built housing community targeted to people over 55 years of age.

Introduction

Various terms are used throughout the literature to describe retirement villages. Indeed, any review of the literature around retirement villages is frequently complicated by the broad use of the term often encompassing discussion of a range of housing options for older adults which may include naturally occurring retirement communities (NORCs) as well as formally organized retirement villages. However, while definitions may change in accordance with government regulations, retirement villages are purpose-built housing complexes characteristically targeted at adults aged 55 years and over, which often combine independent living units with other services and facilities such as nursing home care, and community and recreational facilities (Stimson and McGovern 2002). Key features of modern retirement villages include community centers, libraries, games rooms, swimming pools, exercise/sports facilities, café or dining facilities, hair-dresser/salon, outdoor gardens, and workshop space. Accommodating for the needs of residents, the physical environment of a retirement village combines the features of security, independence, and communality (Gardner et al. 2005; Graham and Tuffin 2004), and through options for incorporating formal living assistance can provide an avenue for older adults to obtain manageable housing with the social and physical supports that enable them to age in place for longer and enter more formal residential care (e.g., nursing homes) later than people in the community (Gardner et al. 2005). Physically, retirement village housing is often very similar to other medium-density housing in the community. However, with the incorporation of physical health, recreation and social supports for those with varying care needs, the residential environment differs

considerably from most other housing within the community.

Retirement villages within Australia and New Zealand (as with other countries around the world) are subject to legislation regulating the rights and obligations of residents and retirement village operators. However, even within jurisdictions various models exist for the structure and specifically the contractual and financial arrangements entered into by residents. Tenure models include: leasehold, freehold, loan/licenses, and rental systems. Importantly, retirement village models have over time evolved in response to the needs and expectations of older adults, and will no doubt continue to evolve into the future. Therefore, distinct from other forms of aged care accommodation (e.g., hostel and nursing home style care), retirement villages represent a desirable housing choice for an increasing number of older adults.

Perceptions of Retirement Villages

Retirement villages are often perceived and promoted in a positive light with emphasis placed on the opportunities they award for a change of lifestyle, socialization, and support for older adults to maintain independence and age in place well into the later life. While some of this may be driven by promotional strategies within the industry, retirement village residents themselves generally report positive perceptions of their village communities. Research from Australia, the USA, and the UK has found that residents, and prospective residents, perceive retirement villages as safe, low maintenance, supportive housing options that provide opportunities for a greater sense of community, security, and independence than living in the general community (e.g., Bohle et al. 2014; Stimson and McCrea 2004; Hollinger-Smith et al. 2012). However, while a growing body of work has found residents report the experience of living in a retirement village as being associated with a number of positive benefits, as will be discussed further below, not all attitudes toward retirement communities are positive. Criticisms

have focused on the concentration of health and welfare service demand to a single area, the exclusiveness and affordability of some villages, and the inherent “agist” nature of identifying age-segregated housing. However, while these issues may represent the concerns held by some, they do not reflect the general status of retirement villages, or importantly, the problems encountered by many residents. The notion that retirement villages promote ageism and the exclusion of older adults is refuted by research highlighting the reduced social isolation and increased independence of retirement village residents in comparison to older people living in the community who may have difficulty accessing services. While this type of housing may not be appropriate or desirable for all older adults, perceptions that the retirement village environment represents dependence and social isolation can generate fears that relocation to a retirement village reflects a loss of independence and privacy (Graham and Tuffin 2004) can in itself reinforce negative stereotypes associated with aging (Fisher 1990; Peterson and Warburton 2012).

Making the Decision to Move

Substantial variability exists in the reasons for relocation to a retirement village. While the perceptions of retirement villages outlined above undoubtedly influence individual decisions to relocate, internationally diverse research investigating the accounts of both older adults and their families highlights that there are a number of motives which may drive relocation to a retirement village. Principally they include: (1) declining health in one’s self or one’s partner; (2) personal security; (3) feelings of social isolation and the desire for greater social connection; and (4) financial pressures (Stimson and McCrea 2004; Bekhet et al. 2009; Krout et al. 2002; Sergeant and Ekerdt 2008). Importantly, though it appears that a combination of push and pull factors underlie relocation. Push factors refer to stressors prompting an individual to leave their current residence (e.g., difficulties and costs

associated with home maintenance; social isolation; and health and mobility issues and the resulting need for assistance). Pull factors refer to desirable characteristics associated with an alternative environment that encourage a move (e.g., village attributes and affordability, location and proximity to public transport and social activities, and the ability to maintain aspects of their existing lifestyle in terms of proximity to family, friends, and services (Stimson and McCrea 2004)).

Importantly, retirement village housing attracts persons aged 55 years and over who display great diversity in their employment, health and functionality, and family status. Research indicates that younger retirees who remain relatively healthy and are likely to be more financially comfortable and married, relocate with the intention of finding a better quality of life and increased access to facilities and services such as community, health, and recreational clubs. In comparison, older retirees, who are likely to have experienced decreases in health and functionality and as such are more dependent and more likely to be widowed, relocate based on assistance needs with the purpose of support services, or to be closer to family (Stimson and McCrea 2004). Secondly, research supports a distinction between “planners,” who indicate future health concerns as major considerations in moving, and the “reactors” who, often older, move because of current health problems (Gardner 1996). Understanding the motives driving relocation provides an important basis for understanding the experience of living in a retirement village.

Health, Functioning, and Safety

Changes in physical health and functioning, and the suitability of the home environment are the most commonly cited motives driving decisions to relocate in later life. Although many older adults retain the ability to remain independent in their own homes, as people age, a decline in physical and cognitive functioning can result in difficulty caring for one’s self and a current or anticipated need for future residential care. As such, declining health of oneself and/or one’s partner may prompt an individual to leave their

current residence (push factor), or the facilities offered within a retirement village for maintaining independence in the face of health decline may encourage relocation to a suitable retirement village (pull factor) (Gardner et al. 2005; Stimson and McCrea 2004; Bekhet et al. 2009; Krout et al. 2002; Groger and Kinney 2006). Moreover, the desire to reduce responsibilities and burden associated with managing a large house or property in favor of downsizing to a smaller unit (Bekhet et al. 2009; Krout et al. 2002; Groger and Kinney 2006), the desire to plan for future health needs, and importantly, a desire to have input into one's future whilst able to do so (Groger and Kinney 2006), all represent motives for relocation to a retirement village.

Concerns regarding neighborhood safety can also be an important motive behind the decision to move to a retirement village (Sergeant and Ekerdt 2008). The neighborhood environment is an important factor in maintaining independence in later life and can have a substantial influence on older adults' continued engagement in positive health behaviors such as physical activity. Confrontational relationships with neighbors, safety concerns, and traffic can all present barriers to older adults maintaining health and remaining in the community and as such are motives for relocation. Retirement village residents report that feelings of vulnerability associated with reduced functional capacity are lessened through relocation to a village where predominantly residents feel safe and secure (Graham and Tuffin 2004).

Social Connection

The perceived social isolation which may accompany changes to one's social networks in later life; and the contrasting community friendly design of many retirement complexes represent important push and pull factors influencing residential location. Research investigating the migration of adults toward retirement village communities in mid to late adulthood suggests that relocation is often motivated by social considerations, particularly when individuals live alone or do not live in close proximity to children (Silverstein and Zablotzky 1996). Specifically, the loss of social support systems as individuals experience the loss

of a partner or the relocation of friends and neighbors can represent major motives for relocation (Bohle et al. 2014; Sergeant and Ekerdt 2008; Gardner 1996). Naturally, these motives center on the location of a retirement community placing older adults desiring social contact in closer proximity to family and pre-existing friends.

Retirement communities may also be a solution to perceived social isolation or loneliness through their community-friendly design and encouragement of social engagement and participation (Graham and Tuffin 2004). Surveys of retirement village residents have found that the community environment, the opportunities for making new social contacts and friends and the social activities can be a principle reason for relocating and significant advantage (Sergeant and Ekerdt 2008; Gardner 1996; Buys 2001; Crisp et al. 2012). Importantly, regardless of the effort made to form new social contacts, condensed housing environments (such as in the case of retirement villages) can increase the likelihood of engaging in informal social interactions with others.

Financial Pressures

The affordability of retirement village living and changes in economic status or financial constraints in later life reflect further important considerations influencing relocation (Finn et al. 2011). Reduced income following retirement or a change in personal circumstances (e.g., the death of a partner) may dictate the viability of residential options. Financial pressures may initiate a move through a need to downsize to a more affordable residence (Stimson and McGovern 2002). Similarly, the financial status of the individual in retirement may influence perceptions of retirement village housing affordability (Finn et al. 2011; Bridge et al. 2011). An examination of the issues reported by retirement village residents in Australia has highlighted various financial concerns impacting the relocation process. Prior to relocation, prospective residents face financial considerations pertaining to the sale of the family home and concern for ensuring financial stability throughout retirement (Finn et al. 2011). Moreover, adding to financial stressors is the perception that retirement communities have complex tenure and leasing

arrangements (Bridge et al. 2011). The influence of housing tenure and the differential ease with which renters in comparison to owner-occupiers may be able to adjust and pursue new accommodation options has important implications.

The Experience of Relocating to a Retirement Village

A growing body of research has found that the experience of living in a retirement village can have a positive impact on maintaining independence, perceived health, social relationships and social integration, and reliance on community services (Buys 2001; Buys and Miller 2007). Investigating health and well-being outcomes, research has indicated greater participation in physical activities following relocation (Buys and Miller 2007); better physical and mental health outcomes over time (Kingston et al. 2001; Rossen and Knafelz 2007; Smider et al. 1996); and that residents report a renewed sense of vitality and overall better quality of life in contrast to comparable general community samples (Gardner et al. 2005; Grant 2007). While, these benefits may be attributable to aspects of the retirement community environment, the pursuit of activities and relationships that provide motivation to maintain an active lifestyle, the more manageable residence, and the access to support services, further research is required to establish the magnitude of these benefits.

As a strong motive for relocation, and key factor in maintaining positive health and well-being in later life, the benefits to social networks and engagement are perhaps of greatest significance to retirement village residents and those wishing to understand the experience of retirement village living. Through both organized activities and informal social interactions with other residents as a function of the condensed housing environment, the retirement village environment increases opportunities for social interaction and engagement that can reduce social isolation and have consequent benefits for the health and well-being of residents. Available research examining the impact of residential location on contact with friend networks has found support for retirement village living promoting the

development of a sense of belonging, new social networks and reducing social isolation (e.g., Buys 2001; Grant 2007). Moreover, research has indicated that residents retrospectively report greater satisfaction with friendships and their social life following relocation (Gardner et al. 2005; Graham and Tuffin 2004).

In light of the benefits to relocation that have been noted it should be recognized that relocation to a retirement village is a major transition and can have a significant impact on not only the individual but also family and the wider community. Importantly, the relocation process can be a stressful experience. It can produce feelings of grief, insecurity, and a loss of control or sense of identity (Morgan et al. 1997). Additional stressors such as changes in social networks, widowhood, illness or financial strain, may underlie motives for relocation but also provide challenges in adjusting to the new environment. Further, negative consequences including increased health decline and associated increases in health care utilization, reduced financial independence, and decreased quality of life may then also accompany the move (e.g., Krout et al. 2002). Moreover, retirement village life is more restrictive than community living. Residents are not only governed by contractual rules but also the behavioral and social norms of the community which evolves. This is a further characteristic associated with this housing model which may negatively impact individuals (e.g., cause stress) through the requirement to conform to expectations (Stein and Morse 2008).

Finally, it is unclear from the literature whether specific factors may influence the apparent benefits to be awarded by retirement villages, and if there are subgroups of older people who may be relatively more or less advantaged by retirement village living. For example, while it appears that living in a retirement village is largely characterized by opportunities for positive social contact and engagement in activities that serve to benefit older adults, the reality may not be such for all residents. Simply living in proximity to others may not combat loneliness for all individuals. Importantly, the impact of age-concentrated housing may vary with individual and social factors (e.g., age, marital status, personality

characteristics), which may influence the relationship between the proximity of residents and the degree of social engagement. While some research exists (e.g., Smider et al. 1996), further investigation is required into specific factors (individual or village level) that may drive the experience of retirement village living.

Conclusion

While a common feature in Australia and the USA, retirement villages as a housing option in later life are a relatively new development in countries such as the UK and New Zealand. However, in light of the aging population they are becoming a housing option of increasing interest to researchers, policy makers, and the community worldwide. In the experience of normal aging-related declines in health and mobility we look for avenues to aid us in maintaining independence. Retirement villages are one housing option that offers independent living in close proximity to facilities and services that may help facilitate this goal. Distinct from other forms of housing for older adults, retirement villages combine independent living with access to a range of recreational, health and care services in a community environment. Overall, current research suggests that retirement villages are an accommodation option that can enhance social networks, engagement and well-being, and provides some evidence that the supportive residential environment can buffer the impact of other lifestyle transitions for those who choose to move to a village. However, variability in the reactions of individuals to this transition suggests that retirement village life should not be regarded as a housing option suitable for all older adults. Issues of privacy and barriers to the formation of meaningful social relationships can and do exist. However, the nature of living in close proximity with other people in a setting such as a retirement village, can indirectly influence the amount of informal contact older adults have with each other. For those individuals in particular who seek alternative accommodation due to isolation or loneliness, the retirement village may be an attractive option and ultimately have a positive impact

on health, well-being and overall quality of life. While future research is required to extend our understanding in this area, it is suggested that environmental factors, social supports, and an individual's sociodemographic characteristics may explain the variability in the reactions of individuals to this transition. Further consideration of the characteristics and motives of those individuals most attracted to retirement village living is important in understanding the nature of the retirement village community and the potential future demand for this type of housing.

Aging; cognition; older adulthood; decision making; risk; risk taking; risk aversion; affect-based mechanisms; cognitive neuroscience of aging

Definition

This entry summarizes several studies that reveal the equivocal nature of the research findings on risk preferences in older adulthood, as well as explores various mechanisms put forth in the literature that have helped in our understanding as to why these discrepancies exist.

As the population of older adults continues to rapidly increase, the need to better understand dynamic age-related changes that occur in cognition has become clear. In a report put forth by the National Research Council (2006), this urgency was made evident when it recommended that the National Institute on Aging increase research support in the domains of social, personality, and lifespan psychology, with a particular emphasis on decision making. Nonetheless, there is a paucity of research investigating how decision making is characterized in older adults and how it changes with age. When it comes to financial decision making, older adults free of neurological and psychiatric illness have been shown to fall victim to fraud (Scheibe et al. 2014) and to be more susceptible to making suboptimal financial choices (e.g., suboptimal use of credit card balance transfer offers, misestimating of the value of

one's house; Agarwal et al. 2009). It goes without saying that the consequences of suboptimal decision making can be devastating at not only the individual level but at the societal level as well.

Although inconclusive, investigation of a specific type of decision making – risk – has started to reveal promising insights and future directions for the fields of psychology and gerontology. In the research domain, decision making under risk is considered to occur when choice outcomes are not certain, but the probabilities of these outcomes are known and can be confidently judged (e.g., 50% chance of winning \$100). While some studies suggest that risk taking decreases with age, other studies have indicated that risk taking increases or remains stable across the lifespan. In this entry, several studies are summarized that reveal the equivocal nature of these research findings on risk preferences among older adults. Additionally, various mechanisms put forth in the literature that have helped in our understanding as to why these discrepancies exist are discussed.

Risk Taking Decreases Throughout the Lifespan

In general, risk taking has been thought to decrease throughout adulthood. That is, when one thinks of decision making and age, a common notion is that adolescence and young adulthood is a time of impulsiveness and risk seeking, whereas as one ages, one becomes more risk-averse, with older adulthood being the pinnacle of cautious decision making and risk aversion. Although this is a pervasive societal conception, only a handful of studies have provided evidence to support this stereotype. To illustrate, in a study conducted by Deakin et al. (2004), 177 healthy participants aged 17–73 years were presented with a gambling task and their decision making preferences were assessed on five key metrics: (1) deliberation time (the time to choose red or blue box), quality of decision making (when a subject chooses a box which is associated with greater probability); (2) risk taking (the proportion of the points a subject wishes to gamble on a trial); (3) delay aversion (the degree to which a subject is willing to withhold a response); and (4) risk adjustment (the degree to

which a subject adjusts his/her risk-taking behavior depending on a ratio of red to blue boxes, e.g., when a subject bets larger amount on a red box when the probability for that choice to be a winning one is higher). Older age was found to be related to increased deliberation time, poorer quality of decision making, reduced risk adjustment, and decreased risk taking. By contrast, older age was found to be unrelated to delay aversion (Deakin et al. 2004). Moreover, a factor analysis of these five metrics led to the conclusion that two independent traits, risk tolerance and delay aversion, underlie performance in risk taking, with age being related to decreases in the risk tolerance factor, but unrelated to the delay aversion factor. Similarly, a study conducted by Lee et al. (2008) demonstrated that older adults engaged in risky behavior less often than younger adults during a task where participants were required to decide whether to take a risk in both safe and risky conditions.

In a novel experiment, Dohmen et al. (2005) administered a survey to a large representative sample of roughly 22,000 individuals with the goal of assessing ecologically valid risk preferences. In this survey, the willingness to take risk was assessed by asking individuals to rate, generally, how “willing” they were to take risks on a scale from 0 to 11, with “0” indicating completely unwilling and “11” indicating completely willing. These investigators found that decreased ratings of willingness to take risks were negatively correlated with increased age. Moreover, a field experiment carried out in a subset of the original sample showed a relationship between the participant's willingness to take risks and real-life risk-taking behavior, including driving, finances, recreational activities, career, and health. However, willingness to take risks was not correlated with performance on a risk lottery task, a common instrument used in the literature to assess risk taking, leading the authors to speculate on the real-world validity of such measures.

Risk Taking Increases or Remains Stable Across the Lifespan

Although it is a prevalent notion that older age is associated with increased conservatism and thus a

decrease in risk-taking behavior, as noted above, there is a growing body of evidence suggesting otherwise. For example, a study carried out by Lauriola and Levin (2001) found that age-related risk taking was particularly dependent on the context of the choice. When asked to make a series of choices between option pairs where no one option was advantageous or disadvantageous because their expected values (i.e., probability-weighted averages) were equal, older adults were less risk seeking than younger adults when deciding between two gains. However, when making a similar choice (i.e., options had equal expected values) between two losses, older adults were more risk seeking than younger adults. Moreover, a meta-analysis of studies examining risk preference found age-related increases in risk seeking in the domain of losses, but no age-related changes in risk taking in the domain of gains (Weber et al. 2004). Furthermore, Weller et al. (2011) reported that on a task that probed decision making under risk in both gain and loss scenarios, there were age differences in risk seeking dependent on whether the decision was in a gain or loss context. More specifically, risk taking decreased with age when the choices were between a sure gain and a larger but uncertain gain, but not when the choices were between a sure loss and a larger but uncertain loss. Interestingly, the approach used in this latter study revealed an important aspect of investigating age-related changes in risk-taking behavior: the domain aspect. A recent study utilized model-based analysis of risk attitudes across the lifespan in both gain and loss domains; conflicting findings were reported (Tymula et al. 2013). In this study, risk attitudes were modeled by taking the subjective value of each option using a power utility function, providing estimates that indicated risk neutrality as well as risk-averse and risk-seeking attitudes. In the gain domain, individuals were risk-averse, regardless of age group. Moreover, an inverted U-shape trajectory was reported in the gain domain for risk aversion across the lifespan, with adolescents and seniors being even more risk averse than young adults and midlife adults. In the loss domain, however, only older adults showed

distinct risk preferences, evidencing more risk seeking than midlife adults, younger adults, and adolescents. These findings raise an interesting question of whether differences in risk-taking behavior in older adults may be partially, or even fully, attributed to the characteristics of the task (e.g., gain and loss domain), rather than choice preference.

A meta-analysis of 29 studies was carried out by Mata et al. (2011) to investigate the discrepancies reported in the literature regarding age-related risk taking. They found that indeed age-related differences were observed in risk taking, but primarily as a function of the learning requirements of each individual task. More specifically, they found no differences in risk-taking behavior in the majority of the tasks and no clear age-related differences as a function of gain or loss framing. In this meta-analysis, the authors concluded that age-related differences in risk taking were most likely a function of decreased learning performance – older adults were more risk seeking compared to younger adults when learning led to risk-avoidant behavior; however, older adults were more risk averse when learning led to risk-seeking behavior. Together, this work suggests that changes observed across the lifespan in risk may be more so dependent on task demands and task characteristics, rather than individual risk preferences (Mata et al. 2011).

In support of this notion, learning has been shown to play a critical role in risk taking across the lifespan using a popular instrument to assess risk taking in clinical and nonclinical populations, the Balloon Analogue Risk Task (BART; Lejuez et al. 2002). Rolison et al. (2012) modeled the process by which younger and older adults make decisions on the BART. Their modeling indicated a divergence in task process early on in the task, with younger adults being more willing to take greater risks, whereas older adults seemed to be more cautious when their decision making was based on their initial perceptions of risk. However, as the task progressed and participants gained knowledge regarding the BART, the two age groups were comparable in their risky decisions.

The Role of Emotion in Decision Making Under Risk Throughout the Lifespan

Although a consensus has yet to occur on how risk taking changes across the lifespan, research investigating the various mechanisms that could be at play has helped inform our understanding as to why these discrepancies exist. Emotion is one mechanism thought to potentially account for individual differences in risk taking across the lifespan. For example, Peters et al. (2007) conducted a review on how affective and deliberative information processes alter decision making in older adults. The researchers came to the conclusion that despite the age-related decline in deliberative decision making process, older adults are able to adapt and compensate for such a decline by relying on an increased focus on emotional information processing and experience (Peters et al. 2007). Thus, the affective component of the situation may influence risky decision making. For example, if an older adult experiences positive affect during a particular situation (as opposed to a situation with negative affect), then that individual may be more willing to engage in risky behavior at that given moment. One might speculate that this affect-based mechanism in decision making may be an underlying cause of why older adults often become victims of fraud such as deceptive advertising.

Many of the differences observed due to framing of risk taking in gain and loss scenarios support this interesting notion that valence plays a critical role in value-based decision making under risk. Emotion itself is thought to change across the lifespan (Carstensen 2006), and many of the mixed findings with respect to risk taking in gain and loss domains can potentially be explained by these changes in emotion.

Neural Underpinnings

Another approach of investigating the source of age-related changes in risk-seeking behavior is aimed at understanding the neural processes that underlie decision making in older adults. A study

conducted by Lee and colleagues (2008) used functional neuroimaging to investigate whether differences in neural activity could account for their finding that older adults were less risk seeking than younger adults. Older adults, compared to their younger counterparts, demonstrated increased activation in the right prefrontal area, in particular in the orbitofrontal cortex (OFC), an area of the brain known for its involvement in complex decision making. Along with the increased activation in the OFC, older adults also demonstrated stronger activation in the right insula when a risky option was chosen over a safe option. Interestingly, increased activation in the right insula was interpreted as being related to the emotional processing of risky situations, providing further support for the theory proposed by Peters and colleagues (2007) which suggests that older adults may rely heavily on affective information processing when making decisions under risk, more so than younger adults.

In a review by Mohr et al. (2010), it was suggested that dopaminergic and serotonergic pathways play crucial roles in economic decision making, especially in the context of aging. During the course of normal aging, dopaminergic systems are thought to undergo a substantial decline. According to Mohr and colleagues, the dopaminergic system and the serotonergic system interact in value-based decision making as well as in reward-based learning. Thus, these changes are paralleled by changes in economic behavior, specifically in risk taking, delay discounting, and reward-based learning (Mohr et al. 2010). Relatedly, functional neuroimaging work by Samanez-Larkin et al. (2010) indicated that age-related suboptimal decision making on a financial risk task was associated with temporal variability in the nucleus accumbens, a region of the brain often implicated as playing a role in decision making and that is rich with dopamine receptors.

Individual Differences

Another way in which the underlying mechanisms of risk-seeking behavior have been

investigated is through individual difference variables, such as personality and sex effects. For example, Lauriola and Levin (2000) examined the relationship between the “Big Five” personality traits (neuroticism, extraversion, openness, agreeableness, conscientiousness) and risk-taking behavior in a sex- and age-stratified sample. The investigators hypothesized that extraversion would predict risk taking positively because of its relationship to the need for arousal; neuroticism would predict risk taking negatively because of its relationship to trait-anxiety; and finally, a combination of hostility, lack of conscientiousness, and openness would predict risk taking positively because a combination of these traits relates to impulsive, aggressive, and antisocial tendencies. The participants were 76 subjects (38 males and 38 females) distributed into three age groups: 21–40 ($n = 26$), 41–60 ($n = 27$), and 61–80 ($n = 23$). The results of the study demonstrated that personality factors did indeed relate to risk-taking behavior. According to the findings, neuroticism and openness predicted risk taking to achieve a gain, both when these factors were considered individually and when their combined effect was considered in conjunction with demographic variables. Participants scoring high on neuroticism and low on openness took less risk than participants scoring high on emotional stability (i.e., low neuroticism) and openness. Interestingly, neuroticism was the only personality trait predicting both risk taking for gains and for losses when controlling for age and sex (Lauriola and Levin 2001). Sex also had a significant effect on risk-taking behavior with males choosing a risky option more often than females. Interestingly, males scored significantly lower than females in neuroticism and agreeableness, which might help explain why males take more risks than females. Overall, the results of the study supported the hypothesis that

Conclusion

In summary, although research has investigated whether risk taking changes across the lifespan,

the field of geropsychology is still far from fully understanding this very nuanced process. While findings are equivocal, detail and precision in the measurements we use to assess risk is critical. Conditions such as domain (e.g., gain, loss), learning demands, and task characteristics (e.g., survey, questionnaire, lottery task) are all vital in properly informing the extent to which risk preferences shift across the adult lifespan. Moreover, a number of factors such as sex, emotion, structural and functional brain activity, and personality are also important to consider in the context of aging and risk. A continued and concentrated effort to better understand various aspects of decision making, including but not limited to risk, will only help to further inform public policy, as well as facilitate successful aging.

Synonyms

Repetitive thought; Rumination; Ruminative thinking

Definition

Rumination is a repetitive thinking style comprised of excessive, recurrent thoughts or themes of previous stressful life events, current difficulties, and anticipated future difficulties, which restricts other types of mental activity (VandenBos 2015; Papageorgiou 2006). While the term “rumination” is broad, it is considered a common cognitive response style to negative mood states, which can increase vulnerability to depression and other psychological disorders (Smith and Alloy 2009; Papageorgiou and Wells 2004). Several theories of rumination exist, each holding differing views of rumination.

Rumination is a risk factor for developing depression both in the general population and in older adults. It is associated with experiencing more frequent, more intense, and longer periods of negative mood states. In addition, rumination is more likely to occur in the context of medical and cognitive problems (Nolen-Hoeksema et al. 1993). Indeed, rumination has been shown to play a role in the development, maintenance, and recurrence of affective disorders, such as major depressive disorder, obsessive-compulsive disorder, and generalized anxiety disorder (VandenBos 2015; Lyubomirsky and Tkach 2004).

Rumination and Mood

Rumination is a general term for negative, recurrent thought processes. These thoughts involve recalling past, personal negative events associated with loss and failure that tend to restrict a person's ability to engage in other forms of mental activity (VandenBos 2015; Papageorgiou and Wells 2004). As such, rumination plays a key role in the development and maintenance of depressive and anxiety states (Smith and Alloy 2009; Papageorgiou and Wells 2004). Individuals engage in ruminative thinking often with the belief that it will give them insight into a problem (Aldao et al. 2010; Papageorgiou and Wells 2004). These recurrent negative reflections of past failures, however, create a vicious cycle of

recalling painful past events without finding a solution to the problem (Coleman 2005).

Theories of Rumination

Rumination is commonly described as a maladaptive coping strategy. Despite a rich supporting literature, there is no overarching definition or unified mechanism for measuring it (Smith and Alloy 2009; Papageorgiou and Wells 2004). Models describe rumination in terms of a cognitive thinking style, emotion-regulation mechanisms, or action tendency (i.e., a desire to act in a way that demonstrates or is connected to a specific feeling) (Smith and Alloy 2009). The problems associated with differing definitions of rumination are reflected in the existing measures of rumination (Papageorgiou and Wells 2004).

Response Styles Theory. The most widespread theory of rumination is the response styles theory, proposed by Nolen-Hoeksema (1991). Nolen-Hoeksema defines rumination as a repetitive, passive, symptom-focused thinking style which occurs in response to depressive symptoms and the possible causes and consequences of one's symptoms (Nolen-Hoeksema 1991). Rumination is a pattern of thoughts and behaviors that focus attention on emotions and in the process hinders attempts at distraction from the negative mood (Nolen-Hoeksema 1991). This passive response style typically does not lead to active problem-solving and serves to prolong and exacerbate depressive symptoms (Nolen-Hoeksema 2004). Further, there are four mechanisms within response styles theory in which rumination serves to worsen depression (Nolen-Hoeksema 2004). First, rumination exacerbates depressed mood making it easier to recall negative memories and thoughts. These memories and thoughts are triggered by depressed mood and then are used to interpret an individual's current circumstances, creating a cycle of negative thoughts and moods (Nolen-Hoeksema 2004). Second, problem-solving is compromised due to fatalistic and pessimistic thinking (Nolen-Hoeksema 2004). Pessimistic thinking can create negative biasing in

processing information, which can further exacerbate depressive symptoms (Nolen-Hoeksema 1991). Third, rumination interferes with active goal-oriented behavior. As a result, individuals who engage in ruminative thinking are less likely to actively problem solve and generate solutions to life problems and stressors (Nolen-Hoeksema 1991, 2004). Fourth, chronic rumination leads to reduced social support, which then reinforces and maintains depressive symptoms (Nolen-Hoeksema 2004).

Goal Progress Theory. Goal progress theory (GPT) views rumination as a reaction to the failure to successfully advance toward a desired goal (Smith and Alloy 2009). Research has shown that while depression and rumination are both precipitated by experiences of failure, ruminative coping remains stable regardless of whether actual or perceived failure experiences are present (Smith and Alloy 2009). Measures of rumination from GPT target several factors of rumination including cognitions (e.g., an employee obsesses over a negative comment made by employer), metacognitions (i.e., self-awareness of thought process), and personal motivation behind the tendency to ruminate which includes both cognitive and behavioral components (Smith and Alloy 2009).

Self-Regulatory Executive Function Theory. Self-regulatory executive function theory (S-REF) is an information processing model. In this model, rumination is viewed as an affective coping strategy, where negative beliefs serve to predispose individuals to engage in ruminative thinking, leading to a variety of emotional disorders (Martin et al. 2004). S-REF targets a person's beliefs about emotions and cognitions, which functions to perpetuate a cycle of worry and inhibits an individuals' ability to search for alternative coping styles and cognitive restructuring (Martin et al. 2004). Within S-REF, rumination can be described as a method of cognitive-emotion regulation in which a person works to cope with a self-discrepancy between meeting personal goals and the obstacles preventing them from meeting those goals (Martin et al. 2004). Since a discrepancy exists between a desired goal and one's current situation, an individual then engages in processing information related to

why and how this discrepancy exists without focusing on goal-oriented action to solve the problem (Martin et al. 2004).

Distinguishing Rumination from Related Constructs

Worry. Depression and anxiety are the most common mental health problems seen in older adults, and worry is a commonly reported symptom in both depression and anxiety (Rewston et al. 2007). Worry can be pathological or non-pathological, with pathological worry being described as uncontrollable and excessive (Rewston et al. 2007). Rumination is hypothesized to be closely related to worry, with rumination and worry sharing the distinct characteristics of being intrusive, uncontrollable, and distressing (Luminet 2004). However, there are also distinct differences between worry and rumination. The most common distinction is the content of the worried or ruminative thoughts. Worry can be characterized by themes of anticipated threat or danger in the future; rumination, however, can be characterized by themes of past personal loss or failure (Papageorgiou and Wells 2004). Compared to rumination, worry has been associated with a higher compulsion to engage in worried thinking and greater confidence in problem-solving ability, as worry has been found to be more controllable. Further, worry has been associated with more active attempts at engaging in problem-solving (Papageorgiou and Wells 2004). Distinguishing between worry and rumination is important for planning targeted treatment interventions.

Negative Automatic Thoughts. Rumination and negative automatic thoughts are also common in depression. According to Beck's content specificity hypothesis, negative automatic thoughts are distinguished from rumination. Negative automatic thoughts stem from a negative view of one's self, others, and one's future (Purdon 2004). Within the content specificity hypothesis for depression, thoughts center on previous personal failure and loss (Papageorgiou and Wells 2004). According to cognitive theory, automatic thoughts occur in multiple, "diverse" situations and arise

from beliefs about how the world operates (Papageorgiou and Wells 2004). However, negative automatic thoughts are thought to be relatively fleeting appraisals, whereas rumination consists of longer series of negative, self-focused, repetitive thoughts (Papageorgiou and Wells 2004).

Consequences of Rumination

The consequences of rumination are variable and can either serve to be maladaptive, perpetuating negative mood, or adaptive, fostering recovery from negative events (Watkins 2004). As a maladaptive coping style, ruminating about oneself and one's negative symptoms has deleterious effects on mood. It negatively biases thinking patterns and distorts how hypothetical life events are interpreted (e.g., minimizing successes and overgeneralizing failures). Rumination can also impair problem-solving, inhibit initiative and motivation, interfere with concentration and cognition, and increase stress (Lyubomirsky and Tkach 2004). Physical and social well-being, physical health, social relationships, and emotional adjustment can also be negatively impacted (Lyubomirsky and Tkach 2004). An individual may believe that engaging in rumination allows them to be realistic about their problems and that recurrently thinking about their problems allows them to face their problems directly (Nolen-Hoeksema 2004). In this view, engaging in rumination may be seen as an attempt to problem-solve or a mistaken belief that rumination will somehow help prevent future failures and mistakes (Nolen-Hoeksema 2004). However, research suggests that rumination tends to have a negative rather than a positive impact on well-being (Lyubomirsky and Tkach 2004). Additionally, once a person engages in rumination, it may be difficult to withdraw from this maladaptive coping mechanism. In short, negative cognitive coping styles tend to increase the likelihood of making maladaptive inferences when faced with stressful situations and leave individuals more vulnerable to developing depression (Lyubomirsky and Tkach 2004).

Depression and Rumination in Older Adults

While depression is less common in older adults than younger adults, prevalence rates for depression in community-dwelling older adults are approximately 2–5% (Fiske et al. 2009; Edelstein et al. 2008). Further, the rates of depressive symptoms and subsyndromal depression in older adults range from 8% to 37% (Edelstein et al. 2008). Similar to younger adults, rates of depression are higher in older women than in older men. Depression in the older adult population is a serious health concern, as it can lead to an increased risk of morbidity and suicide, a decrease in physical, cognitive, and social functioning, and greater self-neglect (Fiske et al. 2009).

As compared to adolescents and younger adults, older adults experience fewer negative life events (Kraaij et al. 2002). However, older adults do experience more loss, such as declining health, the loss of the work role, and the loss of family and friends (Kraaij et al. 2002). Older adults who have experienced negative events such as the loss of loved ones, chronic medical problems, abuse, or relational problems have been found to experience more symptoms of depression than older adults who do not experience these negative life events (Kraaij et al. 2002). While the presence and number of negative life events is strongly associated with rates of late-life depression and depressive symptoms, not all older adults who have experienced negative life events develop depression or depressive symptoms (Kraaij et al. 2002). Whether an older adult who experiences a negative life event develops depression or depression symptoms may be related, in part, on his or her cognitive coping strategies. Certain cognitive coping strategies have been shown to be more or less effective in managing thoughts and emotions associated with negative life events. Understanding these coping strategies and determining which coping strategy is being employed by an individual can help guide treatment. There are a number of cognitive coping strategies used to manage the intake of emotionally arousing information and the resulting thoughts and emotions (Kraaij et al. 2002).

Common coping strategies include self-blame, acceptance, rumination, positive refocusing, focusing on planning, positive reappraisal, putting into perspective, catastrophizing, and other-blame (Kraaij et al. 2002).

As discussed previously, rumination has been defined as repetitive thoughts and the process of thinking attentively, repetitively, or frequently about the self and world (Sütterlin et al. 2012). Depressive rumination often involves repetitively focusing on one's own depression, on depressive symptoms, and on the causes, meanings, and consequences of one's depression (Nolen-Hoeksema 1991). Individuals who engage in rumination tend to fixate on their problems and feelings, often without taking any action (Sütterlin et al. 2012). Rumination has been shown to interfere with decision-making. Individuals who ruminate tend to be ineffective in active, interpersonal problem-solving (Sütterlin et al. 2012). Rumination has also been highly associated with brooding, which has been defined as passive and self-critical thoughts comparing an individual's current situation, thoughts, and mood against a desired goal or standard (Sütterlin et al. 2012). Rumination has consistently been found to be a risk factor for psychopathology, and rumination and brooding are associated with a greater frequency and severity of depressive symptoms (Aldao et al. 2010; Sütterlin et al. 2012). Depressive rumination is seen as a particularly unconstructive, maladaptive, and distressing cognitive coping strategy (Sütterlin et al. 2012).

One theory as to why older adults experience less depression is that older adults are more apt than younger adults at emotion regulation (Nolen-Hoeksema and Aldao 2011). Research has shown that ruminative thinking tends to decline with age, and older adults show low levels of ruminative thinking (Sütterlin et al. 2012; Nolen-Hoeksema and Aldao 2011). This could be due, in part, to better emotion regulation in older adults or that older adults are better at avoiding situations that would make them ruminate (Nolen-Hoeksema and Aldao 2011). However, for older adults who engage in rumination, depression severity may be worse and episodes of depression may be longer and

more frequent, putting them at an increased risk for medical and cognitive problems.

As noted earlier, older women have higher rates of depression than older men. Women appear to use a wider range of cognitive coping strategies than men; while they use more adaptive strategies than men, they also engage in more maladaptive strategies than men (Nolen-Hoeksema and Aldao 2011). Women use maladaptive strategies more often than men, which may put women at an increased risk for depressive symptoms (Nolen-Hoeksema and Aldao 2011). Research has shown that higher levels of rumination in women compared to men may account for some of the gender differences in depression rates (Sütterlin et al. 2012).

Measuring Rumination

Assessing for the presence and severity of rumination in depressed older adults can have important treatment implications. Many of the measures currently used to assess for rumination are self-report scales (Luminet 2004). While self-report measures are relatively easy and quick to administer and score, self-report measures are not without their flaws. Self-report measures may not accurately measure the frequency and content of mental processes (Luminet 2004). They may require higher levels of insight or metacognition than the individual taking the measure is capable of, and the measure could be influenced by overly positive or negative moods or self-presentation biases (Aldao et al. 2010). Further, it can be problematic when using self-report measures with older adults, as many of the measures are initially developed for use with younger adults; normative data may not exist for older adults. Caution must be taken when using the following self-report measures with older individuals.

The Response Style Questionnaire. The Response Style Questionnaire (RSQ) is based on Nolen-Hoeksema's response styles theory, which states that when individuals are in distress, they respond to their moods in several different ways, including ruminating about their distress (Luminet 2004). The original RSQ is a 71-item

self-report measure that assesses four different reactions to negative mood: ruminating, distracting, problem-solving, and engaging in dangerous activities (Luminet 2004). The problem-solving and dangerous activities scales were later dropped due to very low reliability (Luminet 2004). The full RSQ is now comprised of the Ruminative Responses Scale (RRS) and the Distracting Responses Scale (DRS). The RSQ has shown good reliability and validity.

The Ruminative Response Scale. The Ruminative Responses Scale (RRS) is one of the two scales from the updated RSQ. The RRS can be given as a stand-alone measure of ruminative thinking. It is a 22-item scale with items focusing on the meaning of rumination, the feelings related to one's depressed mood, specific symptoms, and on the consequences and causes of the depressed mood (Luminet 2004). The scale has shown high internal reliability as well as good convergent and discriminant validity. The RRS has also shown good predictive validity for depression. There is a 10-item short version of the RRS, which has been found to be highly correlated with the original RRS and has demonstrated high internal reliability. Nevertheless, more research is needed to establish construct validity and test-retest reliability for the short version (Luminet 2004).

Rumination on Sadness Scale. The Rumination on Sadness Scale (RSS) is a 13-item self-report questionnaire that assesses an individual's repetitive thoughts about current distress and the circumstances surrounding the distress or sadness (Luminet 2004). The scale also assesses the intensity and repetitive quality of one's ruminative thoughts. It has been found to have high internal consistency and high concurrent validity with the RRS (Luminet 2004). The scale has adequate test-retest reliability (Luminet 2004).

Treatment of Depression

There are a number of evidence-based psychotherapies that can be used to treat depression in older adults. Common treatment interventions include behavioral activation/behavioral therapy, cognitive behavioral therapy, cognitive

bibliotherapy, problem-solving therapy, brief psychodynamic therapy, and life review therapy (Fiske et al. 2009). Mindfulness-based approaches can also be effective, especially for individuals who engage in depressive rumination, as these approaches teach awareness and acceptance of thoughts and emotions instead of avoiding or ruminating on the thoughts or emotions (Fiske et al. 2009). Psychotherapeutic approaches that incorporate cognitive and problem-solving interventions can be especially beneficial for depressive rumination.

Treatment of Rumination

Treatment of rumination can be difficult, largely in part to the lack of understanding about rumination, the factors that sustain ruminative thinking, and the potential factors or interventions that could halt ruminative thinking (Purdon 2004). Nonetheless, there are a handful of evidence-based therapies, which have been shown to be effective in treating older adults that show potential in treating depressive rumination.

Cognitive Behavioral Therapy. Cognitive behavioral therapy, which addresses negative automatic thoughts about one's self, the world, and the future, is one of the most well-established and effective psychotherapies for depression. Yet traditional cognitive behavioral therapy protocols do not specifically address depressive rumination (Purdon 2004). As depressive rumination can exacerbate depression and prime negative automatic thoughts, it is important to address depressive rumination in treatment (Purdon 2004). It is important to assess for rumination and the content of the ruminative thoughts, which can be done by using a rumination self-report measure. Cognitive restructuring around the ruminative thoughts may be an effective way of ending rumination (Purdon 2004). Further, as depressive rumination is often used as a coping strategy, teaching the individual new, more adaptive coping strategies could also be an effective method of treating rumination (Purdon 2004).

Mindfulness-Based Cognitive Therapy. Mindfulness-based cognitive therapy (MBCT) is

based on Teasdale's differential activation hypothesis and interactive cognitive subsystems model (Purdon 2004). The model proposes that individuals who experience a depressive episode create numerous associations between their depressed moods and their patterns of negative thoughts, which leaves them vulnerable to another depressive episode because a small decrease in their mood activates negative thought patterns, which can exacerbate mood symptoms (Purdon 2004). MBCT teaches individuals to identify negative moods and thoughts and respond to the mood and thoughts in a way that ends "ruminative depressive processing" (Purdon 2004). Unlike traditional cognitive therapy, negative thoughts are not challenged; instead individuals are taught to be aware of and disengage from the negative thoughts. MBCT is one of the first therapeutic interventions to target depressive rumination, and preliminary evidence has shown that MBCT is an effective treatment.

Conclusion

Rumination is the act of thinking attentively, repetitively, or frequently about one's self and world. More specifically, depressive rumination is repetitive focusing on one's depression, on depressive symptoms, and on the causes, meanings, and consequences. Depressive ruminative thinking can be especially dangerous for older adults, as it leaves them susceptible to longer, more frequent, and more severe episodes of depression, which in turn can leave them more vulnerable to chronic physical, cognitive, and social difficulties and can lead to an increased risk for mortality. Assessment of rumination in older adults is important when planning targeted treatments. While this section reviewed common measures for rumination, caution is suggested when using these measures with older adults, as normative data for these measures with this population is scarce. Rumination can be difficult to treat; however, evidence-based practices, such as cognitive behavioral therapy and mindfulness-based cognitive therapy, have shown some promise at relieving the distressing nature of depressive ruminative thinking.

Defining Rural

Definitions of rurality differ across nations, governmental agencies, and levels of analysis. The United Nations (UN) indicates that “countries must establish their own definitions in accordance with their own needs” (source: <http://unstats.un.org/unsd/demographic/sconcerns/densurb/densurbmethods.htm>). The Organisation for Economic Co-operation and Development (OECD) regional typology classifies rurality based on the population density per square kilometer (source: http://www.oecd.org/gov/regional-policy/OECD_regional_typology_Nov2012.pdf), while the US Federal Office of Rural Health Policy defines counties outside of urban or metropolitan areas (classified as non-metropolitan counties) as rural, with lower levels of geography (e.g., US census tracts) also used to identify differing classifications of rurality within county units (source: <http://www.hrsa.gov/ruralhealth/aboutus/definition.html>). Further, the US Census Bureau defines urban spaces based on population density relative to urbanized areas or urban clusters (source: <https://www.census.gov/geo/reference/urban-rural.html>). Several geospatial identifiers also exist in the USA (e.g., FIPS county code, ZIP code, census tract) that can be used to merge datasets with multiple rural classifications (e.g., Rural-Urban Commuting Area Codes or RUCA available at <http://www.ers.usda.gov/data-products/rural-urban-commuting-area-codes.aspx>; Urban Influence Codes or UIC available at <http://www.ers.usda.gov/data-products/urban-influence-codes.aspx>; Rural-Urban Continuum Codes or RUCC available at <http://www.ers.usda.gov/data-products/rural-urban-continuum-codes.aspx>).

Introduction

In 2010, there were 524 million individuals aged 65 and older, also referred to as older adults, representing 8% of the global population (2011). By 2050, this number is expected to rise to nearly 1.5 billion, representing 16% of the global population (2011). Thus, global focus on issues facing older adults is needed now and in the future in order to better understand and ameliorate issues

negatively impacting quality of life, especially mental health-related issues. Older people in rural communities often face different health issues relative to their urban counterparts and in addition may be disadvantaged by poorer access to services due to remoteness or minority status. Instead of providing a comprehensive collection of *all* health and health-related issues affecting these individuals globally, this chapter will highlight some of the major health-related issues facing older adults in rural areas. These include, but are not limited to, mental health or substance use (MHSU) disorder, depression-related disorders, anxiety disorders, health-related quality of life (e.g., related to chronic disease), and overall quality of life.

This chapter pulls information from multiple countries globally; however, key information is taken from United States (US) studies given the USA may hold insights for rapidly developing nations with increasing aging populations. Some developing nations may soon experience epidemiological transitions, where the prevalence of chronic conditions increases with the number of individuals growing to older age and living longer. In addition, there are higher concentrations of indigenous populations in some rural areas throughout the globe, who may face disparities in mental health-related issues. Thus, examples of some of the issues facing these populations are included.

In the USA alone, there were 47.8 million persons, 14.9% of the population, that were aged 65 or older in 2015. By 2030, this population is anticipated to increase to 74.1 million, 20.6% of all US residents (Bureau 2014). Rurality is an aging issue in the USA as the proportion of the population that is 65 years or older increases with rurality from 11.5% in large metropolitan counties to 15.4% in large rural counties, and 17.2% in smaller rural counties (2011 data) (Meit et al. 2014). Given the sharp rise in aging populations globally, and in the USA, identifying strategies that enable older adults to age in place healthfully while maintaining or achieving a high quality of life is essential and timely. Of special need is a better understanding of factors that are associated with improvements in both physical and emotional health.

Salient Issues for Older Adults Impacting Mental Health or Substance Abuse

Globally, rural older adults face multiple challenges that affect their mental health status and the likelihood that they will obtain effective treatment. In this chapter, we highlight some of these challenges including an increased risk for chronic disease, declining health, and death of significant others, each associated with risk for MHSU problems, barriers to receipt of care ranging from stigma to difficulty of travel, and shortages of MHSU professionals in rural communities.

Limited research is available for mental health-related issues solely in rural areas globally. Thus, we provide global examples of issues facing both rural and urban areas here. The World Health Organization's World Mental Health Surveys were conducted in 14 countries across the Americas (Columbia, Mexico, the USA), Europe (Belgium, France, Germany, Italy, the Netherlands, Spain, Ukraine), the Middle East and Africa (Lebanon, Nigeria), and Asia (Japan, PR China – Beijing, Shanghai). Findings from these surveys suggest that anxiety disorders were most common in general, followed by mood disorders, and substance disorders (Demyttenaere et al. 2004). Further, the rate of individuals reporting they “received health care treatment for emotional or substance-use problems during the 12 months” prior was higher in developed countries (highest at 15.3% for the USA) versus developing countries (lowest at 0.8% for Nigeria) (Demyttenaere et al. 2004, pp. 2585–2586). In addition, the severity of illness was related to the receipt of treatment, where those with greater severity have a greater likelihood of reporting treatment (Demyttenaere et al. 2004). The authors suggested that uncertainties exist with regard to the relationship between perceived versus actual need (Demyttenaere et al. 2004). Thus, identifying barriers to and facilitators to treatment for emotional or substance-use problems in both mild and severe cases is a critical need.

The US Institute of Medicine estimates that between 2.6 and 4.0 million older adults, or approximately 6.4–10.0% of the US population aged 65 and older, had an MHSU disorder in 2010

(Eden et al. 2012). When institutionalized persons and symptoms associated with dementia are added, the estimate increases to 5.6–8.0 million persons, or an upper estimate of 20% (Eden et al. 2012). The IOM anticipates this number to increase within the aging population and be seen through cohort effects, principally attributed to greater drug use among the “baby boomer” generation (Eden et al. 2012, p. 77). While limited research is available exploring rural-urban differences in MHSU problems among older adults, some underlying conditions may suggest a greater prevalence in rural populations as related to poorer health status and the greater likelihood of adverse health changes rather than rural residence alone (Probst et al. 2006). Further, effective care is further impeded by policies that place MHSU services in a different, and lesser, category than physical illness for insurance reimbursement.

The Challenges of Age: Chronic Disease, Declining Health, and Loss

Older adults may be likely to suffer from a variety of psychosocial issues related to chronic conditions, thereby negatively affecting their health-related quality of life. Thus, these issues may be either causing or caused by the chronic condition. The prevalence of chronic disease and illness increases with increasing age and has been shown to be more prevalent in rural areas. In the USA, roughly 90% of older adults suffer from at least one chronic disease, while three quarters suffer from at least two chronic diseases (Anderson 2012). Comorbidities with physical chronic illness can affect the mental health of older adults, with depression-related symptoms serving as precursors to other serious mental health issues such as dementia (Karel et al. 2012). In addition, with the increasing number of comorbid conditions comes the potential to have greater complexity in the management of chronic disease (e.g., medication management, failure to adhere to complex medical regimens), which may further complicate or contribute to mental health issues. Furthermore, older adults have shown to be disproportionately underserved in mental health care (Sanders et al. 2008). Thus, these individuals are a particularly vulnerable

population in need of timely and accessible health-related care, which may be less available or accessible in rural settings.

Older adults experiencing mental health problems may have fewer social support systems and weaker informal networks to connect them to mental health services (Choi and Gonzalez 2005). This lack of social supports can be an additional burden to persons experiencing physical disability or chronic impairment, because they may be less able to effectively reach a mental health facility (Choi and Gonzalez 2005). In addition, rural older adults may live far from their family which can cause increased feelings of social isolation and loneliness, leading to adverse effects on well-being and mental health (Sanders et al. 2008).

Special Problems of Indigenous Populations

Globally, there are over 370 million indigenous individuals also known as native or aboriginal peoples (World Health Organization 2007). They are represented in over 70 countries worldwide (World Health Organization 2007). It is outside the scope of this chapter to identify issues affecting all indigenous populations. Thus, select examples are incorporated here to introduce the topic.

In the USA, American Indian/Alaska Native (AI/AN) populations are most concentrated in highly rural states; Alaska, Oklahoma, New Mexico, South Dakota, and Montana have the highest concentration of AI/AN residents, often living in tribal reservations. A history of displacement, discrimination, and poverty has led to increased prevalence of physical and mental disorders. Post-traumatic stress disorder (PTSD) and depression-related disorders (i.e., alcohol dependence) in addition to poverty are more prevalent among American Indian population groups than the general US population (Beals et al. 2005).

Problems faced by indigenous populations are not unique in the USA. Paralleling the USA, Canadian indigenous peoples experience higher rates of heavy alcohol consumption than their nonindigenous counterparts (Canada 2014). In Australia, indigenous adults experienced higher rates of psychological distress than their nonindigenous counterparts (Jorm et al. 2012).

As stated previously, the prevalence of chronic disease and comorbidities is already high among older adults (Anderson 2012). Therefore, there is a combination of multiple health disparities among indigenous populations with the already high prevalence of chronic disease with increasing age. The combination of mental health issues and chronic disease is likely to further negatively influence one's quality of life. What's more, the additional burden experienced among potentially vulnerable individuals in traditionally low-resource settings is another potential complication for these older individuals. It is therefore timely and critical to understand factors associated with potential solutions to health disparities among these individuals that extends beyond national boundaries. Thus, there is a global need to focus health interventions and policy efforts with the goal of eliminating or ameliorating health disparities among indigenous populations. More attention by policy makers and more targeted research will be needed to identify how to increase access to care and eliminate health disparities among these diverse populations. Identifying social determinants of health within these populations and identifying ways in which to ameliorate these issues will be needed both for indigenous and rural-residing individuals in general.

Barriers to MHSU Care for Rural Elders

Lack of Practitioners and Access to Care

One of the most significant issues facing rural areas is low accessibility of mental health services. Globally, rural areas face gaps in access to both mental and general health-care services (Strasser 2003). This gap in the availability, coupled with the higher likelihood of poorer health status among many rural individuals, places emphasis on both the current and future needs of rural individuals (Strasser 2003). Identifying ways to ameliorate these and similar disparities is in critical need. Identifying health professional shortage areas (including mental health professional shortage areas) or medically underserved areas will help to provide targets for potential interventions where they are most needed.

Services addressing the mental well-being of individuals are necessary for their overall health, yet are not easily accessible in rural populations. Rural communities are faced with greater disparities in mental health overall when compared to urban communities, with growing populations at risk for issues such as mental illness, substance abuse, and suicide (Rural and Center 2013). Individuals in rural communities may also face stressors such as isolation and political or social exclusion, which increases their susceptibility to poor mental health (Coyle and Dugan 2012).

Inadequate knowledge and awareness about mental health-care treatment and services on the part of the practitioner can affect the appropriate receipt of mental health care for older rural adults (Sanders et al. 2008). For example, mental health professionals, such as psychiatrists or psychologists, may not be appropriately trained in geropsychiatry, even if they see a large number of older adults in their everyday practice (Sanders et al. 2008; Choi and Gonzalez 2005). Thus, this population may not receive specialized treatment that would be most beneficial to their mental health and quality of life.

Transportation

Rural older adults may face barriers (e.g., transportation, limited supply of providers, low quality of care, social isolation, and economic issues) in accessing health care in rural areas (Goins et al. 2005). These barriers reduce the likelihood individuals will be able to seek care when needed. Thus, rural older adults are a particularly vulnerable population that should be targeted for interventions at the community and policy level to improve or reduce these barriers.

Stigma

Stigmas, or potentially negative views held by society or groups of individuals regarding seeking care for mental health issues, are another important concern. Individuals who feel self-stigma, or the internalization of public stigma, may be less likely to seek help for mental health problems, as they may have feelings of worthlessness or self-blame regarding their mental health status and behaviors (Stewart et al. 2015). This can affect

their attitudes and beliefs about mental health and affect behavior resulting in help avoided until an emergent crisis occurs, rather than early on when severe mental health problems can be prevented (Stewart et al. 2015). Rural residents in particular are more susceptible to higher stigma than those living in urban areas because they may live alone, with less access to resources, and in more socially isolated conditions (Stewart et al. 2015). Thus, there is an ever-pressing need to identify potential solutions to these and other issues facing these individuals.

Potential Solutions

Serving Older Adults with MHSU Needs

Evidence-based health and wellness programs delivered in community settings can reach individuals where they live. It is also important to have clinical interventions to ensure they are reached in any place they go in their community (and that there are adequate referral systems in place). Several evidence-based programs have been shown to be effective at improving individuals' health and quality of life (Towne et al. 2015; Ory and Smith 2015). Examples of these programs include, but are not limited to, the Chronic Disease Self-Management Program (CDSMP), A Matter of Balance (AMOB), and EnhanceFitness (Towne et al. 2015; Ory and Smith 2015). These programs have been able to successfully reach some individuals in rural areas, yet more must be done to increase this reach (Towne et al. 2015; Ory and Smith 2015). For example, AMOB focuses on reducing the fear of falling and improving self-efficacy in preventing falls among community-dwelling adults, while CDSMP and other chronic disease self-management education programs help individuals to better manage their chronic conditions (Towne et al. 2015; Ory and Smith 2015). These resources hold great potential for improving the quality of life and well-being among older adults, given high rates of falls and even higher rates of chronic disease, comorbidities, and complications associated with chronic disease in these populations (Ory and Smith 2015). These

programs may be even more effective for those with depression or with poor health-related quality of life, given the ability to improve several interrelated issues including chronic disease self-management, injury prevention, physical activity promotion, and social engagement. Implementing and sustaining such programs provide a critical resource for community-dwelling older adults. In addition, providing access to multiple evidence-based services for a variety of purposes, including chronic disease self-management education (e.g., CDSMP), falls prevention (e.g., AMOB), and physical activity promotion (e.g., EnhanceFitness), may provide additional benefits for the growing population with multiple chronic diseases and other varied health-related issues (Ory and Smith 2015).

Other community-based solutions may also be successful. In particular, the integration and/or colocation of both behavior and primary care services may be appropriate given limited resources in some rural settings. This has been suggested as one way to work toward providing better quality, better outcomes, and lower cost (Miller et al. 2014). Increasing access to telehealth may also increase access to high-quality care in rural settings. Further, increasing access to home health-care services may enable individuals to receive needed care in their homes and may potentially reduce utilization of more costly care in clinical settings where appropriate. In line with this, ensuring nonemergency medical transportation or other voluntary safe ride programs are accessible to those in need may benefit those in isolated areas and/or those without access to transportation.

Training Clinicians in Rural Areas

Training mental health clinicians is another area with great potential for improvement. Rural providers may have limited access to training or continuing education opportunities (Adler et al. 2013), thus holding potential implications for the quality of care provided by individuals with less access to effective training. Providing training for clinicians via teleconferencing platforms has been shown to be met with satisfaction among clinicians (Adler et al. 2013). Thus, the opportunity for technology connecting

individuals across space, as seen with telehealth, may hold implications to increase connectivity (e.g., communicating remotely using technology) for providers in terms of training. More will be needed to explore this and similar efforts further.

Policy

Policies affecting health and well-being for millions of older adults are varied. In the USA, the Mental Health Parity and Addiction Equity Act (MHPAEA) of 2008 was a first step at increasing access to MHSU services among older adults. In one of its provisions, Medicare co-payments for MH care were reduced from 50% in 2010 to 20% in 2015. However, the MHPAEA did not require insurers, including those who provide Medicare supplement plans, to provide MH services.

The Affordable Care Act (2010) classified mental health services as an essential benefit. This emphasis may focus greater attention on the needs of individuals with mental health-related issues. Similarly, the expansion of public health-care insurance (i.e., Medicaid) to additional low-income persons through the Affordable Care Act may improve access to care for individuals with chronic mental and physical health issues (Mechanic 2014). However, Medicaid expansion, and the Federal subsidies for low-income individuals that were tied to such expansion, was determined to be a prerogative of individual states. In 2015, the majority of rural uninsured persons lived in states that had not approved Medicaid expansion (Anthony 2014). More research will be needed to evaluate the lasting effects of these policy changes on the availability of care for older adults in rural settings.

Exploring policies in developing nations that have been successful at increasing access to appropriate care for rural older adults will also be needed. The rural cooperative medical scheme (RCMS) in China is just one example of a developing nation attempting to use policy to affect greater equity in accessing needed care. More research into this and other similar policies around the globe will be needed to identify the best policy solutions and most effective strategies to increase access to timely and appropriate health-related care in rural settings.

Conclusion

Individuals in rural areas face several barriers in accessing both mental health services and other forms of health care. Rural older adults are a particularly vulnerable group, given anticipated rates of physical decline and related mental health issues. Identifying treatment gaps facing these populations and devising potential solutions is both timely and critical given the rapidly increasing older adult population in developed and developing nations.

Potential solutions include identifying ways to minimize the stigma associated with accessing mental health services. In addition, increasing the availability of both mental health-care services and other more general health-care services where individuals live is another critical step in reducing barriers to seeking care. Grouping such services in the same location may be one way of increasing access. Improving the delivery of multiple evidence-based and community-based health and wellness programs targeted to the unique needs of older adults may improve individuals' ability to manage their health and delay the onset of complications associated with chronic disease. In addition, exploring factors related to the built, natural, and social environments of rural communities will be needed to gain a fuller picture of barriers and facilitators to increased quality of life. Finally, identifying policies that can bridge the gap between those in need of these services and health-care professionals is essential. These and other solutions will be needed to respond to the increasing needs of rural older adults throughout the global community.

Synonyms

Psychosis

Definition

Schizophrenia and Other Psychotic Disorders: Psychiatric disorders involving poor understanding or breakdown of reality due to delusions and/or hallucinations.

Introduction

Schizophrenia and other psychotic disorders are commonly characterized by positive symptoms (i.e., delusions and hallucinations) and less so by negative symptoms (i.e., flat affect, anhedonia, and poverty of speech). These disorders are believed to be one of the most severe types of mental illness with significant health-care and economic burdens around the world. In particular, schizophrenia has been labeled as the eighth

leading cause of disability in the world (Lopez and Murray 1998). In addition, the annual total costs (including health care, unemployment, and disability needs) associated with schizophrenia in the United States has been estimated to be more than \$62 billion (Wu et al. 2005).

Psychotic symptom severity does not necessarily worsen with age in late-life schizophrenic and psychotic disorders. In fact, there is evidence from several review articles of longitudinal studies that psychotic severity, especially positive symptoms, improves in old age compared with younger age (Berry and Barrowclough 2009). For instance, Cohen found that older patients with schizophrenia have a lower rate of auditory hallucinations compared to younger patients with schizophrenia (Cohen 1995). Moreover, Jeste reported that aging was related to a decrease in psychopathology, even after controlling for chronicity (Jeste et al. 2003).

This encyclopedia entry covers schizophrenia and psychotic disorders in aging and will describe clinical and treatment information and issues that are specific to older adults with these serious mental illnesses.

Prevalence

There is some evidence that the prevalence of schizophrenia and psychotic disorders is lower in older adult populations versus younger adults. In the United States, the National Institute of

Mental Health reported that the 12-month prevalence rate of schizophrenia only is 1.1% for the adult age population (National Institute of Mental Health 2011). In comparison, Meesters and colleagues reported that the prevalence of all psychotic disorders in persons aged 60 years and older was 0.71%, specifically 0.55% for schizophrenia, 0.14% for schizoaffective disorder, and 0.03% for delusional disorder (Meesters et al. 2012). In another study of 894 older adults aged 70–82 years, they found that the 1-year prevalence of any psychotic symptoms is 0.9% for those aged 70 years and 1.2% among those aged 78–82 years (Sigström et al. 2009). Notably, these rates are higher in the latter study because they measured psychotic symptoms rather than a clinical diagnosis of schizophrenia.

Late Onset of Schizophrenia

Although it has been estimated that about 85% of older patients were diagnosed before the age of 45 years, there is significant attention and research that focus on late-onset schizophrenia (Cohen 1995; Jeste et al. 2003). Howard et al. wrote a summary about late-onset schizophrenia based on a literature review of related research studies and a meeting by members of the International Late-Onset Schizophrenia Group (Howard et al. 2000). The group reported that about 15% of individuals with schizophrenia have their first psychotic episode after age 40. In late onset, the prevalence is higher in women than in men. They also concluded that symptoms, especially positive symptoms, were similar in early onset (before age 40) versus late onset. But when compared to very late onset (onset after age 60), there was evidence that the very late-onset groups had higher rates of visual hallucinations and lower rates of thought disorder and affective blunting.

The International Late-Onset Schizophrenia Group also concluded that late-onset schizophrenia has somewhat better prognosis compared to early onset (Howard et al. 2000). For instance, persons with late-onset schizophrenia compared to early-onset schizophrenia had less impaired occupational and psychosocial functioning.

They also had better premorbid educational functioning. Nevertheless, late-onset individuals with schizophrenia also often seem to have premorbid schizoid or paranoid personality traits. Cognitively, they have poorer performance in some measures of learning, motor skills, verbal ability, and executive functioning. For the very late-onset patients (onset after 60 years old), the cognitive impairments are more global but not to the same degree as patients with dementia as learning capacity is still not impaired (Howard et al. 2000).

The International Late-Onset Schizophrenia Group also agreed that those with late onset require lower dose amounts of antipsychotics compared to patients with early-onset illness (Howard et al. 2000). Specifically, they concluded that late-onset patients will respond to dose amounts that are about 25–50% of the usual dose for early-onset patients. For the very late-onset patients, they may effectively respond to dosage amounts as low as 10% of the usual dose for early-onset patients (Howard et al. 2000).

Psychotic Disorders Due To Other Conditions: Dementia

In older adults, psychotic problems can occur secondarily to other conditions such as dementia, now called neurocognitive disorders in the *Diagnostic and Statistical Manual of Mental Disorders 5th Edition* (American Psychiatric Association 2013). In a review of 55 studies by Ropacki and Jeste, they found that psychotic symptoms were reported in 41% of patients with Alzheimer's disease (AD; mean age = 75, range = 68.8–84.6) (Ropacki and Jeste 2005). Specially, 36% of the AD patients experienced delusions and 18% experienced hallucinations. Delusions are more prevalent in the moderate stages (compared to mild stages) of dementia, suggesting that a certain level of neurophysiological functioning and neuroanatomical presence is needed to have delusions. They found that in the first 3 years of the psychotic episode, the incidence of psychosis increased and then plateaued after 3 years. In these patients, the duration of the psychosis varied greatly across patients. However, in their review of the literature, they suggest that

psychotic symptoms seem to persist about several months and rarely extend beyond a year (Ropacki and Jeste 2005).

As for risk factors, Ropacki and Jeste found only weak or mixed evidence of the associations of gender, education, and family history of dementia or psychiatric disorders with psychosis (Ropacki and Jeste 2005). As for the factor of age, whether it be patient's age, age of onset, or chronicity, these age-related factors were also mixed. They found several studies that successfully reported and several others that have failed to find these age effects with the older samples of individuals with schizophrenia (Ropacki and Jeste 2005).

But the authors did mention significant ethnic differences and reported research that found that African Americans with Alzheimer's disease were more likely to experience psychotic symptoms compared to Caucasians (Ropacki and Jeste 2005). They also suggested that incidence of psychosis was related to a faster decline in cognition. Particularly, hallucinations, but not delusions, seem to be associated with accelerated cognitive decline in dementia patients.

Remission in Older Adults

Remission can be defined as having little or no psychotic symptoms. Many cross-sectional studies have indicated that there is a higher remission rate in older versus younger adults with schizophrenia. For instance, in 2008, the Schizophrenia Group found that 49% of community-dwelling patients with schizophrenia who developed it before age 45 were in remission among a sample of 198 persons aged 55 years and older (Bankole et al. 2008). Meester et al. found a lower remission rate of 29.4% in adults with schizophrenia with a mean age of 68 years old (Meesters et al. 2011). In this study, both positive symptoms (81.9% of patients) and, to a lesser extent, negative symptoms (57.2% of patients) explained non-remission rates in their sample. Remission was also found to be higher in individuals with schizoaffective disorder (47.8%), compared with individuals with schizophrenia (24.4%) (Meesters et al. 2011).

Mortality Rates

Individuals with schizophrenia have a higher mortality rate than the general population due to a number of contributing factors (Saha et al. 2007). A review of 37 mortalities in schizophrenia studies by Saha, Chant, and McGrath found that the increased rate of death was 2.5 times higher for persons with schizophrenia compared to the general population (Saha et al. 2007). In another study conducted in Finland that examined 66,881 people with schizophrenia, those with schizophrenia were dying on average 25 years earlier than the general Finland population (Tiihonen et al. 2009). Factors impacting mortality in schizophrenia include high rates of suicide, complications secondary to low socioeconomic status, high-risk behaviors, and somatic conditions increasingly caused by the negative effects of second-generation antipsychotic medications (Saha et al. 2007; Tiihonen et al. 2009). Weight gain and metabolic syndrome are also becoming more prominent in the population with schizophrenia leading to higher rates of cardiovascular mortality for this population (Saha et al. 2007). Furthermore, adults with schizophrenia have been reported to exhibit signs of physical aging at an increased rate in comparison to the general population (Jeste et al. 2003).

Research has shown however that long-term antipsychotic medication use leads to overall lower mortality rates in patients with schizophrenia when compared to unmedicated individuals with chronic schizophrenia (Tiihonen et al. 2009). With the exception of some specific second-generation antipsychotics, these medications have been shown to have positive effects on life expectancy, especially when the patient exhibits treatment compliance (Tiihonen et al. 2009). One medication in particular, clozapine, contributed to lower rates of suicide mortality and the possibility of individuals leading a healthier lifestyle to combat the negative cardiometabolic effects of antipsychotic medication (Tiihonen et al. 2009). Though there are drawbacks to the use of clozapine (e.g., frequent blood level monitoring), study results indicating the positive effects on the life span of individuals

with schizophrenia indicate that it should be considered as a first-line treatment (Tiihonen et al. 2009).

Neurobiology and Cognition

There are relatively few studies that have examined brain structures in older adults with schizophrenia. Frisoni et al. mentioned that previous studies have found various brain abnormalities such as cortical and subcortical volume reduction (Frisoni et al. 2009). It is uncertain how much of these reductions were due to schizophrenia per se versus long-term use of antipsychotic medications or possible comorbid neurocognitive disorders such as Alzheimer's disease. In their review, they describe mixed finding in MRI studies. Some have found significant reductions in brain volume such as in the hippocampus and amygdala in older adults with schizophrenia; others have found no differences, such as one study that compared 45–87-year-old patients with early- versus late-onset schizophrenia compared with healthy controls (Frisoni et al. 2009). Frisoni and colleagues conducted an MRI study of geriatric patients with schizophrenia, Alzheimer's patients, and healthy older adults (Frisoni et al. 2009). They found that the older adults with schizophrenia have 10% less left cortical gray matter volume and 11% less right cortical gray matter volume compared with healthy controls. In contrast the healthy controls were 7% higher in left gray matter volume and 5% higher in right gray matter volume compared with the Alzheimer's disease patients. Furthermore, in a sample of individuals with schizophrenia compared with the healthy controls, other regions with significantly less brain volume included the cingulate gyrus and orbitofrontal cortex. Interestingly, the volumes of these brain areas were not statistically different between the persons with schizophrenia or Alzheimer's disease.

In a more recent study by Prestia et al., older individuals with schizophrenia were compared to older healthy adults (Prestia et al. 2015). These older adults with schizophrenia had significantly smaller left and right hippocampus and amygdala

as well as tissue loss in specific connections with the frontal cortical and limbic structures. Volumes of the hippocampus and the amygdala were positively correlated with the severity of negative psychotic symptoms but not with positive symptoms. For cognitive correlates with brain structures, only one measure of executive functioning and language reproduction (i.e., verbal fluency) was positively associated with the left hippocampus volume. There were no significant correlations between volume of these brain structures with any other measures of cognition, specifically learning and memory, language, constructional abilities, and executive functioning.

Multiple studies have shown that general intelligence is about 5–10 IQ points lower in persons with schizophrenia than comparison samples (Jeste et al. 2011). It is unclear if this cognitive deficit is a prodromal indication of the disorder's neuropathology or if it is a risk factor for developing severe mental illness; however, research has illustrated cognitive deficits in persons with schizophrenia as early as the first grade (Palmer et al. 2009). In adulthood, cognitive functioning has been found to be lower in individuals with schizophrenia in several cognitive domains such as learning and memory, attention, psychomotor skills, and executive functioning compared to healthy controls (Berry and Barrowclough 2009). Interestingly, psychotic symptom severity seemed to be independent of degree of cognitive impairment (Berry and Barrowclough 2009). There is evidence of stability in young and middle-aged adulthood (Friedman et al. 2001). In a 6-year follow-up of cognitive functioning of adults with schizophrenia, they found that cognitive decline was limited to those over age 65 (Friedman et al. 2001).

With these cognitive deficits especially in old age, some research hypothesize that diagnosis of psychotic disorders may increase the risk of dementia. In a study by Harvey and colleagues, cognitive decline and conversion to dementia rates were greater for elderly patients with schizophrenia who spent a majority of their lives institutionalized compared to the general population (Harvey et al. 1999). However, up to 90% of older patients with schizophrenia live in the community.

Though these individuals tend to illustrate mild cognitive impairment throughout their lives, studies have found that the rate of cognitive aging in these patients appears to be comparable to individuals without schizophrenia (Jeste et al. 2011). In other words, these community-dwelling patients with schizophrenia exhibited similar age-expected cognitive decline across neurocognitive domains as the general aging population (Jeste et al. 2011). Perhaps then the risk of dementia in this population is very severe psychopathology that results in institutionalization early in life.

Psychosocial Functioning and Quality of Life

Subjective quality of life is a self-report measure used with persons with schizophrenia to assess overall well-being and satisfaction with life (Meesters et al. 2013). Though positive and negative psychotic symptoms greatly impact a person with schizophrenia's life, it has been shown that general psychopathology such as depression and anxiety have a more significant impact on subjective quality of life, especially in older individuals (Eack and Newhill 2007). Additionally, social cognition factors such as theory of mind largely contribute to an individual's assessment of his or her quality of life, as well as psychosocial factors (Meesters et al. 2013). Elderly patients with schizophrenia are likely to have less impaired psychosocial functioning compared to younger patients (Berry and Barrowclough 2009). This is likely due to successfully managing their symptoms in old age that in turn contributes to the overall higher quality of life rating within this subset of the population of individuals with schizophrenia (Meesters et al. 2013). Still, Berry et al. reported that several studies have found that older adults with schizophrenia compared to same-aged controls were still impaired in "communication, transportation, finance, engagement in activities, forming friendships, looking after the home and shopping" (p. 70) (Berry and Barrowclough 2009). They also reported a similar study of patients with schizophrenic and

schizoaffective disorders over the age of 45 years old who have greater global functional impairment compared to bipolar patients (Berry and Barrowclough 2009).

Research has shown that social cognition has the most significant impact on quality of life for individuals with schizophrenia (Tolman and Kurtz 2012). Furthermore, the domain of theory of mind within social cognition has been shown as more influential to an individual's quality of life than emotion perception (Tolman and Kurtz 2012). Impaired theory of mind negatively impacts quality of life as well as intact theory of mind for a more severely ill patient (Tolman and Kurtz 2012). This influence of theory of mind is in contrast to healthy controls and siblings of people with schizophrenia where neurocognitive factors serve as better predictors for quality of life (Tolman and Kurtz 2012). A patient's ability to perceive his or her impact on the surrounding environment and interpersonal interactions is more likely to improve the individual's quality of life in comparison to simply identifying emotional cues displayed by others (Tolman and Kurtz 2012).

Individuals with schizophrenia have exhibited deficits in community functioning such as obtaining and maintaining employment and living in the community independently (Berry and Barrowclough 2009). These deficits are strongly tied to neurocognitive deficits and continued decline throughout aging (Tolman and Kurtz 2012). Interestingly, a recent study on neuropsychological predictors of objective and subjective quality of life suggests that lower neurocognitive functioning may serve as a protective factor in life satisfaction to some extent in that patients with schizophrenia who also have stronger cognitive abilities report lower satisfaction of life due to increase insight into their level of disability and severe illness (Tolman and Kurtz 2012).

As a person with schizophrenia ages, they are likely to see an improvement in psychosocial functioning due to reduced symptoms and fewer subsequent hospitalizations as well as a better understanding of how to manage the disorder (Jeste et al. 2011). They are likely to subjectively rate their quality of life as better than younger or

middle-aged patients with schizophrenia due to acquiring numerous coping skills and construction of adequate social support to improve overall functionality (Jeste et al. 2011). More specifically, structural changes in the brains of elderly schizophrenia patients have been shown as well as normal age-related reduction in activity of the monoaminergic system that can assist in decreasing positive psychotic symptoms (Jeste et al. 2011). Additional contributing factors to improve quality of life and psychosocial functioning in elderly patients include reduced substance use behaviors, increased medication compliance, and longer exposure to psychotherapeutic interventions (Jeste et al. 2011).

Treatment

For schizophrenia and other psychotic disorders, the typical treatment especially if the psychotic symptoms are significantly impairing their daily functioning is antipsychotic medications. Specifically, typical (i.e., first generation such as haloperidol, chlorpromazine, molindone) and atypical (i.e., second generation such as olanzapine, risperidone, and clozapine) antipsychotics have been used to successfully treat positive psychotic symptoms. In general, this remains to be true for older patients with schizophrenia, but specific treatment guidelines must include aging considerations for this patient population.

There is relatively sparse research conducted on the effectiveness of antipsychotic medications in older adults. The studies that currently exist have reported somewhat mixed findings. In one study that examined the efficacy and safety of clozapine in 45 older adults with schizophrenia who were treatment resistant, they found that the medication was well tolerated and was not discontinued by any patient and that the rates for rehospitalization were lower with this medication than when they were on other medications in a 5-year comparison period (Pridan et al. 2015). However, in a 2-year longitudinal study reported by Jeste and colleagues, four different second-generation medications, namely, aripiprazole, olanzapine, quetiapine, and risperidone, were

examined in 332 middle-aged and older adult outpatients. No significant improvements in psychiatric symptoms were detected (Jeste and Maglione 2013).

In comparison to younger adult patients, older adults with schizophrenia are at higher risk of the pharmacological side effects of first-generation antipsychotic medications that include Parkinson-like symptoms, falls, and metabolic problems (Jeste and Maglione 2013). These side effects have been found to be as high as 60% in older patients with schizophrenia compared to only 19% for younger patients. This is likely due to the effects of aging that include slower metabolism and greater receptor sensitivity (Berry and Barrowclough 2009). In the 2-year longitudinal study by Jeste and colleagues that examined four atypical antipsychotic medications in middle-aged and older adults, the rates of significant side effects were 50% for nonserious side effects and 23.7% for serious side effects, including 36% incidence of metabolic syndrome (Jeste and Maglione 2013).

Another factor that strongly affects the success of medications is adherence. Unfortunately, similar to younger patients, adherence rates to medications have been found to be poor in older outpatients with schizophrenia. In the same longitudinal study by Jeste and colleagues, more than 50% of the patients discontinued these second-generation (atypical) medications within 6 months (Jeste and Maglione 2013). This is likely due to the relatively high rates of side effects that were reported in their sample.

As for non-medication treatments, psychosocial as well as cognitive interventions have been found to be helpful for older psychotic patients. For example, Jeste and colleagues described a randomized controlled study conducted by Patterson et al. in 2006 that used a manualized treatment called functional adaptation skills training (FAST) in 240 middle-aged and older psychotic adults over a 24-week (session of 2 h per week) treatment period (Jeste and Maglione 2013). This treatment focused on six areas of daily living functioning including: (1) medication management, (2) social skills, (3) communication skills, (4) organization and planning,

(5) transportation, and (6) financial management. They found significant improvements in social and communication skills but no significant improvement in psychotic symptom severity, depression, or quality of well-being (Jeste and Maglione 2013).

In a more recent study of cognitive-behavioral and social skills training (CBSST) treatment, Granholm et al. conducted a randomized control study of 79 older adults with schizophrenia (Granholm et al. 2013). These researchers found that the CBSST significantly improved life satisfaction, motivation, and self-esteem and lowered symptom distress. Encouragingly, retention rates have been found to be as high as 86% in completing psychotherapy interventions as well as that mean attendance (of sessions) rate to be 92% (Berry and Barrowclough 2009).

In sum, the research is somewhat mixed in the benefits of antipsychotic medications in older adults especially when compared to the costs of these medications and their potential long-term side effects. Randomized controlled trials need to be made in this area to get a clearer understanding of the positive and negative effects of antipsychotic medications on older adults with psychotic disorders. Nevertheless, the use of antipsychotics is still generally the first line of defense for psychotic disorders for older adults. According to Jeste and Maglione, the generally accepted protocol for antipsychotic medication is recommended to be a lower initial dose (25–50% lower compared to young adults with schizophrenia) with slow increase in dosage depending on tolerance of side effects and treatment response (i.e., the significant reduction of psychotic symptoms). As for psychosocial and cognitive treatment studies, encouraging results have been found. This is not to suggest that these treatments are better than medication. Rather, in addition to medication, these treatments can significantly improve the quality of life of these older patients.

Conclusion and Future Directions

As the numbers of geriatric patients with schizophrenia and other psychotic disorders increase in

the United States and all over the world, there is an increased need for continued research in the understanding and treatment of late-life schizophrenia. This entry suggests that while there are many commonalities between younger and older adults with schizophrenia, the differences both qualitatively and quantitatively between these age groups point to the importance of research and clinical investment for geriatric patients with schizophrenia. For these vulnerable groups of patients, they have characteristics of double jeopardy due to old age and severe mental illness. Therefore, more clinical research still needs to be done for tailored and multidisciplinary assessment and treatment of geriatric schizophrenia and psychotic disorders to aid in patient treatment management, reduce economic and family/caregiver burden, and ultimately improve quality of life for these patients.

Second Generation Socioemotional Selectivity Theories

Emotion and aging; Emotion regulation; Emotional well-being; Socioemotional functioning

Definition

Socioemotional selectivity theory has been informing much of the research on emotion and aging for the past 25 years. The theory describes how aging is related to increased importance placed on emotional goals. In the past decade, researchers have developed new theory based on socioemotional selectivity theory, targeting specific aspects of emotional experience. These theories focus on both cognitive aspects involved in processing emotional information (cognitive control hypothesis; positivity effect) and emotion regulation strategies (strength and vulnerability integration).

Socioemotional selectivity theory describes how people's thoughts and behavior change with age as a function of their temporal perspective. According to the theory, as temporal perspective – or how much time people perceive is left in their lives – grows increasingly shorter, people will place more value and importance on emotional goals (refer to the entry on socioemotional selectivity theory for a more expansive description). The importance placed on emotional goals will guide social partner preferences; change how people attend to, appraise, and remember emotional and nonemotional information; and influence emotion regulation strategies and emotional well-being. The wide-ranging applications of socioemotional selectivity theory on social, emotional, health-related, and cognitive processes have been discussed for years (Carstensen et al. 1999). In fact, the continued applications of this theory into new areas of research has resulted in three second-generation theoretical models that articulate age differences observed in specific areas of cognitive and emotional functioning. They include the positivity effect, the cognitive control hypothesis, and strength and vulnerability integration (SAVI).

Positivity Effect

Socioemotional selectivity theory posits that when perceived time left in the life span is limited, as is normative for older adults and not younger adults, saliency of emotional information increases over

nonemotional information. In an early test of the theory, people read a short passage from novel that included both nonemotional and emotional content; then, less than an hour later, participants were asked to recall the contents of this passage in an incidental memory paradigm (Carstensen and Turk-Charles 1994). Results indicated that each successively older age group recalled a greater proportion of emotional to nonemotional material. This increased saliency of emotional information was also examined in later studies, but importantly, Laura Carstensen and her colleagues examined the importance of the valence in these recollections. When recalling events from participants' lives, for example, the autobiographical memories of older adults were more positive than those of younger adults (Kennedy et al. 2004). When either recalling or recognizing positive, negative, and neutral images that they had previously viewed, older age was related to recalling a greater proportion of positive images relative to negative images; younger age, in contrast, was associated with recognizing and recalling relatively more negative to positive and neutral images (Charles et al. 2003). Likewise, another study in Carstensen's lab studied age difference in attention for positive, negative, and neutral stimuli (Mather and Carstensen 2003). The researchers found that older adults focused their attention on the more positive (when presented with positive and neutral faces) and less negative (when presented with negative and neutral faces) facial stimuli. Younger adults, in contrast, were more likely to focus their attention on more negative faces.

Carstensen and her colleagues termed this cognitive phenomenon the positivity effect, whereby older age is associated with attentional and memory performances that favor more positive, or less negative, information (Carstensen and Mikels 2005; Carstensen et al. 2006). Since publication of the first studies and theoretical papers where the term was first presented, more than 100 studies from multiple laboratories have studied the positivity effect, replicating the important finding – when examining positive compared to neutral stimuli, when comparing negative stimuli versus neutral stimuli, or when comparing cognitive processes in relation to all three valences (positive, negative, and

neutral) together in a study (Reed and Carstensen 2012). Furthermore, a recent meta-analysis examined the conditions under which the positivity effect is likely to be observed in empirical studies (Reed et al. 2014). These conditions included: (1) providing participants with no explicit instructions regarding how to examine the information and (2) studying groups of people that spanned a wide age range. The reasoning behind the first effect is explained by socioemotional selectivity. With no explicit instructions, people process information using their own goals. Older adults, who increasingly prioritize emotional goals, will thereby attend to emotional material more than nonemotional material relative to their younger counterparts. If, however, researchers ask older adults to instead prioritize accuracy or another goal, the performance of older adults will reflect this current goal request, and not their own preferences.

The second aspect is related to socioemotional selectivity theory's position that the age-related change in time perspective is linear and gradual across a normative, long, life span. As a result, age-related changes are very small and will best be detected when comparing across a long age range, or when comparing between groups who vary in age to a great extent.

Cognitive Control Hypothesis

Socioemotional selectivity theory posits that time perspective shapes motivational goals, which in turn shape emotional experiences. Other theories, however, have proposed different factors responsible for age differences in emotional experiences. For example, dynamic integration theory discusses how older age is generally related to declines in the cognitive ability to process complex emotional information (Labouvie-Vief 2003). This theory further contends that positive information is less complex and therefore easier to process than negative information. As a result, dynamic integration theory posits that older adults will compensate for this loss in ability by distorting information in a positively biased direction and by appraising the world in a simpler, yet more positive, manner. The more recently proposed aging-brain model also takes a

loss-based approach, stating that older adults are focusing on and remembering positive information over negative information as a result of age-related declines in the amygdala, which differentially affects attention to negative information more so than positive information (Cacioppo et al. 2011).

In contrast to the loss-based explanations, the cognitive control hypothesis states that high-functioning cognitive control is necessary for older adults to act upon and achieve their emotional goals. Thus, people with the highest levels of executive control will be most successful in their emotional goal pursuits as importance increases with age (Kryla-Lighthall and Mather 2009). Researchers tested this hypothesis by examining the positivity effect for older and younger adults who varied on measures of cognitive control and by examining how performance was affected when people were engaged in a divided attention task, which limits cognitive resources for the emotional task at hand (Mather and Knight 2005; Knight et al. 2007). Results indicated that when dividing the group into high and low performers on the executive control tasks, older adults who scored highest were the ones who displayed the positivity effect, whereas younger adults showed a bias toward negative information regardless of their cognitive performance (Mather and Knight 2005). Older adults who scored low on the executive functioning task remembered more negative than positive or neutral information, showing the same pattern as the younger adults. In addition, when older adults were distracted in studies using divided attention paradigms, they no longer displayed the positivity effect and instead showed biases toward negative information (Mather and Knight 2005; Knight et al. 2007). These studies showed that the positivity effect was not the result of low cognitive functioning, as the loss-models presumed, since lower executive functioning leads to increased negativity. In addition, other studies also showed that superior cognitive performance was required for emotional material to that for nonemotional material (e.g., Mikels et al. 2005). For example, one study confirmed the usual association between older age and worse working memory performance only for nonemotional visual images, but no age differences

were present for visual images with emotional content (Mikels et al. 2005). Moreover, older adults had better performance for positive over negative visual information, whereas younger adults showed the reverse pattern. These findings further support socioemotional selectivity theory, and the cognitive control hypothesis, by showing that older adults invest their cognitive resources in the activities most important to them: those aligned with emotional goals.

The cognitive control hypothesis, then, bolsters SST in two ways: first, the hypothesis has generated findings showing that older adults prioritize emotional goals such that they expend cognitive efforts to display the positivity effect. Thus, the positivity effect is the result of older adults' active goal strivings and not a byproduct of a process over which older adults had no active control, such as a failure to inhibit emotional stimuli. In addition, the findings directly contradict researchers who posit that the positivity effect is the byproduct of cognitive decline.

Strength and Vulnerability Integration (SAVI)

SAVI is the most recent theoretical model developed from SST (for a complete description, see the section on strength and vulnerability integration). Most of the research motivated by socioemotional selectivity theory has demonstrated age-related gains in processing emotional information and in levels of positive affective experience. In addition to the previously recognized strengths of aging, SAVI incorporates age-related decline and focuses on the boundary conditions of age-related increases in functioning (Charles and Piazza 2009; Charles 2010). SAVI examines when older adults are able to focus on and achieve their emotional goals (as have many studies of socioemotional selectivity theory), but adds an emphasis to the situations when older adults are no longer able to maintain high levels of control in sustaining emotional well-being.

SAVI incorporates socioemotional selectivity theory to explain why older adults increasingly focus on and prioritize emotion-related goals and

why, as a result, they are motivated to seek positive emotional experiences and avoid situations that elicit negative distress. Socioemotional selectivity theory, as its name implies, emphasizes selectivity, such that older adults strategically select the situations and environments that promote emotional well-being. This is strength of aging, garnered from time perspective, as described by socioemotional selectivity theory, and also by life experiences and time lived, which provide older adults with information about the situations, social relationships, and experiences that are the most beneficial to their emotional well-being. These strengths promote successful emotion regulation and explain why, in large groups of adults spanning a wide age range, affective well-being shows similar levels if not higher levels among the older adults in the sample.

When older adults cannot select their environments to maintain affective well-being, however, they experience distress. Because older adults' motivational goals are focused on avoiding negative affect, stressful situations are often less frequently experienced with age, even to the extent that healthy older adults in their 80s report fewer daily stressors than those in their 60s and 70s, for example (Charles et al. 2010). When a situation arises that elicits high levels of arousal, however, SAVI posits that the benefits of aging will be attenuated. At this point, age-related physiological vulnerabilities will make regulating high levels of arousal difficult. SAVI posits that the effects of physiological arousal will be harder to modulate in an older and more vulnerable system. In addition, the immediate situation will place demands on the system, similar to the divided attention task situations discussed above (Mather and Knight 2005). In such situations, the current physiological demands make it more difficult to use emotion regulation strategies such as positive appraisals, so age differences in affective reports will be attenuated and sometimes may even not be present in the midst of these distressing situations.

When people are immediately faced with a negative event, they lack the time to appraise the situation, and physiological demands on their system will need to be modulated. As time passes, people will use their appraisals and recall the

emotional experience; these appraisals and memories are posited to become more positive and less negative with age. As a result, age differences will be greatest for events that occurred farther away from the time they were assessed and less pronounced for emotional experiences that are closer to the time they occurred. One study, for example, found that older adults report lower levels of negative affect than younger adults when asked about emotions experienced across various time intervals, such as the current day or the past week (Charles et al. 2015); however, age differences were greater the longer the time recalled (across a month, for example, as opposed to a day).

Conclusion

All of these theoretical models originated from studies testing socioemotional selectivity theory. Each one – the positivity effect, the cognitive control hypothesis, and SAVI – incorporates the tenets of socioemotional selectivity theory to explain age differences in thoughts and behaviors. These second-generation theories narrow the focus of socioemotional selectivity theory to apply to specific cognitive processes (positivity effect), cognitive conditions necessary for the theory to work (cognitive control hypothesis), and context-specific conditions when emotion regulation benefits from strength and vulnerability integration (SAVI). As researchers apply socioemotional selectivity theory to increasingly diverse aspects of emotional experience, new information will arise, and new terms and theories to explain them. These theories optimally will serve as a guide for future research when investigating the mechanisms behind age differences in social and emotional experiences.

Synonyms

Action regulation; Goal setting; Life management strategy; Resource allocation

Definition

The model of selection, optimization, and compensation (SOC) encompasses three processes of action regulation in respect to successful aging and life-management: Selection refers to the setting and prioritization of goals, based on personal motives and preferences (elective selection) or due to perceived loss of internal or contextual resources (loss-based selection). Optimization involves the obtainment, improvement, and coordinated use of individual means to pursue important selected goals. Compensation involves the acquisition and application of alternative individual means or the utilization of external or technological aids to substitute lost means.

The Model of Selection, Optimization, and Compensation

Individual well-being and productivity across the lifespan depend largely on access to resources. In terms of the Conservation of Resources Theory (COR) resources can be considered as internal or external entities that are either valued in their own right (e.g., health) or as means to obtain valued ends (e.g., money) by most people within a given culture in a broad array of situations (Hobfoll 2002). An aging individual faces dwindling intra-individual resources (e.g., physical fitness, health, sensory abilities, and basic cognitive functions) that successively outweigh gains of resources (e.g., knowledge, experience, and social status) (Baltes 1997). In that vein, one of the most essential challenges for aging employees is to maintain well-being, functioning, and productivity over the work lifespan despite this relative loss of resources.

The model of selection, optimization, and compensation (SOC), introduced by Paul and Margret Baltes (Baltes and Baltes 1990), provides a theoretical framework to explain three fundamental action strategies that enable individuals to cope with resource losses and to conserve valuable resources throughout the lifespan (Hobfoll 2002). The SOC model suggests that every developmental process encompasses a combination of

three kinds of adaptive behaviors (Freund and Baltes 2002): Selection refers to the setting and prioritization of goals, based on personal motives and preferences (elective selection) or due to perceived loss of internal or contextual resources (loss-based selection). The SOC model suggests that successful personal development and life management requires a focus on specific goals – in contrast to allocating energy among multiple goals. Selection, therefore, guides and organizes individual behavior, directs personal development, and creates a feeling of purpose in one's life. Optimization involves the obtainment, improvement, and coordinated use of individual means to pursue important goals that were selected individually. Thus, optimization refers to the quality and also persistence of resource allocation. Compensation, like optimization, also refers to means. It specifically addresses the question of how aging individuals who face permanent or temporary loss of resources are still able to maintain a desired level of functioning. Compensation involves the acquisition and application of alternative individual means or the utilization of external or technological aids to substitute lost means.

In sum, the SOC model assumes that available resources can be used more efficiently when individuals focus on fewer, but important goals, pursue these goals in an optimized way, and by doing so, apply adequate compensatory means (Baltes 1997).

SOC at Work

The SOC model has stimulated research in various fields and has received broad empirical support (Riediger et al. 2006). In the last years, a growing number of studies applied the SOC model to the work context in order to explain organizational behavior and coping with age related changes in occupational contexts. The following questions and issues were investigated in particular:

The Association Between SOC at Work and Subjective Well-Being

Studies indicate that high utilization of SOC strategies is related to increased levels of well-being

both in the work and in the family domain (Wiese et al. 2000), and better work-family balance (Baltes and Heydens-Gahir 2003; Young et al. 2007). Moreover, SOC appears to be related to job satisfaction (Schmitt et al. 2012), work engagement (Weigl et al. 2014), and positive expectations about future opportunities at work (Zacher and Frese 2011). In an extension of these cross-sectional findings, first longitudinal studies also demonstrated the prospective impact of SOC on subjective well-being (Wiese et al. 2002).

Beyond the assumption that SOC contributes to a more effective resource allocation and thus enhance personal functioning and well-being, there are complementary explanations for these positive effects of SOC on well-being. SOC can also be considered as a set of behavioral strategies that represent active coping (Dewe et al. 2010). Moreover, SOC is expected to promote goal disengagement and foster goal re-engagement. For instance, loss-based selection refers to the setting of new feasible goals to respond to disadvantageous internal or contextual changes. Thus, SOC might counteract mechanisms of inflexible and rigid organizations of action which might affect mental well-being (Fresco et al. 2006).

The Association Between SOC at Work and Job Performance

Investigations suggest that the use of SOC at work contributes to competency maintenance and job performance (Abraham and Hansson 1995; Yeung and Fung 2009). Moreover, the well-known positive effects of conscientiousness on job performance seem to partly operating through the use of SOC (Bajor and Baltes 2003). In the same vein, generalized optimization strategies appear to be indirectly – i.e., through specific strategies of career planning – linked with various indicators of career success such as increased pay, higher ranked job positions, and career satisfaction (Wiese et al. 2000). However, studies so far failed to demonstrate whether the use of SOC can also predict career success over time (Wiese et al. 2002).

In regard to the single SOC strategies, particularly selection strategies seem to be conducive for

performance (Abraham and Hansson 1995; Yeung and Fung 2009; Bajor and Baltes 2003). However, selection strategies were also shown to enhance the negative impact of burnout on the performance in secondary job tasks, and compensation seems to be most successful strategy in buffering the negative effects of burnout on performance (Demerouti et al. 2014). Thus, the strength and direction of the interrelation between single SOC strategies and performance might be affected by moderating factors as well as the specific performance-dimension under consideration.

The Association Between SOC at Work and Work Ability

A growing body of research particularly in the field of nursing and healthcare work demonstrates that SOC can explain efficient and adaptive resource allocation in terms of maintaining work ability, i.e., the perceived balance between the employees' resources and their job demands (Müller et al. 2012, 2013a; von Bonsdorff et al. 2014; Weigl et al. 2013). Representative findings in older employees in Germany indicate that this association is also true for professions outside of healthcare (Riedel et al. 2015). However, the effects of SOC on work ability seem to be considerably weaker compared to the effects of important job characteristics (Riedel et al. 2015). With respect to the single SOC strategies, optimization, and compensation strategies appear to be the most efficient strategies to maintain work ability (Riedel et al. 2015).

The Interaction Between SOC at Work and Work Characteristics

The application and the consequences of SOC at work are both dependent on the design and characteristics of the task as well of the work environment. It appears that SOC requires job autonomy (Weigl et al. 2013, 2014; Müller et al. 2012). Moreover, research indicates that SOC is related to supportive supervisory behavior (von Bonsdorff et al. 2014), as well as learning and developmental opportunities on the job (Weigl et al. 2014). These findings suggest that in organizations, the development and successful applications of individualized behaviors like SOC

is dependent on sufficient control and latitudes to make own decisions, and requires joint agreements between the supervisor and the employee. In regard to work stressors, role conflicts and role ambiguity have shown to be positively related to selection and compensation strategies (Abraham and Hansson 1995). This indicates that employees apply SOC in response to unfavorable and stressful work conditions.

Beyond that, SOC is presumably intertwined with work characteristics. In other words, the use of SOC seems to reinforce or buffer the effects of work characteristics on individual outcomes. Comparably, work characteristics seem to reinforce or buffer the effects of SOC: Empirical findings indicate that SOC accentuate the positive effects of high job autonomy on work ability (Weigl et al. 2013; Riedel et al. 2015). Thus, taking advantage of SOC seems to add to the mere effects of job autonomy. In contrast, when job autonomy is low, the use of SOC might even have detrimental effects such that SOC can actually be counterproductive if the employee does not have the formal authority to use those (Weigl et al. 2013).

Despite interactions with job autonomy as an important contextual resource and situational enabler, SOC also seem to interact with unfavorable work characteristics: The use of SOC appears to support employees in managing more difficult tasks (Yeung and Fung 2009). Moreover in low-complexity jobs SOC appears to contribute to employees positive expectations about future opportunities at work (Zacher and Frese 2011). Finally, high use of SOC was shown to significantly buffer the relationship between problem solving demands and fatigue (Schmitt et al. 2012).

Studies also revealed that the single SOC strategies have a different effect when quantitative job demands are high, and even detrimental effects are conceivable (Riedel et al. 2015): Employees who apply selection strategies may be able to diminish negative effects of high quantitative job demands, whereas optimization has been shown to strengthen negative effects of high quantitative job demands, and conversely, optimization appeared to compensate for a lack of skill discretion. Thus, from a perspective of resource

allocation (Hobfoll 2002), under condition of high job demands the selection of specific tasks might prevent overload whereas optimization might even increase overload when complying with many job demands. On the other hand, the acquisition of resources through optimization might make up for a lack of environmental resources.

Effects of SOC at Work in Relation to Age and Health of Employees

SOC seems to be particularly effective for older employees (Abraham and Hansson 1995; Yeung and Fung 2009; Müller et al. 2013a; Weigl et al. 2013) which agrees with the assumption that SOC contributes to the more efficient allocation of personal resources. Moreover, SOC strategies turned out to be particularly effective for older employees under specific challenges: SOC seem to maximize the supportive effects of job autonomy particularly in older employees (Müller et al. 2012; Weigl et al. 2013). Again from a resource perspective, older employees may particularly benefit from high job autonomy because it provides opportunities either to balance out age-related losses that hamper the acquisition of SOC at work or to maximize age-related gains, like experience. Likewise, SOC at work was shown to be effective particularly among older employees in low-complexity jobs for focusing on future opportunities at work (Zacher and Frese 2011). However, in difficult task situations employment of SOC strategies seems to support older employees to increase momentary performance, but global performance was only supported by SOC in younger employees (Yeung and Fung 2009). The authors concluded that in the long run older employees might need other strategies than SOC to handle difficult tasks successfully. Accordingly, one recent study pointed to a stronger relationship between SOC and work ability in younger compared to older nurses (von Bonsdorff et al. 2014). These inconsistencies call for further investigations into the interplay of chronological age and SOC at work.

From a resources perspective, recent studies investigated whether the use of SOC contributes to reduce consequential losses of poor health. One study with older employees from 60 to 85 years

indicated that high use of SOC buffered the effects of health status on the intention to remain employed (Müller et al. 2013b). In participants with low use of SOC, there was a weaker intention to remain employed when health status was poor, while this intention was stronger in case of a better health status. Concerning burnout, a prevalent state of diminished health, an investigation showed that compensation was the most effective SOC strategy in buffering the negative effects of burnout on performance, and selection strategies enhanced the negative impact of burnout on performance (Demerouti et al. 2014). Thus, developing and applying compensatory means might be an effective way of coping with limited resources and instrumental in order to maintain performance. Selection strategies potentially reduce the scope of activities into which employees invest their energy which might include detrimental effects (Demerouti et al. 2014).

Future Research Directions

The research on SOC at work has made substantial progress across the past years. Notwithstanding, several limitations in the current evidence base need to be addressed and overcome.

Future studies that explicitly incorporate specific work as well as individual characteristics are needed to further discover the complex interplay of SOC behaviors, individual, and contextual characteristics. Available evidence on the relationship between SOC at work and desirable individual outcomes are respectively based on very few studies. Therefore, replications are needed.

The vast majority of studies on SOC at work have a cross-sectional design which limits insights into cause and effect relationships. It is mainly assumed that the use of SOC at work predicts better well-being, performance, or work ability. Potentially, effects might also be existent in the opposite direction, because SOC is in the short term a resource-demanding strategy. Thus, employees with more personal resources, e.g., high well-being, might thus be able to apply more SOC. Moreover, the long-term effects of SOC at work are not known. SOC behaviors that

are advantageous in the short run might turn out detrimental in the long term (Yeung and Fung 2009). For example, a narrowed scope of selected goals might restrict further development and skill acquisition particularly in early career stages.

In cross-sectional designs a bias due to “healthy worker effects” cannot be ruled out. The existing findings on SOC at work may be valid for professionals with superior well-being because employees with poor health may have already withdrawn from the surveyed workplaces or the active workforce. Although there are first attempts to examine the interaction between health and SOC (Demerouti et al. 2014; Müller et al. 2013b), research is needed to investigate whether employees with poor health are capable to effectively apply SOC behaviors at work or whether SOC strategies work differently.

With one exception (Zacher et al. 2015), there is yet hardly any empirical support for the basic assumption of SOC theory, that the orchestrated use of the three SOC behaviors is the most beneficial strategy. Most of the existing research on SOC at work has either reported the aggregated effects of all three SOC behaviors or their individual effects respectively. Such analyses are not able to disentangle different combinations of SOC strategies and to provide insights into specific behavioral strategies that blend single SOC domains. As an example, the same average SOC score might represent a variety of combination of single SOC strategies, i.e., high selection, low optimization or compensation; or low selection, high optimization or compensation. Hence, the combinations represent totally different regulatory strategies in terms of directions and efforts to enhance or allocate resources. Thus, further investigations of meaningful combinations of SOC behaviors at work might be worthwhile.

Finally, applying self-directed behaviors such as SOC at work almost inevitably affects work procedures, distribution of tasks, responsibilities, and cooperation. As an example, selection behaviors like “delegating tasks to colleagues” or compensation efforts like “asking for help” might be associated with a higher workload for colleagues. Therefore, there is a need for research on the inherent “social aspect” of SOC at work to

account for the complexity and interrelatedness of work systems. Future research might therefore develop designs to investigate the effective organization of SOC on the team level.

Conclusions and Implications for Practice

An increasing body of research demonstrates that using SOC at work is on average a promising strategy to maintain well-being, performance, and work ability. These effects refer – not exclusively – but particularly to older employees or employees with limited resources. Thus, in accordance with theory, SOC behaviors seem to contribute to the efficient allocation of personal resources, to balance out lack of environmental job resources, and to boost the effects of available job resources. Beyond that, the available empirical evidence on SOC at work also mainly fits the perspective of active coping as well as flexible goal engagement and disengagement on individual well-being.

Since the majority of studies revealed positive effects of SOC at work, it seems advisable to inform employees about the SOC model and to train individuals to deal more effectively with diminished resources. Organizations may offer trainings for employees to craft their work places and jobs so that employees experience engagement and motivation as well as cope successfully with the job demands at hands. Nevertheless, practical measures and interventions based on SOC have to take into account the complexity of sociotechnical work systems. Applying individualized behaviors like SOC at work requires that the employee is allowed to make autonomous decisions about important aspects of its job and has the support of its supervisor and colleagues. As a coordinated strategy SOC at work might balance out detrimental effects of high job demands, low job resources, and booster the effects of high job resources. However, under specific circumstances, SOC use might be detrimental. Detrimental effects of SOC at work can particularly be expected when the work environment does not sufficiently tolerate autonomous

decision making of employees (Weigl et al. 2013), in case of an unbalanced use of effortful optimization strategies under demanding work situations (Riedel et al. 2015), as well as an unbalanced use of selection strategies when individual resources are already depleted presumably by choosing a too narrow range of resource investment that hamper the retrieval of resources (Demerouti et al. 2014). These findings have to be considered when SOC measures are implemented in occupational practice.

Since various studies demonstrated that the effective use of SOC at work is closely related to work and task characteristics, measures that concurrently address individual as well as organizational or task characteristics might be promising. Drawing on available SOC research we assume that top-down approaches that reduce job demands and increase job resources should be aligned with individual bottom-up approaches that foster individual coping or job crafting strategies.

Self-Theories of the Aging Person

Manfred Diehl and Allyson Brothers
 Department of Human Development and Family
 Studies, Colorado State University, Fort Collins,
 CO, USA

Synonyms

Cognitive schema; Self-concept; Self-knowledge;
 Self-schema; Self-understanding

Definition

Self-theories of the aging person focus on how a person's self-representations and self-understanding change with age. Self-representations are those attributes that (a) are part of an individual's understanding and knowledge about the own person, (b) are the focus of self-reflection, and (c) can be consciously acknowledged by the person through language and other forms of communication.

General Framework

Self-theories of the aging person focus on how a person's *self-representations* and *self-understanding* change with age but also how, in turn, self-representations and self-understanding influence individuals' psychological and behavioral aging and related outcomes (Markus and Herzog 1991). Thus, the focus in self-theories of the aging person is on the individual's *self-concept* or *self-representations*. For the purposes of this entry, we will use these two terms interchangeably to refer to those attributes that (a) are part of an individual's understanding of and knowledge about the own person, (b) are the focus of self-reflection, and (c) can be consciously acknowledged by the person through language or other forms of communication (Diehl 2006; Harter 2012).

Contemporary psychological theories conceptualize self-representations as a multidimensional, contextualized, and dynamic *cognitive structure* with important adaptive and self-regulating functions (Brandtstädter and Greve 1994; Higgins 1996). This conceptualization implies that individuals' self-concept is viewed as a *cognitive schema* containing knowledge about personal traits, values, and beliefs, episodic and semantic memories, and knowledge about social roles, positions, and interactions. This cognitive schema is involved when self-relevant information is processed. From a life-span developmental and gerontological perspective, several theorists (Markus and Herzog 1991; Brandtstädter and Greve 1994) have pointed out that the self-concept gives individuals a sense of continuity

and permanence, allows them to distinguish themselves and their developmental history from others, and gives their experiences meaning within a larger life story (Diehl 2006; McAdams 2013). Moreover, self-concept theories also provide an explanatory framework that can account for the fact that human personality is both stable and flexible across the adult life span (Roberts and Mroczek 2008). That is, the notion that self-representations are hierarchically organized makes it meaningful to distinguish between representations that are essential to a person's general identity (i.e., core self-representations) and representations that are linked to specific contexts. Core self-representations tend to be relatively stable across contexts, whereas context-specific self-representations are responsive to the demands of different social roles, life events, or challenges associated with life stage-specific developmental tasks (Markus and Herzog 1991). Thus, self-concept theories provide a suitable framework to account for continuity and discontinuity in adults' development – two processes that are at the heart of the overall aging process. Self-representations are also of critical importance because the biological and psychosocial changes intrinsic to the aging process challenge the self-referential knowledge that constitutes a person's conception of him- or herself (Brandtstädter and Greve 1994).

Self-theories of the aging person are different from other psychological or sociological theories of aging because they put the individual squarely at the center of their theorizing and investigative efforts. Like action-theoretical accounts of psychological aging, self-concept theories emphasize the role of the individual as an *active, self-reflexive agent* who not only passively reacts to internal or external age-related changes and processes but who also intentionally and actively shapes these processes. This view is best illustrated in Brandtstädter and Greve's (1994) model of *accommodative, assimilative, and immunizing processes* that the aging person (more or less consciously) employs to negotiate age-related changes that challenge his or her positive identity. Thus, the main purpose of this triad of processes is the protection of a person's

positive self-representations in different behavioral domains against the potentially negative onslaught of the aging process and to preserve the biological and psychosocial integrity of the person.

Specifically, *assimilative adaptations* involve instrumental and self-corrective activities (e.g., efforts to enhance or maintain a desired ability or level of performance), compensatory activities (e.g., using external aids), and self-confirmatory actions (e.g., choosing environments that conform to a person's self-definition). Brandtstädter and Greve (1994) postulate that assimilative activities should be the preferred mode of adaptation when individuals realize that age-related losses have occurred or are imminent, but when they still believe that these losses may be reversible or can be counteracted through appropriate actions. The authors also postulate that individuals very likely will switch from an assimilative to an accommodative mode if they perceive that assimilative efforts are not effective or become too costly in terms of effort or resources. Consequently, *accommodative adaptations* involve (a) disengagement from blocked goals, (b) adjustment of personal aspirations and self-evaluative standards (e.g., gradual rescaling of self-evaluative standards), (c) self-enhancing comparisons (e.g., downward social comparisons), and (d) palliative interpretations, such as positive reappraisals or the discounting of unattainable goals. In support of the overall model of adaptive behavior, Brandtstädter and Renner (1990) showed that over the course of adulthood (age range 25 to over 75 years), individuals reported an increasing shift from assimilative to accommodative actions (see also (Diehl et al. 2014a)). The authors suggest that this developmental shift may account for the observed stability of self-esteem and subjective well-being in most adults.

Finally, Brandtstädter and Greve (1994) described *immunizing mechanisms* as the third mode of self-concept stabilization. According to the authors, immunizing processes protect self-representations that are highly relevant to a person's self-definition and self-esteem and can be categorized as data-oriented or concept-oriented.

Data-oriented immunization is a bottom-up process in which behavioral data (e.g., actual cognitive performance, feedback from the social environment, etc.) fundamentally challenge an individual's self-related beliefs so that he or she engages in a number of immunizing maneuvers to protect his or her self-representations in the respective domain against these data. These maneuvers may include downgrading the diagnostic relevance and validity of the behavioral data (e.g., "My memory is still good even if I forgot a few items on my shopping list") or shifting the temporal focus of self-evaluation so that past accomplishments can be used to stabilize current and/or future self-representations. In contrast, *concept-oriented immunization* is a top-down process in which the person engages in self-stabilizing maneuvers by emphasizing behaviors and attributes that are positively related to age and by de-emphasizing aspects that tend to decline with age. It is important to note that immunizing processes are, by definition, different than defensive mechanisms, because the person can usually acknowledge that the standards for self-definition and self-worth in a certain domain have changed as he or she has grown older (Greve and Wentura 2003). For example, although a good memory may have been a critical self-defining attribute for an individual in young adulthood and midlife, the same attribute or behavior may not be a self-defining feature of cognitive competence anymore in later adulthood.

In summary, Brandtstädter and Greve's (1994) model provides a framework that describes the psychological processes that underlie changes in self-representations across the adult life span. Indeed, there is evidence from numerous studies showing that assimilative, accommodative, and immunizing processes can account for a number of developmental changes in adults' self-representations (Brandtstädter and Renner 1990; Greve and Wentura 2003; Rothermund and Brandtstädter 2003). However, this model is only one approach that tries to explain how individuals' self-representations change over the adult life span. Several other explanations also need to be taken into account.

Specific Accounts for Changes in Adults' Self-Representations

The other accounts we consider here link adults' self-representations to their *constituent elements*, such as personality traits, social roles, life plans, and normative expectations, as well as individuals' personal memories and their awareness of personal lifetime. The overall argument with regard to these approaches is that changes in these domains give rise to changes in self-representations because they constitute the elements and the content of a person's self-concept and, in particular, of his or her context-specific self-representations.

In terms of *personality traits* such as the Big Five (i.e., agreeableness, conscientiousness, extraversion, openness to experience, and neuroticism/emotional instability), it is well documented that significant changes in mean levels occur across the adult years (Roberts and Mroczek 2008; Helson et al. 2002). For example, over the course of adulthood, men and women tend to become more emotionally stable (i.e., mean-level decline in neuroticism) and more agreeable and conscientious (i.e., mean level increases in these traits), whereas the mean levels of openness to experience and extraversion tend to stay fairly stable, especially in midlife and into old age. Although the exact causes of these changes in key personality traits are not entirely known (see Roberts and Wood 2006), it is logical to conclude that these mean-level changes are also reflected in adults' changing self-representations. For example, mean-level changes in agreeableness are likely to be reflected in adults' self-representations related to getting better along with others, coping with conflict more constructively, and perhaps being more tolerant toward the opinions and attitudes of others. Similarly, mean-level changes in conscientiousness may be represented in the self-concept as having become more serious about personal tasks and responsibilities and having stronger commitments to certain pursuits, such as performance in the workplace or taking better care of one's physical health, financial security, or psychological well-being. Thus, although the connection between changes in personality traits and

self-representations has not been extensively investigated (Diehl 2006), some studies suggest that such a connection exists even into very old age (Troll and Skaff 1997) and, hence, requires more scientific attention.

Changes in self-representations are very likely also the result of changes in *social roles* and changes in role expectations and responsibilities. For example, most societies have normative age-graded expectations with regard to certain social roles, such as family-related roles, work-related roles, or community-related roles (Settersten and Hagestad 2015). Indeed, life-course sociologists have coined the terms “social clock” and “social age” (Hagestad 1990) to indicate that individuals’ lives are structured and evaluated according to certain sociocultural timetables. As such, individuals can be on-time or off-time with regard to these social timetables, and the degree of synchrony or asynchrony with such timetables very likely is reflected in their role-specific self-representations. Also, whereas changes in social roles in young adulthood are primarily characterized by the entry into new social roles (e.g., committed relationship, transition to parenthood, first steady employment, etc.), in midlife and old age, the opposite is primarily the case. That is, changes in social roles in midlife and old age are primarily characterized by *exit events*, such as the last child leaving home, retirement, loss of friends, widowhood, relocation, or the relinquishing of roles in the community, which can greatly challenge a person’s self-concept and sense of self-esteem (see Kling et al. 1997).

Finally, changes in self-representations are also tied to individuals’ *life plans* for and *normative expectations* about the adult years, including the occurrence or nonoccurrence of *life events* and individuals’ perceptions of *personal lifetime*. For example, research by Heckhausen et al. (1989) has shown that adults possess quite well-defined expectations regarding their psychological and social development across the adult life span. These expectations are shared by young, middle-aged, and older adults and are rooted in social and cultural norms that use chronological age as the indicator for having met certain developmental goals (MacMillan 2005). In combination with

the occurrence of expected or unexpected life events (Helson et al. 2009) and personal perceptions of lifetime (Neugarten 1979; Carstensen et al. 1999), these social timetables often motivate individuals to engage in a midlife stock-taking or “*midlife review*” (Stewart and Vandewater 1999), with profound influences on their personality and self-representations (Helson and Soto 2005). In particular, during this process of midlife review, adults may have to come to grips with the fact that certain life plans did not materialize as hoped and that certain goals may have become unattainable. Thus, adults may realize that they have passed what Heckhausen et al. (2001) referred to as *developmental deadlines* or that time for the attainment of a desired goal is running out. Under more favorable circumstances, however, they may realize that the attainment of a certain goal and the realization of a certain life plan may require a “midcourse correction” and reorientation (Stewart and Vandewater 1999). Regardless of what scenario an individual may be confronted with (e.g., in family and personal relationships, at work, and in professional career), in each instance the psychological processes and potential action choices very likely will have an effect on the person’s self-representations and will activate the self-stabilizing processes described by Brandtstädter and Greve (1994). A particular outcome associated with these processes is the person’s increased awareness of his or her own age (Diehl and Wahl 2010) and also a keen awareness of personal lifetime (Carstensen et al. 1999). That is, individuals’ time horizons of past, present, and future selves are likely to shift (Ryff 1991) when they realize that they have less time to live than they have already lived – a realization that usually happens in late middle age or early old age (i.e., approximately between 45 and 60 years). In addition, actual age-related changes in an individual’s behavior, such as physical appearance and health, cognitive functioning, interpersonal relationships, or social-emotional functions, are likely to become noticed by the individual, creating an awareness of his or her own aging. Thus, this increasing awareness of one’s own aging is likely to become a defining feature of the aging self (Diehl and Wahl 2010).

This important developmental process, however, has not been systematically investigated in the context of self-representations, and therefore we are focusing on this aspect in more detail in the following section.

Awareness of Aging as a Central Feature of the Aging Self

The construct of *awareness of aging (AoA)* refers to an individual's perceived experience of growing old(er) and can be assumed to become an integral part of the self-concept. AoA encompasses concepts such as age identity, self-perceptions of aging, and awareness of age-related change (AARC), all of which are concerned with how individuals perceive and interpret their own aging process (Diehl et al. 2014b), that is, how and what kind of self-representations individuals form of their own aging. AoA deserves scientific attention because of its well-documented associations with health and well-being in later life (Westerhof et al. 2014).

To illustrate the connection of AoA with adults' functioning and potential developmental outcomes, we use the example of a single-item question of subjective age, which simply asks adults "How old do you feel?" (Kastenbaum et al. 1972). The difference score between the age a person states in response to this question and the individual's actual chronological age is a robust predictor of a whole host of behavioral outcomes, including functional health and mortality (Hublely and Russell 2009; Westerhof and Barrett 2005). However, what is less known is the exact nature of the "tacit knowledge" that goes into this simple measure of subjective aging, making it such a powerful predictor of late life development. The concept of *awareness of age-related change* (AARC; Diehl and Wahl 2010) was proposed to provide a conceptual framework for investigating the subjective knowledge that forms the foundation for the predictive validity of a number of subjective age ratings.

Diehl and Wahl (2010) define AARC as "... all those experiences that make a person aware that his or her behavior, level of performance, or ways

of experiencing his or her life have changed as a consequence of having grown older" (p. 340). Compared to other AoA constructs, AARC is a new concept because of its focus on the actual behavioral experiences that underlie adults' subjective perceptions of aging. For instance, AARC focuses on age-related changes in five behavioral domains, such as physical health, cognitive functioning, or interpersonal relationships, and addresses both positive and negative changes in these domains. Because of this elaborated structure, the systematic elaboration of the AARC construct provides an opportunity to advance both theoretical and empirical endeavors in the field of subjective aging.

Based on the theoretical model proposed by Diehl and colleagues (2014b), it is possible to postulate certain factors which can be expected to influence the development of AARC. For instance, developmental influences such as early life experiences, lifetime health, and social relationships are likely to shape a person's AARC across the life span. Furthermore, socioeconomic resources (e.g., education, finances, and access to health care), cultural influences (e.g., cultural age norms and expectations, aging-related social policies), and psychological resources (e.g., coping, emotion regulation, and personality) are also theorized to influence the development of AARC. Longitudinal evidence from investigations of other AoA concepts, such as attitudes toward own aging (ATOA), supports expectations of the importance of developmental, socioeconomic, cultural, and psychological resources. For instance, findings from a 12-year study (Miche et al. 2014) showed that a variety of personality, socioeconomic, and health-related factors influenced ATOA in middle-aged individuals (early 1940s to mid-1950s), whereas health and physical functioning were more relevant predictors among young-old adults (early 1960s to mid-1970s).

Understanding the role of AARC as part of adults' self-representations is also important in the context of behaviors that individuals may or may not engage in to promote their own health and well-being across the adult years. A large body of research suggests that most individuals

hold negative views of aging (Hummert 2011), and these negative views can and often do undermine individuals' efforts to engage in behaviors that promote healthy and successful aging (Levy and Myers 2004). There have been some investigations so far into the specific pathways (Levy 2009) by which attitudes interfere with engagement in health-promoting behaviors. For instance, a psychological pathway may manifest as a low degree of *perceived control* over the environment (Lachman et al. 2011) or as the *misattribution* of a health problem to the inevitable process of "getting old" (Sarkisian et al. 2007). Such pathways involving AoA are consequential because they limit and undermine individuals' participation in health-promoting behaviors. Given the well-documented connection between AoA and health behaviors, researchers have also begun to ask whether targeting AoA and the associated self-representations may be a fruitful way to promote healthy and successful aging (Kotter-Grühn 2015). In recent years, there have been several attempts to change negative views on aging with such a goal in mind (Sarkisian et al. 2007; Wolff et al. 2014).

In summary, AoA represents a central aspect of adults' self-concept, and a growing body of evidence suggests that it is associated with a number of important outcomes in late life (Diehl and Wahl 2015). Because AoA is not a fixed state, but rather a process that unfolds over time as a result of many different life experiences, it also holds promise with regard to intervention and prevention. Specifically, research on AoA holds the promise to open new views and to lead to new approaches on how adult development and aging can be optimized. The long-term goal of these endeavors is the improvement of adults' health and well-being and the delay of age-related disease and impairment.

Conclusions and Outlook

As this entry shows, a self-theoretical approach to adult development and aging has a number of unique features that are not represented in other theoretical approaches. First, a focus on

self-representations is concerned with individuals as active agents and as producers of their own development, including the dialectics that are inherent in the related psychological, social, and interpersonal processes (Diehl 2006). In particular, self-theoretical approaches can theoretically and empirically account for key processes of adult development and aging such as continuity and discontinuity.

Second, a self-theoretical approach can enhance the explanation of certain phenomena that have puzzled aging researchers for quite a while. Among these puzzles is the "paradox of well-being," which refers to the fact that despite an increasingly negative ratio between gains and losses across the adult life span and despite objective losses, older adults tend to show fairly high levels of psychological well-being. Brandtstädter and Greve's (1994) model of assimilative, accommodative, and immunizing processes, for example, can describe and explain how "strategic" adjustments to self-representations and personal goals stabilize a person's sense of self-worth when it is threatened by the challenges and losses associated with growing old(er).

Finally, recent theoretical developments that view awareness of aging as a central component of middle-aged and older adults' self-concept (Diehl et al. 2014b) also open new vistas for intervention and prevention efforts. In particular, by focusing on adults' negative views on aging, and drawing on motivational approaches to improve these negative views, new intervention programs are being designed to promote behaviors that are known to promote healthy and successful aging. One of the big challenges of the ongoing global population aging is how to get individuals to take greater responsibility for their own adult development and aging and how to delay the onset of age-related diseases. Essentially, the delay of disease onset or disease-related loss often requires that individuals need to embrace and engage in behavior change for the long run. Self-theoretical approaches may provide some of the key elements to achieve such long-term behavior change and to optimize current and future generations' aging experience.

Primary progressive aphasia semantic; Semantic variant primary progress aphasia (svPPA); Temporal variant frontotemporal dementia

Definition

Semantic dementia (SD) is a progressive neurodegenerative syndrome characterized by a gradual

decline in semantic processing and related language abilities. SD patients typically show difficulty with the comprehension and expression of words and a deterioration of semantic knowledge about places, people, objects, and general information (Murre et al. 2001). While the ability to produce speech remains unchanged, individuals with SD often struggle finding the correct word during conversation, first for less commonly used words and then for more rudimentary ones. These symptoms progress until the ability to understand the basic components of language and semantic relationships is lost, resulting in impaired ability to read, write, and partake in conversation (Kertesz et al. 2010).

What Is Semantic Dementia

Semantic dementia is one of several clinical syndromes within the broad construct of frontotemporal dementia (FTD). FTD is still sometimes referred to as Pick's disease after Dr. Arnold Pick, the eighteenth-century physician who first described a patient with the collection of behavioral and language symptoms now associated with FTD (Bott et al. 2014). The nosological classification of FTD and its associated syndromes have been debated ever since Dr. Pick's description at the turn of the century. Dr. David Neary and colleagues (Neary et al. 1998) created a consensus study group, proposing a broad construct called frontotemporal lobar degeneration (FTLD), which encompasses several syndromes that selectively affect the frontal and temporal cortex. FTLD consists of three clinical syndromes: FTD, progressive nonfluent aphasia, and progressive fluent aphasia.

Updated since 1998, a revised conceptualization of FTLD is generally broken down in to clinical subtypes characterized by changes in behavior (behavioral variant FTD or bvFTD) or changes in language (primary progressive aphasia or PPA). PPA is further divided in to semantic dementia (also known as semantic variant PPA), nonfluent variant PPA, and logopenic variant PPA (Bott et al. 2014; Gorno-Tempini et al. 2011).

The cognitive profile now associated with SD was first described by Dr. Elizabeth Warrington in her seminal 1975 publication (Warrington 1975).

She presented the case study of three patients, all of whom demonstrated a pronounced loss in semantic memory and associated language processes, coupled with preserved speech production and solid performance in other areas of cognition (Warrington 1975; McCarthy and Warrington 2015). However, the emphasis of the paper was primarily on understanding semantic memory deficits, as compared to describing a unifying disorder. The term semantic dementia was first presented in 1989 by Dr. Julie Snowden and colleagues and then further refined by Dr. John Hodges and colleagues in 1992, providing a label for the collection of cognitive impairments presented by Dr. Warrington (Hodges et al. 1992; Snowden et al. 1989).

Diagnostic Criteria

The most recent international consortium criteria for SD were established in 2011 (Gorno-Tempini et al. 2011). Inclusion criteria for SD requires the presence of three core features: language difficulty as the most prominent clinical feature, language difficulty as the cause of impaired ability to perform daily living activities, and the presence of aphasia as the most significant deficit at symptom onset and during the initial phase of the disease. Exclusion criteria include the presence of prominent initial behavioral disturbances, episodic or visual memory impairments, or visuoperceptual difficulties, and the symptoms cannot be better accounted for by psychiatric or nondegenerative nervous system or medical disorders.

The 2011 consortium criteria also provide three levels of diagnostic certainty for a diagnosis of SD: clinical diagnosis, neuroimaging-supported diagnosis, and definite (Gorno-Tempini et al. 2011). A clinical diagnosis of SD requires impairments on tasks of confrontation naming and single-word comprehension, with at least three out of four additional core features, including (1) impaired object knowledge, (2) surface dyslexia or dysgraphia, (3) spared repetition, and (4) spared speech production. Neuroimaging findings consistent with SD are required for an imaging-supported diagnosis of the syndrome and must show either predominant anterior

temporal lobe atrophy or predominant anterior temporal hypoperfusion or hypometabolism on SPECT or PET imaging. The presence of genetic or pathological confirmation of FTLN is required for a definitive diagnosis of SD.

Pathology and Genetics

Pathological studies suggest that SD is a tauopathy and is thus best classified within the category of FTLN, instead of a variant of amyloid-associated dementias, such as Alzheimer's disease (Rossi and Tagliavini 2015). SD appears to often be associated with Pick bodies, in which a protein called tau clumps together inside nerve cells, inhibiting function and eventually resulting in the death of the cell. However, neuropathological findings are varied, and other studies suggest that SD is associated more with ubiquitin-positive, tau-negative intraneural inclusions typical of motor neuron disease; some patients even show atypical distribution of Alzheimer's disease pathology (Davies et al. 2005; Rossor et al. 2000).

Semantic dementia is characterized by focal atrophy and dysfunction of the anterior and posterior inferior temporal lobe, including the inferior and middle temporal gyri (Mummery et al. 1999). The temporal atrophy is typically left sided, but may also be bilateral. The hippocampus is believed to be spared although findings are somewhat mixed, as studies have found SD-related pathology in the dentate gyrus (Hodges et al. 2010). This selective atrophy of the polar and infero-lateral temporal regions is a unique characteristic of SD and is not seen in Alzheimer's disease (Murre et al. 2001).

An estimated 40% of all FTD cases include a family history of dementia, with approximately 10% of patients being autosomal dominant, affecting first-degree relatives across two generations (Bott et al. 2014). Of autosomal dominant cases, *MAPT*, *GRN*, and *C9ORF72* are the most common genes responsible for the inheritance of FTD. Of FTD syndromes, SD is the least likely to be hereditary, with a predicted familial rate between 2% and 7%, although a mutation in the

MAPT gene has been reported in a case of SD (Hodges et al. 2010; Goldman et al. 2005; Bessi et al. 2010).

Clinical Presentation and Cognitive Deficits

As defined in the diagnostic criteria, the common complaint by individuals with SD is difficulty with aspects of expressive and receptive language, as language dysfunction is often the main symptom during the first 2 years of the disease (Bang et al. 2015). This is due to the disease's selective targeting of the left temporal lobe, a region of the brain critical for language abilities (Kertesz et al. 2010). Importantly, the ability to produce speech is preserved and remains fluent, but words start to lose meaning. Patients with SD may start substituting words in conversation, such as saying "that thing" in place of a noun, or progress from using more specific words to terms representative of broader concepts (e.g., from penguin to bird to thing). The progressive loss from specific to broad word categories may reflect the relative strength and frequency of use for each concept or word within the semantic network. More familiar, common items are associated with deeper, richer, and more robust semantic networks. This robustness results in a higher probability of a term or concept being resilient and remaining preserved despite initial degradation of semantic networks (Lambon Ralph et al. 1998).

Semantic dementia-associated language deficits are present across multiple modalities, not just for words, suggesting the disease represents a breakdown in networks important in conceptual knowledge (Bozeat et al. 2000). This breakdown in semantic networks in turn results in the more clinically evident deficits in language associated with the disease (Lambon Ralph et al. 1998). As such, patients with SD not only experience difficulty with word finding but also in the ability to recall the meaning of words and related concepts. Patients may ask "What does that word mean?" even for vocabulary commonly used in the past, as well as lose the ability to understand how concepts are related across semantic constructs (e.g., how a

giraffe and a tiger are related). This deficit results in difficulty with comprehension and expression during conversations, as patients rely on related yet incorrect words to communicate a message. SD-related deficits in verbal comprehension have profound effects on patient's daily activities. Tasks that involve spoken or written language, such as holding a conversation or watching television, become very difficult to undertake. The loss of word comprehension and related word concept is fairly unique to SD, as word knowledge is largely preserved across the aging process. Patients may also decline in other abilities that rely upon semantic processing, such as the ability to spell, comprehend written material, and remember names.

SD is associated with deficits across a variety of neuropsychological measures. Along with word comprehension and word finding difficulties, individuals with SD demonstrate impaired performance on other tests that rely upon semantic knowledge, including confrontational picture naming, matching words based on their semantic relationship, producing words within a semantic category (e.g., provide the names for as many types of animals as possible), and providing the name of an item based on its description (Murre et al. 2001).

While language-related abilities decline in patients with SD, other cognitive abilities not mediated by anterolateral temporal lobes remain preserved. Whereas episodic memory declines in other neurodegenerative diseases, such as Alzheimer's disease, this ability may remain largely untouched in SD. Interestingly, patients with SD are better able to remember more recent as compared to remote information, although may struggle when asked to provide more detail (Hodges and Graham 1998). This pattern is a reversal of the temporal gradient typically seen in other dementias and is likely due to the selective atrophy of the neocortex of the temporal lobes, combined with the largely spared hippocampal integrity frequently seen in SD (Hodges and Graham 1998). Executive functioning, performing math, visuospatial skills, nonverbal reasoning, and daily activities such as driving are largely preserved until later in the course of

the disease. This intact ability to perform daily tasks creates an odd juxtaposition. For example, patients may be able to use a hammer, but may be unable to provide the name or understand the word for the object.

SD is primarily described in terms of language deficits, as the syndrome typically presents with left greater than right atrophy of the anterior temporal lobes. In left variant SD, functions pertaining to the right hemisphere are sometimes "released." In such cases, patients can develop visual-based compulsions, including painting, puzzle work, jewelry beading, and collecting items (e.g., coins, brightly colored objects) (Bang et al. 2015).

Twenty-five percent of cases present with right greater than left atrophy (Thompson et al. 2003). When SD starts in the right temporal lobe, patients may have difficulty recognizing faces and experience changes in behavior. Typical behavioral symptoms include a lack of empathy and engagement, an increase in compulsive behaviors such as writing notes, rigid thinking, awkward social interactions, loss of insight into behavior, difficulty with theory of mind, and restricted food preferences (Bott et al. 2014; Bang et al. 2015). Regardless of the side of onset, SD usually spreads to involve the contralateral side as the disease progresses.

Daily Functioning

Patients diagnosed with semantic dementia, unlike the behavioral variant of frontotemporal dementia, often do not display significant behavioral changes at the onset of the disease. However, as the disease progresses and begins to impact regions beyond the temporal lobes, a variety of behavioral changes more typical of FTD may occur that impact daily functioning and interpersonal relationships. Individuals in later stages of SD may present as disinhibited, engaging in socially inappropriate behavior with little insight in to how they are perceived by others, including a lack of embarrassment. Individuals may also show disregard for the feelings of others and display a general social coldness that includes a lack

of empathy (Bang et al. 2015). Individuals with SD may also neglect basic aspects of self-care, such as bathing regularly, due to general apathy and difficulty with initiation.

Symptoms of depression are seen in 44% of individuals with SD and occur regardless of side of disease onset (Bang et al. 2015). However, symptom presentation varies, as right-sided SD is associated with anxiety, atypical depression, and denial of symptoms, while patients with left-sided SD are more likely to report anhedonia and other classic depressive symptoms (Edwards-Lee et al. 1997). Individuals may also demonstrate exaggerated emotional responses to situations, such as extreme happiness or sadness and generally increased lability. This lability may be correlated with events or tasks that pertain to the patient's self-interests or clash with the patient's increased mental rigidity. Patients with a predominately right-sided disease focus may be prone to violent outburst and be argumentative, while patients with left-sided disease may become more "mellow" (Edwards-Lee et al. 1997).

The obsessions and compulsions of individuals diagnosed with SD can take many forms and may increase in intensity to the point of interfering with daily activities. Individuals may become focused on watching clocks, eating only select foods, or fixating on certain games or puzzles. The obsessions of individuals with predominately left-sided temporal lobe disease tend to focus on visual compulsions, such as painting or collecting objects. In contrast, right-sided SD often manifest in verbal compulsions (Bang et al. 2015).

These changes in empathy and personality can be very trying and difficult for the family members of individuals with SD, as the patient's behavior and disposition are often in stark contrast to how he or she was prior to disease onset. The lack of emotional reciprocity and awareness of social etiquette can be especially difficult, straining interpersonal relationships and making social outings challenging.

Course of Disease

Semantic dementia is estimated to represent 20–25% of all FTD cases and 3% of all dementia

cases (Kertesz et al. 2010). The age of disease onset is often earlier than what is seen in Alzheimer's disease and similar to other forms of frontotemporal dementia, usually ranging from 45 to 65 years old, although late-onset SD does sometimes occur in the elderly (Shimizu et al. 2011). The mean age of symptom onset is age 60 with diagnosis occurring 4 years later on average (Hodges et al. 2010). Postmortem studies reveal a median survival rate of approximately 8 years with a range of 3–15 years (Hodges et al. 2003). However, this finding was based on a relatively small sample size ($n \leq 20$) and may have "been biased by the restriction to patients reaching autopsy." (Hodges et al. 2010) Another study by the several of the same authors utilizing a larger sample size reported a variable survival rate, as patients may pass away anywhere from 2 to 3 years after diagnosis to 17 years, with a 50% survival rate of 12 years (Hodges et al. 2010).

Conclusions

Semantic dementia (SD) is a neurodegenerative disorder characterized by a decline in semantic processing and language abilities, while the ability to produce speech and other cognitive abilities remain initially largely untouched. Couched within broad construct of frontotemporal dementia, SD has been characterized through a rich history of the case studies and only more recently is being studied empirically with larger sample sizes. SD often initially presents as difficulty with word finding and then transitions to problems with language comprehension and a breakdown in larger semantic memory-dependent tasks. As the disease progress, individuals with SD may begin to show changes in personality and behavior. The age of disease onset ranges from 45 to 65 years old, with a 50% survival rate of 12 years.

Definition

This entry reviews the interacting relationships between sensory (audition, vision) and

sensorimotor (gross and fine motor) aging and cognitive aging. Evidence from experimental age-simulation, clinical, intervention, and neuroimaging approaches is summarized, along with major theories linking sensory/sensorimotor aging to cognition.

Background

The impact of sensory aging on cognitive status is a growing focus of research (Salthouse 2010; Scialfa 2002; Schneider and Pichora-Fuller 2000). On this topic, the visual and auditory systems have been most closely examined given that these are the two predominant sources of environmental input for further perceptual and cognitive analysis. For instance, the integrity of signals entering the cognitive system via auditory or visual channels, if compromised or degraded by aging, have been shown to impede efficient cognitive processing of that information due to a need to engage in top-down processing (e.g., contextual knowledge) to “fill in the blanks.” A less commonly considered influence on cognitive functioning is the age-related decline of sensorimotor processes. This domain of functioning, which encompasses gross and fine motor tasks, requires the integration of multiple sensory inputs (tactile, visual, vestibular, proprioceptive). As such, sensorimotor aging has more recently been considered in terms of its indirect effects on cognitive processing efficiency. For example, motor tasks such as postural control and object manipulation appear to enlist more cognitive capacity in old age, consequently detracting from ongoing cognitive tasks such as memory retrieval, language processing, or navigation.

Within each domain (auditory, visual, motoric, cognitive), there is well-established evidence of gradual age-related degeneration that can be observed at anatomical, neuronal, and behavioral levels. What is currently less well established is our understanding of how, across domains, multiple age-related declines influence one another. The extant research has focused on theoretical questions concerning the directionality of influence (unidirectional, reciprocal, indirect) and

whether other more general factors can account for correlated declines in sensory/sensorimotor and cognitive domains. On a more applied level, another topic of interest is whether the accurate assessment of cognitive abilities is hampered or biased when individual differences in sensory impairments remain uncorrected or when cognitive assessment tools are not optimally designed for individuals with subclinical sensory declines.

Much of the contemporary research linking sensory/sensorimotor aging and cognitive aging stems from a large-scale longitudinal study known as the Berlin Aging Study (BASE), which began with a sample of old-old (aged ≥ 70 years) community-dwelling individuals recruited using German city registry information. Multiple indices of physical, psychological, intellectual, and social functioning were collected at regular intervals. Using the early cross-sectional data, it was found that the age-related variance in general intellectual functioning was well accounted for by standard clinical tests of visual acuity (64.5%), auditory acuity (74.5%), and balance and walking speed (82.6%). Markedly lower correlational values were observed in a comparison group of young and middle-aged adults (Baltes and Lindenberger 1997), suggesting an increasingly strong connection between sensory/sensorimotor abilities and intellectual functioning with aging. Subsequent large-scale multivariate studies indicate broad agreement, although the identification of a singular “common cause” underlying sensory/sensorimotor and cognitive aging has been challenged by other efforts such as the Australian Longitudinal Study of Aging (ALSA). Follow-up longitudinal analyses of the BASE sample indicate weaker support for a single-factor model linking sensory and cognitive aging than the original cross-sectional report, leaving open the possibility of co-occurring factors such as cognitive compensation for sensory aging.

What follows is a review of the three main areas of research linking auditory, visual, and sensorimotor aging with cognitive functioning. Highlighted are key methodological approaches such as experimental age simulations of sensory decline, structural and functional neuroimaging,

and sensory remediation. Current theoretical views and future research directions are then presented in an effort to integrate and reconcile findings generated from three areas that have advanced in relative isolation from one another.

Effects of Aging Audition on Cognition

The most prevalent type of auditory impairment in old age is presbycusis or loss of sensitivity to high frequency sounds. However, hearing is also impacted by other age-normative changes including both peripheral and cognitive factors (Schneider and Pichora-Fuller 2000; Schneider et al. 2010). Although hearing loss may account for speech-recognition difficulties in quiet conditions, peripheral changes in the auditory system can only account for a portion of the difficulties experienced by older adults in noisy and multi-speaker situations. To this end, to fully comprehend an auditory scene, listeners must locate and perceptually segregate the sound sources in their environment in order to focus their attention on target sources and ignore the processing of information from irrelevant sources. In addition to locating speakers in space and focusing attention on relevant information, speech comprehension is affected by temporal processing, partly under the control of the central auditory nervous system. With age, processing speed and interaural timing are affected, with the auditory system becoming slower and more asynchronous, respectively. However, cognitive theorists have suggested that in addition to signal degradation from a deteriorating peripheral auditory system, older adults may be more vulnerable to intrusions from irrelevant or distracting stimuli than younger adults due to age-related changes in cognitive functioning such as changes in working memory, slowed speed of processing, and a deficit in inhibition. In tandem, older adults also utilize cognitive resources (e.g., working memory) to compensate for age-related hearing loss.

Epidemiological studies have revealed a correlation between hearing loss and cognitive function that remains even after correcting for individual differences in comorbid conditions, chronological

age, and cognitive status. Furthermore, the prevalence of hearing loss is greater in demented than non-demented groups (Schneider et al. 2010). While the auditory-cognitive link is well replicated in such approaches, explorations of underlying causes require more experimental designs.

One such research strategy is to simulate aspects of age-related hearing loss by degrading the auditory speech signal to mimic a specific feature of the auditory system that is hypothesized to decline and affect cognitive performance. Examples of such experimental manipulations include presenting speech in noise, increasing the rate of speech, or adding temporal jitter, to mimic age-related declines in perceptual segregation, processing speed, and temporal processing, respectively. In studies of speech perception, older adults derive more benefit from informative sentence context than young adults (Pichora-Fuller et al. 1995; Schneider and Pichora-Fuller 2000), and performance is influenced by the predictive context of the stimulus (Burke and Shafto 2008). However, this utilization of top-down resources has been thought to detract from other cognitive processes: When auditory memory stimuli are presented in background noise such as multi-talker babble, age and noise have similar negative effects on long-term memory but not immediate memory, presumably because the auditory challenge interferes with capacity-limited memory encoding processes. Similarly, when speech rate is manipulated, the effects of age, hearing loss, and accelerated speech are more detrimental in syntactically complex sentences than in simple ones (Schneider et al. 2010). Therefore, age-related changes in hearing ability may be compensated for by recruiting cognitive resources, but at a cost to other ongoing cognitive activity. An implication of such findings is that when a listening task is simple or provides adequate environmental support, the older listener may successfully perform the task but expend more cognitive effort or capacity to do so. Effortful listening is a common complaint of older adults even when auditory acuity is within the normal range.

The interpretation of top-down cognitive compensation has been further explored using

dual-task methodology. In this approach, participants are administered an auditory task and a nonauditory task separately (i.e., single-task conditions) and simultaneously (i.e., the dual-task condition). This approach assumes that if older adults recruit more cognitive capacity to perform listening tasks, they should show larger dual-task costs than young adults. Dual-task costs are typically defined as a drop in performance from single-task to dual-task conditions, as expressed by absolute or proportional difference scores. Accordingly, compared to their age-matched peers, individuals with hearing loss show greater dual-task costs on a nonauditory secondary task while maintaining good auditory task performance under dual-task conditions. Notably, this pattern holds even after hearing loss is corrected by increasing the signal intensity or by improving the signal-to-noise ratio. This pattern is consistent with the view that more cognitive resources are needed to compensate for sensory deficits (McDaniel et al. 2008). Very new work using structural and functional magnetic resonance imaging (MRI) shows global decreases in brain volume in hearing-impaired older adults as compared to their age-matched peers and increased involvement of prefrontal cortical regions in older adults while performing listening tasks.

Others have investigated the impact of correcting for auditory impairments on cognitive functioning. In those older adults with diagnosed hearing impairment, sensory remediation (i.e., hearing aid use) has resulted in significant improvement on cognitive measures administered within the same modality as the intervention. This finding supports the importance of assessing hearing acuity in both research and clinical assessments of cognition. Furthermore, cognitive scores (working memory, general intelligence) correlate with measures of speech perception, even after amplification with hearing aids. Finally, individual differences in cognitive capacity are predictive of the degree to which individuals can benefit from more complex, cognitively demanding hearing aid models (Schneider et al. 2010), suggesting a reciprocal relationship between auditory and cognitive aging.

Effects of Aging Vision on Cognition

As with the aging auditory system, there are multiple anatomical changes to the visual system that occur gradually during the normal course of aging. Normative age-related transformations of the eye structures (e.g., decreased pupil size, increased lens density, yellowing, and opacity) result in reduced accommodation to near objects (presbyopia) and less light reaching the retina. Older adults show reductions in light sensitivity, contrast sensitivity, retinal illumination, and color vision, which affect more complex visual processes (Schneider and Pichora-Fuller 2000). Age-related slowing of visual processing has implications for older adults' ability to detect, identify, and track visual stimuli. These visual functions are fundamental precursors to many upstream cognitive processes. There is considerable evidence for age-related decline in visual tests of inhibition, selective attention, task switching, multitask processing, and processing speed (Burke and Shafto 2008; Kramer and Madden 2008). Older adults exhibit a slowdown in visual target detection, recognition, and identification of visual objects which adversely affects top-down processes that are typical of cognitive aging, including working memory. As demonstrated in the hearing-cognition literature, longitudinal and cross-sectional research has shown strong correlations between visual acuity and fluid cognitive abilities such as memory and attention (Scialfa 2002).

Age-simulation techniques have also been used in the visual domain to examine the interplay between age changes in cognition and sensory function. For instance, partial occlusion filters were used to simulate reduced visual acuity in middle-aged adults who were given standard tests of intelligence. However, this manipulation did not cause significant decreases in cognitive performance as compared to control participants wearing clear goggles. By contrast, subsequent work using similar simulation methods revealed worsened cognitive performance in samples of older adults, whose cognitive capacity is more limited than that of middle-aged adults. Possibly, the earlier findings did not yield significant effects

because there is sufficient spare cognitive capacity to compensate for the occlusion effects in midlife. In other age-simulation work concerning visual search tasks, older adults show slower and more effortful search compared to young adults. Manipulations that reduce luminance or duration of the visual presentation, to mimic lens opacity and slowed processing respectively, cause younger adults' pattern of visual search performance to resemble that of older adults (Scialfa 2002).

Other age-simulation work has shown larger age effects in visual processing speed when attentional load and background visual noise are increased. In the useful field of view (UFOV) task, the examinee is instructed to indicate the location of a peripheral target which may be embedded among an array of distractors. It is shown that older adults' UFOV is worsened when performed with a simultaneous cognitive task (Owsley 2011). Taken together, given a sufficiently demanding task, older adults' performance is disproportionately worsened in comparison to younger adults when either the visual demands of a cognitive task are increased or when the cognitive demands of a visual task are increased.

Further evidence of age-related cognitive recruitment comes from neuroimaging studies in which there are age-related differences in the pattern of brain activation during a cognitive task. For example, in selective attention tasks, older adults show greater activation of frontoparietal regions and reduced activity in visual cortices during visual search compared to younger adults. Sensory aging is also found to be associated with age-related decline in visual cortex activation during word recognition (Kramer and Madden 2008). Studies of visual language processing (dependent on visual acuity and contrast sensitivity) show that increments in word length differentially increased the lexical decision latency in older adults compared to younger adults, and this was linked to less activation of visual cortex. Similarly, in a fMRI study of lexical decision, older but not younger adults showed improved performance when word frequency increased. This frequency-related benefit was linked to increased activation of anterior and posterior regions of the occipitotemporal pathway.

The interpretation given was that older adults utilize higher-order functions as a compensatory mechanism for declines in sensory processes (Burke and Shafto 2008), similar to what has been shown in the auditory aging research.

Intervention studies have shown that practice may improve cognition through the utilization of top-down mechanisms that outweigh the use of bottom-up sensory processes (Scialfa 2002). For example, visual processing speed and the ability to perform multiple attention tasks can be enhanced through a training program in which older adults practice the detection and discrimination of visual stimuli (Owsley 2011). Surgical intervention in the form of cataract surgery has yielded improvements to cognitive performance to some degree, although the clinical significance of the observed improvements has been called into question (Jefferis et al. 2011).

There is support for the notion that visual deficits produce age-related changes in cognition that may cause difficulty for older adults to process test material (Scialfa 2002). Therefore, cognitive tests are possibly biased against individuals with poor vision who attain poor cognitive performance scores. For example, seniors show larger Stroop interference effects which are commonly understood as a decline in selective attention. However, it has been shown that age-related deterioration in color vision might be responsible for an increase in the interference effect (defined as the difference between color naming and reading color-neutral stimulus latency) in seniors (Ben-David and Schneider 2009). Consistent with this finding, researchers have examined the Montreal Cognitive Assessment (MoCA), a widely used screening test for mild cognitive impairment (MCI), in terms of its suitability for older individuals with low vision. When four visual items were removed from the global score, test specificity increased, but the sensitivity to detect MCI in visually impaired older adults was reduced, suggesting that visual impairment may be a harbinger of cognitive impairment (Wittich et al. 2010).

Importantly, one should consider the role of sensory function in experimental design to diminish the effect of sensory loss on cognitive

performance. For instance, participants should be screened for visual health (near and far acuity, contrast sensitivity, UFOV) as appropriate for the experimental tests in question. Furthermore, visual test stimuli should be presented in consistently optimal conditions by avoiding low luminance and contrast, high spatial and temporal frequency, or short wavelengths (Scialfa 2002).

Effects of Sensorimotor Aging on Cognition

Following from the early correlational findings generated by the BASE and ALSA projects, a growing body of research has concerned the link between sensorimotor aging and cognition (Seidler et al. 2010; Woollacott and Shumway-Cook 2002; Yogev-Seligmann et al. 2008). Age-related loss of muscle mass leads to slowed contraction speed, loss of receptors in the joints reduces proprioceptive input, and degeneration in the basal ganglia, cerebellum, and motor cortex results in disruptions in movement onset, timing, and coordination of movement, respectively. Further age-related changes in sensorimotor integration affect movement velocity and correction (Ketcham and Stelmach 2001). Apart from such age-normative changes, conditions such as rheumatoid arthritis or Parkinson's disease affect the ease and control of movement.

Early models of gross motor control assumed that standing balance and locomotion were primarily driven by spinal and not cerebral circuits. Only recently has there been broad acceptance of the role of cognition in these motor tasks. This conceptual shift was, to a large degree, initiated by a clinical observation of dementia patients who, when asked a question, either stopped walking to answer or continued to walk while answering. Patients who stopped fell more frequently in the subsequent 6-month period than those who managed to dual task, suggesting that individual differences in cognitive capacity might be related to motor control. Indeed, measures of walking correlate positively with measures of executive functioning and processing speed, suggesting that there is shared neural circuitry underlying both

domains of functioning. A large body of research has since been generated using experimental dual-task methods borrowed from cognitive psychology.

In much of this work, the emphasis has been on the dual-task costs that arise when a cognitive task is performed simultaneously with gross motor tasks such as walking or balancing. As much of this research has stemmed from the medical and movement sciences, the physical outcomes have been of greater interest than the cognitive. However, one can also consider the detrimental effects on cognitive performance that occur when the motor system is challenged by arthritis or tremor or when fear of falling is at issue and cognitive capacity is allocated to motor control instead of a concurrent cognitive task.

In keeping with other age-simulation work, reduced sensory inputs have been examined in the context of balance control in which the individual is instructed to stand upright without movement for a short period of time (e.g., 30 s). For example, altering proprioceptive input by balancing on a compliant foam surface or restricting vision while balancing is more detrimental to older adults' balance than young adults', and these effects are further exacerbated by the addition of a cognitive load. Similarly, in postural recovery studies involving unpredictable platform movements, older adults commonly show greater dual-task costs than young adults, both in terms of cognitive performance and in the efficiency of postural recovery, again suggesting that sensorimotor and cognitive systems compete for common capacity.

In dual-task studies of walking, it has been shown that older adults have a tendency to allocate more attention to walking than to the concurrent cognitive task, owing to the instinctive desire to prioritize physical safety over cognitive performance. Similar to the auditory and visual age-simulation work, higher-order cognitive processes such as memory encoding and language production have been shown to suffer under dual-task conditions as compared to single-task cognitive conditions. Conversely, dual-task costs in the sensorimotor domain seem less affected by age, suggesting that older adults are less willing to

relinquish cognitive capacity and truly divide their attention between cognitive and locomotor tasks compared to younger adults. This pattern supports the “posture-first principle” or postural prioritization hypothesis. Postural prioritization is commonly expressed by showing greater dual-task costs in the cognitive than in the sensorimotor domain, despite instructions to treat each task with equal importance. Not surprisingly, this prioritization behavior emerges more frequently when testing older fallers and those with self-reported fear of falling or when walking is restricted to a narrow or elevated path that induces fear of falling. In sum, postural prioritization may be seen as an indirect way in which sensorimotor aging can have a negative impact on cognitive performance.

Unlike the dual-task research on visual and auditory perception, in some instances the addition of a concurrent cognitive task is facilitative: Particularly for older adults, balancing or walking paired with a simple cognitive task may improve motor performance compared to single-task conditions, but these benefits turn into costs as the cognitive task increases in complexity (Frazier and Mitra 2008). One interpretation of this nonlinear pattern is that directing full attention to walking or balancing is unnatural and detracts from motor coordination; hence, a simple cognitive task helps by providing an external attentional focus. However, once cognitive complexity exceeds one’s available capacity, performance costs are commonly observed.

Fine motor performance has been examined using finger sequencing and reach-to-grasp protocols measured under single- and dual-task conditions. These investigations reveal similar patterns of age-related increases in dual-task costs. As well, functional neuroimaging studies of older and younger adults performing hand or foot movements, finger sequencing, or tapping commonly show patterns of greater neural activation with age in prefrontal and sensorimotor cortical areas. In contrast to functional neuroimaging studies of visual and auditory tasks, in motor performance studies, it is less common to observe under-activation of regions more associated with peripheral processing that are more typically recruited in young adults.

More recently, portable neuroimaging (functional near-infrared spectroscopy) of walking has revealed that prefrontal brain regions are more involved in walking while talking compared to walking alone and that older adults underutilize the prefrontal cortex to coordinate dual-task performance. Findings from clinical populations provide convergent evidence for the link between cognition and mobility: Patients with Parkinson’s and Alzheimer’s disease exhibit more gait abnormalities when performing a simultaneous cognitive and walking task compared to healthy controls. Intervention studies targeting cognitive attentional training have led to improved gait speed, standing balance, and dual-task walking and balancing (Seidler et al. 2010; Yogeve-Seligmann et al. 2008).

Theoretical Perspectives

Based upon the variety of findings reviewed, a number of explanatory models have been entertained (Schneider and Pichora-Fuller 2000, for an overview). Perhaps the simplest model, *sensory deprivation*, proposes that long-term decline in the sense organs leads to deterioration and atrophy of higher-level cognitive structures. The strong view of this model (irreversible deterioration) has been disconfirmed in studies showing improved cognitive performance following treatment to correct peripheral deficits, although these findings are mixed. A future aim would be to correct for more than one aspect of aging sensory functioning at a time. Further, the sensory deprivation view appears more applicable to the aging of vision and hearing than to motor processes, at least in its strictest form. A more parsimonious but indirect possibility is that declining hearing, vision, and mobility may lead to social withdrawal as activities become more effortful. This in turn might lead to cognitive under-stimulation and eventual cognitive deterioration.

A second major view is the *common-cause hypothesis*, stemming from the original BASE correlational findings. This view states that a third general factor underlies multiple domains of age-related decline. Candidate common factors

include: global neural degeneration, dopaminergic transmission efficiency, behavioral slowing, and genotypic variation. This perspective holds appeal in light of correlations between sensory measures and cognitive measures that have no obvious sensory requirement (e.g., letter fluency). However, as Schneider and Pichora-Fuller (2000) have noted, the third-factor explanation assumes that there is modularity or functional independence of sensory and cognitive systems, which is a debatable assumption.

Quite different from a modular view is the *shared resource* or *integrated system* view, which states that perceptual and cognitive systems share neural structures and resources. Within this perspective, cognitive decline could influence performance on perceptual tasks, and conversely, increased perceptual or motoric challenge would draw more resources from cognitive networks. Age-simulation designs, in which increasing sensory load results in reductions to cognitive performance, support the shared resource view. Similarly, studies in which cognitive load is increased by adding task complexity or by adding a concurrent task frequently result in costs to perceptual or motor performance.

Related to this is the *cognitive compensation* perspective, as illustrated in functional neuroimaging studies showing supplementary brain activation in prefrontal or contralateral regions more so in older than in younger adults and in behavioral studies of word perception in which older adults benefit more from the presence of semantic context as compared to young adults. Across auditory, visual, and motor aging literatures, the strict criterion for cognitive compensation is the observation of age-equivalent performance levels. However, age equivalence may not be attainable when cognitive resources are not sufficient to both compensate for sensory/sensorimotor declines and address the cognitive demands of the task at hand (Seidler et al. 2010), for example, when auditory memory encoding processes are disrupted by presenting stimuli in noise (Schneider et al. 2010).

Future Directions

The work on sensory/sensorimotor aging and its effects on cognition are moving toward further consideration of cross-domain and reciprocal interactions. For example, epidemiological work links hearing acuity and mobility, showing that older adults with hearing impairment are at greater risk of falling than their normal-hearing peers. Also on the topic of age-related hearing loss, combined audiovisual presentation shows promise in improving performance on comprehension and working memory tasks. In future work, longitudinal designs will be essential for the elucidation of lead-lag relationships among domains of functioning and should move beyond the aim to identify candidate common factors, taking into consideration the possibility of cognitive compensation. Currently these aims have been examined using distinct methodological approaches. The emerging research also calls for a closer examination of the sensory and motoric requirements inherent in standard neurocognitive assessment tools and adaptations to improve measurement sensitivity and specificity. Further work on the implications of combined sensory and cognitive impairments for everyday functioning would complement existing work showing that cognitive status plays a significant role in how well those with sensory impairments fare with activities of daily living (Heyl and Wahl 2012). Lastly, elucidation of the limits of sensory correction (e.g., hearing aid use) within complex real-world environments with multisensory and cognitive demands (postural control, multitasking) will better inform clinicians, end users, and industry.

Synonyms

Attitudes toward sexuality and aging; Geriatric sexuality; Sexual behavior; Sexual dysfunction; Sexual expression in older persons

Definition

Sexuality and aging are a complex field, with attitudes toward sex and sexual expression characterized by factors such as historical context, cultural, and societal expectations as well as

shaped by numerous biological, psychological, and relationship factors.

Introduction

People have increased longevity, and with this comes the notion that they are sexually active for a longer period of time. Biomedical interventions have enabled older people to maintain an active sex life as well as vitality in the bedroom. However, it has only been within the last few years that research has investigated the sexual behavior of older adults, rather than relying on the stereotype that as people age, the need and desire for sexual activity may be less prominent (Marshall 2012). Over the past decade, clinicians and researchers in this field have acknowledged some of the factors associated with sexual functioning in older people, such as the availability of a partner as well as good physical health. It is only recently that the expression of sexuality and sexual behavior in people over the age of 50 years has been explored. This entry presents an overview of the history to sexuality and aging followed by the contemporary view of sexuality, including current attitudes, cultural differences, and sexual expression, in addition to differences between generations on marriage, cohabitation, and dating. It also considers the factors associated with sexual functioning and treatment in older people, with implications for clinical practice and future directions.

From Historical to Contemporary Views of Sexuality

Before the medicalization of sexual dysfunctions, loss of interest in sex as well as ability to function sexually was generally viewed as part of the natural aging process. If individuals experiencing sexual difficulties were to seek treatment, they may have been offered counseling to assist them to adjust to the changes in their bodies, rather than receiving interventions to address the problem. Pioneers in the sex research field, Masters and Johnson (1966) suggested that sexual activity

was still possible among older people and that although some adjustments should be made in accommodating physical and health changes, sex could be enjoyed into older life by placing an emphasis on intimacy, rather than sexual performance. Although the nature and frequency of sexual activity may vary for individuals, there was little evidence available to suggest what was “normal” in regard to sexuality and sexual expression in older people.

The availability of medications to improve sexual functioning, such as the release of Viagra in 1998, has driven the more recent view that older people can maintain a healthy and active sex life. In addition, more is now known about effective therapies for the treatment of sexual dysfunction. Despite this, there is a poor understanding of the factors associated with the continuation and maintenance of sexuality for older people as well as what healthy aging in regard to sexual expression may encompass. There is limited research available on people over the age of 50 to suggest what they are currently experiencing and what they would like to experience in regard to their sexual expression. Given the health and lifestyle factors associated with aging, it is likely that the expression of sexuality will differ from when they were younger. For example, some older people may feel relieved, as they may not want to be as sexually active as they were previously, perhaps due to physical frailty or that they do not perceive sex to be important in the relationship. For others, it may be that sex is critical, and sexual expression will continue into older age, including kissing, touching, and hand-holding. Thus, numerous factors including cultural standards, societal expectations, and individual features may influence sexual behaviors in older age people.

Contemporary Views of Sex

In general, the population has lower mortality rates and an increasing aging population. The focus on physical illness and disease in aging has shifted to the maintenance of good health, with continued sexual functioning being viewed as a positive aspect of the aging process.

Specifically, the “baby boomers” have experienced the sexual revolution of the 1960s and other social changes such as the feminist and gay rights movements. This indicates that there may be a changing of societal norms, values, and trends in relation to sexual attitudes and sexual behavior, and what is socially acceptable may differ for this generation in comparison to previous cohorts of older people. It is highly likely that people within the “baby boomer” era will have very different views and expectations of sexuality. Therefore, previous data on sexual behaviors and expectations in the aging population may no longer be relevant to present-day aging.

Attitudes to Sex and Sexual Expression

To date, there have only been a few studies that have examined the sexual attitudes and behaviors of men and women above the age of 50. The National Social Life, Health, and Aging Project (NSHAP) (Waite et al. 2009), the National Survey of Sexual Health and Behavior (Herbenick et al. 2010), and the American Association of Retired Persons (AARP) study (Fisher 2010) provide some important insights into the attitudes and sexual practices of people aged over 45 years.

Sex and Sexual Behavior

Studies have demonstrated gender differences in attitudes toward sex as well as differences between age cohorts within the aging population. In a study of 1,670 adults over the age of 45, Fisher (2010) found that of the 1,487 people who completed the survey aged over 40 years, 80% of all men and 62% of women under the age of 70 years rated a “satisfying sexual relationship” as important to their quality of life. Only 8% of women over the age of 70 years reported that they agreed with the statement that “sex is only for younger people.” Gender differences have also been found in the literature, with men of all ages rating themselves as more positive about sex and sexual expression than women, regardless of the circumstances (i.e., whether married, dating, or single). Among women, 71% believed there was too much emphasis on sex today, compared to 58% of men.

On the other hand, 67% of men agreed that sex is critical in a good relationship, compared with 50% of women in the sample.

In another study, of men aged 57–64 years, 68% agreed with the statement “Sexual ability decreases with age” (Waite et al. 2009). This increased to 72% of those aged between 65 and 74 years and 78.5% of men aged between 75 and 85 years. For women, the findings were 71%, 83%, and 89%, respectively. Nevertheless, conservative attitudes remain among the older cohort, with many asserting that “religious beliefs guide their sexual behavior” (Waite et al. 2009). In a review of the literature, DeLamater (2012) concluded that a substantial proportion of older people are more likely to believe that sex declines in importance as they age. Moreover, further analyses of the AARP data conducted by DeLamater and Sill (2005) found that men and women who agreed that sex was important also reported significantly greater levels of sexual desire compared to those who did not rate sex as important. Thus, positive attitudes toward sexuality appear to be important for the maintenance of sexual activity in older people. It is also critical to consider the factors that may influence the importance that people place on sexual activity as they age. For example, the burden associated with becoming a caregiver for aging parents, looking after grandchildren, or transitioning into the role of the carer for a partner with declining health may impact on the desire or importance of sex in the relationship.

It has been demonstrated that healthy and physically active individuals over the age of 45 years report greater satisfaction with their sex lives than those who report health problems or increasing physical frailty. Indeed sexual satisfaction decreases sharply with age. Fisher (2010) reported that 12% of the respondents were more satisfied with their sex lives at present than they were 10 years ago, but 46% were currently less satisfied. In a study of sexual activity in adults aged 57 years and older, Waite et al. (2009) found that the most commonly cited reason men gave for not engaging in sex was the health of their partner. Supporting this, the most common response from women was that their own health limitations interfered with sexual activity. Also critical is the

importance of maintaining a sexual relationship for a couple and whether the level and nature of sexual activity throughout their lives is related to a decline in sexual activity in older age.

Sex and Sexual Expression

It has been suggested that older people may consider the use of other forms of sexual activity, such as oral sex and self- or mutual masturbation, when vaginal sex cannot be part of their repertoire. However, one study has shown that 62% of men and 53% of women aged 57–64 reported they had “any” oral sex in the preceding year, which compares with only 28% of men and 36% of women in the 75–85 year age range (Waite et al. 2009). Moreover, studies have shown that a large proportion of older people still engage in vaginal sex in their later years. Herbenick et al. (2010) found that vaginal intercourse was reported by 58% of men and 51% of women aged 50–59. This declined to 43% among men over the age of 70 and more sharply to 22% among women 70 years and older. Similarly, of people aged 57–64 years, 87% of women and 91% of men stated that vaginal intercourse is “usually” or “always” part of sexual activity (Waite et al. 2009). In older cohorts this diminished to 75% of women and 84% of men who indicated that vaginal sex was usually or always part of sexual activity. Thus, people aged above 75 years may not consider the use of oral sex as a substitute for vaginal sex. This may change over time in aging baby boomers, who have more liberal attitudes toward sex and sexuality and who may continue to engage in higher rates of oral and vaginal sex than current cohorts of older people.

DeLamater (2012) found that solo masturbation was common among the older cohort (70+ years), with 46% of men and 33% of women indicating they engaged in this behavior. Interestingly, men with partners were less likely to engage in solo masturbation, whereas for women, solo masturbation was unrelated to partner status. However, some caution in regard to sexual behaviors such as masturbation is advised, given the possibility of a “cohort” effect influencing women who came of age after sexual revolution of the 1960s rather than an effect driven by biological age (Waite et al. 2009).

Marriage, Dating, and Cohabitation

Fisher (2010) found that the number of people aged over 45 years who believe that unmarried people should not have a sexual relationship dropped from 41% 10 years ago to 22% in 2009. This suggests that people in this generational cohort may be more accepting of different forms of relationship and that more people over the age of 45 may be willing to seek a sexual partner if they are widowed or divorced. In particular, the baby boomers have demonstrated more accepting attitudes toward divorce and remarriage as well as cohabitating without marriage. In the study by Fisher (2010), 54% of the participants stated that they were married, and 15% stated that they were dating or engaged, which included those who were single, divorced, and widowed and those who were separated and dating. Interestingly, those who were married reported less sexual satisfaction than those who were currently dating (52% compared to 60%).

Overall, significant gender differences have been found in the research, in that generally men report higher levels of sexual activity and place a greater level of importance on sex in the relationship than women. However, caution is warranted as men are more likely to be partnered, particularly in the older cohort studied (i.e., over 75 years), when compared to women. Women tend to live longer than men and are unlikely to re-partner in older age, explaining to some extent why there is a sharp decline in reported sexual expression in older women (Herbenick et al. 2010). Moreover, Waite et al. (2009) found that among women without a current partner, disinterest in sexual activity increased with age, suggesting either that the lack of a partner in itself lowered sexual interest or that no longer seeking out a partner might have lowered sexual desire. This is in contrast to older men without a partner who still expressed interest in finding a partner (Waite et al. 2009).

Cultural Perspectives

The limited research investigating attitudes toward sexuality and sexual expression in older people has predominantly involved Westernized cultures. Therefore, there is relatively little

information available regarding cross-cultural perspectives of sexuality and aging. However, the few studies that have been conducted in non-Westernized cultures have demonstrated substantial differences between the Western and Asian cultures. A study of 26,000 people aged between 40 and 80 years found that both women and men from China, Japan, and Thailand reported that sex was significantly less important than their Western counterparts (Laumann et al. 2006). Moreover, their sexual satisfaction was significantly lower than men and women from Western countries. People from Asian countries also reported lower levels of satisfaction with their relationships. Nevertheless, gender differences in beliefs about the importance of sex in the relationship and sexual satisfaction remained consistent across the countries; with men reporting higher rates of sexual satisfaction and importance on sex than women (Laumann et al. 2006), a finding that is also reflected across Westernized cultures.

A study by Yan and colleagues (2011) also found gender differences when they investigated the meaning of sexuality for Chinese men and women aged 61–85 years. Specifically, women who were interviewed reported that sex was part of their responsibility to procreate as well as to fulfill their husband's sexual needs, and men reported that sex was important for fulfilling their physical drive. Both genders though agreed that kissing, hugging, and caressing were not "sexual" activities. Interestingly, both felt that sex was neither pleasurable for women nor that it was needed in a similar manner to men (Yan et al. 2011). The differences in sexual expression and attitudes expressed by Western or non-Western cultures highlight the importance of considering the cultural context of sexuality, both in regard to assessment for people who present within the clinical setting and directions for further research. These studies demonstrate some of the complexities in understanding factors associated with sexuality and aging.

Aging and Sexual Functioning

It has been widely accepted that with increasing age, there is deterioration in sexual activity and

functioning. This is based largely on the research findings showing strong links between aging and a decrease in sexual functioning. However, the findings are varied in more recent studies. For instance, research shows that erectile dysfunction, but not premature ejaculation or low desire, was found to be associated with age (Waite et al. 2009). It was also found that with the exception of lubrication issues, there were no major differences in the level of sexual dysfunction among women in younger (i.e., 57–64) and older (i.e., 75–85) age groups (Waite et al. 2009). It has also been suggested that sexual desire and frequency of orgasm decrease with age. However, this does not appear to be the case, with research showing that for partnered women and men, it is the decline of physical vitality rather than a decline in sexual interest that impacts most on their sexual functioning (Waite et al. 2009).

Factors Associated with Sexual Functioning

There are many factors that may have an impact on sexual functioning as we age – related to biology, psychology, and relationships. It is important to recognize that sexual functioning may not decrease as a direct result of the aging process, but that older individuals have increased risk of developing health concerns, which may impact on sexual functioning.

Biological Factors. There has been extensive research on the associations between aging, medical conditions, and medication as factors associated with male sexual dysfunction. Aging has been found to be a strong predictor for erectile dysfunction. In particular, Laumann et al. (2007) reported a several-fold increase in moderate to severe dysfunction with age, particularly between the ages of 40–49 years. A lack of interest in sex has also been demonstrated to be associated with age and the aging process. However, it has been found that age does not appear to increase the risk of all sexual dysfunctions for men. For instance, one study has shown that while age was a significant factor in predicting erectile dysfunction and problems with low sexual desire, it did not predict problems with delayed ejaculation or premature ejaculation (McCabe and Connaughton 2013).

Although there is less research on the biological factors associated with female sexual functioning, the influence of hormonal, neurological, vascular, and anatomical factors is recognized (McCabe et al. 2010). For women, life stage changes – such as pregnancy, childbirth, and in particular, menopause – have been shown to impact on sexual functioning. Lubrication problems with age have been well documented (McCabe et al. 2010). Hormone level changes are not restricted to women, but in both genders; it tends to be associated with a reduction in sexual functioning.

The reduction in sexual functioning in the course of aging may have several explanations. With a growing aging population, the risks of medical conditions such as diabetes mellitus, hyperthyroidism, high cholesterol, lower urinary tract problems, prostate disease, and cardiovascular disease also increase. All these conditions have been found to be associated with sexual dysfunction (Laumann et al. 2007). Of note are medical conditions such as vascular and endocrine difficulties that may lead to decreased penile blood pressure, which, in turn, exacerbates the difficulty developing and maintaining an erection. Other conditions such as arthritis may cause sexual activity to be very painful and therefore restrictive. Neurological conditions such as dementia and Parkinson's disease may act as both precipitating and maintaining factors for both male and female sexual dysfunction. Moreover, not only does the risk of complex medical conditions increase with age, but the use of medications, such as antihypertensives and antidepressants (McCabe and Connaughton 2013), as well as the hormonal contraceptive pill has become more prevalent, which have also shown to impact sexual functioning.

Psychological Factors. There are a number of psychological factors known to influence sexual functioning in men and women. Studies of women have found that low levels of sexual desire tend to be associated with negative attitudes toward sex in the family of origin (Giles and McCabe 2009). Other research has found that more severe problems in arousal and orgasm are related to negative current attitudes toward sex for both men and

women (McCabe and Connaughton 2013; Giles and McCabe 2009). An individual's level of general anxiety has been associated with poorer sexual functioning irrespective of gender, as is depression and stress and comorbid anxiety and mood disorders.

Negative beliefs and thoughts related to poor body image have been identified as factors that may predispose, precipitate, and maintain sexual difficulties and low sexual satisfaction in men and women, leading to distraction during sexual activity and increased sexual avoidance. Research shows that men with erectile problems are not only distracted during sexual activity by thoughts of sexual performance (i.e., the maintenance of their erection) but also with concerns of body dissatisfaction and sexual undesirability (McCabe and Connaughton 2013). This has implications for the aging male and female, in that negative appraisal of age-related physical changes may lead to a higher level of risk for the development of sexual problems.

Relationship and Social Factors. Relationship factors may be both a cause and consequence of sexual dysfunction in both men and women. In particular, a lack of intimacy, communication difficulties, and poor relationship satisfaction have all been associated with poorer sexual functioning in both men and women (Althof et al. 2005; Basson 2000). It has also been found that the longer the relationship duration, the greater the risk of sexual dysfunction and that sexual dysfunction in one partner may precipitate sexual dysfunction in the other. Particularly salient for older adults is the impact of life transitions on sexual functioning. The experience of children moving out of home, retirement, the emergence of grandchildren, diminished income, and moving into an aged care facility can all have negative implications for levels of sexual desire as well as opportunity for sexual expression.

Treatment of Sexual Dysfunction

Psychopharmacology. The focus on biological causes of sexual problems and subsequent ready availability of medication such as sildenafil (Viagra), in the late 1990s, resulted in a shift in the medicalization of sexual dysfunction. There is

a substantial body of literature showing that these medications can be effective in the treatment of erectile dysfunction. Moreover, medications for the treatment of other male sexual dysfunctions, such as premature ejaculation, have also been shown to be effective. In contrast, pharmacotherapy for female sexual dysfunction has been of limited benefit. Since the approval of sildenafil for male erectile dysfunction, there has been a search for a similar treatment for women in the form of a “pink Viagra.” However, study findings are inconclusive, and currently there is only one drug for female sexual dysfunction approved in Europe and none approved in Australia or the United States. Hormone treatments for female sexual problems have focussed on the delivery of estrogen and testosterone, both of which play key roles in female sexual response (Wylie and Malik 2009). Estrogen therapy is commonly used for sexual dysfunctions in women undergoing hormonal changes due to menopause and target symptoms such as diminished levels of lubrication and decreased vulvar sensation (Wylie and Malik 2009). To date though, there is no direct evidence that estrogen therapy is efficacious in the treatment of female sexual dysfunction, and this is in the context of considerable negative side effects of estrogen therapy that include increased risk of endometrial cancer, gallbladder disease, and venous thromboembolic events (Wylie and Malik 2009). Overall, there is a greater likelihood that men and women in their 50s and 60s have the expectation that sexual expression will continue as they age. Thus, despite the relative ineffectiveness of pharmacotherapy for women, it is nevertheless likely that there will be greater acceptance and use of medications to assist with sexual functioning in the future.

Behavior Therapy. The primary focus of Master and Johnson’s (1970) behavioral sex therapy is to assist the couple to re-experience sexual pleasure without the anxiety of performing intercourse. Sensate focus begins by focusing on the pleasure of nongenital touching, followed by sessions involving self-exploration of the genitals, shared genital exploration with partners, intercourse, and finally orgasm. While participating in these tasks, men and women are instructed to

focus on the sensations that accompany the experience with an absence of performance demand or excessive self-monitoring, which interfere with sexual functioning. Studies have demonstrated the effectiveness of behavioral techniques to treat sexual dysfunction in both men and women (Berner and Gunzler 2012).

Cognitive-Behavioral Therapy. The cognitive-behavioral therapy (CBT) treatment for sexual dysfunction aims to modify attitudes, beliefs, and expectations underlying the sexual dysfunction. In a review of the literature on couples with sexual dysfunction, Berner and Gunzler (2012) found that CBT successfully improved the sexual functioning of men, particularly those with erectile dysfunction. In women, CBT also was found to be effective for the treatment of hypoactive sexual desire disorder and was somewhat effective for the treatment of vaginismus (Berner and Gunzler 2012). Couple therapy using CBT has also resulted in significantly improved overall sexual functioning for women.

Although age is associated with an increased risk of sexual dysfunction, it is also the case that such dysfunction is not an inevitable outcome of the aging process. All the above data needs to be considered in light of large numbers of men and women above the age of 65 years reporting good sexual functioning well into their 80s and 90s (Waite et al. 2009; Herbenick et al. 2010; Fisher 2010).

Challenges, Considerations, and Future Directions

Given only a few studies have investigated the prevalence of sexual activity in later life, it is difficult to generalize from these findings about what may constitute a “healthy, sexual relationship” in people aged over 50 years. Further research is required in order to obtain a good understanding and awareness of how to provide adequate support and accurate information for older people who want to remain sexually active. It would also be useful to gain a deeper understanding of the meaning of sexuality in older age persons by utilizing qualitative research methods.

In this way we can better understand not only what older people are currently experiencing in their sexual lives but also what they would like to experience. This information would not only enhance understanding but could be used to facilitate the development of interventions to assist older people to achieve their goals.

Training for Medical Practitioners

Research has shown that older people tend not to seek assistance from their medical practitioner, largely due to the assumption that the sexual difficulties are a “normal” part of aging. This would be better managed were medical practitioners, health-care nurses, and psychologists given additional training to enhance screening, assessment, and evidence-based treatments for sexual difficulties in this population. Most importantly, providing basic training and awareness to practitioners to inquire about sexual health and sexuality in older clients is imperative (Hinchliff and Gott 2011). Given the high level of shame and embarrassment of sexual dysfunctions, previous research has suggested that people were more likely to seek help for sexual dysfunctions if their doctor had asked about their sexual functioning in a routine visit during the previous 3 years (Hinchliff and Gott 2011).

Clinicians also need to utilize appropriate assessment strategies across a range of biological, psychological, and relationship factors to formulate suitable treatment recommendations for older men and women who are challenged by difficulties in sexual function. For example, research has shown that erectile difficulties are one of the most common reasons why men seek medical assistance. Screening for possible causes – whether medical, pharmacological, psychological, or relationship based – is important when men present to their medical practitioner for treatment. Moreover, there may also be a lack of education in regard to sexual expectations in older people. For example, DeLamater (2012) suggested that some people with heart conditions may fail to initiate sexual activity with their partner because of fears that it may lead to negative consequences. This demonstrates that clinicians have an important role in the education of men and women

regarding their sexual health as well as appropriate strategies to address sexual dysfunction (see chapter “► [Training Psychologists in Aging](#)”).

The Use of the Internet to Facilitate Understanding and Treatment

The use of online technologies as a way of accessing information, communicating with health professionals and groups, as well as Internet-based therapies is also worthy of consideration for this particular age group. Using Web-based programs and apps on mobiles is becoming increasingly common. This has important implications for the accessibility of information, communication with others via chat rooms, as well as the use of social media to form new friendships, seek social support, and maintain connections with others. In particular, given the embarrassment and shame surrounding seeking advice from medical professionals in regard to sexual functioning and the limited training and awareness by medical professionals to ask about sex lives, Internet-based treatments (also called e-therapy, Web-based therapy, and cybertherapy) for sexual dysfunction are likely to grow in popularity. Either group or individually based therapy provides privacy, is convenient to clients, and is accessible to geographically isolated members of the community, as well as people who find it difficult to leave the house due to limited mobility. The anonymity inherent in Internet-based therapy may be especially helpful in attracting older clients with sexual difficulties, who may otherwise delay or avoid treatment opportunities due to misconceptions with sexual dysfunction, such as sexual difficulties resulting from the “normal” aging process.

Over the past decade, clinicians and researchers in this field have begun to investigate the effectiveness of Internet-based sex therapy for a variety of male and female sexual difficulties. However, given the complexities with medication use and health factors associated with aging, Internet-based programs must also recommend screening for health concerns and biologically based factors commonly associated with sexual dysfunction by a medical practitioner. Another consideration in regard to the use of the Internet

is that given research on sexuality and aging is relatively limited, sexual information on the Internet may not necessarily be correct or relevant for older populations. Therefore, it is imperative that clinicians can provide information that is accurate, evidence based, and tailored to the needs of this particular demographic to clients.

Nursing Homes and Sexuality

It is expected that the number of people in the population above the age of 70 will increase substantially over the coming decades. The implication is that more people may need to access nursing homes and other support accommodation facilities which may not be conducive to the changing view of sexuality and positive aging. It may become difficult for married couples living apart to continue a sexual relationship. Living conditions in nursing homes and supported accommodation tend to lack of privacy, have few separate rooms, and poor staff education in regard to the importance of sexual activity for older adults – all of which curtail sexual expression between partners (Roach 2004). Moreover, sexual behavior in the nursing home may be viewed as an inappropriate behavior by staff and family members, who may resort to seeking medical interventions to alleviate shame and embarrassment of reports of sexual behaviors from their family members. In addition, although people who identify as gay, lesbian, bisexual, and transgender orientation are increasingly accepted in society, they may face discrimination when they require access to aged care facilities and wish to share accommodation with their partners. This highlights the need for education and support to nursing staff as well as a better understanding of the sexual needs of those in residential care (see “► Retirement Villages” for a more comprehensive review).

Conclusion

The importance of maintaining a healthy level of sexual activity will likely increase as more people live longer and live in better health than previous generations. More liberal attitudes

toward sexuality and sexual expression are likely as the expectations of being sexual continue throughout the aging process. While a shift has occurred in the definition and awareness of what constitutes “normal” sexual functioning for the aging population, these perceptions and expectations may be based on a society that highly values medication and antiaging products. However, further research needs to investigate narratives of the meaning and understanding of aging and sexuality. Although societal and cultural factors are important in shaping expectations of sexuality, ongoing sex and sexual expression is a process that is highly individual and is based on the physical, psychological, and social health of the couple.

Sleep Effects on Cognition with Aging

Definition

Sleep is important to optimizing memory and cognitive functioning in young adults. With increasing age, sleep becomes fragmented and decreases in quality. Evidence suggests that getting good sleep quantity and quality can predict how well cognitive functioning is preserved in older age.

Introduction to Sleep

Sleep has historically been conceptualized as a period of time in which the body restores itself. It is perhaps surprising then that many individuals sacrifice sleep on a nightly basis. According to Gallup polls, the percentage of Americans sleeping for 6 or fewer hours per night has risen from 11% in 1942 to 40% in 2013. Rather than validating the propensity to cut back on sleep, current research suggests that sleep serves multiple functions and could be most important for the brain. Consider, for example, the last time you only slept for 3 or 4 h. You likely experienced an inability to focus and to learn in class, as well as feeling a relentless internal drive to fall asleep.

Like hunger and thirst, the internal drive to sleep persists until the need is met, and there are serious consequences to not sleeping. When rodents are kept awake for two weeks, they die (Rechtschaffen et al. 1989). In rare cases, humans have stayed awake for several consecutive days (the longest confirmed case was 11 days), and in such cases these individuals experienced cognitive deficits and hallucinations. Thus, the functions of sleep are vital and likely more diverse than a simple shut-down-to-restore mechanism.

To understand the functions of sleep, one needs first to understand normal sleep physiology in adults. The most common approach is to use *polysomnography* (PSG), which refers to the electrophysiological recordings of brain waves (EEG), muscle activities, eye movements, breathing rates, and heart beat rhythms. PSG recordings have revealed that adults cycle through stages of sleep throughout the night. Therefore, “sleep” is actually an umbrella term that encompasses

physiologically distinct rapid eye movement (REM) stages and non-REM stages. A full cycle of the sleep stages takes approximately 90 min and most adults will have five to six cycles per night.

Adults first enter Stage 1 of non-REM sleep, which is considered to be a transitional state between sleeping and waking. Participants who are awoken during Stage 1 sleep will sometimes contend that they were not truly asleep (though they often cannot describe what was on their mind prior to the awakening). Stage 2 of non-REM is considered to be “true” sleep (Martin et al. 2000) and is represented by slower EEG activity (<8 Hz) interleaved with bursts of thalamocortical sleep spindles. Individuals next enter into non-REM Stages 3 and 4, which are characterized by even slower EEG oscillations (<4 Hz) and are therefore collectively referred to as *slow wave sleep* (SWS). Slow EEG oscillations are generated in the neocortex (particularly in frontal regions) (Massimini et al. 2004) and are believed to orchestrate the firing of both sleep spindles and hippocampal-cortical sharp wave ripples (Buzsáki 1998). Subcortical and sensory systems are largely suppressed during SWS, thus leaving a quiet background for the aforementioned neural activity (Buzsáki and Peyrache 2013; Logothetis et al. 2012). Following these non-REM stages, the sleeping brain enters into REM sleep, which is distinguished by vivid dreaming and increased cerebral blood flow in several regions such as the amygdala (Maquet et al. 1996). Humans spend the majority of the first half of the night in SWS, whereas the second half of the night is dominated by REM sleep and Stage 2 sleep.

Contemporary sleep science has capitalized on the advanced understanding of sleep physiology to link how sleeping “well” (i.e., minimal fragmentation, high levels of REM and SWS) benefits mood, body weight control, cardiovascular function, immune system function, and other aspects of health (Kryger et al. 2011). One of the most active contemporary areas of study concerns how sleep impacts cognitive functioning. Anyone who has pulled an “all-nighter” knows that their ability to maintain attention over a long period of time is

greatly diminished. Even more interesting, however, is sleep’s role in *memory consolidation*, which refers to the brain’s ability to transfer information from short-term storage (e.g., hippocampus) and preserve it in long-term storage (e.g., neocortex).

Sleep and Memory Consolidation

Though scholars have long suspected that SWS and REM sleep actively benefit memory (e.g., Jackson 1884), scientists have only recently been able to experimentally demonstrate this effect. Initial evidence for memory consolidation during sleep arose from animal studies. In the 1990s, researchers recorded the firing rates of single cells to identify how the rodent’s hippocampus learned to run a maze. These studies typically showed that particular hippocampal neurons would fire in particular locations in the maze during learning (termed place cells). A turning point for the sleep field came in 1994 when Matt Wilson and Bruce McNaughton (1994) continued to record the hippocampal firing patterns during sleep and discovered that memories (i.e., represented by hippocampal firing patterns) were replayed during sleep. Subsequent work showed that this memory replay was causally associated with memory benefits the following day (Bendor and Wilson 2012).

Since Wilson and McNaughton’s (1994) seminal study, psychologists and neuroscientists have conducted hundreds of experiments to translate this research to humans (Rasch and Born 2013). For example, to mimic the paradigm used in animal studies, Peigneux et al. (2004) had participants undergo neuroimaging while learning a virtual maze and then undergo neuroimaging again while sleeping that night. The researchers found that to the extent that the hippocampus showed reactivation during sleep, participants were better at the virtual maze task the next day. Early PSG studies suggested that consolidation of episodic memories (i.e., explicit memory for events) occurs during SWS, and consolidation of procedural memories (implicit, motor, or skill memory) occurs during REM sleep (Plihal and

Born 1997). However, this sleep stage by memory-type distinction remains an area of active debate (Scullin and Bliwise 2015a).

One approach to linking sleep physiology to memory is to attempt to experimentally control memory consolidation during sleep. For example, studies that have directly manipulated features of SWS using transcranial direct current stimulation (tDCS) have demonstrated a causal role for SWS density in episodic memory consolidation. Marshall et al. (2004) had subjects learn word pairs and then tested them 3 h later after SWS or a wake-only interval. They applied tDCS or a placebo stimulation during sleep to affect the density of SWS. Relative to placebo stimulation and wake conditions, tDCS stimulation during SWS led to significantly greater SWS density and greater word retention (i.e., memory consolidation).

Similar evidence for a causal role of SWS in memory consolidation arises from the targeted memory reactivation procedure (Oudiette and Paller 2013). In this approach, participants learn a series of card pair locations on a grid (e.g., try to remember the grid locations of matching cards such as two pictures of a cat). Every time a card is studied (e.g., picture of a cat), it is paired with an associated sound (e.g., “meow” sound). Participants are tested on their memory of the card locations following a sleep or wake interval, but critically, during the sleep or wake retention interval, the experimenter plays half of the sounds that were previously studied. The central finding of this literature is that reactivating memories (via replaying the associated sounds) is more likely to improve later memory when reactivated during sleep than during wake, and especially if the episodic memories are reactivated during SWS (Rasch et al. 2007). Thus, there is strong evidence for sleep being conducive to episodic memory consolidation. One noticeable feature of this literature, however, is that the preponderance of evidence has emanated from studies of healthy young adults (ages 18–30). The remainder of this chapter focuses on how age-related changes in sleep quality, quantity, and physiology affect cognitive functioning, memory consolidation, and may even increase risk for dementia.

Changes in Sleep in Advancing Age

Of all the changes in behavior and physiology that are observed with advancing age, changes in sleep are one of the earliest and most pronounced (Bliwise 1993). These age effects on sleep are summarized in Table 1. First consider subjective evaluations (i.e., complaints) about sleeping. Individuals can fall asleep as easily as young adults, but they typically fall asleep earlier in the evening. Many older adults complain of frequent nighttime awakenings as well as waking up too early and not being able to fall back asleep. Individuals often introspect that the cause of their sleep fragmentation is due to nocturia, or the need to use the bathroom in the middle of the night. However, there exists a debate as to whether a full bladder causes awakenings from sleep or if instead individuals wake up due to other causes (e.g., sleep apnea) but simply attribute the awakening to their bladder. Regardless of mechanisms, because sleep is more fragmented in older adults, *nocturnal* sleep duration is typically shortened. Total sleep time over a 24-h period may however be preserved due to an increased frequency of napping with increasing age.

Next consider physiological studies of sleep (PSG). Several age-related changes to sleep stages are consistently observed (Table 1). Older adults spend more time in the “light” stages of sleep (Stages 1 and 2 of non-REM sleep) than young adults, which may contribute to their sleep fragmentation because one is easily awoken during Stages 1 and 2 of sleep. REM sleep may also demonstrate some changes with normal aging (and particularly with Alzheimer’s disease) such as decreased density of REM burst activity. The most profound age-related change in sleep physiology appears to be to SWS. Older adults show about half the amount of SWS as young adults, and there even exist studies in which *zero* minutes of SWS were observed at night in *any* of the older adults who participated. Such observations are most likely to occur in very old men, because on average females display more SWS than males. Almost every EEG aspect of a slow wave is affected in older adults: slow waves are smaller (lower amplitude), faster

Sleep Effects on Cognition with Aging, Table 1 Changes in sleep behavior and physiology with increasing age

Sleep issue	Effect of aging	Description
Subjective (self-report) observations		
Sleep onset latency (falling asleep)	None or minimal	Older adults can usually fall asleep as easily as young adults
Nighttime awakenings (fragmented sleep)	↑ with aging	Increased nighttime awakenings indicate fragmented sleep and can affect perceived sleep quality
Nocturia (waking up to void)	↑ with aging	Need to use the bathroom in the middle of the night may fragment sleep
Early morning awakening	↑ with aging	Waking too early may decrease total sleep time
Phase advance (timing of sleep/wake cycle)	↑ with aging	Older adults fall asleep earlier in the evening, which may contribute to early morning awakenings
Physiological (polysomnography) data		
Stage 1 NREM sleep	↑ with aging	Increased time in these “light” sleep stages may contribute to sleep fragmentation
Stage 2 NREM sleep	↑ with aging	
REM sleep	↓ with aging	Density of REM burst activity decreases and may precede development of dementia
Slow wave sleep (SWS)	↓ with aging	Decreased SWS may impair episodic memory consolidation during sleep
Sleep apnea	↑ with aging	Sleep apneas cause sleep fragmentation and hypoxia and impair memory consolidation

(i.e., higher frequency), less continuous (i.e., lower density), and are altered in morphology (e.g., the slope of the slow wave is affected) relative to young adults.

Beyond sleep stages, PSG studies show that older adults are at increased risk for developing several sleep disorders, for example, sleep apnea, which is a condition in which individuals may stop breathing for ≥ 10 s and, in particularly severe cases, for over a minute. Apneas may repeat hundreds of times every night and go unrecognized for years, but they are problematic because they cause sleep fragmentation and deprive the brain of oxygen (hypoxia).

The causes of poor sleep with advancing age are still being studied, but several factors such as a sedentary lifestyle, physical pain, depression and anxiety, reduced exposure to zeitgebers (e.g., sunlight), nocturia, use of medications that disrupt sleep architecture, and atrophy in regions that are important to sleep maintenance (e.g., ventrolateral preoptic area, suprachiasmatic nucleus) (Kryger et al. 2011). The take-home message from sleep and aging studies is that most indicators of good sleep quality in young adults are impaired in older adults.

Cognitive Consequences of Diminished Sleep Quality with Aging

If sleep is critical to cognitive functioning in young adulthood (Rasch and Born 2013), but is diminished in quantity and quality with increasing age (Bliwise 1993), then poor sleep may contribute to cognitive aging. The approaches toward addressing sleep’s role in cognitive aging have ranged from basic science experiments in animal models to experimental cognitive psychology studies to population-based epidemiological studies (Scullin and Bliwise 2015a).

Self-Report, Population-Based Studies

In many epidemiological studies, individuals self-report how much sleep they are getting, how much they are waking in the middle of the night, and how sleepy they feel during the day. There are now approximately 50 papers that have evaluated subjective sleep quality in relation to objective measures of cognitive functioning in aging adults. These studies often have very impressive sample sizes ($N > 100,000$ in ref (Sternberg et al. 2013)

that are generalizable to the population. In cross-sectional studies of middle-aged adults (40s and 50s), short sleep and fragmented sleep were frequently associated with poorer cognitive performance on a range of memory and attention tasks (Scullin and Bliwise 2015a). In older age, these correlations were more sporadic. For example, Miller et al. (2014) examined the association between episodic memory and short sleep duration in middle-aged (50–64 years) and older-aged (65+ years) adults and found that short sleep in middle age, but not older age, was associated with poor episodic memory performance.

An interesting theme that has emerged from longitudinal epidemiological studies is that short sleep and fragmented sleep in middle age might accelerate cognitive decline observed by the time one reaches their 60s, 70s, or 80s. There are at least six longitudinal studies that have found that short sleep in one's 40s, 50s, or 60s predicts faster cognitive decline as much as two decades later (e.g., Kulmala et al. 2013; Virta et al. 2013), even after controlling for many demographic and comorbidity variables. The implication is that investing in sleeping well when one is relatively young may have cumulative benefits as one ages.

Polysomnography Correlational Studies

As informative as epidemiological studies have been to showing that sleep complaints are associated with – and can even predict – cognitive decline, such studies are limited by their lack of precision. Using PSG, researchers have attempted to identify the sleep physiological correlate of cognitive decline. Though a few PSG studies suggest that short sleep per se is important to cognitive decline, the majority of the literature suggests that fragmented sleep and REM sleep dysfunction are markers (or potential causes) of cognitive decline (Scullin and Bliwise 2015b). The evidence for poor REM sleep (e.g., low duration or density) exacerbating age-related cognitive decline spans nearly 50 years (Feinberg et al. 1967) and was recently supported by the large-scale Osteoporotic Fractures in Men (MrOS) sleep study. In the MrOS study (Song et al. 2015), 2,601 older adults underwent PSG and cognitive testing (MMSE and Trail Making B) at Time 1 and then

repeated cognitive testing 3–4 years later. They found that individuals with low REM sleep and high Stage 1 sleep (i.e., a marker of light, fragmented sleep) showed a twofold increased rate of cognitive decline.

Memory Consolidation Studies

A quickly developing area of research concerns how sleep benefits memory consolidation. Though some of the more exciting recent advances in this area have arisen from the tDCS and targeted memory reactivation approach (Oudiette and Paller 2013), such approaches have yet to be successfully applied in older adults (Eggert et al. 2013). The more common approach to testing for memory consolidation is to teach individuals a memory task in the evening and then retest them following sleeping. Relative to wake-only control groups (i.e., learning in the morning and testing in the evening), this sleep condition is typically associated with better memory. Circadian factors (e.g., morning versus evening testing) tend not to strongly influence consolidation effects (Scullin and Bliwise 2015a), and though reduced daytime interference during sleep has some impact on memory (Jenkins and Dallenbach 1924), qualitative changes in memory traces with sleep suggest active consolidation mechanisms (e.g., Ellenbogen et al. 2006; Payne et al. 2008; Scullin and McDaniel 2010).

If sleep benefits memory consolidation in young adults and if sleep quantity and quality are impacted detrimentally by aging, then one would predict that memory consolidation should also decline with aging. Animal studies support the view that memory consolidation declines with aging. When applying the same hippocampal memory replay procedure used in the classic Wilson and McNaughton (1994) work, researchers have found that memory replay is absent in older rodents (Gerrard et al. 2008). Similar patterns of decreased memory plasticity during sleep have even been observed in *Drosophila melanogaster* (fruit fly) models (Donlea et al. 2014).

In human subject research, most studies have also suggested that memory consolidation declines with aging. Most memory consolidation

and aging studies have used either procedural memory tests or verbal episodic memory tests. Nearly all of the experimental studies (seven of eight) that compared procedural memory (i.e., skill memory or motor memory) consolidation across sleep and wake intervals in middle-aged or older adults have suggested that there is a gradual loss of procedural memory consolidation with increasing age (Scullin and Bliwise 2015a). For example, Wilson et al. (2012) compared 24 healthy young adults, 32 healthy middle-aged adults, and 31 healthy older adults on a motor sequence learning task following wake-only and sleep intervals (within-subject manipulation). They found that the benefit due to sleep on procedural memory improvements was large in the young adults, reduced but present in middle-aged adults, and absent in older adults.

Identifying the PSG correlate of reduced procedural memory consolidation in aging adults has been difficult. In young adults, prospective memory consolidation is typically associated with REM sleep (Plihal and Born 1997) or sleep spindle density (Fogel and Smith 2011). However, attempts to experimentally increase REM sleep or spindles in older adults have had inconsistent effects on procedural memory (Hornung et al. 2007). Other studies have investigated brain activity during sleep *after* learning a procedural memory versus no learning. The idea here is that recently learned tasks should be replayed during sleep and that such replay will be evidenced by greater hemodynamic (fMRI) or electrophysiological (EEG spindles) activity. Using neuroimaging, Fogel et al. (2014) found post-training increases in activation in several frontal, parietal, and hippocampal regions in healthy young adults. No such post-training increases in activation were observed in older adults, suggesting that these older adults were not “replaying” the trained procedural memory task.

Similar age effects emerge for consolidation of episodic memories (explicit memory for events). Scullin (2013) compared the retention of paired word associates across sleep and wake intervals in 57 healthy young adults and 41 healthy older adults. The young adults demonstrated greater

episodic memory retention following the sleep interval than the wake interval, as well as a strong positive correlation between retention and amount of SWS. The older adults showed low SWS overall and no sleep benefit to episodic memory retention. This age-related decline in episodic memory consolidation seems to begin well before older age. Backhaus et al. (2007, 2006) found that episodic memory consolidation was impaired in a group of adults in their 40s and 50s, particularly for middle-aged adults who showed very little SWS.

Some of the age-related declines in episodic memory consolidation may be due to declining SWS, but other factors such as age-related atrophy of prefrontal regions and hippocampal regions and diminished prefrontal–hippocampal connectivity likely contribute (Mander et al. 2013). Memory consolidation may even depend on the amount of oxygen saturation levels in the prefrontal cortex during sleep. Most young adults show an increase in oxygen saturation levels from wakefulness to SWS (measured via cerebral oximetry), but most older adults show the reverse pattern (i.e., reduced prefrontal oxygen saturation levels during SWS (Carlson et al. 2008). However, older adults who showed increased prefrontal oxygen saturation levels during SWS performed better on episodic memory tasks (Carlson et al. 2011). Furthermore, Scullin et al. (2012) observed that individuals whose oxygen saturation levels dropped below 90% for 5 or more minutes (measured via pulse oximetry) during sleep showed no sleep-dependent memory consolidation.

Can Sleep Disorders Cause Dementia?

If poor sleep is associated with poor cognitive functioning, then one might wonder whether sleep disorders could increase risk for dementia.

One sleep disorder that is consistently linked to the later development of dementia is REM sleep behavior disorder (RBD). In normal REM sleep, there is muscle atonia (i.e., individuals are paralyzed). The function of this muscle atonia is to prevent individuals from acting out dreams and

hurting themselves or their bed partners. RBD patients, however, will commonly act out violent dreams including fighting pirates, hunting and stabbing deer, and defending oneself against home intruders. There are even dramatic cases of suicide or homicide during sleep. For example, in July 2008, Brian Thomas was dreaming that he was fighting an intruder and woke up to find that he had strangled to death his wife of nearly 40 years. The charges against him were dropped, in part due to his history of sleepwalking, but also due to irregularities in his REM sleep that were observed during a PSG test.

Not only can dream enactment be dangerous, but RBD is often a sign of neuropathology. RBD is associated with dopamine dysfunction and brainstem pathology (including alpha-synuclein deposition and Lewy bodies). Individuals diagnosed with RBD – typically older men – have a 30% chance of developing Parkinson's disease within 3 years and a 66% chance within 8 years (Postuma et al. 2015). In one documented case, RBD symptoms predated the development of Parkinson's disease by 50 years. RBD patients tend to show deficits in episodic memory, executive function, and visuospatial processing and an increased risk for clinical dementia (Vendette et al. 2007).

Though the association between RBD and later Parkinson's disease and dementia is strong, the RBD sleep disorder per se is unlikely to be the cause of the dementia (i.e., the Lewy body neuropathology is presumed to be the cause of both RBD and dementia). The causal link between dementia and sleep may be more direct in Alzheimer's disease. Several PSG studies have found that sleep architecture differs between patients with Alzheimer's disease relative to healthy controls (Bliwise 1993), with the largest deficit being to REM sleep (but also sleep fragmentation and SWS). Moreover, epidemiological studies have found that subjective reports of short and fragmented sleep in middle age are longitudinal predictors of Alzheimer's disease decades later (Benedict et al. 2014). Several studies have also connected poor sleep to the hallmark pathology of Alzheimer's disease – amyloid plaques and neurofibrillary tangles (tau) – by using Pittsburgh

Compound B neuroimaging and cerebrospinal fluid (CSF) measures (Ju et al. 2013; Spira et al. 2013). Highly controlled animal studies have experimentally demonstrated that depriving a rodent of sleep leads to a buildup of amyloid plaques and tau deposition (e.g., Kang et al. 2009). Perhaps the most interesting recent advance in this literature is that one of the functions of sleep may be to clear the brain of harmful metabolites. Xie et al. (2013) found that CSF flow increased by up to 60% during sleep and this increase in CSF flow was instrumental in clearing amyloid out of the brain. Thus, losing out on sleep may cause a buildup of amyloid deposition whereas gaining normal sleep may help clear the brain of amyloid. Whether treating sleep disturbances in young and middle-aged adults reduces the risk of Alzheimer's disease or slows general cognitive decline remains a provocative question for future research.

Conclusions

One of sleep's normal functions appears to be bolstering memory consolidation and cognitive functioning. With increasing age, sleep becomes shortened, fragmented, and changed in architecture (e.g., less SWS). These changes are paralleled by declines in cognitive functioning, such as a reduction in memory consolidation. Whether improving sleep in older adults could help ameliorate or reverse cognitive declines is an open question; however, there is now ample evidence that the quality of sleep in youth and middle age has predictive value for how rapidly cognitive functioning will decline years into the future. The practical implication is that people should invest in their sleep throughout the lifespan and, at the very least, during youth and middle age, to promote health, well-being, and graceful aging.

Small-Scale Homelike Care in Nursing Homes

Hilde Verbeek

Department of Health Services Research, Faculty of Health, Medicine and Life Science, CAPHRI School for Public Health and Primary Care, Maastricht University, Maastricht, The Netherlands

Synonyms

Autonomy; Group living; Person-centered care; Small-house nursing homes; Small-scale living facilities

Definition

Small-scale, homelike nursing homes are an innovative example of long-term institutional care for people with dementia. They reflect a common psychosocial care concept, focusing on residents' autonomy and opportunity for choice, and aim to sustain a sense of self and control. A small number of residents (usually six to eight) live together in a homelike environment, and nursing staff is part of the household. Residents are encouraged to participate in daily household activities, emphasizing normalization of daily life with person-centered care. The physical environment resembles an archetypal home.

Cultural Change

Small-scale, homelike nursing homes are the result of a changing care concept that has been developed during the past decennia's in health and dementia care, in which quality of life and well-being have a prominent place (White-Chu et al. 2009). In dementia care, there is a trend toward deinstitutionalization. Older people want to live at home for as long as possible (also referred to as aging in place), although this is not always feasible as care needs increase. Dementia in particular has a large impact on the ability to live within the local community, and approximately one third lives in long-term institutional care. Long-term institutional care for people with dementia has shifted in terms of philosophy and practice from a medically oriented care environment toward a resident-centered, individualized care environment (Verbeek et al. 2009a). Traditionally, nursing homes for people with dementia were based on a medical-somatic model of care, emphasizing illness and treatment of underlying pathology. Nursing homes were institutions, protected settings in which basic nursing and medical care services were provided aimed at keeping residents safe. Physically, they would resemble hospitals, with long corridors, a nurses' station, and staff uniforms. Their rules and routines governing daily life permit little individualization.

Nowadays, person-centered models of care are prominent in dementia care and emphasize strengthening residents' autonomy and overall well-being. Older people should be enabled to continue their lifestyle as before admission to a nursing home. Program design ensures that residents are known as people. Families are an important part of the care process in small-scale, homelike settings and prepare, for example, biographies for staff (Verbeek et al. 2009a). Furthermore, they not only focus on their own relative in the home but look after other residents as well. Adopting a homelike, person-centered care approach has proven to be very difficult in existing traditional large-scale nursing homes. The care environment often does not match with the therapeutic goals, which is perceived as an important barrier. As a result, new initiatives have been developed in the world that provide health, social, and nursing care in a small-scale and homelike environment. Radical alterations have been made in comparison with traditional nursing homes, implementing changes in the organizational, physical, and social environment of settings.

Worldwide, several small-scale, homelike concepts have been implemented, such as group living in Sweden, group homes in Japan, shared housing arrangements in Germany, the Green House concept in the United States, and small-scale living arrangements in the Netherlands. Some of these have become regular dementia care settings, such as group living in Sweden and small-scale living arrangements in the Netherlands (Verbeek et al. 2009b).

Environmental Characteristics

There is a wide variation of small-scale, homelike care environments for people with dementia across and within countries. The location varies from units in a larger nursing home, toward purpose-built stand-alone facilities in the community. Some small-scale, homelike facilities are situated on the area of a larger nursing home. Stand-alone facilities prevent institutional characteristics to reappear in small-scale, homelike

settings, and being built in the community aims to maintain residents' social network. However, such facilities are often not feasible due to financial constraints and organization of (mental) health care. Physical characteristics of buildings resemble an archetypal home, including a kitchen, laundry area, dining room, and living room (Verbeek et al. 2009b). The vast majority of small-scale, homelike settings have private bedrooms, and some have also private bathrooms. The care environment can be considered as an active component in the dementia care process. Current theories stress that a match is needed between the person's needs, his/her abilities, and environmental demands to elicit adequate behavior in people with dementia, also referred to as person/environment fit (Lawton and Nahemow 1970; Cohen-Mansfield 2000). If environmental demands exceed patients' ability to cope, they have more difficulty to maintain adequate behavior, which decreases their quality of life. These principles have important implications for care environments, especially for people with dementia, as they experience diminished physical and/or mental disabilities due to their illness, increasing the environments' influence on their behavior. Several guidelines have been established on how to design dementia care environments. Most evidence exists for unobtrusive safety measures such as camouflaging exit doors; varying the ambience, size, and shape of space; private bedrooms, big enough for a reasonable amount of personal belongings; and control of stimuli such as noise and lighting (Fleming and Purandare 2010; Calkins 2001). Less evidence exists about the use of signage of various sorts (e.g., colors, objects).

However, to create a homelike environment, changing the physical setting alone is not sufficient as it can only facilitate (Judd 1998). Social and organizational aspects of the environment are necessary components in the development of a small, homelike therapeutic setting. The number of residents usually is between six and ten residents per unit in small-scale nursing homes. The main aim of a small group is to promote social activities and create a family-like structure, although in practice group, size may also be

determined by practical considerations such as available space, staffing, and financial issues. A small and fixed team of nursing staff takes care of the residents, which allows for close contact and communication. As nursing staff, residents, and family caregivers form a group, there is opportunity to become familiar with each other. The organizational environment in small-scale, homelike nursing homes is very different from traditional institutional care. In small-scale, homelike nursing homes, residents and their caregivers mainly determine daily life. They can decide, for example, when they want to get up in the morning and have their meals. On the contrary, in traditional nursing homes, the routines of the organization mainly determine daily life. Furthermore, nursing staff has integrated tasks in small-scale, homelike nursing homes, meaning that they are not only responsible for personal and medical care but also organize activities and do domestic chores such as cooking. In traditional large-scale nursing homes, tasks are highly differentiated with separate personnel to assist meals, do activities, and provide nursing care.

Target Population

In general, small-scale homelike care facilities provide 24 h of nursing care to residents with dementia. In practice, characteristics of residents are heterogeneous across settings. Some small-scale, homelike nursing homes are designed for people with dementia in the earlier stages of their disease. Admission criteria to these settings may apply then, such as sufficient mobility and being ambulatory, being able to participate in social activities, or having communication skills. These settings manifest themselves as intermediate care facilities between home care and institutional nursing care. Residents may be transferred when criteria are no longer met. Challenging behavior, such as aggression, is perceived as especially problematic in small groups and that is often seen as a reason to relocate residents in larger nursing homes. Other small-scale, homelike care settings, however, are aimed to provide a home for life and are seen as an alternative to traditional

large-scale nursing homes providing all necessary health and social care services. Despite a similar level of care needs, residents in small-scale, homelike care settings appear to have a better cognitive and functional status compared with residents living in traditional nursing homes.

Experiences

Residents with dementia, their family caregivers, and nursing staff have mainly positive experiences with small-scale, homelike care settings. Research shows that residents with dementia expressed feeling at home because they could maintain their personal characteristics and experience being connected and united within the household. Providing small-scale, homelike care in nursing homes creates structural opportunities for individualized care and attention to the residents' personal needs. The extent to which a nursing home has small-scale and homelike characteristics positively influences occupation of residents with their preferred and diverse activities.

Family caregivers highly appreciate personal contact and attention from nursing staff, not only with the residents but also with family caregivers themselves. They feel a strong sense of involvement and welcome the freedom that small-scale, homelike care puts on making one's own choices. This makes it easier for them in accepting that their relative can no longer live at home, since the environment is adapted to support residents in their autonomy. Furthermore, nursing staff appreciated the broadening of their tasks and had the feeling that they could spend more time with residents. They not only interact with residents during standard nursing care moments but also encourage residents to participate in daily activities. These household chores may serve as a handle for undertaking meaningful activities and provide opportunity for reciprocity. Negative aspects were mentioned as well. Family caregivers indicated a lack of amenities and general facilities such as a restaurant in some small-scale, homelike care settings. Furthermore, nursing staff worked alone a lot, and some missed a team to discuss difficulties and share responsibility.

Effectiveness

Despite the fact that experiences with small-scale, homelike care environments are mainly positive, effects on residents, family caregivers, and nursing staff are limited. Several studies have been conducted in various countries comparing small-scale, homelike care settings with traditional large-scale nursing homes showing mixed results. The most consistent evidence suggests that residents living in small-scale, homelike care environments have more social interaction (de Rooij et al. 2012; Verbeek et al. 2014). Small-scale, homelike settings seem to offer a more attractive environment for people with dementia to encounter meaningful stimuli, thereby enhancing social engagement. Environmental stimuli can influence social engagement, especially when related to real-world tasks (Cohen-Mansfield et al. 2010). This may be due to a lifetime exposure, and, for example, household activities have meaning in themselves, which is an important characteristic fulfilling residents' desire to make oneself useful. Additionally, it is of great importance to individualize activities to residents' self-identity roles by tapping into past experiences, hobbies, and interests as this also increased engagement. Furthermore, less physical restraints are used in small-scale, homelike care settings. This may reflect the difference in care philosophy and organizational context in comparison with traditional nursing homes. For other resident-related outcomes, such as quality of life and neuropsychiatric symptoms, no evidence was found (Verbeek et al. 2010; te Boekhorst et al. 2009; Wolf-Ostermann et al. 2012). Neuropsychiatric symptoms appear similar for residents in small-scale, homelike care settings and traditional nursing homes, although residents in small-scale, homelike care may express sometimes more agitated behavior (e.g., restlessness). Family involvement is similar for both settings. Family caregivers visit equally frequent and perform similar activities. Furthermore, indications for less perceived caregiver burden were found, although more research is needed. In general, higher satisfaction is found among family caregivers in small-scale, homelike nursing homes (Verbeek et al. 2012).

When nursing staff members become more involved with family caregivers and keep open lines of communication as they do in small-scale, homelike nursing homes, family caregivers' satisfaction increases. This may improve their feeling of confidence that their loved one is well being cared for.

Implications for Staff

Nursing staff who work in small-scale, homelike care settings have different roles and tasks compared with staff employed in more traditional facilities. Overall, staff working in small-scale living facilities inclines more toward integrated care: nursing staff members are part of the household and have integrated tasks, including personal and medical care, organizing activities, and daily household chores. For example, in small-scale homelike care environments, daily nursing activities are characterized by working all around and independently, whereas nursing staff in traditional wards collaborate with each other and have differentiated tasks. This affects their job characteristics, such as perceived autonomy, social support, workload, and demands. Nursing staff report a higher perceived autonomy and more social support and experience a lower workload compared with staff working in traditional large-scale settings (Willemse et al. 2014). Furthermore, staff in small-scale, homelike nursing homes encourage residents in their autonomy instead of focusing on disabilities and taking over tasks from residents. Therefore, a culture change within formal care is necessary, as staff should focus on the remaining functional capacities of people with dementia and to encourage their autonomy. The organizational policy of small-scale, homelike nursing homes is important in establishing meaningful social interactions with residents, developing a sense of community, and preserving community roles, thereby creating a supportive environment. Staffing patterns focus on meaningful activities and integrated tasks in a nonhierarchical structure (Smit et al. 2012).

For staff working in small-scale, homelike nursing homes, there might be a tension between the focus on everyday life and the medical needs

of older people with complex chronic diseases such as dementia. When normalization of living for older people with dementia is the main focus of interest, there is a risk that professionalism in dementia care may be lost. Social care aspects and the creation of a homelike environment are integral to residents' quality of life and quality of care. However, an exclusive social model of care is inadequate to meet the needs of vulnerable older nursing home residents with dementia (Tolson et al. 2013). Skilled staff with adequate training and education is essential for future dementia care. In small-scale, homelike nursing homes, this is especially relevant as nursing staff work alone during a great extent of the day. They have a large responsibility for residents' care and require skills such as being able to observe, being alert for changes, and being able to respond adequately. Training (both in educational models as training on the job) should focus on dementia and consequences of the disease for caregiving, taking into account the whole residents' system. Since multimorbidity is present in many residents, more knowledge of other chronic diseases highly prevalent in older people (such as cardiovascular diseases or diabetes) and the interplay among diseases are essential. Nursing staff need to know the consequences of the disease for daily functioning and how to support this, taking into account what residents themselves are still able to do.

Future Directions

Small-scale, homelike nursing homes have promoted a continuation of self and normality: knowing the person, welcoming the family, providing meaningful activities, being in a personalized environment, and experiencing flexibility and continuity. This development has encouraged changes in institutional care for people with dementia in a positive way, both in regular nursing homes as well as in the development of new dementia care facilities. The key question in realizing dementia care facilities should focus on how to reach optimal well-being for residents, their family caregivers, and nursing staff in the actual

care provided. This provides opportunities for residents and their family caregivers to make a choice on which care facility suits their wishes and beliefs best.

The working mechanisms of small-scale, homelike care environments and how they exert an effect remain unclear. As a result, changes are implemented in daily practice without knowledge on which components in the physical, social, or organizational environment should be altered and are most effective. The main focus in research and practice has often been on physical aspects of the environment, such as location, design features of an archetypical home (e.g., doorbell, kitchen, and bringing own furniture), and (group) size. This is understandable, since physical aspects are visible, relatively easy to measure, and therefore provide a clear distinction with traditional nursing homes. However, it is the interplay among physical, organizational, and social aspects of the care environment that should be taken into account to realize timely, effective care tailored to the needs of people with dementia.

Social Cognition and Aging

Elise K. Kalokerinos¹, William von Hippel² and Julie D. Henry²

²School of Psychology, The University of Queensland, Brisbane, QLD, Australia

Definition

Social cognition refers to the processes through which people make sense of themselves and others to engage with their social context (Fiske and Taylor 2013). Social-cognitive research draws from models developed in cognitive psychology as a tool for understanding social functioning. A social-cognitive perspective is useful for enhancing our understanding of the aging process, particularly because of the extensive research literature documenting age-related changes in cognition (Salthouse 2012). The cognitive changes that emerge with age paint a complex picture of loss and gain, as some losses in cognitive functioning interact with some gains in knowledge or ability in other domains. Social-cognitive changes with age are made even more complex by the fact that motivational and emotional changes brought about by changes in life goals (Charles and Carstensen 2010) interact with changes in cognitive function to produce diverse patterns of responding.

Determinants of age-related social-cognitive change

Two broad determinants of social-cognitive change with age are investigated in this entry. First, research on cognitive function generally paints a picture of loss as the norm with aging, with older adults typically showing a decline in areas that tap the “mechanics of the mind” such as processing speed, memory, executive function, and complex reasoning (Salthouse 2012). These deficits in cognitive processing often co-occur with other age-related losses, such as reduced physical and perceptual functioning, suggesting an underlying general physical decline. Despite these losses, however, there are also important areas of preserved and even enhanced function in late life. These are usually in domains that tap “experience of the mind” such as vocabulary and general knowledge (Salthouse 2012). In these domains, smaller age differences emerge, and older adults often outperform younger adults. Thus, the first key determinant of social-cognitive change with age is whether the task relies more on mechanics or experience.

Social cognition involves dual processes, with automatic and controlled processes each contributing to, or competing for, social outcomes (Smith and DeCoster 2000). Although aging disrupts processing speed and other factors that play a role in automatic processes, the primary impact of age is on controlled processes (von Hippel and Henry 2012). Because controlled processes are sometimes recruited to inhibit automatic ones, as the influence of controlled processes declines with age, the influence of automatic processes can become more apparent. This interaction between controlled and automatic processes is also influenced by the fact that the two processes appear to operate in a compensatory fashion, such that some automatic processes peak when controlled processes are at their weakest. Thus, a second important determinant of social-cognitive change with age is whether the task at hand relies more on automatic or controlled processing and whether the two tend to work together or in opposition. This entry will outline the broad categories of social-cognitive change with age and the role

that mechanics, experience, and automatic and controlled processes have in determining these changes.

Emotional and Motivational Changes

One group of age-related changes occurs in emotional goals and functioning (Charles and Carstensen 2010). These changes have an important impact on the ways in which older adults process social and emotional information. One marked change in older adults, compared with those who are younger and in middle age, is in the processing of positive and negative information. Many studies have demonstrated an “age-related positivity effect” whereby older adults preferentially attend to and remember positive over negative information (Charles and Carstensen 2010). Interestingly, several studies find that cognitive control resources are recruited to maintain the positivity effect: The positivity effect does not occur when cognitive resources are diverted to a secondary task. In addition, older adults recruit medial prefrontal regions, which have been implicated in top-down emotion regulation processes, when processing negative but not positive stimuli, indicating controlled downregulation of negative emotion (Reed and Carstensen 2012). It has also been demonstrated that older adults with better executive function, that is, older adults who demonstrate greater cognitive control on tasks demonstrated to require top-down, controlled processing, show a greater positivity effect (Reed and Carstensen 2012). This possibility is currently debated, but it suggests that older adults may recruit their limited cognitive resources in an attempt to maintain a positive outlook, a step that is indicative of the potential importance of positivity to older adults.

Emotion regulation is the process by which emotions are increased, decreased, or sustained. When compared with younger adults, older adults also show maintained or even improved emotion regulation (Charles and Carstensen 2009). They are able to implement emotion regulation strategies both before and after the onset of the emotional response with similar effectiveness to

younger adults. In some areas, older adults even show better emotion regulatory functioning than younger adults. For example, some studies have demonstrated that older adults are better able to suppress the expression of emotion than younger adults. This strategy is usually cognitively costly; however, other research has demonstrated that emotion suppression incurs fewer cognitive costs for older than younger adults: After suppressing their emotions, younger adults showed reduced working memory performance, but older adults did not. Research examining emotion in daily life has also found that older adults may be better at emotion regulation: after an experience of negative effect, older adults returned to a neutral or positive state more quickly than younger adults. Finally, older adults appear to rely on more effective emotion regulation strategies (e.g., cognitive reappraisal) than younger adults (e.g., expressive suppression). Taken together, this work suggests that older adults rely on the emotion knowledge accrued during their lifetime to implement emotion regulation strategies in a more emotionally intelligent and perhaps less cognitively demanding way.

Cognitive Changes

Executive functions are a group of mental processes responsible for initiating, planning, and coordinating basic cognitive processes. Executive functions include task switching, working memory, and inhibition of thought and behavior. As such, executive functions are not a single ability, but a group of higher-order processes that permit the regulation of cognition. Executive functions recruit frontal brain regions, and these areas are among those affected by age-related deterioration. As a result, aging is associated with declines in executive functioning (Salthouse 2012). These declines in executive function are associated with a wide range of outcomes, which we will briefly discuss below.

Behavioral restraint. Age-related declines in executive function have been linked to a broad range of cognitive deficits, such as disruptions in attention and memory. The consequences of a

decline in executive function, however, are broader than just these cognitive deficits. Executive functions play a central role in social processes, and as a result, the age-related deficits observed in executive function have been found to lead to problems with social behavior across a variety of domains (von Hippel 2007). In particular, deficits in inhibitory processes have been linked to socially disinhibited behavior with age. As a result of decreased inhibitory ability, older adults are more likely than younger adults to talk excessively about topics that are irrelevant to the conversation, to inquire about private issues in public settings, and to engage in a variety of socially inappropriate behaviors than younger adults (von Hippel 2007). Importantly, this effect of executive decline appears to be independent of the effect of general cognitive decline, suggesting that executive deficits have an important unique effect on social appropriateness.

Stereotyping and prejudice. Devine (1989) proposed that our environment is filled with stereotypes, and as a result, these stereotypes are automatically activated upon encountering a stereotyped group member. She suggested that this automatic activation of stereotypes occurs among both prejudiced and non-prejudiced people, but that non-prejudiced people reject and inhibit these stereotyped thoughts, whereas prejudiced people do not. Older adults are less capable of inhibiting their automatically activated thoughts than younger adults, and thus, one implication of this model is that older adults may be more prejudiced. Several lines of research now support this idea (von Hippel and Henry 2012; von Hippel 2007). Older adults show greater prejudice on self-report scales and are rated by their peers as being more prejudiced than younger adults, and these age differences in prejudice appear to arise through executive function decline. Older adults do not seem to show greater automatic bias when compared with younger adults; they are just less successful at inhibiting this bias. These findings suggest that age differences in prejudice emerge in response to executive function decline and are not simply the result of a greater willingness among older adults to express their prejudices.

Understanding others. As outlined earlier, older adults tend to prioritize emotional and social goals. One implication is that aging might lead to improvements in social understanding. In contrast to this suggestion, however, research finds important losses in understanding others' emotions, intentions, and mental states with age. Broadly, there seems to be an age-related decline across all modalities of emotion recognition, although there is some evidence that unconscious emotion recognition may be better preserved than conscious emotion recognition (von Hippel and Henry 2012). Additionally, in some contexts, older adults seem to use more sophisticated heuristics than younger adults in forming social judgments, suggesting that the accumulation of social experience across the adult life span can lead to some benefits in understanding others (Peters et al. 2007).

Emotion recognition and empathy. Emotion recognition is an important skill for social interaction, and indeed, emotion misrecognition in older adults is associated with reduced social and interpersonal functioning, poor communication, and inappropriate social behavior (von Hippel and Henry 2012). Across most emotions the pattern is of age-related decline, and the recognition of anger and sadness is particularly impaired (Ruffman et al. 2008). This specific decline in recognition of negative emotions may be a function of the tendency for older adults to focus on positive over negative information in processing, as inattention to negative expressions may make their identification more difficult.

Older adults also show deficits in cognitive empathy, that is, they have a poorer understanding of others' complex emotions and mental states (von Hippel and Henry 2012). As with social dysfunction, deficits in cognitive empathy appear to emerge as a result of age-related decline in executive function, with older adults showing greater impairment on measures where greater executive control is required. Relatively less research has been conducted examining older adults' emotional empathy or their emotional responses to the cognitive or emotional state of another. The research in this area so far has examined mimicry and found that although

subconscious mimicry seems to be spared in later adulthood, later stages of mimicry may be interrupted by difficulties in emotion recognition.

Attribution and social inference. The processes covered earlier in this section rely primarily on the mechanics of the mind and thus are negatively affected by brain atrophy. There are, however, some aspects of social inference that rely more clearly on the experience of the mind, and in these areas, age has the potential to result in improved function. Indeed, across some domains of social inference, older adults are able to use more adaptive strategies (Peters et al. 2007; Blanchard-Fields 2007). For example, older adults require fewer cues than younger adults to form clear impressions of others, perhaps because they can rely on their greater social experience. Older adults are also more skilled at making trait inferences about others and are more able to use important diagnostic trait information in making social judgments. Finally, older and middle-aged adults are more sensitive to social context than younger adults, which can provide helpful information for understanding others.

Attitudes and persuasion. Attitude change involves a number of cognitive and motivational processes that change in older adulthood, suggesting that there are likely to be corresponding changes in persuasibility, that is, the degree that one is able to be persuaded of an idea, with age. Consistent with this possibility, attitude change follows a U-shaped curve with age, with younger and older adults being the most susceptible to attitude change (Visser and Krosnick 1998). This effect seems to emerge in part because younger and older adults also report lower attitude certainty, attitude importance, and attitude-relevant knowledge than middle-aged adults. One source of these changes may be cognitive losses with aging, which limit older adults' ability to counterargue against persuasive messages. Two other noncognitive mechanisms may also underlie age-related susceptibility to attitude change: reduced social support for attitudes and role changes with age that bring about attitude changes. That is, older adults may find that there is no longer social support for the attitudes they used to hold and so change their attitude

accordingly. They are also less likely to have a social role involving power: Powerful roles call for a resolute approach in the face of persuasion attempts, and because older adults do not usually hold these roles, they are likely to be more persuasible. At this point we do not know the degree to which these factors may underlie changes in persuasibility among older adults.

Decision-making. Decision-making is affected by both age-related gains and losses. As with other domains, the general cognitive decline observed with aging is often associated with poorer decisions. It is also the case, however, that older adults make better use of cognitive shortcuts in decision-making and benefit from their greater life experience, and emotional and motivational changes mean that they are often happier with their choices (Peters et al. 2007). Broadly, the research literature shows age-related deficits in the decisions necessary for everyday life (Thornton and Dumke 2005). This effect is robust across most markers of decision quality, with the exception that older adults' self-ratings suggest either preserved decision-making or even better everyday decision-making than younger adults. These findings suggest that older adults perceive themselves as making better decisions despite actually making worse decisions. Because older adults tend to focus on the positive, it is possible that older adults are simply happier with their decision outcomes than younger adults and thus rate themselves as better decision-makers despite their objective deficits.

Although older adults show decline in most domains of decision-making, they show preserved ability and even improvements in interpersonal decisions (Blanchard-Fields 2007). Older adults may outperform younger adults in interpersonal domains because of their accumulated life experience, but they also have some additional advantages. First, they tend to take a long-term perspective and focus more on preserving interpersonal relationships than on solving personal problems (Blanchard-Fields 2007). Second, they do not overweight negative information, which may be helpful in some interpersonal decision-making domains (Charles and Carstensen 2010). Third, they are strategic about when they use

controlled processing strategies, correctly perceiving cognitive control as a limited resource (Peters et al. 2007).

Various types of decision processes are also impacted by the age-related pattern of deficits in cognitive control processes but preservation of automatic processes. For example, controlled processes are often required to correct for possible sources of bias in decision-making, and as a result, older adults are less able to correct for biases (Peters et al. 2007). Cognitive control processes are also required in generating counterfactual simulations of possible alternative outcomes to decisions, and as a result, older adults are less able to create detailed simulations of the future. Naturally, this deficit has the potential to negatively impact their decision-making.

In contrast, the relative preservation of automatic processes in older adults allows them to make use of a number of automatic heuristics, which are fast, effortless, and generally accurate enough for most everyday purposes (Peters et al. 2007). The use of these heuristics may be helpful in allowing older adults to make rapid decisions while relying less on controlled processes. It is also the case, however, that older adults may be less able to suspend their reliance on automatic heuristics by implementing cognitive control processes when it is necessary to do so.

Individual Differences in Loss

In assessing cognitive loss with age, it is also important to consider whether these losses can be prevented and whether there are traits that may buffer age-related deficits in social-cognitive functioning.

Age stereotypes. There are number of stereotypes about cognitive loss with age, and these stereotypes are widely endorsed by older adults themselves (Levy 2003). Not surprisingly, research suggests that age stereotypes can have a causal effect on cognitive outcomes. For example, older adults who are led to think about aging and wisdom perform better on a memory test than older adults who are led to think about aging and

senility. These acute stereotype effects may be induced through stereotype threat (or the concern that one may be judged on the basis of negative stereotypes about one's group), which has been shown to lead to performance deficits in a wide variety of domains. The more chronic consequences of age-related stereotypes are likely to be induced through a combination of stereotype threat and self-stereotyping (Levy 2003). That is, to the degree that older adults expect to show stereotypic age-related losses, they are likely to do so. This has been demonstrated across many domains, but perhaps the most striking is research demonstrating that negative stereotypes of aging measured early in life predict poorer health and earlier mortality in late adulthood. Overall, the data suggest that negative stereotypes about aging are likely to exacerbate age-related cognitive decline. They also suggest, however, that promoting positive stereotypes of aging may be an important intervention tool.

Mental activity. Mental activity levels may also play an important protective role in the cognitive aging process. Complexity in education, work, and in everyday life all delay the onset of cognitive decline (Valenzuela and Sachdev 2006). The facilitating effect of mental activity may be analogous to that of physical exercise. Even short-term mental activity may have beneficial effects, and thus, it may be possible that older adults could benefit from acute cognitive training (Lustig et al. 2009). A systematic review concluded that cognitive training in healthy older adults produces strong and persistent protective effects on cognitive performance, particularly in the domains that were the major focus of the intervention (Valenzuela and Sachdev 2009). That is, cognitive training seems to be most helpful when it is targeted: For example, training in attention enhances attention but does not always enhance memory, and training in memory enhances memory but does not always enhance attention.

Mental activity does not just delay the onset of cognitive aging; it can also compensate for it. One important example of compensation shown by older adults is neural "over-activation," in which additional brain regions are recruited by older adults to solve the same problems as

younger adults (Reuter-Lorenz and Cappell 2008). Although there is no single explanation for over-activation, it appears to be at least in part a compensatory process to attempt to address declines in cognitive function.

Conclusions

It is clear from the phenomena discussed in this entry that social-cognitive aging is a complex process, influenced by a variety of different sources. Age-related decline in cognitive control processes can sometimes be offset by preservation of automatic processes, but sometimes the inability to inhibit automatic processes can itself lead to poorer performance in older adults. In contrast, age-related changes in experience and knowledge accumulated throughout life can enhance social-cognitive function in some domains, and it is important to understand these experiential changes that occur in tandem with cognitive decline. Finally, motivational and emotional changes with age also play an important role in any attempt to understand social-cognitive outcomes, and the interactions between cognitive, experiential, and motivational changes can create complex patterns of behavior. It is clear that social cognition changes in many important ways with advanced age, and research is only just beginning to understand this complexity.

Synonyms

Social capital; Social integration; Social networks; Social participation; Social support

Definitions

The above synonyms are often used interchangeably to imply social connectedness, but they do not fully capture the breadth of the construct. Social network refers to the structure of relationships and their interconnections. Social support is typically derived from social relationships and is broadly defined as the care that is either provided or perceived to be readily available in times of need. These are all interrelated concepts. For instance, you are more likely to receive social support from those with whom you are socially networked. Other synonyms, notably social integration and social capital, while intended to capture wider dimensions of connectedness, can be vague and are often used inconsistently. Social integration encompasses the behavioral (or participatory) and cognitive (a sense of belongingness) elements of social relationships. Social capital is typically defined as the network of relationships between people who live and work in a society or community that support

their effective functioning. These constructs imply, but do not fully capture, what it means to be socially connected. In this entry, social connectedness is defined as the sense of belonging and subjective psychological bond that people feel in relation to individuals and groups of others. This definition also captures the idea that identification with others is the basis for social connectedness – something that we explore further in this entry as a possible mechanism for the health-enhancing effects of social relationships.

Social Relationships and Health

It has long been recognized that mortality and morbidity rates vary dramatically as a function of the social conditions in which we are born and raised, live, work, and age. The extent of these is considerable, with life expectancy 48 years lower in the least advantaged nations (e.g., Sierra Leone) and 20 years shorter among the most disadvantaged within the same nation (Marmot 2005). Many have argued that such disparity in life expectancy should not be inevitable, particularly as there is nothing fundamental in our biological makeup that should make this so. Rather, the cause of such disparity is fundamentally *social*, created through inequality in opportunities for stable education, work, housing, and wealth. These upstream factors not only affect our exposure to, and experience of, illness, but they also affect our response to illness – which is driven primarily by our knowledge, attitudes, beliefs, and behaviors around health. Clearly, then, when it comes to managing health, interventions that target these social determinants are as vital as those that target the medical.

Various strategies and policies have been proposed at national and international levels to overcome these health disparities. However, there is also recognition of the importance of understanding the social conditions that reduce such inequality at more local, or community, levels. Explanations for the presence of health disparity at this level tend to be framed in terms of social capital, which tends to be represented by a range of indices (e.g., number of social ties, whether one

lives alone or with others, trust, engagement with civic associations) measured at both individual and community levels. However, researchers have questioned the extent to which this captures the subjective and experiential aspects of social relationships that are integral to one's sense of social connectedness, which is lacking or markedly reduced among members of disadvantaged groups in unequal societies. Addressing this point, researchers have incorporated concepts such as social engagement, participation, social support, and influence into their analysis, in addition to documenting the number of objective social resources that a person or group has. Increasingly, the contribution of social *identification* – defined as the sense of self that people derive from their membership with various social groups (e.g., family, work team, church) – is also gaining prominence, due to its capacity to explain why not all relationships are beneficial for health and why we seek engagement and support from particular people but not others. Other developments have focused on the types of relationships (spousal versus friendship and one-to-one versus group-based relationships) that might be more beneficial for health.

We address these developments in this entry as mechanisms proposed to account for the benefits that arise from social connectedness, after considering the evidence of the impact that social relationships have on the health of older adults in domains of life expectancy, mental health, and cognitive health.

Social Connectedness and Life Expectancy

The relationship between social engagement and mortality was first identified in a pioneering study conducted by Berkman and Syme in 1979 (Berkman and Syme 1979). This research focused on Californians aged between 30 and 69 years and found that those who lacked social contacts were more likely to die earlier than those who were well connected. This relationship held after statistically controlling for physical health, health behaviors (e.g., smoking), health practice, and use of health

services. Further analysis of these mortality data, following people over a period of 17 years, found that social connectedness was particularly important for the life expectancy of people aged over 70 years (Seeman et al. 1987). Indeed, those with the lowest social network index scores (based on ratings of marital status, perceived isolation, contacts with friends and relatives, and membership of church and other groups combined) had a 50% greater risk of mortality than those with the highest scores.

Findings from these studies were later replicated in longitudinal investigations involving American (Glass et al. 1999), Australian (Giles et al. 2005), and European (Bennett 2002) populations. Other studies also show that it is not just the leisure or physical activity, but rather productive engagement with others in the process of participating in these activities that confers a survival advantage (Maier and Klumb 2005). Findings also show that these relationships hold over the age span with social networks predicting longevity among the older-old (Giles et al. 2012). In the study conducted by Giles et al. (2012), relationships with friends were found to be more beneficial for survival than those with children and relatives, though this is not always the case. Other studies that include wider social networks (e.g., community and other group activities) also find evidence of increased life expectancy (Glei et al. 2005).

Social Connectedness and Mental Health

The findings from the life expectancy literature extend to the mental health literature. It has been shown that older people with integrated social support networks (comprising family, friends, neighbors, and community groups) are generally less depressed and report greater well-being (Wenger 1997). While the impact that social relationships have on mental health is seen across all age groups, older adults are particularly vulnerable to mental health problems arising from social isolation due to their increased risk of physical disability and illness. Loneliness is a specific risk factor for depression in older adults (Cacioppo

et al. 2006), with Golden and colleagues (2009) reporting that where loneliness is experienced among people over 65 living in the community, 35% present with an associated depression.

However, not all relationships are created equal, and some can be more supportive of mental health than others. Speaking to this point, Litwin (2001) found that intensive family ties were more restrictive for older adults in Israel and generally less supportive of health than diffuse network ties that were characterized by large and diverse networks with variety in potential sources of social support. These data highlight the importance of multiple resources for health, combining notions of both relationship quantity and relationship quality.

Further studies have indicated that these findings are robust and generalizable to other populations, including older people living in the United States (Fiori et al. 2006). Here again, it was found that people with diverse networks (typically involving interaction with family, friendship, and religious and other informal group memberships) reported fewer depressive symptoms. Those with restrictive networks, whether confined largely to family or through having very limited social ties, had worse outcomes – all consistent with earlier findings. This suggested that network diversity is important to mental health in many different cultural contexts.

An important implication of these findings is that particular types of relationship may be more important for mental health. Taking this a step further, Cruwys et al. (2013) investigated the contribution that social group memberships made to depression outcomes in older adults. This study drew on data from the English Longitudinal Study of Ageing and found that participation in social group activity was not only protective against the development of depression in healthy participants but also preceded recovery and reduced the risk of relapse among those with a history of depression. Of particular interest was the fact that risk of relapse reduced incrementally as a function of the number of groups to which people belonged. Specifically, an increase in one group membership reduced the risk of relapse by 24%, but an increase of three group memberships reduced the risk of

relapse by 63%. As the authors conclude, these data show that one's connectedness to social groups can both protect against the development of depression and provide a "social cure" (p. 185) (Cruwys et al. 2013) for existing depression.

Social Connectedness and Cognitive Health

There is equally strong evidence of the role that social relationships play in protecting against cognitive decline. Most studies in this area are longitudinal and involve older adults living independently in the community. The majority draw the same general conclusion: that people with greater social connectedness enjoy better cognitive health and are less vulnerable to progressive decline (Haslam et al. 2014a).

The size of these effects is considerable. To illustrate, Barnes and colleagues (2004) found that the rate of cognitive decline was reduced by 39% for those in their sample of older people who had the greatest social network size. This was reduced even further, by 91%, where people actively participated with others in those networks – confirming the point made earlier that quantity alone fails to capture fully the protective benefits of social connectedness. There is also evidence that the rate of memory decline is halved among those who are most socially connected (Ertel et al. 2008).

Data from Bennett et al. (2006) provide an interesting biological perspective on the role of connectedness. These researchers followed healthy older people who, on first contact, showed no signs of Alzheimer's disease pathology. Yet, at postmortem examination years later, they found greater evidence of tangle density (a marker of such disease) among those who were least socially connected. Clearly, as Cohen (2004) suggests, social relationships have the capacity to get "under our skin" in ways that shape the biological processes that are detrimental to health.

There are questions, though, about causality in the cognitive health literature. This is because the correlational nature of much of this research limits the conclusions that can be drawn – in particular,

due to the possibility of reverse causality. That is, it may be the case that people who are in better cognitive health have greater capacity to engage actively with their social networks, rather than the other way around. In support of this argument, there are a few studies that observe a positive association between social connectedness and cognitive health cross-sectionally, but not longitudinally. Other studies have directly addressed this issue by focusing only on higher-functioning seniors with low likelihood of existing cognitive impairment or by analyzing subgroups of respondents whose abilities were preserved at the start of data collection (Bennett et al. 2006; Ertel et al. 2008). While findings from these latter studies support the conclusion that social connectedness influences cognitive integrity and reserve, only experimental studies can definitively establish causality.

A parallel debate concerns the types of relationships that are particularly advantageous for cognitive health. As noted earlier, having more connections with friends in particular is associated with increased life expectancy (Giles et al. 2012). However, in the cognitive domain, researchers have tended to base their analyses on a social network index that combines information about one's relationships and activities both with significant others (i.e., spouse, children, friend, relative) and with other social groups (e.g., church, voluntary, recreational clubs). This makes it difficult to establish whether any particular type of relationship is especially protective. This is exacerbated by the tendency for researchers intuitively to place greater emphasis on one-to-one relationships with significant others than on group-based relationships. In an attempt to disentangle these influences on cognitive health, Haslam et al. (2014b) examined the separate contribution that group and one-on-one social interaction made to cognitive integrity over time. Drawing on three waves of data from the English Longitudinal Survey of Ageing, they found that group activities were especially protective against cognitive decline and that this effect was more impactful with increasing age. More specifically, above-average group engagement was of moderate importance for the youngest respondents, such that those aged

50 years functioned cognitively at the level of a person aged 46 years. However, the functional savings were more substantial at the older end of the age spectrum, with the more socially engaged 80-year-olds performing cognitively like the 70-year-olds. These data are also consistent with those of Gleib et al. (2005) and Sugisawa et al. (1994), who found that relationships with significant others, such as a relative or friend, did not reduce the risk of cognitive decline and mortality, respectively. Instead, Gleib found that those who participated in one or two group activities displayed 13% fewer cognitive deficiencies 3 years later and that those who participated in three or more groups had 33% fewer deficiencies. Individual relationships were not associated with the same positive cognitive outcomes. Such data suggest that there may be particular value in targeting and developing group-based relationships when it comes to preserving cognitive health.

Mechanisms Underlying Social Connectedness

In most of the above studies, enhanced health outcomes were independent of sociodemographic factors, physical and psychological health status, and baseline physical and cognitive abilities. So, when we control for these factors, how exactly does social connectedness enhance the health of older people? A number of mechanisms have been proposed across these domains of health that can be broadly conceptualized as physiological and psychological. Although we describe these separately below, it is clear that these factors do not operate independently. The psychological experience of stress, for example, produces physiological changes, and these changes will feedback into our appraisal and response to that stress. Thus, the pathways through which social connectedness enhances health are multiple and interactive.

Physiological Mechanisms

One means through which social isolation might influence mortality is through its action on the biological pathways of stress. In the wider context

of the social determinants of health, social disadvantage (whether due to financial hardship, social stigma, or discrimination) is only one of the many recognized causes of ongoing stress (that include loss of one's spouse, being diagnosed with illness) – all of which can have damaging effects on the body. Stress triggers the release of cortisol, cytokines, and other substances that put pressure on immune and other physiological systems. The hypothalamic-pituitary-adrenal axis is particularly important in this regard as it is responsible for adapting to stressful circumstances and environments. In the absence of factors, such as social support, to buffer against the stress response, there is slower adrenocortical recovery which, when cumulative, can accelerate physiological decline. Supportive networks are believed to buffer these effects, controlling the body's response to heightened arousal and stress (Uchino 2006) and, through this, providing protection against damaging neurodegenerative outcomes.

Additionally, neuroendocrine and immune function regulation appears to be enhanced among people who are more socially connected. It has been argued and found that social networks provide a basis to suppress neuroendocrine responses, which reduces vulnerability to disease development. Lower overall cortisol (Turner-Cobb et al. 2000) and higher oxytocin levels (Knox and Uvnas-Moberg 1998) have been found among those with greater social support from their network ties.

An alternative perspective argues that it is the damaging effects of social isolation, rather than the protective effects of social connectedness, that is the cause of these findings. Social isolation is a stressor in its own right, increasing neuroendocrine responses and cardiovascular reactivity, which has the effect of suppressing immune function (Cohen 2004). In line with this proposition, in studies of patients with HIV, those who were more disconnected socially were found to have fewer helper T cells over time to combat the disease (Theorell et al. 1995). More diversity in social networks has also been found to reduce vulnerability to developing the common cold after exposure to the virus (Cohen

et al. 1997). Greater cardiovascular reactivity in response to stress is associated with higher blood pressure, which can be reduced in the presence of a significant other or friend (Kamarck et al. 1990). Moreover, there is evidence that blood pressure is lowered in general among people who are more socially connected (Steptoe et al. 2000).

The physiological effects of social connectedness appear to go further to protect against the development of carotid artery atherosclerosis and progression of cardiovascular disease. Like the above studies, these examined the impact of social connectedness via perceptions of social support – highlighting again the dynamic relationship between physiological and psychological processes in protecting against health decline.

Psychological Mechanisms

Social connectedness increases access to the psychological and material resources that buffer against stress, thereby reducing its impact on physiological processes that are associated with disease. Of these resources, *social support* is recognized as pivotal and comes in various forms – emotional, instrumental, and informational. Social support has been shown to offer some protection against the damaging physiological effects of stress and is associated with more functional, or adaptive, coping styles (Cohen and Wills 1985). Emotional support, in particular, appears to reduce the impact of stressful life events and has been repeatedly linked with greater longevity.

Interestingly, though, not all forms of support seem to lead to positive outcomes. Penninx et al. (1997) found that receiving high levels of instrumental support, that can arguably promote greater dependency, is associated with greater risk of early death. Moreover, *perceived* support appears to be key, with evidence showing that it is not the receipt of support that is critical, but the belief that it is (or will be) available when needed.

Self-efficacy, defined as the confidence with which we perform particular behaviors, is another psychological resource believed to carry protective properties. It has been argued that greater self-efficacy enhances one's sense of control and purpose in life which, in turn, reduces the impact

of age-related changes and disease processes. Indeed, research suggests that having purpose in life confers a survival advantage, mediating relationships between social networks and health outcomes in depression and exercise. Among older adults in particular, a reduction in social contact is associated with a decline in self-efficacy, which can impact further on one's engagement in health-productive behaviors (McAvay et al. 1996). There is also a relationship between social support and perceived efficacy. Where social support is perceived positively, it can enhance one's sense of control and efficacy, but where it reinforces dependence and is disabling, it can erode self-efficacy and self-esteem.

Berkman, (Cohen et al. 2004; Berkman et al. 2000) also recognize the important role of social influence, arguing that active participation in social networks makes people open to the influence and control of others. When our social networks encourage positive health norms, such as good eating habits and regular exercise, then they are likely to rub off, increasing our openness to engaging in these same productive behaviors. But we are also likely to be guided by those in our social networks who set negative examples. For example, we engage in more smoking and drinking when we are in the company, or the influence, of network ties for whom this behavior is normative. As these examples illustrate, our social relationships have a major influence on our attitudes to health (e.g., about the benefits of exercise and a healthy diet) and how we respond when health might be compromised (e.g., by seeking health services and adhering to treatment adherence). Notably, greater exposure to these effects, as you might expect with age, does not make us less susceptible to social influence. However, the one advantage of longevity is that with increasing age, the physiological effects of social support appear to be cumulative, with evidence of lower resting blood pressure among older adults who have greater perceived access to support (Uchino et al. 1999).

Missing from this discussion of psychological mechanism is an explanation of *why* only particular networks influence our attitudes about health behavior, impact on our self-esteem and

self-efficacy, and provide a basis for giving and receiving support. Researchers from the social identity tradition argue that *identification* with significant individuals and groups of others is what makes social participation possible. This is because social engagement does not occur in a psychological vacuum. There must be a basis, reason, and motivation to participate, and this is more likely to be present when people perceive themselves as sharing a common bond or connection with others (as members of the same family, neighborhood, or a community group).

This reasoning has driven recent development of the Social Identity Approach to Health (Haslam et al. 2009; Jetten et al. 2012). This framework draws on social identity theorizing to account for the conditions in which social connectedness enhances health. It has recently been applied to account for the beneficial effects of social relationships for cognitive (Haslam et al. 2014b) and mental (Cruwys et al. 2013) health, with a particular focus on the value of our connectedness with social groups. Fundamental to this framework is the idea that social groups (whether they comprise family, friendship, religious groups, or community groups) provide an important and distinctive basis for self-understanding and self-definition. Groups frame and inform our beliefs and values, drive our thoughts, influence our emotions, and shape our behavior only when, and to the extent that, they are internalized as part of our self-concept.

Importantly, this sense of social identification with others also influences the dynamics of social support. Here, it is often assumed that social support will have positive implications for health, but, as intimated above, research shows this is not always the case. Indeed, speaking to this point, meta-analyses indicate that the effects of across-the-board support on mortality and health are close to zero – explained largely by these data combining both positive and negative perceptions of support (Schwarzer and Leppin 1991). So what is it that makes support more (or less) beneficial for health? The social identity approach helps to answer this question, explaining the dynamics of support with reference to two key ideas. First, when people define themselves in terms of a

Social Connectedness and Health,

Fig. 1 Number of journal articles on social identity and health cited from 1990 to 2014 (Data abstracted from Web of Science, March, 2015 and updated from that reported in (Haslam 2014))

given social identity (as an older adult, a member of the Taylor family), they will see other ingroup members as *part of the self* (rather than as external to self). Second, this sense of shared identity then provides a basis and motivation for people not only to promote their own health and well-being but also to advance the interests of other ingroup members (other seniors and Taylor's) through the provision of useful forms of help. At the same time, this shared social identity also provides a basis for interpreting the helping behavior of others in positive ways – so it is seen as constructive (e.g., as an act of kindness or in their best interests) rather than regarded with suspicion.

Drawing on these ideas, we can make several predictions about the health benefits that our connectedness to these groups makes possible. Because social identification underpins positive forms of influence and support, groups will tend only to enhance health when (and to the extent that) their members identify strongly with them. Accordingly, I am more likely to benefit from my connectedness with other seniors when they are a group that is particularly important to me and one with whom I share strong bonds. When this is the case, group membership and group connections will serve as a psychological resource from which we can draw strength and positive support, particularly when facing challenges that threaten health. Yet, in the absence of such identification,

proffered support and social contact are more likely to be perceived as unnecessary or undesirable and indeed may only impose further strain – and hence may actually be detrimental to health.

Put simply, this theorizing suggests that the active ingredient in social relationships is social identification. This can account for the helpful and harmful effects of social group relationships, the dynamics of support and influence, and the particularly beneficial effects of group-based relationships. While this index of connectedness has yet to be incorporated into the broader literatures on social capital and social determinants of health, it is gaining momentum. This is also true of the Social Identity Approach to Health more generally – as the growth in research on social identity and health attests (see Fig. 1 (Haslam 2014)).

Conclusion

There is no doubt that social relationships matter for health, whatever our age, and that some relationships are more protective than others. Our knowledge of the mechanisms through which social connectedness protects health is growing, with increasing evidence of the interrelationships between psychological and

physiological processes. There is also growing recognition in the literature of the need to clarify the vital ingredient through which social connectedness builds key psychological resources, such as support and influence. To this end, there is increasing evidence of the important role that social identification plays in health, not least through its capacity to provide a basis for meaningful forms of social connectedness. Targeting these social processes in intervention is as important as targeting medical factors when seeking to protect and enhance health. Aging is inevitable, but its impact on increasing vulnerability to health disparities that hinder social connectedness need not be – particularly when we have the means to develop the social interventions, needed to promote social cure, at our disposal.

Definition

Social exchange and aging is defined as the change and stability of exchanges among individuals across the lifespan.

Introduction

Social exchange theory proposes that social behavior and interactions among individuals are a result of an exchange process. This perspective suggests that the relationship between individuals is generated by the pursuit of rewards and benefits and the avoidance of costs and punishment. In this entry, social exchange theory is defined and discussed as it applies to the aging process.

First, social exchange theory, which is rooted in economic, psychological, and sociological foundations, is introduced, followed by a description of how social exchanges change and develop as individuals age, why they are important, and innovative perspectives on social exchanges. Next, major psychosocial and sociodemographic factors that can influence the development of social exchanges over the life course are considered. Finally, the chapter concludes with a summary of how best to apply social exchange theory to later life.

Social Exchange: An Overview

Social behavior as an exchange process is a concept introduced by the sociologist George Homans in 1958 (Homans 1958). Grounded in sociological and psychological perspectives, Homans suggests that social exchange can be viewed as reinforcement. Individuals ascertain and learn from their past interaction experiences whether their behaviors are rewarding or costly. These positive or negative behavioral consequences reinforce, extinguish, or modify future behaviors in order to achieve desired outcomes and minimize costly ones. As individuals interact with others over time, they tend to select social exchanges that have positive consequences and do their best to minimize those that have negative consequences.

Social Exchange, as Interdependence. Behaviors performed by individuals in a dyad, and among individuals in a group, are interdependent (Thibaut and Kelley 1959). Relationships are invested in depending on whether there is a strong enough value or reward relative to the cost or alternative outcome. For example, one may choose to stay with a romantic partner if one feels that love and support are both given and received, but may choose to terminate the relationship if one feels that the relationship is unbalanced or inequitable, i.e., one party is giving more than receiving in the relationship. The evaluation of equitability, however, may be complicated. One could evaluate a relationship as equitable if one partner provides emotional support and the

other tangible support. The evaluation of this type of exchange is very likely dependent on the nature of the relationship between the partners. For example, there is more of an expectation of mutual affection and support between spouses, but less so among friends or neighbors. Interdependence influences with whom individuals continue to interact, as well as the kinds of social exchanges in which they choose to engage as they move through time and live our lives.

Social Exchange, as Economical. Apart from sociological and psychological perspectives, which will be considered more fully below, social exchange has been viewed from economic and utilitarian perspectives. Assuming that people are rational, interactions are shaped by a reciprocal exchange of tangible (e.g., financial) and intangible (e.g., emotional) resources. A profit is calculated by subtracting the costs from the rewards. Within an exchange context, power dynamics are created when there is an unequal exchange and one person gets more rewards than the other (Blau 1964; Emerson 1976). Economic exchanges are relatively straightforward assessments of money, status, and power. While economic equal and unequal exchanges are direct and uncomplicated, evaluation of social exchanges can be more complicated as they are influenced by the nature and type of social relationships over the course of our lives. Social relationships involve psychological and social characteristics, although how these are evaluated may not always be evident. Thus, some forms of support (e.g., emotional support) might be worth more than other types of support (e.g., money) to some people. Such assessments might not be readily ascertainable to the neutral observer.

Aging as a Social Exchange Process

A core principle to these perspectives on social exchange is that they develop over time and accumulate as individuals learn from past interactions, assess their current reciprocal or nonreciprocal exchanges, and decide on future behaviors. James Dowd expanded on the basic social exchange theory to address the circumstances of

older people (Dowd 1975). He argued that as people age, the ratio of rewards to costs associated with social interactions might shift based on social status (e.g., being an elder) and personal resources (e.g., money, power, the ability to work or provide care to others). In his exchange theory of aging, Dowd highlighted the perceived loss of status and power that he assumed are associated with aging (Dowd 1975). He argued that because resources decline with age (e.g., health, income, loss of work or community roles, etc.), older people are more likely to be in unequal or imbalanced social exchanges. These imbalanced relationships can result in a power disadvantage, wherein the older person is required to depend or rely on others to meet their basic needs.

Fortunately, this negative exchange theory of aging has not been widely supported by empirical evidence. People seem to adapt exchange calculations to the individual situation and life circumstances. Rather than taking a contemporaneous and rigid view of exchanges which would often leave the elder at a disadvantage, people appear to take a long-term and flexible view of exchanges with respect to close and/or loved elders. Taking a long-term or lifespan view allows the provision of support to an elder to be considered repayment for support received at an earlier point in time. An adult child might repay financial assistance from a parent during her young adulthood with financial assistance or caregiving during the parent's old age. The provision of one type of support might also be seen as an equitable exchange for the receipt of another type of support, e.g., care of grandchildren by a grandparent might be seen as an appropriate and equitable reciprocation of assistance received from an adult child in negotiating the health care system.

Another unique perspective on the social exchanges of older people is the developmental stake hypothesis first proposed by Bengtson and Kuypers (1971). Their focus was on intergenerational exchanges. Taking an intrafamily multigenerational perspective, they argued that older people have more experience and a lifetime of family relations, which creates a greater investment in the family and shared family values. As a consequence, older people

are more interested in highlighting the closeness of relations with the younger generation, while younger people, more interested in establishing their own adulthood, may be less inclined to do so. The goal of the older generation is to encourage the transmission of important unique family characteristics to the younger generation. The older generation has a developmental stake in such transmission and is, therefore, more likely to emphasize similarities than dissimilarities and closeness rather than distance. Data from the Longitudinal Study of Generations supports this case. Given the older generation's enhanced investment in passing on their values and norms to the younger generations, they maximize the probability of positive exchanges by perceiving their relationship with the younger generations as closer than the younger generation perceives them to be. The older generation is seeking to maintain and optimize connectedness, while the younger generation may be more interested in creating their own contributions. They may see the only way to do so is by establishing distance and independence (Bengtson and Kuypers 1971).

There is considerable evidence suggesting that taking a long-term or lifespan view will offer greater insights into the nature of social exchanges, especially those where the relationship is close. Fung, Yeung, Li, and Yang found that negative exchanges were associated with greater feelings of closeness 2 years later (Fung et al. 2009). One might interpret these findings as indicative of investment, i.e., one cajoles, reminds, and persists with the loved ones one cares about in order to persuade or convince them of one's perspective. Successful investment may create an increased perception of similarity across close relations, especially across generations. Additional supportive evidence of the developmental stake hypothesis can be seen in a recent study. Birditt et al. (2015) found that parents reporting that they felt their relations with their children were important but also more negative had higher feelings of well-being. On the other hand, adults who felt their relationships with their own parents were more important than their relationships with their adult children had poorer well-being. Clearly, lifespan and family

transmission perspectives as illustrative of the developmental stake hypothesis provide a useful framework for interpreting these exchanges and their effects.

Developmental stake is likely to change over time and over the lifespan of generational family members. A more nuanced approach suggests that younger generations may wish to achieve independence and accomplishments on their own, but not necessarily by rejecting their indebtedness to the older generations. The younger generation recognizes that the older generation cared for them when they were young. They appear to be quite willing to reciprocate by providing assistance to the older generation when vulnerabilities emerge, as they often do with increased age. The types of assistance provided are wide-ranging and are likely to depend on the particular circumstances, relationship, and history. They might include needs resulting from declining health, widowhood, functional limitations, or financial strain. Provision of assistance can be considered a continuation of the exchange process. The young are now fulfilling a debt incurred when they were younger by providing to their elders as needed. This type of exchange is more flexible and may not represent a specific payback, i.e., from individual to individual, but rather a broader sense of social exchanges. Thus, an exchange might skip a generation with grandchildren reciprocating for support provided by a grandparent to a parent, when and if the parent is not available.

It should be noted that there are additional potential influences on the interpretation of social exchanges. Not all social exchanges in aging imply negative balances. In some cultures, for example, aging is associated with the higher social status of being an elder, which is associated above all else with respect and power. In addition, older individuals are more motivated to seek out relationships and experiences that provide emotional meaning. They, therefore, adopt strategies that optimize positive social exchanges and minimize negative ones by avoiding conflicts (Carstensen et al. 2003). These strategies allow older individuals to focus on maintaining or increasing the rewarding social interactions with close friends and family members who are most meaningful to

them. As noted above, older individuals can continue to provide in different ways, including caregiving for grandchildren as well as providing financial help to needy adult children. In the following section, a discussion is provided on the development of social exchanges across the lifespan and why they are important.

Changes in Social Exchanges over the Lifespan

The concept of social convoy represents a useful heuristic for examining changes in social exchanges across the lifespan. A convoy is defined as a group of close social relationships that surround an individual. This convoy moves with individuals across time as they age and can consist of family, friends, and other close ties, such as colleagues or neighbors. The convoy model of social relations highlights this dynamic nature of social exchanges as it pertains to adulthood and aging (Antonucci et al. 2011). The framework of the convoy model is developmental by nature and it represents social exchanges as complex, multidimensional, and changing over the life course. It accounts for personal characteristics, such as age, gender, race, and education, as well as contextual characteristics, such as role expectations, community, and work environments. These characteristics are crucial to shaping our social relationships as well as our social exchanges.

Over the life course, convoys can change in terms of structural characteristics, for example, size and composition, as well as functional characteristics, such as providing or receiving aid, affect or affirmational support. Parents, siblings, and teachers may be the closest social exchanges to a child as they provide shelter, emotional support, and learning opportunities. Convoys can increase in size when the individual makes more connections as s/he becomes an adult. Other social ties, such as those with supervisors, colleagues, and romantic partners may become increasingly important in young adulthood as individuals start to establish careers and families. In middle and older adulthood, individuals may

have fewer social ties as aging relatives and friends pass away, and older individuals become more selective in maintaining rewarding social exchanges rather than forming new ties. Aging parents, adult children, and friends are some examples of close ties in adulthood that are often earmarked by frequent social exchanges.

Support Exchanges in Aging. An important part of close social exchanges is the exchange of support. Positive social exchanges can provide support and buffer against stress. Support can come in many different forms, including aid, instrumental/tangible support (e.g., financial, buying groceries), affect or intangible support (e.g., emotional), affirmation or informational support (e.g., advice), and companionship (e.g., spousal relationship). In the context of aging, health can be a source of stress and need for support. Support exchanges are very important to health and well-being. For example, perceiving greater support from a partner or spouse is associated with better physical health (Ryan et al. 2014). Support is also linked to better cardiovascular, endocrine, and immune health, as well as lower mortality risks (Uchino 2006).

Social exchanges can also be stressful, involving tensions, conflicts, and arguments. In fact, most social exchanges are both positive and negative. For example, one can have a loving relationship with a spouse but still experience conflicts. Although positive relationships are generally associated with lower mortality and negative exchanges are generally associated with poorer health, under certain circumstances, such as conditions of serious illness, having negative relationship quality with children and friends has been shown to be associated with lower mortality (Antonucci et al. 2010). One possible explanation for this counterintuitive finding is that the negative relationship stems from increased demands from children and friends to engage in healthier behaviors, such as exercising and adhering to prescribed medical regimens. Furthermore, the absence of close social ties, which are usually associated with frequent exchanges, seems to have greater negative implications than having a low positive or high negative relationship as it is related to loneliness. Older individuals who report

feeling lonely have higher mortality risk, which highlights the importance of having close social ties in old age (Luo et al. 2012).

Factors Influencing Social Exchanges

There are many factors that influence the quantity and quality of social exchanges as individuals age. In keeping with the concepts of social exchange and the convoy model, two major factors that play a role in shaping close relations are considered. These are: (1) psychosocial characteristics, such as reciprocity and the related concept of a support bank and (2) sociodemographic and contextual characteristics, such as age, gender, race, and culture.

Psychosocial Factors

Reciprocity. Reciprocity is the norm in the American culture. An equal or comparable exchange of tangible aid, emotional affection, advice, or information between people or groups is preferred as optimal in social exchanges. This norm can be complicated by considerations of whether there are expectations that the reciprocity be achieved immediately or over the long run, which in turn depends on the relationship to the person with whom the exchange or reciprocity is being maintained. Most research suggests that the two are related. Relatively short-term and less close relationships call for immediate, in-kind reciprocity. For example, borrowing money or a cup of sugar should be returned as soon as possible with exactly what was received, i.e., money or sugar. On the other hand, long-term relationships do not have the same demand characteristics. Money or sugar received might be returned in kind, but there is also the expectation that reciprocity might be achieved over an extended period of time. Thus, the money, sugar, or any other need might be reciprocated in the distant future as needed with whatever is needed. In short-term relationships, immediate reciprocation is expected because it is unclear how long the relationship will last. With long-term relationships, however, there is an

expectation of availability into the distant future. Reciprocation can be achieved in the future and can be modified to meet the other's needs as they emerge.

Support Bank. This is a related concept that extends the perspective of reciprocity in the long term to include what essentially amounts to an accounting system similar to a savings account. Support provided at earlier points in time can be assumed to accumulate over time, much as they might in a savings account. Support deposited can be drawn upon in the future as needed and a withdrawal might be directly or indirectly comparable. A parent providing sick care to a child might expect to receive care at a future point in time when s/he becomes sick. Similarly, the provision of economic aid at an early point in time might result in an expectation of sick care or other tangible assistance in the future (Silverstein et al. 2002). Some versions of the support bank have outlined the transmission of deposits across people or generations. Supporting a child through caregiving by a mother or financial support by a father might translate to support expectations provided to a sibling, niece or nephew, other parent or grandparent. As such, the support bank works best within very close, longstanding relationships, i.e., the closest relationships in the convoy model. It provides a useful mechanism for long-term exchanges while at the same time maintains the norm of reciprocity.

Sociodemographic and Contextual Factors

There are a large number of sociodemographic factors that have been shown to influence social exchanges. Four such factors which are illustrative, especially with respect to influences on social exchanges in adulthood, are examined. These are age, gender, race and culture, and context.

Age. Initial thoughts concerning social exchange and reciprocity over the lifespan might suggest that younger compared to older people are most likely to report reciprocal relationships or that they provide more than they receive. In keeping with Dowd's argument that older people

are at a considerable disadvantage as they age because they have fewer resources available to them with which to reciprocate, one might assume a linear trend. This is less the case than one might suspect. Overall, in a sample of older people from ages 50 to 74 years, everyone reports that they provide more support than they receive (Antonucci and Jackson 1990). Only among the oldest group, i.e., those over 75, does another pattern emerge. This group is about equally likely to report that they provide more than they receive or receive more than they provide. A very small proportion of people in this age group report reciprocal exchanges. Interestingly, closer examination of this pattern indicates that health and disability rather than age accounts for the change.

Gender. Gender differences in social exchanges emerge with respect to the frequency of support, the effects of stressful exchanges, and the specific kinds of support. Women have more social ties than men, provide more frequent social, especially emotional, support than men, and tend to mobilize more support from network members than men during stressful times (Kawachi and Berkman 2001). In addition, women are more affected than men by their close social network members who are stressed, with the stress of others often having a detrimental effect on both their physical and psychological health. There are also differences in the specific kinds of support provided by men and women. Women, for example, are likely to report providing more sick care than they receive across all ages. On the other hand, men report providing more financial support than women, again across all ages. Of course, this gender difference may disappear in future cohorts as women are more frequently employed outside the home and men more often involved with caregiving.

Race and Culture. A series of studies offers some unique insights into how other factors might influence the experience of reciprocity. For example, in a comparison of African American, White American, and French elders, several differences emerge. First, comparing older people in these three groups, the majority of people across all groups reported that their support exchanges were reciprocal. The next most common response

was that they provided more support than they received. Reports from African Americans indicated that they provided more support than White Americans and therefore were also less likely to report that they received more support than they provided. A comparison with the French sample of elders, however, puts these differences within a cultural perspective. While the French reported patterns of exchange more like African Americans than White Americans, French elders were unlikely to report that they provided more support than they received and extremely likely to report that they received more support than they provided. While the pattern was similar, the distribution was quite different. Interpretation of these patterns might include socioeconomic differences or cultural differences in expected patterns of exchange. Very likely both explanations are correct. For example, people of lower socioeconomic status may more frequently be in a position where friends and family need help and at the same time be less likely to be able to provide it. Yet although they may be less likely to provide support, there is a greater likelihood of providing support rather than receiving it. Similarly, some cultures emphasize providing over receiving support as the cultural norm, thus making it more likely that people in some cultures report providing support rather than receiving it.

Other Contextual Factors. Apart from cultural factors, other contextual changes may lead to changes in the structure, composition, and quality of social exchanges. Common examples in the aging context include retirement, relocation, and widowhood. For adults who have been working, especially those who have been working for many years, retiring and leaving the workplace could mean reduced contact or leaving important relationships that have been formed with coworkers. If those relationships were positive, retirement could represent a loss in supportive and meaningful interactions, which is associated with worse health. However, if those relationships were negative, retirement may actually lower interpersonal stress and be beneficial to psychological and physical health. Interestingly, research has found that some work-related relationships are likely to continue after retirement, which suggests that many

of those relationships are rewarding and meaningful (Cozijnsen et al. 2010).

Moving to a new location, as is often the case among older people, whether it is to another neighborhood or to another country, also leads to changes in social ties. This is particularly true in old age if these individuals have difficulty with physical mobility and cannot maintain their previous close relationships after migrating. Older adults who relocate often have to overcome stressors in addition to diminished or lost close social ties. These stressors might include discrimination and anxiety, which could then be associated with significant declines in physical health and life satisfaction. People who have moved recently and those who moved later in life are particularly at risk for depression (Bradley and Van Willigen 2010). Social exchanges, having positive social relationships, and making new social connections are important to adjusting to changes in older adults' living environment. This is especially the case for widows who move after widowhood to be closer to family and friends who provide support.

Experiencing the loss of a spouse or partner, usually one's closest social network member, can be extremely difficult. It can be even more difficult if the relationship was close and positive, if the death was sudden and unexpected (e.g., car accident), and if the spouse or partner who died was younger. On the other hand, chronic illnesses are a major cause of death as couples age. Caregiving for a spouse/partner with a chronic illness can be very stressful and can take a toll on the caregiver's physical and psychological health. In this case, while bereavement is difficult, it can bring some relief as the burden of caregiving is lifted. Close children and friends often play significant roles in the adjustment to widowhood, especially for wives who tend to outlive their husbands (Ha 2008). It is important to note that many widows, men and women, continue to lead engaged and meaningful lives after widowhood, often by engaging in new exchanges or providing support to other close relations, such as children and grandchildren.

In this section, broad psychosocial and sociodemographic factors as a means for

understanding social exchanges among older adults were examined. The concepts of reciprocity and the support bank offer two theoretical frameworks for understanding social exchanges. At the same time, consideration of age, gender, race, culture, and context as factors influencing social exchanges indicate that both broad and specific characteristics influence support exchanges in late life.

Summary and Conclusions

Evidence suggests that social exchanges are critical across the lifetime and take on added significance as people age. Some cultures, such as the United States, emphasize the importance of reciprocity in exchanges. However, how that reciprocity is achieved can vary depending on the nature of the social relationship. Classic research indicates that short-term or less close relationships require contemporaneous and precisely equal reciprocity. Yet, long-term, close relationships seem to be more flexible, thereby allowing that reciprocity to be achieved over time and in comparable, though not necessarily, identical exchanges. These differences are important for older people who often have a number of close, long-term relationships and perhaps fewer short-term, distal ones.

The changing nature of the lives of older people suggests that a new view of their social exchanges is needed. Whereas previous theories emphasize the lost power, status, and resources of older people, changing sociodemographics may call for a new perspective. Older people are living longer and are healthier for more of that time compared to previous generations. In addition, there are notable changes in their family demographics. Although they are living longer, more people are entering old age unmarried either because they have never married, are divorced, or widowed. They are likely to have fewer children, children-in-law, and grandchildren, all of whom are also not as likely as in the past to live nearby, which influences the type and frequency of exchanges provided and received.

Notions of reciprocity as explicated by the convoy model and the support bank offer potential, innovative ways for older people to maintain equitable social exchanges. Rather than considering living longer a deficit-inducing circumstance, an individual's life history and experiences, such as age, gender, race, culture, and context, can prepare them for a new old age. Family continues to be important to middle age and older people, as does their stake in the family's future. However, middle age and older people appear to be creating circumstances that will permit them to maintain reciprocal exchanges, either by developing new short-term, contemporaneous relationships, e.g., service exchanges, or by developing multiple types of innovative long-term relationships, e.g., group or congregate housing.

Each of the above theories and perspectives offers insights into how to predict and potentially influence the exchange experiences of older people. Boomers may be redefining social exchanges and aging. As the healthiest generation of older people with the longest life expectancy, boomers are creating new opportunities for exchange through second careers, traveling, education, volunteer work, increased community activism, and active grandparenting. Rather than rely on any single type of exchange relationship, the new generation of older people create new opportunities to both give and receive exchanges. They are finding ways to prepare for and minimize deficit exchanges while maximizing resource building in the experience and anticipation of a healthy, active, and extended old age.

Social Group Interventions for Older Adults

Catherine Haslam

School of Psychology, The University of Queensland, Brisbane, QLD, Australia

Synonyms

Social cure; Social groups; Social treatment

Definition

Interventions in the present context are defined as actions taken to improve a state of affairs, which in the case of older adults typically involve enhancing various aspects of health, mood, and general well-being. Social interventions are those that deliberately use or target social processes and occur in a social context that involves one or more people. This entry focuses specifically on social interventions that are delivered in group format.

Social Group Intervention

There is considerable power in social groups. They provide an important basis for collective action, social influence, self-esteem and self-efficacy, and, most important for the present entry, social support. Social group interventions offer a means to harness this power, provided the group is one that enables formation of a strong sense of connectedness among its members and is a positive source of influence and support. These group-based interventions are primarily

advocated for social purposes as strategies to reduce loneliness and social isolation. Extending on this work, more recent research has promoted the use of social group intervention as a means of shaping identity and influencing broader health-related and well-being outcomes. This entry considers the range and effectiveness of these approaches in reducing loneliness and in protecting the health and well-being of older adults.

Social Interventions to Reduce Loneliness

Changing demographics are putting older adults at increased risk of social isolation. Recognition of the growing cost that loneliness poses to society has led to the development and evaluation of a range of strategies to counter its negative effects, particularly on health (Hawkey et al. 2006; Cruwys et al. 2013). As Masi and colleagues note (Masi et al. 2011), these tend to fall into four domains – strategies aimed at developing social skills, increasing social contact and interaction, facilitating social support, and challenging faulty cognitions. These differing approaches highlight the various causes of social isolation with the implication being that they should be more successful if tailored appropriately to the particular problems facing individuals. In practice though, it appears that these are offered as a function of availability and are not always systematically targeted.

Social skills training is thought to be beneficial for those who have difficulty initiating social contact or for whom loneliness appears to be an enduring trait. For the latter group in particular, increasing opportunities for social interaction is unlikely to be effective unless there is a change in their social engagement style which training may address. To this end, social skills training draws on behavioral techniques that incorporate role play, modeling, and feedback in the course of participants practicing their skills (e.g., initiating and continuing conversation) with others in and outside their group and in a range of contexts (e.g., in person, via telephone). Strategies that

increase social contact focus on managing the external, or structural, constraints to social participation – notably, the lack of time due to competing demands, physical constraints that include geographical isolation, and limited funds. Methods to tackle these constraints include environmental modification to increase the availability of social spaces and the creation of more locally accessible community activity and interest groups. Relatedly, support groups are commonly offered to help people cope with loneliness arising from loss associated with separation or bereavement. These groups target awareness and understanding of emotional reactions to loss in addition to countering feelings of marginalization through sharing these experiences with others. Finally, strategies targeting faulty beliefs draw on a range of cognitive behavior therapies with the intervention focusing on challenging self-defeating and maladaptive thought patterns. Here the aim is not only to raise awareness of these cognitions but also to regard these as hypotheses that can be challenged through testing.

A number of qualitative and systematic reviews have tried to establish the effectiveness of these interventions specifically in older adults. The first, conducted by Rook (1984), highlighted many weaknesses in the methodological quality of studies, which to some extent accounts for the mixed support found across most categories of intervention targeting loneliness. Though, there was recognition in this review of the importance of social bonding that group-based interventions offered and their value in social skills training in particular. McWhirter's review (McWhirter 1990) suggested that a combination of cognitive behavioral and social skills training was more effective than either in isolation and may be particularly beneficial when it comes to managing and dealing with the consequences of ending relationships. The review conducted by Findlay (2003) found little support for using social intervention to reduce loneliness, attributing this largely to weak study designs. Consistent with this, only 6 of the 17 studies reviewed used randomized controlled trial methodology. Nevertheless, of the studies reviewed, findings indicated that loneliness was reduced in 1/5 individually based, 4/6

group-based, 1/2 service-directed, and 1/4 Internet-based interventions. Thus, despite the low quality of studies, there appeared to be greater success in group-based interventions. The two reviews conducted by Cattan and colleagues (Cattan and White 1998; Cattan et al. 2005) considered the differential contribution of group and one-to-one interventions directly, and both studies drew the same general conclusion – that the more successful interventions tended to be long-term group-based interventions that were targeted at specific populations. Being conscious of the low methodological quality of studies, the review identified 13 higher-quality studies. Among these studies, all the interventions effective in reducing isolation ($n = 6$) were group based, while four out of the five ineffective interventions were individually delivered. Notable too was the fact that the intervention strategy used in successful interventions varied and ranged from the use of support groups (self-help and bereavement) to education in association with support and physical activity. So it seemed that the more important factor was the mode of delivery rather than intervention strategy.

As a number of these reviews show, group-based interventions tend to be more beneficial than individually directed treatments in reducing loneliness in older adults. This has been attributed to a range of factors – with groups recognized as providing a good vehicle for communication and contact with others who are experiencing similar concerns and are working toward common goals. Groups also provide opportunities to test developing skills and, most fundamentally, the opportunity to actively engage in a supportive social context. In more recent investigations, researchers have emphasized the capacity inherent in group interventions to shape identity and through this counter the negative health effects of social disconnection. The effectiveness of these group interventions that aim to build a meaningful social identity is discussed in the next section.

Findings from the meta-analysis conducted by Masi and colleagues (Masi et al. 2011) are particularly pertinent given it represents the only study to date that has quantified the effect of loneliness interventions based on the four strategies noted earlier. While this did not focus primarily on

older adults (i.e., people aged over 65 years), 48% of the studies meeting criteria either comprised seniors or included seniors in their larger sample. The studies included in this meta-analysis were classified according to three design types: single group pre-post design ($n = 12$), nonrandomized group comparison ($n = 18$), and randomized group comparison ($n = 20$). All design types were found to have a significant effect on reducing loneliness, with effect sizes ranging from small to large. It was only among those studies using a randomized group comparison design in which intervention strategy was a significant moderator, with studies that addressed maladaptive cognitions producing the largest effect size (mean effect size of -0.598). Irrespective of strategy, most studies incorporated group-based intervention (66%). However, the effect of group versus individual intervention was only examined in the randomized and nonrandomized group comparison studies. Only the former was found to have a larger effect in reducing loneliness in nonrandomized design studies, but this difference was not significant.

On the whole these studies suggest that perceptions of loneliness can be reduced with social intervention, but data relevant to what the intervention should comprise are somewhat mixed. Qualitative reviews of older adult studies tend to find greater support for the use of social group-based intervention. The only meta-analysis conducted recommended a focus on maladaptive cognitions due to its larger effects in reducing loneliness. However, it is also worth bearing in mind the fact that 70% of those studies addressing maladaptive cognitions were delivered in groups and that the overall analysis was based on studies conducted with participants across the age range (i.e., from 7 to 96 years). Clearly there is a need for quantitative analysis on the effects of strategy and delivery mode (group versus individual intervention) specifically in older adults to identify the optimal form of intervention.

Social Interventions that Aim to Build Social Identity

There is a growing body of evidence that speaks to the value that social group interventions play in

protecting the general health and well-being of older adults. This direction in intervention draws on evidence from the social capital literature showing that older adults who are more socially engaged are generally healthier and experience better well-being. While these data are based on the integration of different types of social relationships, there is evidence that social group relationships may be especially beneficial for health (Haslam et al. 2014, 2015). This benefit has been attributed to the contribution that social groups make in shaping our sense of self through providing us with a sense of meaning, purpose, and direction (see entry on ► [Social Connectedness and Health](#)). When they are a positive source of influence and support, social groups act as a psychological resource from which people can draw strength and health-enhancing support (Jetten et al. 2014). This reasoning has particular relevance to social group intervention, as it predicts that health and well-being is only improved to the extent that people identify strongly with their intervention group. Thus, unlike the social interventions described above that target loneliness, the strategy applied here is to build and strengthen social identification with others in the group to achieve health and well-being gain.

Results from a number of experimental studies conducted with older adults living in residential care support this prediction. The content and purpose of the social intervention in these studies varied widely and included reminiscence groups who collectively recollected memories and experiences from the past (Haslam et al. 2010, 2014a), design teams tasked to decorate communal spaces (Knight et al. 2010; Haslam et al. 2014b), water clubs to combat dehydration (Gleibs et al. 2011a), and men's clubs to counter social isolation (Gleibs et al. 2011b). The common factor was that all provided a meaningful basis for social interaction. This was even the case in reminiscence which is often characterized as a form of cognitive stimulation, but is also recognized as having an additional social function (Woods et al. 2005). Having a common purpose strengthened members' sense of identification with their social group, and this, in turn, was associated with enhanced cognitive health, mental health, and well-being.

Two studies were particularly notable in their investigation of the contribution that group and individual delivery of the same social intervention had on health outcomes. The first of these directly compared the effectiveness of group and individual reminiscence on memory in a randomized controlled trial (Haslam et al. 2010). Residents engaged in this activity over a period of 6 weeks, either with one member of the research team or in a small facilitated group. Thematic content and time engaged in reminiscence was controlled, as were the materials used to facilitate discussion (comprising tangible props such as objects and photographs from particular time periods). Results showed that group reminiscence, but not individual reminiscence, enhanced memory performance and that this was associated with a greater sense of maintained connectedness among those who reminisced in a social group context. Those reminiscing one on one felt very different and disconnected from others in care after the intervention. Thus, despite engaging in the same content, it took group interaction for the memory benefits to emerge from reminiscing. The second study involved residents in care learning about the benefits of water (Gleibs et al. 2011a). Here, residents were randomly assigned to a water or control intervention (focusing on news and current affairs), which was delivered either in a facilitated social group context or individually with a member of the research team. Only residents in two of these four conditions – water clubs and news clubs – showed any health enhancement which was particularly apparent in their reduced need for general practitioner appointments. Mediation analysis further showed that these benefits were achieved through provision of social support, which emerged in response to a strengthened sense of social identification that developed primarily among residents in the clubs.

One of the clearest demonstrations of the particular role that social identification plays in group intervention is provided in another reminiscence study. In this case, the standard form of group reminiscence, experienced through collective sharing of memories from the past, was compared with a form of song reminiscence involving collective recollection and singing of songs from the

past (Haslam et al. 2014a). Although not uncommon in the reminiscence field, overall analysis showed no effect of reminiscence on either cognitive or well-being outcomes. However, further interrogation of initial identification data (i.e., participants' initial sense of belonging and connectedness to their group) was more positive. These findings indicated that only those who developed a strong sense of identification with their reminiscence groups from the start showed improvement in general cognitive performance and life satisfaction. In this case, identification with others in the social group intervention was the driver of enhanced outcomes.

An interesting dimension to these studies is that engagement in socially stimulating activities had an effect on cognitive performance. Cognitive enhancement is typically associated with cognitive, and not social, stimulation. While it can be argued that cognitive stimulation is a feature of standard reminiscence, it was less prominent in the remaining activities involving water clubs and song reminiscence. Stronger evidence speaking to this point comes from a study conducted by Pitkala and colleagues (Pitkala et al. 2011). In this clinical trial, 235 lonely older adults were recruited and randomly assigned to take part in socially stimulating group activities, that they chose on the basis of preference and interest, or to receive normal community care. Only those who received the social group intervention showed an improvement in cognitive performance as indexed by the Alzheimer's Disease Assessment Scale. This led the authors to conclude that even socially stimulating activities targeting loneliness can improve cognition.

Identification processes have also been shown to be central in managing the mental health of a recognized minority in residential care – older men. Many social activities and interventions in residential care contexts are targeted toward women, and it is not surprising that these have limited appeal to older men. In response, a growing number of men's sheds and clubs have emerged, but there are few investigations of their effects on the health and well-being of older men. One exception to this was a study conducted in the United Kingdom investigating the effect that joining men's clubs had on older men in residential care (Gleibs

et al. 2011b). Given the low numbers of men in the facility, the activity coordinator recruited older men from the community to join the clubs, and together the men engaged in activities that they chose (e.g., watching a sports game, going to the pub). The impact of this social group intervention was compared to that for women taking part in ladies' clubs, which represented the control condition in the study. Results showed no change in the mental health and well-being of women who were already highly identified with others and were neither anxious nor depressed. However, men experienced a significant reduction in depression and anxiety and significantly enhanced well-being in association with feeling more identified and connected with other men through the clubs.

As these data attest, group-based social interventions can be more powerful in enhancing health and well-being. However, they also show that it is not simply a case of joining any intervention group on offer. The social group intervention must be meaningful and valued by those taking part for identification to develop and strengthen. Additionally, the social group must provide a positive basis for influence and support. In the absence of a positive sense of identification, there is no reason or motivation to engage or persist with an intervention, nor any basis for health and well-being gain. Nevertheless, as the Masi meta-analysis shows, there are studies that do not find significant effects of group delivery. Establishing the reasons for these mixed findings is difficult without better process measures, particularly those indexing the extent to which people identify with their social intervention group.

Conclusion and Future Directions

Social group interventions are commonly used with older adults to target specific problems – primarily social isolation and, more recently, health. Interestingly, the frequency of group-based delivery tends to outweigh individual delivery, and this is not simply a reflection of funding constraints or efforts to make savings. There is evidence showing the greater impact of group-based interventions in reducing loneliness and in enhancing cognitive

health, mental health, and life satisfaction. However, this is not the case in all studies, and this field would benefit from a quantitative review of the effect of group-based social intervention on older adults specifically. Clarity over the best mode of social intervention delivery is just a first stage. Questions still remain about the nature of the intervention, in terms of the best strategy to apply in older adults for particular outcomes, and the dose of intervention. There are currently no clear recommendations about how often social intervention should be delivered nor for how long. Answers to these and other related questions will provide the basis for stronger guidelines to optimize outcomes from social group intervention.

Social Identity Change and Driving in Later Life

Nancy A. Pachana and Jolanda Jetten
School of Psychology, The University of
Queensland, Brisbane, QLD, Australia

Synonyms

Driving cessation; Social Identity Model of Identity Change (SIMIC)

Definition

Driving is a key activity of daily living, one which not only serves a functional purpose but which can influence one's self-definition and social identity (i.e., that portion of a person's self-concept derived from group membership). Continuing to drive and even the possession of a valid license to drive in the absence of actual driving have been linked to a positive social identity (e.g., belonging to a group of older adults that is still young and active). Because of this, driving cessation has also been linked, in qualitative and quantitative research, to social identity loss – the change from seeing oneself as belonging to a group of older adults that is independent and active to one that is more frail, less independent, or, simply, older with respect to perceived (as opposed to actual) age. This is one of the reasons why driving cessation as an act (either voluntary or involuntary) has been linked to reduced physical and emotional health and well-being.

Social Identity Change and Driving in Later Life

Driving is a familiar activity of daily living, one in which many individuals worldwide participate, in most cases without thought for when this important activity may have to be suspended, either on a temporary or a permanent basis. Indeed, although in some densely urban metropolitan centers car

ownership is rare and thus driving less important, in many societies throughout the world, people are heavily dependent on automobiles as the predominant means of transportation (Buys et al. 2012). Continuing to drive is reported by older adults as important for maintaining independence and quality of life (Adler and Rottunda 2006). However, declines in health and cognition may result in older adults ceasing to drive, either voluntarily or involuntarily (Edwards et al. 2008). In turn, driving cessation may affect health and well-being negatively for a number of reasons.

Since driving is not only a practical and useful skill but is symbolically associated with many desirable qualities such as independence, competence, and freedom of mobility, stopping driving is typically associated with many negative emotions and is associated with a decline in physical and mental well-being and an increase in isolation (Fonda et al. 2001; Mezuk and Rebok 2008; Ragland et al. 2005). Consistent with this, older people who stop driving report a loss of control and self-efficacy (Windsor et al. 2009), decreased quality of life (Oxley et al. 2010), and increased dependence upon others (Yassuda et al. 1997).

However, the cost of driving cessation goes well beyond the greater dependence caused by the inability to drive from A to B. It often represents an important life change, one that is associated with social identity change and/or loss. One's social identity can be described as the portion of an individual's self-concept that is derived from perceived membership in a social group (Tajfel and Turner 1979). Traditionally, social identity theory has been used as a framework for describing intergroup behaviors and is increasingly seen as a means to not only explaining but also as a means to influencing such behaviors (Tajfel and Turner 1979; Haslam et al. 2010). In recent years, the theory has been applied more broadly, for example, to explain the way changes to social identity affect health and well-being (Jetten et al. 2012). The Social Identity Model of Identity Change (SIMIC; Iyer et al. 2008; Jetten et al. 2009) views identity change quite broadly and includes anticipated life changes such as the transition from work to retirement, as well as more sudden changes to one's identity such as those that

might result from an acute illness, or with having to stop driving. At the core of SIMIC lies the assumption that, because self is in important ways defined by the groups that we belong to (e.g., age groups), changes in group membership or loss of valued group memberships affects a person’s sense of self in important ways.

Driving cessation can be viewed as an identity change process not unlike other important life transitions such as retirement or changes in health status, in that it can occur acutely or over time and can be voluntary or involuntary. It thus involves many of the factors associated with SIMIC that make it harder to adjust to such a change. Specifically, driving cessation involves giving up a valued identity as a driver and the taking on of a new identity as a nondriver, which is viewed as unattractive and often stigmatized (Eisenhandler 1990). This new identity is very often permanent, with negative effects on the individuals’ broader identity network with respect specifically to maintaining membership in social groups and group activities (Jetten and Pachana 2012).

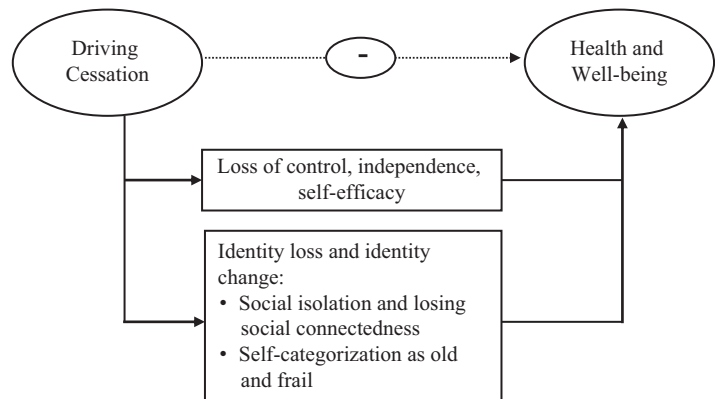

There are at least two ways in which driving cessation involves identity change and identity loss (see Fig. 1). First, driving cessation implies increased barriers to participation in community life and social connectedness (e.g., Glasgow and Blakely 2000). Driving cessation may result in a change in one’s relationship to others, to the extent that one no longer feels they belong to, or identify with, the same social groups as previously. This may be reflected in membership of specific groups oriented around an activity

which is no longer able to be pursued due to changed driving status (such as a hobby or volunteer activity), but also membership in a more abstract group (people who are independent). Thus, an individual who stops driving is likely to find it harder to engage in the social networks and social groups to the same extent as they did before ceasing driving. The social isolation that can occur and the potential for loss of group membership as a result of driving cessation are therefore likely to impoverish the individual’s social identity and, by extension, his or her personal identity (Jetten et al. 2010), and this will negatively affect health and well-being.

Second, driving cessation is also associated with changes in how a person views himself or herself and their relationships to others. When identity change involves a sense of losing identity (e.g., from being a driver to a nondriver), this not only implies a change from a positively valued identity (e.g., a healthy older adult) to a more negative identity (e.g., a frail older adult, unable to drive), it is also a marker of aging (i.e., self-categorization as “young-old” to “old-old”). In this way, driving cessation may well hinder an older adult from feeling they are younger than their chronological age and thus no longer able to “pass themselves off as something they are not” (Hornsey and Jetten 2003). This can be viewed as a categorization threat, whereby others may place them into a social category to which they would rather not belong (Branscombe et al. 1999). In effect, they have lost one means of staving off old age (Gardezi et al. 2006).

Social Identity Change and Driving in Later Life,

Fig. 1 A schematic representation of processes that affect the relationship between driving cessation and health and well-being

There is now a growing body of work showing evidence for these different negative consequences of driving cessation on health and well-being. For instance, there have been several qualitative and, more recently, quantitative studies published that shed light on how older adults think of themselves in relation to stopping driving and the potential impact of driving cessation on social identity in later life. Rudman and colleagues (Rudman et al. 2006) used focus groups of older adults who were either still driving (aged 55+) or had stopped driving (aged 65+) to explore their perspectives on self-regulating their driving behaviors. Continuing to drive was viewed as indicating independence and well-being; those who had not yet ceased to drive in this study almost could not envision themselves in the position of no longer driving: “I can’t imagine not driving” (p. 70). Donorfio and colleagues (Donorfio et al. 2009) examined, among other things, what mid-aged adults thought driving meant to them, personally. As reported by the authors, driving to these persons “meant much more than getting from A to B” (p. 223), hinting at meanings to driving beyond mere functionality.

In one of the first papers to address driving cessation and identity, possession of a valid driver’s license has been seen as explicitly linked to a positive sense of self, while loss of one’s driver’s license was associated with taking on an “older” identity (Eisenhandler 1990). In another qualitative survey, this issue of stopping driving being equated with being older was reported by one participant, after listening to a media program on driving and driving cessation: “I saw a documentary and then there was a radio phone-in. It took me a while, then I thought. . . this is actually about me, now. I suddenly realised I was old and needed to be more careful. It was that that started me thinking (female, aged 75)” (Musselwhite and Shergold 2013), pp. 94).

In a recent qualitative study of driving cessation in persons with dementia, the difficulty of bringing up the topic of stopping driving, due to its high emotional impact, was mentioned frequently by caregivers: “It meant transport, it meant independence, but it was also something about the activity itself that was so important to

him . . . It was his manly activity” (Liddle et al. 2013, pp. 2038).

In a recent quantitative study on the meaning to self in ceasing driving (Pachana et al. 2015), over 200 older adults who had either ceased driving or were contemplating stopping driving were surveyed. Driving cessation was a significant life event, one associated with subjectively feeling older. Irrespective of current driving status, these older participants identified the state of having ceased driving as associated with feeling older than their real age and the state of not having stopped driving as associated with feeling younger than their real age. Participants’ expectations about both the practical hassles involved in stopping driving, as well as identity changes with respect to, for example, social networks, were both significant predictors of the stress associated with driving cessation.

Several authors have also provided evidence that continuing to drive may be an effective way of holding off the *individual* perception of growing older (Gardezi et al. 2006; Rudman et al. 2006; Siren and Hakamies-Blomqvist 2005). Since the changed driving status is associated with so many negative and socially undesirable traits (e.g., dependence), an older adult may have great difficulty making and accepting this social identity transition. In fact, driving cessation for some individuals signals a transition from being young-old to old-old, which is often associated with greater exclusion from mainstream society (Jetten and Pachana 2012). Moreover, this can be viewed as a very public (and likely permanent) transition – an undeniable sign to others that one has become old.

Conclusion

Driving is an important aspect not only of participating in activities and maintaining mobility but also in maintaining a social identity as independent and effective and possibly even as functioning at a level that belies one’s chronological age. Driving cessation, on the other hand, is associated not only with decreases in physical and mental well-being but also with a shift in social identity to

one which is less desirable and more stigmatized, namely, a nondriver. This shift in social identity and its aftermath are congruent with the Social Identity Model of Identity Change (SIMIC; Iyer et al. 2008; Jetten et al. 2009).

Social networking

Definition

“Social media” collectively refers to a range of applications that allow user-generated content and person-to-person or person-to-network content sharing via the Internet (Kaplan and Haenlein 2010). This includes applications like Wikipedia, Facebook, YouTube, Flickr, and Twitter, to name a few commonly known examples, as well as blogging sites and online communities. All these applications share the capacity to facilitate interaction, discussion, and exchange between individuals and groups of individuals, who might be physically dislocated but can nonetheless be copresent or who can interact in an asynchronous way, in virtual space.

Background

“Social media” rose to prevalence in the early to mid-2000s following a series of technical innovations known as “Web 2.0.” Web 2.0 does not refer to any specific advance in technology or programming, but rather is used to refer to the accumulated changes that increased the capacity for user-generated content and made the sharing of this and social interaction via the Internet more possible. Although social media applications share these capacities, individual social media platforms differ on a number of dimensions, including their specific purpose (e.g., social, political, commercial; informational versus entertainment), content and layout (e.g., primarily text or image based), and scope of individual contributions (e.g., being relatively more public versus private, anonymous versus identified, active versus passive in terms of use and engagement). On the boundary of social media are applications that also allow for specific forms of social interaction via the Internet, including email, instant messaging platforms, and Skype, but do not meet the formal definition of “social media” because they do not involve the creation and public sharing of content that exemplifies social media properly. Nonetheless, these applications and technologies also provide opportunities for users to connect with each other and with networks, to share content and interact, and to do so instantly and beyond the constraints of physical and temporal co-location. As such, these forms of online social interaction and networking are often discussed in connection to social media more generally.

Social media are now deeply embedded in the societies of most developed nations and many developing nations also. Social media play a significant role in the everyday personal lives of individuals around the globe and have also been implicated in social and political life via their role in facilitating social movements and collective action (e.g., as exemplified by the “Arab Spring” protest movements in 2010). In the context of aging, interest in social media has been driven by two broad, but related, concerns. First, social media are seen by some to hold considerable promise as tools for supporting the social

participation of older adults who might otherwise be at risk of isolation. Second, as access to information and social services increasingly becomes “digital by default,” concerns have been raised about digital literacy among older adults and the extent to which deficits in skills or access to technology could be creating digital divides that further contribute to the marginalization of older adults. These twin concerns speak to the role of social media, and online interaction more broadly, in contributing to social inclusion versus exclusion. Current research that speaks to these issues is summarized below.

Aging, Social Media Use, and Well-Being

Social isolation and loneliness are issues of concern across the life span, and research has established significant links between the quantity and quality of individual social connections, or the subjective representation of these (e.g., in terms of felt loneliness), and individual mental, cognitive, and physical health outcomes. To broadly summarize this body of research, people who have access to more social connections, who are more satisfied with their relationships, and who participate across multiple social groups tend to be more emotionally and physically resilient in the face of stress, tend to experience better mental and cognitive health, and tend to live longer. Although such patterns are evident in younger and older populations alike, the negative health effects of social isolation and associated feelings of loneliness tend to amplify with age (Hawkey et al. 2006; Ong et al. 2012). As such, the negative consequences of social isolation and loneliness are an issue of particular concern among older adults. Moreover, aging itself is associated with a variety of physical, cognitive, and social changes that can contribute to, or exacerbate, social isolation and feelings of loneliness among older adults. For example, physical impairments can restrict mobility and thereby reduce opportunities for ordinary contact with others in the local community; cognitive impairments can create barriers to easy and effective communication; bereavement can restrict one’s social network;

and moving into long-term care facilities can create distance between one’s self and one’s family. For all these reasons, finding ways to support positive social relations among vulnerable older adults is an important priority both for research and for aged care and public health policy more generally given the aging global population.

Because of their capacity to bridge physical and temporal divides, to enable alternative forms of communication, and to facilitate social connections (Neves 2013), social media applications have been viewed by some as promising tools to reduce social isolation among older populations. Specifically, social media seems to offer a way to help those who have limited physical mobility, who may be living away from their families, or who may be experiencing difficulties with verbal communication, to maintain their social networks and to engage with these effectively. Beyond these uses, social media can also connect people to other public health developments such as tele-care and tele-health, in which interaction with and monitoring by carers and health professionals are conducted remotely, thus having a potentially wider field of application in relation to aging.

There is evidence that older people who are more digitally active tend to experience better well-being. For example, data from large-scale, population-based surveys of older adults in the United Kingdom (English Longitudinal Study of Ageing) and the United States of America (Health and Retirement Longitudinal Study) show significant longitudinal relationships among Internet use and reduced depression (Cotten et al. 2014), improved cognitive capacity (Xavier et al. 2014), and more positive health behavior in areas of physical activity, diet, and smoking (Xavier et al. 2013). These relationships hold when controlling for important demographic indicators (e.g., gender, education, functional impairment, and wealth). Interestingly, the relationship between Internet use and reduced depression was found to be the strongest (and indeed only significant) among older adults who were living alone, or with only one other person, rather than those living in larger households. This particular pattern speaks to the idea that Internet use might provide a useful supplement to social activity

among those who have fewer local opportunities for interaction, thereby attenuating the negative effects of social isolation. However, such links could also be explained by a variety of other processes. For example, relationships between Internet use and improved cognition could be explained both by enhanced social engagement and by increased learning and mental stimulation (Ybarra et al. 2008), and relationships between Internet use, depression, and health behavior could be accounted for by access to health information and other resources, as well as by processes associated with social support, advice, and influence from one's network (Smith and Christakis 2008).

However, correlational links like these, even when longitudinal, could also be explained by other uncontrolled factors associated with Internet use. As such, experimental research is important for understanding the causal links between engagement with specific forms of technology and individual health and well-being outcomes. In contrast to this correlational picture, evidence for the causal role of Internet use in general, and social media specifically, in enabling social connections and contributing positively to cognitive and mental well-being is currently scarce, especially with respect to older adults. Moreover, the studies that have been conducted on this issue have produced mixed findings. Some small-scale earlier studies in this area showed positive effects of Internet provision and supportive training on the well-being of older adults involved (McConatha et al. 1994, 1995). However, more recent larger-scale studies found no or limited evidence of improved outcomes among older adults assigned to receive a computer, Internet connection, and supportive training (Slegers et al. 2008; White et al. 2002; Woodward et al. 2011). Thus, while there is suggestive evidence that points to the potential for social media and other online applications to support the social connections of older adults and through this improve their well-being, at present the evidence for this is inconclusive (Shklovski et al. 2004). To resolve this issue, there is clearly a need for more large-scale well-controlled experimental studies to quantify the causal effects of social media

provision and training, and individual engagement with these, on the capacities and well-being of older adults over time.

Perceptions and Use of Social Media and the Internet by Older Adults

Beyond the specific benefits that may or may not flow from social media use, researchers have also examined the perception and use of social media among older adults. It is often assumed (by younger people) that older adults are not interested in computers and social media or that they are not capable of using these fully and effectively. In line with this, surveys show that age is associated with lower levels of computer use and less engagement with social media. However, despite the persistent age gap, computer use is increasing across time for all ages, and recent US data suggest that the use of social media has increased particularly sharply among adults over 50 years (Madden 2010). These trends suggest that older adults are increasingly interested and engaged with computers, technology, and social media applications. Indeed, there are some who suggest that the age-based "digital divide" may be a historical problem – because current generations have been raised with technology and the Internet. Moreover, as social media becomes more pervasive and part of one's ordinary daily life, this digital literacy will remain as people age. Of course, technology itself ages, becomes obsolete, and is replaced by newer developments. As such, there are still reasons to suspect that the gap in digital literacy between younger and older groups might persist (Friemel 2014).

There may also be specific functional and attitudinal aspects of computers and social media use that act as barriers to individual engagement among older adults. Functionally, for example, physical and cognitive changes associated with aging may make computer use progressively harder: impaired vision and hearing makes it harder to engage with content displayed by computers, and reduced dexterity makes it harder to use a keyboard and mouse to navigate these. However, computers themselves are changing by

becoming more portable and more user-friendly. The use of assistive devices (e.g., a stylus in conjunction with a touch screen) and minor modifications can help to overcome some of the physical barriers to computing experienced by older adults. Beyond functional restrictions, attitudinal barriers might exist. For example, self-perceived ability may limit willingness to engage with computers. A lack of comfort with the perceived norms of social media, the potential for exposure to inappropriate content, and especially fears about privacy and the sharing of personal information have also been identified as particular attitudinal barriers to engagement with social media among older adults (Nef et al. 2013; Xie et al. 2012). With respect to these attitudinal barriers, it is also worth noting the important role of encouragement and support from social networks in facilitating older adults' engagement with technology and the Internet (Friemel 2014). In this respect, features of older adult's offline social networks are likely to contribute to whether and how they engage with social networking online.

Another barrier to older adults' engagement with social media may be what they do or do not find when they go onto social networking sites. Social media can be a useful way for supporting social connections only to the extent that they provide access to others with whom one wants to connect. Given that social media use generally reduces with age, older people might find it difficult to locate friends and peers with whom they would want to interact on social networking sites. The perceived absence of friends online may limit individual participation, thereby creating a reinforcing pattern of underrepresentation of older adults in social media fora. Of course, older adults may not want to only interact with people of their own age. Because social networking is so pervasive among younger adults and children, social media might provide opportunities for intergenerational contact that are welcomed by older adults (Nef et al. 2013).

Aside from the types of social contact that are available, older adults might also be confronted by negative stereotypes about their age group via social media. Ageism is a common form of social prejudice and unlike many other prejudices is one

that is openly expressed and perceived to be legitimate (North and Fiske 2012). This, in combination with the dominance of younger users, could lead to the expectation that age-based prejudice and negative stereotypes on social networking sites should be fairly frequent. Indeed, a recent study conducted an analysis of 84 open-membership Facebook groups that included terms related to older adults in their descriptions and found that the overwhelming majority of these referenced negative stereotypes (Levy et al. 2014). Although this possibility has not been systematically investigated, it seems plausible that exposure to negative stereotypes and prejudice toward older adults via social media sites might negatively affect individual motivations to engage with these.

To the extent that older adults do engage with social media, studies highlight specific features of these that are valued by this population. Consistent with the perceived potential for social media use to address social isolation, studies suggest that one of the most common uses of computers and Internet technology among older adults is for communication and social support (Wagner et al. 2010). As noted above, providing the opportunity for intergenerational contact has also been suggested as a specific value of social media (Nef et al. 2013). Finally, social media provide the capacity for accessing, sharing, and discussing health information, something that may be of particular interest and relevance to older adults – and that might contribute to better health and well-being to the extent that the information found is reliable and contributes to better decisions. Indeed, seeking health information is a common use of computers among older adults (Wagner et al. 2010). However, trust in the credibility of such information can also be an issue for this population (Zulman et al. 2011).

Summary

Social media represent both the accumulation of technological advances and a shift in the form through which many people now engage with social connections. Reflecting the broader uptake

of social media across society, older adults are increasingly computer literate and increasingly engaged socially online. Because of their unique capacities to transcend time and space, and to offer alternative ways of communicating, sharing, or otherwise being “copresent” with others, it is often suggested that the Internet and social media applications might be useful tools for tackling social isolation among older adults. However, to date, systematic evidence for the effectiveness of Internet connectivity, Internet use, or social media use, more specifically, in supporting the health and well-being of older adults who might be vulnerable to social isolation is limited and, at best, mixed. As such, more research exploring how older adults engage with Internet technology and social media, and the consequences that this might have for their health and well-being, is clearly needed.

Social Policies for Aging Societies

Terry Lum and Gloria Wong
The University of Hong Kong, Hong Kong, China

Definition

In this entry, social policies refer to policies that affect well-being of individuals and families. They are usually referring to income maintenance policy, educational policy, social welfare policy, housing policy, and health policy. Aging society refers to a society that has at least 14% of its population aged 65 years or older.

Background

Population aging affects all aspects of human experience and requires specific social policies that address the needs of older people. Older people face a higher risk of poverty and income insecurity. They have increased needs for health and long-term care. Governments are developing policies to promote successful aging, productive aging, and aging in place. Although population aging affects both developed and developing countries, policy challenges for developed and developing countries are distinct. In this entry, we review four major social policy issues related to aging societies: old-age income support, health

care and long-term care, successful and productive aging, and age discrimination and age equity. In doing so, we draw on policy examples from developed countries such as the OECD countries and developing Asian countries to illustrate the diversity of policy responses to population aging.

Old-Age Income Support Policies

Economic activities, and hence income, expenditure, and saving, are not distributed evenly across the life span. Typically, younger adults save for retirement throughout their working years via different public and occupational retirement saving programs and private saving. By the time they become too old to work, they finance their consumption by gradually dissolving their assets and by support from their children. Over the last century, governments have developed policies and programs to protect against the risk of poverty in old age and smooth the transition from one's work life into retirement (Holzmann and Hinz 2005; Holzmann et al. 2008).

The social safety net, public pension, and social insurance are three major policies that aim to protect older people from economic hardship and to smoothen consumption over the life course (Smeeding and Sandstrom 2005). The social safety net is noncontributory social assistance program for lifetime poor, sick, and disabled elders who have no or very limited work history. It is usually funded by the general tax revenues and provides minimum safety net benefits against old-age poverty. It can be universal or means-tested. The public pension is generally universal and contributory, either through defined contribution or defined benefit, providing a cash transfer paid regularly to older people. The cash payment is usually small, funded by salary tax in a pay-as-you-go arrangement. It provides a higher-income replacement rate for low-income earners. Social insurance is contributory, mandatory, and universal. It generally links benefits to earning history and provides effective financial protection against old-age economic hardship by spreading the risk over all insured people, within and across generations. Some social insurance programs, such as

the Social Security program of the USA, also provide spouse and dependent children benefits. These three programs, together, create the first three pillars of the World Bank's pension system framework (Holzmann et al. 2008). The fourth pillar of its framework is a voluntary employment-related retirement saving plan, usually in the form of a fully funded defined-contribution individual retirement account or a defined benefit pension plan. Most governments use a combination of these policies to reduce the risk of old-age poverty and improve the economic status of older people. In the USA, the Social Security program alone reduced the old-age poverty rate from 44.4% to 9.1% and lifted 15.3 million older people out of poverty (Van de Water et al. 2013).

Old-age income support programs are under stress in many countries as the size of the elderly population grows rapidly. Population aging increases the needs of old-age income support and at the same time reduces the contribution to those programs. Governments are exploring different ways to reform their old-age income support programs to make them sustainable. These reform efforts can be grouped into two strategies, namely, eligibility-restricting reforms and generosity-restricting reforms. The eligibility-restricting reform aims to abolish or restrict early retirement schemes, increase the statutory retirement age, and gain greater equality in the age at which men and women retire. In generosity-restricting reforms, governments adopt a lower pension benefit ratio to decrease or stabilize pension expenditure (European Commission 2014). Politically, it is easier to adopt and implement the eligibility-restriction reform than generosity-restriction reform.

Health Care and Long-Term Care Policy

Health care and long-term care are other pressing policy issues in aging societies. It is well documented that the rates of morbidity and mortality increase with age. Population aging also affects disease profile, shifting from infectious

and acute diseases that are relatively inexpensive to treat to chronic diseases that are expensive to manage. Therefore, many policy makers assume that population aging is associated with increased utilization of health services and higher health spending. Such perception has also been supported by health-care utilization data. For example, in the USA, elderly people comprised 13% of the total population in 2010, but consumed 34% of the total health-care spending (Centers for Medicare and Medicaid Services 2015). In Europe, older people account for about half of the hospital bed-days (McKee et al. 2002). Governments, therefore, are trying to slow the growth of health spending by finding new ways to finance and organize health care to produce the best health outcomes by the most efficient means (National Research Council 2001). These usually include better coordination of care across health and social services, across different levels of health care, and across private and public health resources; moving treatments and care out of hospital; and enhancing health promotion and disease prevention programs that target amendable risk factors such as obesity, hypertension, mental health, and inactivity (Economist Intelligence Unit 2009; Rechel et al. 2009).

However, recent research findings cast doubt on the population aging-higher health-care spending connection and suggest that other factors, such as the use of advanced medical technology, public health spending, and end-of-life care, may have a larger impact on health-care costs in an aging society (Rechel et al. 2009; Werblow et al. 2007). For example, the USA spent 16.4% of its GDP on health care in 2014, which represents 7.5 percentage points above the OECD average of 9.3%. This is despite the fact that the USA has a much younger population than OECD countries (OECD 2014). Similarly, an analysis of OECD health spending data between 1965 and 1995 also found that age has a negligible effect on an individual's health-care expenditure when proximity to death is controlled for. In fact, most health-care expenditure is driven by medical technology and decision on end-of-life care than by aging population (Werblow et al. 2007).

Long-term care (LTC) is a set of multidimensional services that comprise health care, social care, personal care, and housing and is directed at persons with limited self-care ability due to cognitive decline, functional decline, or chronic illness. It differs from health care as the goal is not to cure or rehabilitate, but to maintain and to reduce the impact of cognitive and functional decline on the quality of life of older people. LTC can be delivered at home (e.g., chore services), in the community (e.g., adult day-care services), or in institutions (e.g., nursing and residential care facilities). Although governments have been increasingly providing long-term care to older people, family members are still the major caregivers of frail elders in all societies, including advanced Western countries such as the USA and UK. Most governments have complicated policies that regulate providers of long-term care services, including manpower, qualifications, safety, hygiene, and physical environment.

LTC is usually financed through taxation, LTC insurance, or through national health-care spending. In some Nordic countries, LTC is tax-funded and is an integral component of their universal health-care system. In the USA, LTC is mainly funded by the Federal Government's Medicaid program and is means-tested. Other governments, in countries such as Japan, Korea, and Germany, use a stand-alone insurance to finance LTC. The LTC insurance is usually contributory and mandatory. A few countries, such as the USA, adopt the medical model of LTC and fund LTC services through the public health system (Francesca et al. 2011).

Many governments are trying to rebalance their LTC services by shifting more resources to home- and community-based care that encourage frail elders to age in place. Some countries are also trialing various forms of participant-directed care, also known as the money-follow-the-older-people programs or personalized social care. The participant-directed program allows frail elders, with support from their family or informal caregivers, to develop individual budgets to support access to more personalized services that meet their individual needs.

Many governments see ensuring and improving the quality of LTC as an important policy priority in aging societies. The most common policy approach in quality control focuses on controlling input, such as staff ratio and infrastructure, by setting minimum acceptable standard and enforcing compliance. Very few countries have a system of systematically monitoring the quality of LTC.

Successful and Productive Aging Policies

Successful and productive aging are two different, but related, concepts. Successful aging is a multidimensional concept covering physical, mental, and social functioning; life satisfaction; and psychological resources (Rowe and Kahn 1997, 1998). To age successfully, older people work to improve their overall health, minimize their functional loss, increase their social participation, and enhance their capabilities (Rowe and Kahn 1998). Similarly, for those more frail, successful aging involves optimizing physical, cognitive, and social functions, but in the context of accommodating for their long-term disabilities. Regardless of ability and age, autonomy and meaningful engagement are essential for successful aging. Social policies, therefore, aim to minimize the negative impact of disability and health deterioration on functioning and social engagement and to maintain high levels of autonomy. Successful aging policies cover various community support programs that provide older people opportunities to optimize their health and functioning, to engage in socially meaningful activities, and to enhance their autonomy and capability. Environment is crucial to successful aging, and governments have increasingly adopted policies that promote age friendliness in local communities. The Age-Friendly City domains from the World Health Organization have been adopted by a number of societies as guiding principles for age friendliness.

Productive aging policy focuses specifically on increasing opportunities for older people to continue their productive engagement in the context

of aging. Productive engagement of this form refers to any activity that is seen to have economic value (Hinterlong et al. 2001). Economic value can be measured in terms of goods or services produced (e.g., full-time or part-time paid employment) or of the economic cost involved in supporting older people not involved in those activities (e.g., caregiving and volunteering). Productive aging policies also incorporate activities that enhance productive activity in older people, such as education and training. Productive aging engagement has positive effects on older people's health and mental health, but, typically, tends to be taken up by more educated and middle-class elders (Hong and Morrow-Howell 2010; Lum and Lightfoot 2005; Musick et al. 2000). For low-income elders who wish to volunteer, financial support from the government helps reduce the economic barrier associated with participation and makes such participation possible. In the USA, the Federal Government funds the Senior Corps that provides service opportunities for Americans aged 55 years and older. The Senior Corps programs offer modest stipends to help offset the costs of volunteering. Similarly, the AARP Experience Corps® (EC) offer high-commitment volunteer opportunities that bring older adults into public elementary schools to improve the academic achievement of students.

Age Discrimination and Age Equity Policy

Some employment policies are not age friendly. Nevertheless, governments have an obligation to protect people from age discrimination in the workplace. Age discrimination typically arises in response to age stereotyping, where characteristics are attributed to people based on their age. It can result in the setting of arbitrary age limits for hiring, promotion, compensation, and other employment decisions, regardless of an individual's actual ability or potential for job performance. Age discrimination arises when employers use such stereotyping to make employment decisions. For example, an employer may assume that older workers are less interested in training and thus

make decisions about the training opportunities they offer on the basis of age. They may also assume that younger workers are more productive and make hiring decision based on age. Age discrimination, intentional or unintentional, is not only illegal but also harms business when the workforce is rapidly aging. For example, in the USA, the median age of the working population is already 40 years and older (AARP 2006). In the USA, the Age Discrimination in Employment Act has been in place since 1967 to make it illegal for employers, employment agencies, and the federal government agencies with at least 20 employees to discriminate against employees and job applicants who are 40 years or older. It also prohibits age discrimination by labor organizations, such as unions, that have at least 25 members. The best way to prevent age discrimination is to make age-neutral decisions on hiring, firing, work assignments, and benefits and to base these decisions on how well an individual's abilities and qualifications match the criteria set for the job. Finally, an age-friendly work environment, such a more flexible employment term and retirement age and more support in using assisted devices in workplace, is essential for the future of aging societies. Unless we can attract a very large number of older people to remain in the workforce, many societies will face severe labor shortage.

Conclusion

Population aging creates pressing needs that drive social policies. The diverse responses to address these needs reflect the unique strengths and challenges of different societies. These may include different rates of population aging, levels of economic development and wealth, maturity of health and LTC infrastructure, and availability of human resources and dependency ratio. With reference to these previous responses, a new generation of social policies for population aging can be designed, with innovations that turn challenges into opportunities. The interrelatedness and synergetic effects of the four major social policy issues outlined in this entry is an area to be further explored.

Synonyms

Affect; Centenarians; Culture; Emotional regulation; Social support

Definition

Social resources are characterized by structural (social network availability, culture) and functional (instrumental support, emotional support) attributes originating from social interaction and interpersonal engagement. The interplay between structural and functional characteristics in social resources is vital to positive adaptation and

long-term survivorship in human aging. Specifically, social resources contribute to the sustainability of individual health, emotional regulation, positive psychological disposition, and quality-of-life among long-lived adults.

Social Support Ties and Centenarians

Although social resources increase the probability of living long, they often present a quandary for persons living 100 years or longer. Survivorship beyond the expected normative limits of human life expectancy is generally accompanied by co-occurring and simultaneous declines in biological potentials including but not limited to impaired cognitive orientation to time, space, and place; short- and long-term memory deficits; reduced sensory acuity in vision and hearing; poor functional mobility; and diminished performance in everyday decision-making and activities of living (Poon et al. 2010). The acceleration of age-associated losses in human biology experienced by persons living extremely long lives contributes to an increased dependence on sociocultural provisions to manage and sustain individual functioning and well-being (Poon et al. 2010; MacDonald 2007). Paradoxically, researchers commonly assume that most centenarians have outlived the majority if not all of their close immediate familial attachments, as well as other familiar but informal sources of support (e.g., friends, neighbors; Poon et al. 2010; MacDonald 2007). This limited support network of family, friends, neighbors, and others puts centenarians at a unique social disadvantage in terms of both a diminished social functioning and quality of life compared to younger age cohorts (Poon et al. 2010; MacDonald 2007). In some cases, centenarians may have an increased concern about dependency and whether they may have an adequate supply of social provisions to meet their personal needs (Poon et al. 2010). As a result, contemporary centenarian researchers have pursued three primary areas of scientific inquiry pertaining to social resource provisions among persons living 100 or more years: (a) where centenarians live and from whom they

receive social support, (b) the associated link between social resources and functional health in extreme longevity, and (c) the interplay between social resources and experiential and evaluative attributes of emotional well-being.

Living Arrangement and Social Resources

Recently, centenarian researchers have begun to consider the structural conditions of social resources and in particular the comparative examination of interpersonal living arrangements among centenarians. A primary focus of this work has involved identification of where and with whom centenarians may reside, as well as what types of resource provisions centenarians receive from their social network affiliations. Results of this focus include the identification of noticeable sociocultural differences where centenarians may live and from whom they may receive sources of care. For example, the care of old and very old adults in the United States conforms to a Western cultural tradition of filial obligation (Blieszner and Hilkevitch-Bedford 2009). This implies a sense of social duty as well as obligatory ethical practices by blood-related offspring or a legally designated third party (e.g., legal guardian, long-term care/medical institution) to manage and provide social resources for society's older members. Relative to the care of long-lived adults, social provisions are exchanged to sustain a shared sense of autonomy and well-being for both care recipient and care provider (Blieszner and Hilkevitch-Bedford 2009). According to the U.S. Census Bureau (2012), this generally translates into a continuum of support relative to where centenarian men and women reside: (a) alone and independently at home without the presence of assistance others within the household (33.3% of centenarian men vs. 34.0% of centenarian women); (b) independently but with family members or others in the household who may provide unpaid or paid 24-h assistance with basic activities of daily living (43.5% of centenarian men vs. 28.5% of centenarian women); (c) under 24-h direct medical supervision within formalized

long-term care setting (18.2% of centenarian men vs. 35.2% of centenarian women). This appears to confirm that centenarian men in the United States tend to live more often with various family members (e.g., son/daughter, grandson/granddaughter, niece/nephew) and therefore receive more family-based support in the maintenance of everyday social functioning (e.g., mobility, cooking, financial management); whereas centenarian women more likely require more formalized and long-term socioenvironmental provisions (e.g., Medicare/Social Security, nursing and medical care).

Investigators from the Georgia Centenarian Study (GCS) studied social resource differences among centenarians residing in private homes, assisted-living facilities, and nursing homes (Randall et al. 2011). Evidence from the GCS suggests that centenarians residing in nursing homes tend to report lower self-reported social provisions overall compared to their counterparts residing in private homes or assisted-living centers (Randall et al. 2011). This finding appears to persist even for those centenarians who have larger social networks. Although quality of life may be enhanced by interacting with social network members, centenarians living in nursing homes may find it intrusive or even tiring when numerous people come to visit and interact (Cho et al. 2012). Nonetheless, social resources remain essential in improving the degree to which centenarians feel prepared to face everyday life challenges (Randall et al. 2011; Cho et al. 2012). In most cases, centenarians who possess high-quality social ties feel more capable of handling life circumstances regardless of current residential status (e.g., at home, in an assisted-living facility, or nursing home).

Among centenarians living in the United States, those originating from other countries are more likely to coreside at home with others. This appears to be very predominant among centenarians representing Asian countries such as China, Taiwan, and Japan (U.S. Census Bureau 2012). For example, an estimated 61.4% of Asian-American centenarians reside with others in the household compared to only 26.4% of White-Caucasian and 47.8% of African-American centenarians. A majority of social provisions

reciprocated in the care of a centenarian are generally initiated by an adult child or grandchild (Yang 2013). This appears to reaffirm an Eastern cultural philosophy known as filial piety or the act of good conduct and care toward one's parents, elders, and ancestors (U.S. Census Bureau 2012). This is a cultural tradition across many Asian cultures. Traditionally, it is the duty of a male heir to behave out of respect and love while pursuing acquisition of material means to be used in care and support of one's parents or elders (U.S. Census Bureau 2012). Such conditional lifestyle factors contribute to a greater number of centenarians living at home regardless of whether they may or may not need to use public welfare provisions to support normative activities of daily living (Yang 2013). Most interesting is the fact that centenarians do not view their need for support as a burden that increases with continued survivorship (Yi et al. 2008; Wong et al. 2014). Yet, family care providers of centenarians seem to exhibit similar self-reported feelings of burden, symptoms of depression, health problems, and energy compared to noncentenarian care providers (Yang 2013; Yi et al. 2008; Buetner 2008). In effect, family caregivers of centenarians are not immune to caregiving stressors that may eventually compromise one's own need for social resource functioning (Yang 2013).

Characteristics of filial piety have been reported to persist within the social networks of individuals living 100 years and longer in Japan. Investigators have cited evidence that Japanese centenarians commonly endorse a sense of shared history, death/grief, and life domains such as lifestyle habits and work within collectively tight-knit and age-homogeneous groups (Martin et al. 2013). Centenarians on the island of Okinawa, Japan, are most noted as maintaining membership within small collective social network groups known as "moai." Moai typically consist of a shared social network of centenarians who attend to the social needs of other centenarians (Martin et al. 2013). This reflects a reciprocated social system in which elders support and care for other elders. In many instances, moai include a lifelong group of centenarian friends who often coreside together or within very close proximity

(Martin et al. 2013). Moai serve as a “social safety net” in the exchange of social capital (e.g., guidance, physical care, financial assistance, dietary wellness) within everyday social interactions between companions (Martin et al. 2013). In effect, social resource quality appears to be essential in the continued well-being of Okinawan centenarians.

Social Resource-Health Functioning Link

In addition to investigating social living arrangements and underlying resource needs of centenarians, investigations have attempted to clarify the empirical link between social resources and functional health capacity. A majority of reported findings surrounding association has come from the Georgia Centenarian Study (GCS) in the United States. Of key interest has been the determination of how social resources are associated with the performance of activities of daily living by centenarians. Investigators from the GCS have reported negative changes in the performance of activities of daily living (ADL) and social resource provisions to be significantly greater among centenarians compared to persons in their 60s and 80s (Poon et al. 2010; MacDonald 2007). This contributes to a deficiency of age and functioning well at 100 years of age and older. As centenarians experience noticeable declines in their ability to complete everyday instrumental tasks in living (e.g., using the phone, meal preparation, shopping, handling money), an ever-shrinking social support network erodes opportunity to maintain frequent contact with social resource ties that commonly provide assistance (Poon et al. 2010; MacDonald 2007). Among centenarian participants within the GCS, social resources significantly moderate the performance of instrumental tasks in everyday life. Centenarians may initially possess greater social resources, but they continue to experience steeper declines in their functional capacity to perform instrumental tasks over time compared to younger age cohorts (Poon et al. 2010; Randall et al. 2011; Cho et al. 2012). Unlike younger age-groups, centenarians experience increasing reductions in ADL performance

which translates into a simultaneous need for greater social assistance in meeting daily living tasks (Poon et al. 2010; MacDonald 2007). Investigators from the GCS have also extended confirmation of these findings to include the perspective of proxy informants (Buetner 2008). In particular, caregiver reports indicated that centenarians, especially those living independently at home, tend to be in better overall physical health and therefore more likely to effectively perform daily tasks of living on their own (Buetner 2008). Yet, centenarians who receive encouragement from members of a caregiver support system are more likely to attempt performing activities of living, despite experiencing age-associated limitations (Buetner 2008). Thus, the support received from caregivers is an essential social resource and determinant in the functional well-being of centenarians.

Beyond the United States, international-based research efforts have given primacy to understanding the associated link between social resources and physical health functioning among centenarians. There has been some minor global debate whether social resources are essential determinants of health functioning among centenarians. Researchers with the Japanese Centenarian Study conducted a nationwide census-based study ($N = 1,907$ centenarians; (Ozaki et al. 2007)). Within this sample, approximately 10.4% of centenarians were regarded as “autonomous centenarians (Ozaki et al. 2007).” Such centenarians maintain a strong cognitive reserve and numerous other alternative psychosocial resources (e.g., cognition, diet, exercise, lifestyle habits) that play an essential role in health functioning. Relative to social resources, Japanese centenarians who remain self-sufficient in the performance of daily activities of living tend to view the status of their family relations more favorably than relationships with friends or other nonrelatives (Ozaki et al. 2007). Furthermore, Japanese centenarians who reside alone at home with family are more likely to maintain better cognitive ability and overall functional capacity than their counterparts who may reside within hospital or institutional care settings (Ozaki et al. 2007). Family relations are believed to bolster autonomy

among centenarians to the point of eliminating dependence on nonfamilial supports for health-related assistance in everyday life activities (Ozaki et al. 2007). It may be that the ability to demonstrate competence in completing everyday activities by one's self and without feeling dependent on others external to one's family is a valuable resource for some centenarians.

The issue of autonomy versus dependency as social determinants of centenarian health functioning has also been further explored by a group of Korean researchers (Kim et al. 2012). In this investigation ($N = 796$ Korean centenarians), social connectedness and activity at 100 years of age and older were identified as essential attributes in reducing the presence of disease and lowering the need for assistance in everyday activities of living (Kim et al. 2012). These findings suggest that social provisions improve health functioning among centenarians. Thus, a case may be made that social resources are valuable to healthy longevity for many centenarians. Still, there are some centenarians whose health seems to fare better without help from others (Poon et al. 2010; MacDonald 2007; Kim et al. 2012). Further clarification of this paradox in the social resource-health functioning of centenarians link is warranted and an opportunity for future investigations.

Socioemotional Resources of Well-Being

A final area of empirical interest in centenarian research involved socioemotional resources of well-being. A majority of this research focused on understanding how social resources operated in tandem with experiential (e.g., positive and negative affect, loneliness, happiness) and evaluative (e.g., life satisfaction, quality of life) attributes of well-being (Poon et al. 2010). For example, Martin et al. (1997) conducted an earlier cross-cultural comparison of loneliness in centenarian samples representing two countries, Sweden and the United States. Contrasting culture differences in social support and loneliness were evident across the two samples. Among centenarians in Sweden, reported feelings of loneliness

were increased by the presence of greater social resources. Martin et al. (1997) speculated that this counterintuitive finding was likely due to the provision of social support which heightens individual awareness of social losses, and thereby increases emotional longing for close attachment ties which the centenarian has outlived. However, centenarians in the United States indicated feeling more lonely in the absence of supportive resources (Martin et al. 1997). Among other European centenarian studies, such as those in the Heidelberg Centenarian Study, there is supportive evidence that self-reliant beliefs may regulate the extent to which basic social capital (e.g., social support, job training, and extraversion) increase or decrease socioemotional affective outcomes. According to Jopp and Rott (2006), centenarians generally remain resilient to reduced resources that would otherwise produce negative affective outcomes. This is mostly due to proper self-regulation in adapting to loss (Jopp and Rott 2006). Yet, it is important to remember that poor socioemotional regulation can contribute to underlying symptoms of anxiety and depression, which can potentially hinder positive adaptation and overall quality of life (Poon et al. 2010; Riberiro et al. 2014). Further investigation into the interplay between social resource deficiencies, psychological adaptation, and socioemotional well-being among centenarians is warranted.

Recent evidence from the Georgia Centenarian Study (GCS) has confirmed that greater social interaction enhances perceived quality of available social resources among centenarians in the United States. The more accessible social resources are perceived to be, the more positive the centenarian feels in terms of their own psychological state (Poon et al. 2010; Randall et al. 2011; Cho et al. 2014; Margrett et al. 2011). Additional empirical evidence suggests that this may be particularly true relative to cognitive perceptions of fatigue, feelings of loneliness, and cognitive-affective appraisals in life (Poon et al. 2010; Cho et al. 2014; Margrett et al. 2011). In particular, centenarians who possess greater social resources have significantly reduced cognitive-affective perceptions associated with feeling mentally exhausted, socially

isolated and lonely, and dissatisfied and unhappy with life (Poon et al. 2010; MacDonald 2007; Cho et al. 2014; Margrett et al. 2011). However, such reported associations between social support and psychological well-being outcomes may be partially explained by the extent to which U.S. centenarians feel they are in good physical health, can foster positive social relationships, or have the ability to independently perform activities of daily living needing assistance (Poon et al. 2010; MacDonald 2007; Randall et al. 2011). Researchers with the Iowa Centenarian Study have reported significant mean-level decreases in positive affect but not negative affect (Martin et al. 2012). Most notably, growth-curve changes in positive affect appear to reflect simultaneous decrements in social assistance, physical health status, and self-reported health functioning over time (Martin et al. 2012). In turn, it appears that any shift from positive to negative emotionality among centenarians over time may be due to co-occurring life events linked to changes in one's biological or social resources.

It should be noted that life history is an often forgotten yet equally important social element of underlying emotional well-being reported by centenarians (Poon et al. 2010). da Rosa et al. (2014) conducted a cross-cultural comparison of U.S. and Japanese centenarians (da Rosa et al. 2014). This examination involved a cross-examination of life event data reported from $N = 239$ centenarian participants from the Georgia Centenarian Study and $N = 309$ centenarian participants from the Tokyo Centenarian Study. Results provided valuable insights into overall cultural differences in socioemotional history of centenarians. For example, centenarians in the United States more frequently endorsed positive socioemotional experiences linked to achievement-oriented events commonly interconnected with everyday social living including education/schooling, marriage, and the raising of children (da Rosa et al. 2014). Although Japanese centenarians were somewhat similar in their reporting of these events, da Rosa et al. (2014)

reported that positive social experiences seemed to be counterbalanced by socioculturally shared traumas reflecting human suffering and hardship. Specifically, Japanese centenarians endorsed more cohort-linked sociohistorical events surrounding warfare (e.g., World War II) and natural disaster (e.g., Great Kanto Earthquake of 1923). The endorsement of these traumatic sociohistorical events by Japanese centenarians appears to demonstrate a collective or shared cultural response in coping with human loss and mortality (da Rosa et al. 2014). Initial evidence across various centenarian studies suggests that positive and negative historical events impact the degree to which centenarians achieve contentment and finitude in life (Poon et al. 2010). Future investigation is needed to clarify the extent to which the sociohistorical lives of centenarians act as resource by which socioemotional well-being is derived.

A qualitative study of near-centenarians and centenarians in Hong Kong recently revealed four major themes that best summarize the interplay between social resources and living long and well (Wong et al. 2014). First, it is not the quantity of people in one's life that necessarily count, rather it is the quality of persons by whom one is surrounded that matters most to flourishing. Second, interpersonal connections through social engagement are essential to achieving a sense of meaning and passion in life. Third, social domains (e.g., living arrangement, work) represent valuable sources of comparison by which a long life can be appraised, judged, and accepted. Fourth, the conditions of social life operate as a mechanism by which individuals can deepen a sense of faith and hope in living a better future one day at a time. These four themes seem to reiterate the value and impact of social resources for persons living 100 years of age and beyond. Based on the evidence presented in this summary, there are still many unanswered questions regarding how social resources are maintained, managed, and used by centenarians residing across varying residential environments and sociocultural contexts. Nonetheless, there is no denying that social resources

remain an intricate, yet essential, element of individual functioning and well-being at the extreme upper limits of life.

Definition

As innately social beings, social relationships are integral to survival and well-being. From the cradle to the grave individuals depend on their social ties for resources and support. Social relationships, although often beginning with maternal attachments, encompass a whole range of people across the life span including family, friends, and peripheral ties. This article begins by defining social relationships; then discusses the current theories and the research with regard to life span changes in relationship quality and the implications of relationships for health and well-being. The article ends with a discussion of directions for future research.

Positive and Negative Dimensions of Relationships

Across the life span, individuals engage in a whole variety of social relationships from immediate families, to spouses, friends, coworkers, and neighbors. These social ties vary widely in their positive and negative qualities (Rook 2015). Positive aspects of relationships include the support provided, companionship, affection, and social control. Support include instrumental, informational, and emotional support. Instrumental support includes financial and other types of material support as well as errands and sick care. Informational support involves advice. Emotional support involves listening and providing affection. Relationships also provide control or regulation of health behaviors. Negative aspects of social ties include inappropriate support,

unsolicited support, criticism, demands, irritations, and conflict. Ambivalent relationships are defined as those that are simultaneously positive and negative.

Theories of Social Support

Convoy Model

According to the convoy model of social relationships, individuals are surrounded by close social ties across the life course and those ties are sources of support as well as strain (Antonucci et al. 2013). Social ties vary in their quality (e.g., positive and negative), function (e.g., types of support exchanged), and structure (number of network members, contact frequency, geographical proximity). The social ties that surround the individual vary by both personal (e.g., gender, age) and situational factors (e.g., social roles) and those factors as well as the characteristics of close social ties are closely linked with health and well-being. According to the convoy model, the support provided as well as the negative aspects of those ties are more closely linked with well-being than the structure of those ties. Over the life span the convoy is continuous in some ways but changes in others. Young adults have larger networks that tend to be more diverse, that is, with more family and friends, than older adults who tend to have a greater number of family members in their networks. However, older adults with diverse social networks generally report higher well-being; those with restricted or socially isolated networks are associated with the lowest well-being. Social networks also vary by gender. Women generally have larger social networks but also feel more burdened by those network members than men.

Socioemotional Selectivity Theory

According to socioemotional selectivity theory (SST; Carstensen et al. 1999), individuals change across the life span in terms of their goals and those goals directly influence their relationships. When individuals are young and perceive time as more limitless, they have more information-focused goals in which they are willing to engage

with a variety of social partners in order to achieve careers and meet romantic partners. As people age and perceive time as more limited, they become motivated by emotion-focused goals and become narrower in the selection of social ties in which to engage. Having emotionally meaningful and poignant connections with people becomes paramount. Studies testing this theory document that the number of close social ties is similar for different age groups, but numbers of casual acquaintances are smaller among older adults. This preference is theorized to be less driven by age and more by temporal perspective; for example, a study examining middle-aged adults with a life-threatening disease found that people with shorter life expectancies had similar social partner preferences to older adults (Charles and Carstensen 2007). Research also reveals that as people age they reduce their interactions with people with whom they feel less emotionally close. Older individuals are also less likely to attend to and remember negative information than are younger individuals, a phenomenon referred to as the positivity effect (Carstensen and Mikels 2005; Mather and Carstensen 2005).

The Strength and Vulnerability Integration Model

The strength and vulnerability integration (SAVI) model emerged from SST. According to the model, as people age they experience increased ability to avoid negative experiences due to improvements in emotion regulation skills (e.g., attention, appraisals, behavior). In turn, avoidance of negative experiences is associated with improvements in well-being. As a result of the ability to avoid negative experiences, older adults report more positive and fewer negative interpersonal experiences. Older adults will look similar to or worse than younger people, however, when they are not able to avoid negative experiences. For example, under circumstances in which older adults experience increased and sustained negative emotion (e.g., when under chronic stress), they have less physiological flexibility to recover and thus experience decreased well-being (Charles 2010).

Functional Specificity Theory

According to the functional specificity theory of relationships (Weiss 1969), relationships are specialized in terms of the functions they serve. There are six different emotional support provisions of relationships, which together help to maintain individuals' well-being. These provisions are: (1) attachment, or an emotional bonding that provides security; (2) reassurance of the individual's worth or value; (3) guidance when it is needed; (4) reliable help and assistance in times of need; (5) a sense of shared values, interests, and companionship; and (6) being needed by another for love and care. This theoretical approach implies that having people in one's social network who together can provide all of these provisions is ultimately more beneficial for one's health and well-being than having a restricted network where only a few of these provisions are represented.

Relationship Quality Across the Life Span

Overall, research suggests that relationships improve in quality as individuals grow older. In general, older people report less negativity in their relationships and they are more likely to use avoidance in response to interpersonal conflict than are younger people. This has been found across relationships with the exception of the spousal tie. For example, in a 12-year longitudinal study, Birditt et al. (2009) found that the parent-child tie and the friend tie decreased in negative relationship quality over time whereas the spousal tie actually increased in negativity when people remained married to the same person. Studies also show that the parent-child relationship often increases in quality after adolescence.

New research is emerging indicating that examining average trajectories does not provide a complete picture of how relationships change over time; for example, spousal ties vary in terms of whether they remain consistently happy or decrease in happiness over time. Couples may experience early marital stressors and these

stressors may lessen only during late middle-age in marriage when the challenges couples face – such as establishing careers and raising a family – have decreased. This suggests that relationship satisfaction increases as children leave home or retirement is reached. For example, studies show that for many women, their relationship satisfaction with their spouse increased as adult children left home, as opposed to the commonly-held belief that many middle-aged parents are faced with an “empty nest” (Gorchoff et al. 2008). The departure of children and imminent retirement may provide opportunities for couples to share leisure time, as well as encourage greater relationship satisfaction.

Relationship Quality and Gender

Men and women often show different approaches, expectations, and social network quality in all types of relationships, whether with a spouse, friend, or family member. Compared to men, women typically have larger social networks, are thought to have more complex and intimate relationships, and are relied on more often as providers of support. Women tend to be more upset by interpersonal arguments and demands from others whereas men become more upset by work and financial problems (Almeida and Kessler 1998), reflecting societal gender norms of nurturance and intimacy for women, and agency and instrumentality for men (Eagly et al. 2000). In general, men also tend to continue occupying positions of power in societies while women continue to be more responsible for the care of others. These factors lead to differential socialization in the expression of emotions, especially negative ones; for example, among men it is more acceptable to express anger, whereas among women it is more acceptable to express sadness. However, the body of literature concerning gender differences in all types of social relationships presents a complicated picture: although women are more prone to reinforce affiliative social norms in general and to have more positive and emotionally close relations than men, they may also be relatively more demanding, feel more burdened by others' problems, and report more negativity in their relationships (Birditt and Antonucci 2007). A brief

summary of some of the literature concerning gender differences in spousal, friend, and family relationships is provided below.

Arguably, the close relationship that has been most researched in terms of gender differences is the spousal relationship. Extant theory and research suggest that this relationship is an especially close, intimate, and unique source of support, and that – particularly, perhaps, in older age – positive and negative aspects of spousal relationships relate to well-being for both men and women in similar ways (Antonucci et al. 2001). However, the mechanisms required to maintain spousal relationships may differ by gender and change over time. Often, for example, wives are perceived as better providers of support than husbands. In examining this phenomenon in younger couples early in their marriages, Neff and Karney (2005) found that although husbands and wives did not differ in the amount of support they provided each other, they differed in when they provided support: Wives tended to provide better support on days that their husbands experienced greater stress, but when wives experienced greater stress, husbands displayed both support and negativity. However, in older couples (in their 70s, on average), researchers have found fewer gender differences in either negative or positive quality in relationships with spouses (Antonucci et al. 2002).

How husbands and wives react to stress, either within the context of negative marital quality or in general, can also differ. Husbands may be more likely to react physiologically than emotionally, given their propensity to internalize their emotions in the marital context. In contrast, wives may be more visibly reactive to marital stress than husbands, due to their greater relational orientation and investment. For instance, wives tend to use more destructive conflict and demand strategies whereas husbands are more likely to report constructive and withdrawal strategies. This demand/withdraw pattern of marital conflict states that the demander is usually the woman, who pressures the other through emotional requests, criticism, and complaints, and the withdrawer, usually the man, retreats through defensiveness and passive inaction. Some research has found

that, although women are no more demanding, men are more likely to withdraw, such that the wife-demand/husband-withdraw interaction is more likely than husband-demand/wife-withdraw interaction, especially when discussing a change the wife wanted (Christensen and Heavey 1990). Adding complexity to gender differences in negative spousal relationships is the idea that, at least in midlife, this relationship can be a particularly important source of support among people without best friends, who are more likely to be men (Birditt and Antonucci 2007). In addition, women are more likely to report low quality relationships, or express disappointments in relationships.

Friends are an important source of social support, often sharing an accumulation of experiences and often originating from the same historical cohort. Women typically have larger social networks than men, and they tend to seek supportive interactions with other social network members when key sources of support, such as a spouse, fail to provide it. For example, women may be more likely to express their feelings of being let down and how their husbands get on their nerves to close friends. In research on married adults aged 60–91 who also had a best friend, women with friends in whom they could confide were more satisfied with life compared with women without a confidant, whereas men who confided in a friend were less satisfied with life than men who did not (Antonucci et al. 2001). In contrast, women with a best friend who got on their nerves also exhibited higher life satisfaction, whereas men in the same situation exhibited lower life satisfaction, indicating that women and men view friendships in very different ways.

Indeed, the extent to which men and women self-disclose in friendships also differs: Married women often tend to disclose as much to close friends as they do to a spouse, whereas married men do not. Gender differences in relationships with friends seem to be stable across the adult life span, although friends may become an even greater source of social support for women who tend to outlive their spouses. In research examining older adults (mean age = 73), women frequently had higher expectations of friends than men, and placed a greater emphasis on intimacy,

whereas men's friendships often focused more on shared activities (Felmlee and Muraco 2009).

Consistent with gender norms of nurturance, women are more involved in adult child–parent relationships (Lye 1996). Adult child–mother relationships are closer than adult child–father relationships, particularly for daughters, although older mothers also confide in their daughters more than their sons. Additionally, older mothers may also prefer to rely on their daughters for both instrumental and emotional support. Again, however, this relationship is a complicated one: Although women report feeling closer to their children, they also report feeling both more positive and more negative about them (Antonucci et al. 2011).

Relationships and Health/Well-Being

Overall, a great deal of research has shown that relationships are important for psychological well-being, health, and a longer life span (Thoits 2011; Uchino 2004). In general, negative aspects of relationships are more highly associated with well-being and health than are the positive aspects of relationships. Relationships also buffer the effects of stress on health and well-being.

The literature with response to the two closest relationships people often report having, the spousal tie and the parent–child tie is reviewed below. Married people report better physical health, live longer, and are less distressed than unmarried individuals. Better quality marriages are associated with fewer psychological and physical health problems and greater life satisfaction and, in general, married individuals in middle age and older adulthood report better overall health than those who are unmarried. Destructive conflict behaviors (e.g., yelling, insults) in response to marital conflict are associated with increased blood pressure and endocrine changes. Greater physiological reactivity in the laboratory predicts divorce and lower marital satisfaction 10 years later. Daily diary research has revealed links between couples' interactions (e.g., intimacy, affection, communication) and self-reported well-being, cortisol, and DHEA-S levels. Marital quality is also associated with cardiovascular health. In a meta-analysis assessing the relationship between

marital quality and health, Robles, Slatcher, Trombello, and McGinn (Robles et al. 2014) found that marital dissatisfaction was consistently related to structural indicators of cardiovascular disease as well as functional indicators, including blood pressure.

Researchers still debate whether there are gender differences in the link between relationship quality and health, often finding that men are more physiologically reactive than women to marital conflict. However, more recent research indicates that there are few gender differences in the link between marital relationship quality and physical health (Robles et al. 2014). In a recent study, Birditt and colleagues conducted an examination of marital couples (Birditt et al. 2015) and found that there were interesting dyadic effects of negative marital quality and stress such that husbands had higher blood pressure when wives were more stressed, although the reverse was not evident. These associations were greater when husbands reported more negative feelings about the relationship. Thus, when examining married couples there may be more evidence of gender differences because the gender differences are within rather than between couples.

The parent–child tie has significant effects on well-being and health. Parents report greater well-being when their children provide them with emotional support or affection and when they report greater positive quality relationships with children. Parents also reported fewer depressive symptoms when children relied on them for tangible support. Thus it appears that parents benefit from both receiving and giving support to their children. Additionally, parents' well-being appears to be affected by their perceptions of how well their children are doing in their lives: parents whose adult children have more problems report lower well-being whereas parents who report that their children are well-adjusted (e.g., happier, satisfied with their lives) have greater levels of well-being.

Studies have also assessed associations between parental ambivalence and parental well-being. Parents who report greater ambivalence (i.e., high positive and negative relationship quality) report greater depression. Lowenstein

(Lowenstein 2007) examined mothers and fathers aged 75 and older in England, Norway, Germany, Spain, and Israel to determine whether their feelings of ambivalence, solidarity, and conflict predicted quality of life. In all countries, ambivalence predicted lower quality of life, whereas solidarity predicted greater quality of life. Additionally, solidarity had a greater impact on quality of life than ambivalence.

Parent–child relationship quality also influences adult children's well-being. Adult children who reported lower parental support as children also reported greater depressive symptoms and chronic illnesses in adulthood. Less support from mothers and greater strain with mothers and fathers were associated with greater psychological distress among adult children. It is important to note, of course, that these studies are cross-sectional. Children who report lower well-being may be more likely to view their parents in a negative light and remember their childhood experiences as having been more negative.

Other studies have examined the associations between parent–child relationship quality and well-being for both generations simultaneously. Fingerman et al. (2008) assessed the associations between ambivalence and well-being among parents and offspring and found that ambivalence predicted lower psychological well-being among mothers, fathers, and offspring. Overall, it appears that relationships have important influences on physical and psychological well-being. More research is needed, however, on the longitudinal effects of the relationship on well-being.

Future Research Directions

There are several directions that future research should pursue in the field of social relationships, aging, and health. For example, studies need to examine more deeply how relationships change over time as people grow older; current longitudinal studies of social relationships do not have several waves and are not lifelong in nature. The present literature also often includes one individual's perception of relationships, and it is clear from the marital and parent–child literature that

it is important to include multiple perspectives because individuals in the same relationship may not agree or have distinct perspectives on the same tie. Widening the focus on gender differences in the perception of relationship quality would be useful. For example, examining how men and women approach long-term friend or family relationships over time, particularly in nongender-matched relationships, such as male–female friendships. Additionally, more research needs to examine multiple social ties in the same study because social ties may interact in unique ways to influence well-being. Further, although there have been advances in the examination of biological systems that account for links between social ties and health, they have primarily been used in the study of the marital relationships. Further studies need to examine the influence of multiple social ties on biological indicators of health in order to understand how relationships, and perhaps particularly relationship qualities, “get under the skin” to influence health and well-being.

Conclusion

In sum, social relationships vary widely in their supportive as well as positive and negative qualities. The negative and positive dimensions of relationships have important implications for health and well-being across the life span. Theories of social support suggest that although relationships change across the life span they become increasingly salient for well-being as individuals grow older.

Socioemotional Selectivity Theory

Tammy English¹ and Laura L. Carstensen²

¹Washington University in St. Louis, St. Louis, MO, USA

²Department of Psychology, Stanford University, Stanford, CA, USA

Definition

Socioemotional selectivity theory is a life-span theory of motivation that posits age differences in goals result from shrinking time horizons. When time is perceived as expansive, individuals will prioritize information-focused goals. When time is perceived as limited, individuals will prioritize emotion-related goals.

Overview

Socioemotional selectivity theory (SST) is a life-span theory of motivation grounded in the uniquely human ability to monitor time.

In particular, the theory posits that age differences in goals result from shrinking time horizons. Goals influence social preferences and the composition of social networks. Because goals also direct cognitive processing, SST postulates that attention, memory, decision-making, and emotional experience are influenced fundamentally by the perception of time. Unlike most developmental theories of adulthood, which place primary emphasis on past experience, SST considers ways in which perceptions of the future change motivation. Indeed, in some ways, SST is not a developmental theory at all but rather a social psychological theory about perceived time and goals. SST maintains, for example, that younger people who face endings through terminal illness, wars, or other more benign endings, such as geographical relocation, display similar changes in motivation.

According to the theory, temporal horizons direct two overarching sets of goals that govern much of human social behavior. One set of goals concerns the acquisition of knowledge; another concerns the regulation of emotional states. Both sets of goals activate behavior across the life-span, but the relative importance and priority placed on them varies as a function of time horizons. The emphasis on a mechanism of perceived time, which can be cleanly separated from age as well as subjected to experimental manipulation, affords SST an unusual strength among developmental theories. SST is falsifiable. That is, the postulates of this theory can be tested and evidence can be gathered that either supports or fails to support its predictions.

SST is based on the idea that goals are set in temporal contexts, such that individuals focus their energy on goals that are feasible to pursue given the time they have available. When time is perceived as expansive, SST posits that individuals will prioritize information-focused goals. Under these conditions, people allocate their resources in a way that will help them prepare for the nebulous far-off future. Time is spent exploring the environment and gathering all manner of information in case it may be useful down the road. Individuals who perceive the future as long will invest in emotionally taxing activities if

the experience may allow for new learning or future opportunities. When the future is constrained and time is perceived as limited, emotion-related goals grow in importance. Under such temporal conditions, individuals prioritize emotional satisfaction over exploration and gathering information. People are motivated to invest in emotionally meaningful experiences that will provide more immediate payoffs. They spend time engaging in activities that make them feel good and savoring the positive aspects of life.

History

The first publication describing SST appeared in 1991 in the *Annual Review of Gerontology and Geriatrics* (Carstensen 1991) and was later elaborated in the 1993 volume of the *Nebraska Symposium on Motivation* (Carstensen 1993). In 1999, the *American Psychologist* published an overview of the theory in an article titled, “Taking Time Seriously in Life-span Development” (Carstensen et al. 1999). An essay describing the theory was published in *Science* in 2006 (Carstensen 2006).

In its original formulation, the theory was offered to provide an account of the purported “paradox of aging,” a term coined to refer to high levels of emotional satisfaction despite age-related losses. In this formulation, the theory focused on goals as instantiated in social preferences. As evidence accrued and new hypotheses were put to test, SST was applied to emotional experience and later to cognitive processing.

Social Preferences and Relationships

According to socioemotional selectivity theory, as temporal horizons shrink, people live in the present. They shift attention away from the long-term future and prioritize the most important aspects of life. For most people, this prioritizes close relationships and emotionally meaningful interactions. As a result, the composition of social networks changes, as do social interactions, such that individuals choose to spend more of their time

with close others as time horizons diminish. Initially, the fact that social networks get smaller as people age led to concern about older adults being lonely and depressed. Subsequent research, however, revealed that this change in social networks reflects a proactive pruning process whereby older adults increasingly invest their limited time in relationships with close others (Lang and Carstensen 2002). That is, older adults maintain their most meaningful, core relationships and let go of less satisfying, peripheral social partners. Similarly, when asked to imagine they have a half hour of free time, older adults prefer to spend time with a close social partner rather than a novel one, whereas younger adults do not show this preference. Moreover, relationship quality improves over time with children, spouses, and other meaningful partners, presumably a reflection of both experience and motivation.

Reasoning from SST, these age differences in social interaction are due to changes in time horizons. Older adults have relatively shorter time horizons (because they have less time left in life), so they prefer spending time with close others who provide a sense of emotional meaning. If time is limited for younger adults, they too would be expected to show a preference for emotionally meaningful partners, theoretically because they would then prioritize emotional goals over information-focused goals. Similarly, if time is expanded for older adults, they would be expected to prefer novel social interactions that have the potential to provide new information or future opportunities.

Several studies have manipulated time perspective to determine whether it changes social preferences, as postulated by SST. One of the first studies to do so found that when younger adults were asked to imagine moving alone across the country, their preferences aligned with those of older adults (Fredrickson and Carstensen 1990). When primed to think about this social ending, younger adults preferred to spend time with family rather than a novel social partner (an acquaintance or author). Artificially expanding time horizons in older adults also eliminates age differences in social partner preferences. When asked to imagine a medical breakthrough that

would allow older people to live an additional 20 years in relatively good health, older adults no longer prefer to spend time with family; in this case, social preferences are indistinguishable from those of younger adults.

Naturally occurring events also shift time horizons, preferences, and goal pursuit. After the terrorist attacks on the USA on September 11th, young adults reported preferring to spend time with family rather than novel social partners, presumably because the fragility of life had been highlighted by these events (Fung and Carstensen 2006). A similar pattern of findings emerged among young adults in Hong Kong in the months before the handover of Hong Kong to the People's Republic of China, when the future of the country was uncertain and the end of an era loomed large. Consistent with SST, a year after the handover, young adults in Hong Kong preferred novel social partners, as they had the year before the handover (Fung et al. 1999). Young adults who have shortened time perspective due to terminal illness also display social preferences similar to older adults. Before there was an effective treatment for HIV, young HIV-positive men who were experiencing symptoms of AIDS were found to conceptualize social partners similar to the elderly (Carstensen and Fredrickson 1998). HIV-positive men who were not yet experiencing symptoms of AIDS appeared similar to middle-age adults, and healthy gay men conceptualized the social world as an age-matched representative sample did.

Time horizons can be constrained by the experience of social endings or endings that represent the culmination of important chapters in one's life (e.g., graduations, births, weddings, moving). According to SST, changes in time perspective have important implications for how individuals choose to spend their time and with whom they will surround themselves. When constraints are placed on time, people focus on emotional goals and enjoying meaningful interactions with close others.

Emotional Experience and Regulation

SST postulates that focusing on the present and prioritizing emotionally meaningful experiences

will benefit emotional well-being. By the late 1990s, scores of cross-sectional studies had documented superior emotional functioning in older as compared to younger adults. Although one notable exception, Charles et al. (2001), observed improvement in emotional well-being in multiple cohorts over time, there remained concern that cohort differences rather than age accounted for the findings. Carstensen's group undertook an innovative longitudinal study utilizing experience sampling in the late 1990s in order to examine intraindividual change in emotional experience in everyday life (Carstensen et al. 2011). They found an increase in emotional well-being, as well as emotional stability, across a 10-year period. Emotional experience became increasingly positive as individuals grew older. When older people experienced negative emotions, they reported intensities comparable to younger people. The frequency of experiencing negative emotion, however, was significantly lower for older adults.

Emotional life does not simply become more positive with age, but rather it becomes richer and more complex. Older adults are more likely to experience positive and negative emotions at the same time. According to SST, this poignancy arises as a result of the bittersweet moments that occur when time horizons are constrained. Indeed, even young adults experience poignancy in situations where endings are salient. When asked to imagine being in a personally meaningful location for the last time, individuals report mixed emotions (i.e., feeling both happiness and sadness) regardless of their age (Ersner-Hershfield et al. 2008). Similarly, on graduation day, college seniors experience more poignancy when reminded it is the last day they will be a student at that university (i.e., college is ending for them). When time perspective is constrained, individuals focus on emotional meaning, resulting in a more satisfying and rich emotional experience.

The Positivity Effect and Cognitive Processing

The *positivity effect* was identified in experimental tests of SST. The effect refers to an age-related

preference in attention and memory for positive relative to negative information (Mather and Carstensen 2005). Older adults' tendency to focus more on positive information is thought to reflect cognition operating in the service of emotion-related goals. That is, because goals direct cognitive resources, SST predicts there are age differences in processing emotional information.

Initial work on SST and cognitive processing focused on age differences in preferences for emotional information in general. For instance, it was revealed that older adults are more likely to prefer and remember advertisements framed in terms of emotional meaning (e.g., "capture those special moments") rather than information gain (e.g., "capture the unexplored world"). When asked to imagine a medical advance that would allow them to live an extra 20 years in reasonably good health, however, older and younger adults were comparably likely to prefer the information-focused ads as the emotion-focused ads (Fung and Carstensen 2003). These findings suggest that emotional information is more salient for older adults because they typically have more limited time horizons than do their counterparts.

In subsequent work, researchers began to test the idea that certain types of emotional information may be particularly salient for older adults. Older adults' prioritization of emotional goals may direct their attention to positive information more than negative information. Now referred to as the *positivity effect*, the phenomenon has been documented across a wide range of emotional stimuli, including faces, pictures, words, and music, and in various types of experimental paradigms (Reed et al. 2014). For instance, when presented with pairs of faces, older adults orient more towards happy faces than neutral faces and orient away from sad faces compared to neutral faces. They are also more likely to remember happy faces than sad faces. Younger adults do not show this attentional bias or differential memory for happy versus sad faces. Age differences in processing of emotional information have also been observed at the neural level, whereby older (but not younger) adults show less amygdala activation to negative pictures than positive pictures (Mather et al. 2004). In an important test of SST,

Mather and colleagues examined the role of executive functioning in the positivity effect. If positivity is driven by age-related differences in goals, then positivity should be reduced when older adults have insufficient cognitive resources to direct towards their emotional goals. Indeed, older adults no longer show a disproportionate preference for positive information when cognitive resources are constrained in a dual attention task. There is also less positivity in memory among older adults who perform poorly on cognitive control tasks (Mather and Knight 2005). These findings suggest that the positivity effect reflects a top-down controlled process whereby individuals attend to goal relevant information.

The most recent work on the positivity effect has focused on the impact it may have on health-related behaviors and decision-making. For example, older adults' preference for positive information has been documented in the context of framing health behavior messages (Notthoff and Carstensen 2014). In one study, young and older adults were given pedometers and provided information about walking. Older adults who had been told about the benefits of walking (positive framing) walked more over the ensuing week than did those who had been told about the risks of not walking (negative framing). In contrast, younger adults walked the same amount regardless of the type of information they were provided. In a follow-up study, older adults who were told about the benefits of walking showed an increase of about 1,000 steps per day across 4 weeks, while older adults who were warned about the risks of not walking did not show a significant change in their walking. These findings suggest that promoting health changes in older adults will be better served by highlighting the benefits of engaging in health behaviors rather than focusing on the risks of failing to engage in such behaviors.

Consistent with SST, age-related positivity is not found when older adults are focused on information-related goals, either because it is demanded by experimental tasks or because they are naturally motivated to gather more information in that context. In one study, younger and older adults were asked to imagine they had to choose a new physician and health plan (Löckenhoff and

Carstensen 2007). They were presented with a grid of information that described four different physicians (or health plans) on a number of dimensions. Compared to younger adults, older adults were more likely to focus on positive characteristics when reviewing information and when later recalling features of the different physicians and health plans. These age differences in information processing were eliminated when individuals were told to “focus on the specific facts and details” when reviewing the different options. In this information-focused condition where goals were equated across age groups, younger and older adults showed a similar even-handed review (and recall) of the information they had been presented. A recent study found that positivity is also reduced in contexts where older adults are naturally motivated to focus on information gathering (English and Carstensen 2015). In particular, relatively unhealthy older adults were less likely to show positivity in their review of information when making health-related decisions than were healthier older adults. Importantly, being in poor health was only associated with lower positivity for health-related decisions. When making decisions that were not related to health (e.g., choosing a new car), older adults showed similar levels of positivity regardless of their health status. These findings suggest that personal relevance or importance of the decision can shift goals, and thus, processing of information.

Older adults naturally tend to prioritize emotion-related goals, and therefore, they focus more on positive features in the environment that can enhance their emotional well-being. There are times, however, when older adults instead prioritize knowledge-acquisition. In these situations, SST would predict a redirection of cognitive resources, such that older adults no longer favor positive over negative. The age-related positivity effect only emerges when goals are unconstrained by the context and individuals have the cognitive resources required to pursue their goals.

Conclusion

For many years, social scientists presumed that old age was a time of loneliness and despair.

As evidence accrued, it became clear that not only are older people less lonely than young people, they suffer lower rates of virtually all mental disorders than their younger counterparts and report greater happiness and satisfaction with their relationships. According to SST, older adults show these improvements in social functioning and psychological well-being because their limited time horizons lead them to prioritize emotional goals. Age is typically a good proxy for time left in life, and it is the perception of time, rather than age per se, that influences goal priorities and, therefore, the allocation of cognitive resources and the behavioral patterns individuals display.

Definition

SONIC study is a longitudinal epidemiological survey. The purpose of this study is clarifying age similarity and difference in factors associated to healthy longevity and maintaining higher well-being among different age groups from 70 to 90 years.

Limitation in Centenarian Studies

The main methodological limitation of centenarian studies is derived from the specificity of their focused age group: “centenarian.” More specifically, even though that collecting data from centenarians are time consuming and highly loaded

work, it is difficult to find clear evidences for longevity factors or psychological and social characteristic of centenarian without setting up control group(s). Comparisons with reference data (population norm or control group(s)) make it possible to highlight specific characteristic of the group of centenarians. However, even in centenarian studies that do use control data, it can be difficult to clarify the characteristics of centenarians by simple comparison, because the true control for centenarian would be individuals of the same cohort who did not survived to 100 years of age. Specifically, cross-sectional comparisons between centenarians and younger controls cannot distinguish aging-related changes or the influence of studied factors on longevity. Overall, these problems make the findings of centenarian studies difficult to generalize.

There are centenarian studies that collect data only from centenarians (Jopp et al. 2016; Gondo et al. 2006; Stathakos et al. 2005; Samuelsson et al. 1997; Motta et al. 2005). In many of these cases, researchers were attempting to describe the characteristics of centenarians in the target population. However, focusing solely on centenarians – in other words, not using younger control data or comparable population norms – precludes understanding centenarians' relative functional status or specific characteristics. This is a fatal disadvantage of centenarian studies, particularly if the researchers are interested in human aging process or factors related to longevity. The average life expectancy and age-specific mortality rates differ substantially across different countries and populations. Therefore, control data from the same population would be needed for each centenarian study to ensure sufficient generalizability of results. Furthermore, this framework is essential if researchers are aiming to compare findings with other centenarian studies.

Despite these limitations, researchers can still perform useful correlational analyses to clarify the relationships among the variables and construct models to predict subjects' physical, emotional, and cognitive functions using only centenarian data (e.g., Jopp et al. 2016). Such studies have a variety of applications, such as identifying the

necessary support needs for centenarians. However, it is still difficult to conclude whether the findings obtained from such studies are unique to the centenarians or are common phenomena among other age groups. We would be unable to make any definitive conclusions regarding these effects without running the same analysis on the control group(s).

It is quite possible that differences in medical, physical, social, and cognitive function will have different influences on psychological state in different age group(s). Recent studies on emotion have indicated the importance of cognitive resources for maintaining well-being in elderly people (Mather 2012; Scheibe and Carstensen 2010); in contrast, oldest old people maintain a higher level of well-being regardless of cognitive decline (Gondo et al. 2013). This phenomenon is also shown in the final part of this entry. To develop theories that resolve such paradoxical phenomena, concurrently collected control data are important. So far, only a few centenarian studies have established control group(s) to overcome the abovementioned problems. For example, Georgia centenarian study has 80 Octogenarians (80–89) and 100 young controls (20–59) as references (Poon et al. 2007).

A second important methodological issue is that even centenarian studies that utilize younger control group(s) or that compare their data with existing norm(s) will be unable to provide a clear picture of centenarians' characteristics if they rely on cross-sectional comparisons. The exceptions to this limitation are certain variables that are static over time, such as birth order or genotype. In such cases, we could interpret the observed finding as a characteristic of longevity even when a comparison is made with an exciting epidemiological data set. For example, centenarians have been repeatedly found to have a higher frequency of the E2 genotype of apolipoprotein E (APOE), which is currently believed to be the strongest genetic factor for longevity in comparison to younger age individuals (Blanché et al. 2001). However, see the argument of accepting this method by Lewis and Brunner (2004).

In contrast to these static variables, psychosocial variables (e.g., well-being or family

membership) and other biological features (e.g., blood albumin or number of teeth) are not stable characteristics; rather, they change with age especially in the oldest old. Accordingly, it would not be possible to determine from the results of direct comparison of these characteristics between controls (e.g., octogenarians) and centenarians whether the observed differences are reflection of the innate characteristics of long-lived individuals or merely indicating the result of aging-related changes.

Centenarian studies seeking to understand longevity-associated personality traits face this problem. Researchers often contrive new ways to obtain precise results, by using a new analysis framework (Martin et al. 2006; Masui et al. 2006) or by developing new designs such as focusing offspring of centenarians (Givens et al. 2009). As an example of the former, Masui et al. calculated expected scores for personality traits at the age of 100 years using accessible data from individuals aged 50–79 years old (Masui et al. 2006). They calculate formulae of aging-related change of personality traits based on the abovementioned middle- to old-aged individual data then estimated personality scores of 100 years old for deceased individuals. Finally, they compared these scores with scores of living centenarians to highlight personality traits associated with longevity. Although this approach is currently considered the best possible way of utilizing cross-sectional data, it still does not avoid the risk of type I error because cross-sectional data tend to overestimate age-related changes. As far as they adopt any cross-sectional design, centenarian studies cannot escape from this limitation.

As an example for the latter, the New England Centenarian Study compared personality traits between offspring of centenarian parents and offspring of non-centenarian parents. They suppose that centenarian offspring share 50% of genetic characteristics with centenarian. This pseudo-case-control design has the advantage of saving time and the findings can be verified by employing the longitudinal follow-ups. Here, the “case” refers to the centenarian candidate (offspring of centenarian) and the control refers to an individual in the same cohort who did not

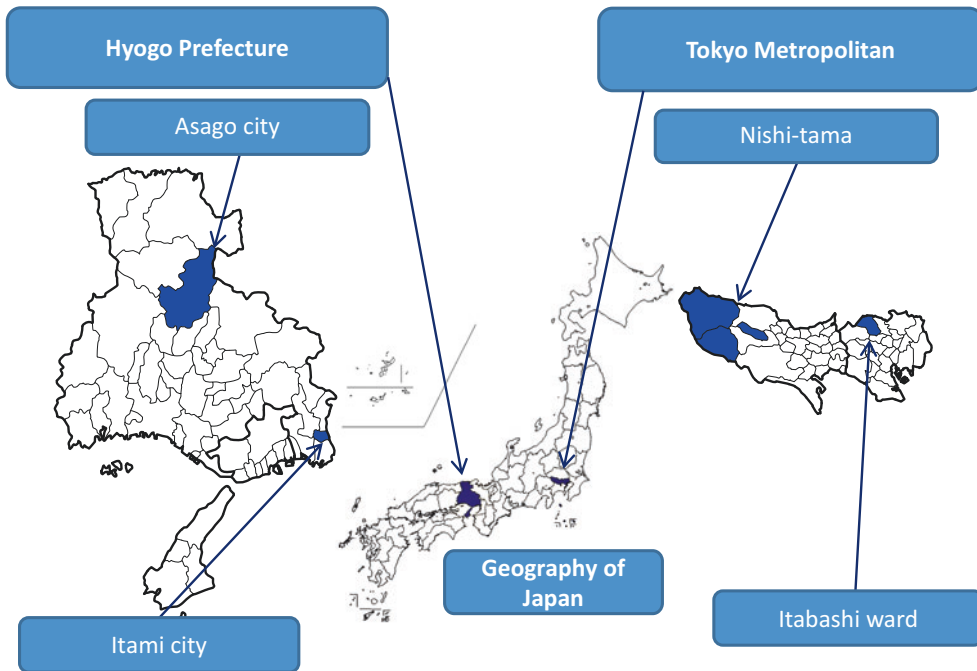

survive to 100 years old (e.g., spouses of centenarian offspring). Ideally, cases and controls should be extracted from existing large-scale longitudinal epidemiological studies that have been accumulating data for a long time. A case-control longitudinal study would also enable researchers to make a more accurate estimation of average aging-related changes in variables for both survivors and non-survivors. This idea was used as reference in designing the SONIC study and will be described in more detail later on.

Concept of SONIC Study

As mentioned above, a major limitation of centenarian studies is a lack of appropriate control group(s). To overcome this limitation, we conceived SONIC as a longitudinal case-control study as this was considered the best solution for clarifying the characteristics of centenarians, by including a large group of individuals who might survive until 100 years old. The most preferable research design is to follow up the same birth cohort over a long period. This procedure is similar to a sequence of projects using Danish individuals from 1895, 1905, and 1915 birth cohorts (Christensen et al. 2013; Engberg et al. 2008). The authors of those projects asked cohort members to participate in a study at the ages of 90 and 100. Adapting this concept, the SONIC study adopted three methodological considerations.

First, the SONIC study utilizes three control groups of different ages (70s, 80s, and 90s) for a centenarian cohort, which we are planning to run in the future. At the same time, these control groups can serve as controls for other centenarian studies, such as the Tokyo Centenarian Study (Gondo et al. 2006). The first-wave data is available for identifying the genetic characteristics in comparison with centenarian studies and can be used to explore age-group differences/similarities in the factors influencing well-being and other psychological variables.

Second, we are planning to follow up the three control cohorts over a long period and expect that a certain number will become centenarians. This longitudinal portion of the study enables us to run

SONIC Study, A Longitudinal Cohort Study of the Older People as Part of a Centenarian Study, Fig. 1 Location of four survey regions in Japan

case-control comparisons between centenarians and non-survivors and thereby explore factors influencing longevity. Additionally, longitudinal data would enable precise estimates of aging-related changes in targeted variables for each age group in both deceased and survived individuals.

Third, we used a narrow age-range cohort design (Hofer and Sliwinski 2001). Each cohort includes individuals whose ages fall within a range of 3-years (e.g., 69–71 for a 70-year-old cohort). The main reason for setting up narrow age-range cohorts was to focus more on individual differences in the aging process and health outcomes. When considering individuals of a wide range of ages while focusing on individual differences, we can use chronological age as a covariate to control age differences in variables not at the focus of the analysis. Recent studies however indicated that this method of statistical control might not be appropriate for variables in the medical or biological dimensions. Indeed, inter-individual and intra-individual variability of biomarkers are much greater in higher chronological

age groups, and correlations between chronological and biological age are much smaller than expected (Mather et al. 2011; Sprott 2010). Therefore, in the SONIC study, we utilized the 3-year narrow age range, which is ignorable age difference in each age group.

In addition to these methodological qualities, the diversity of environmental conditions such as main industries (e.g., agriculture in the rural, light and heavy manufacturing in cities), social resources, and infrastructure in survey regions are a notable characteristic of the SONIC study. We selected two subregions (an urban area and a rural area) from major geographic regions (the Tokyo metropolitan area, in eastern Japan, and Hyogo prefecture, in western Japan). In total, we collected data from four separate regions with different social and economic environments (Fig. 1). The Table 1 indicates the names of the city/village and their total populations.

Along with offering control data for other centenarian studies, the SONIC study has two main purposes as an independent study. The first is to

SONIC Study, A Longitudinal Cohort Study of the Older People as Part of a Centenarian Study, Table 1 Total population, sampled invitee, and participant of SONIC study in each four region

Regions	City/ Rural	Total Population	Aging ratio (%)	70s cohort			80s cohort			90s cohort		
				Sampled	Participated	Participation ratio	Sampled	Participant	Participation ratio	Sampled	Participant	Participation ratio
Itami	City	196,127	20	1,000(471)	250(124)	25.0(26.3)	1,566(653)	317(157)	20.2(24.0)	530(133)	72(29)	13.6(21.8)
Asago	Rural	32,814	30	1,155(547)	243(114)	21.0(20.8)	1,249(524)	195(92)	15.6(17.6)	315(84)	36(22)	11.4(26.2)
Itabashi	City	535,824	21	1,075(510)	239(94)	22.2(18.4)	1,295(507)	269(118)	20.8(23.3)	921(277)	130(54)	14.1(19.5)
Nishi- tama	Rural	164,592	25	1,077(543)	268(147)	24.9(27.1)	1,281(560)	192(90)	15.0(16.1)	208(67)	34(18)	16.3(26.9)
Total		929,357		4,307(2,071)	1,000(479)	23.2(23.1)	5,391(2,244)	973(457)	18.0(20.4)	1,974(561)	272(123)	13.8(21.9)

Note: number shown in parentheses indicate men

clarify aging-related changes in multiple domains of human functioning and the dynamics of interaction among these domains throughout the extreme old age period (from 70 to ≥ 100 years). Most previous studies have reported declines in functions with age, but there is no guarantee that aging-related decline is linear. For example, the incidence of diagnosis of arteriosclerosis or dementia incidence appears to increase until at around age 90 years, after which it plateaus (Homma et al. 2001; Miech et al. 2002). However, Corrada et al. (2010) presented contrary evidence for dementia incidence. This phenomenon can be understood in terms of survival effect, namely, that individuals who exhibit progression of arteriosclerosis do not survive to an age of 90 years. However, we do not have enough data to examine such phenomena. In case of arteriosclerosis, we could not conclude whether arteriosclerosis progression in nonagenarians becomes slower and maybe stops at this age or whether individuals with mild atherosclerosis are able to survive their 90th birthday and longer. The longitudinal follow-up of the three narrow age-range cohorts will doubtlessly be able to help answer this type of question.

The second purpose is to identify the factors influencing healthy longevity, including psychological well-being. The target variables were chosen not only from centenarian studies but also from studies of younger elderly participants. Therefore, the SONIC study can examine whether findings from centenarian studies can be replicated in younger elderly individuals and at the same time examine whether younger elderly participants show results that are consistent with those of centenarian studies. Below, we will describe the detailed methodology of the SONIC study.

Overall Design of SONIC

In addition to assessing the three main cohorts, namely, septuagenarian (70s), octogenarian (80s), nonagenarian (90s; details see below), we are planning to collect data from a parallel cohort of centenarians in 2022 with similar methodology as

the three main age cohorts. In that year (i.e., in 2022), the first 90s cohort participants assessed in 2012 will reach 100 years of age. So far, however, we have been conducting only a small centenarian survey in various regions of Japan with different research design and the procedure to improve methods to collect data from centenarians. Therefore, centenarian portion of the SONIC study will not be mentioned in this entry, and we will call the 70s, 80s, and 90s cohorts the SONIC main cohort in the following.

Sample Size Estimation

Because of the multiple study purposes (description of the aging process and identification of factors influencing healthy longevity) and multidiscipline nature of the variables collected in the SONIC study, it was not possible to calculate which might be an appropriate sample size. Hence, we prioritized maximizing the number of participants expected to survive to 100 years old. At the planning phase, we aimed at have 100 centenarians in each age cohort as endpoint. We calculated the estimated sample size of first-wave participants based on the survival ratio for each age and sex derived from a complete life table of Japan. The results indicated that about 1,600, 1,300, and 700 participants were necessary to obtain 100 centenarians from the 70s, 80s, and 90s cohorts, respectively. However, it was not feasible to collect such a large number of participants with a limited budget. Therefore, we decreased the targeted number of first-wave participants to 1,000 for 70s and 80s cohorts. Consequently, the expected number of centenarians would be between 60 and 70 for these two cohorts. Because we estimated the participation ratio for 70s and 80s cohorts as 25% and 20%, we oversampled the 80s cohort in comparison to the 70s cohort. For the 90s cohort, considering the high ratio of certification for long-term care (in the 90–94 age range, 66.2% had this certification in 2013 in Japan), we invited all individuals among the targeted age range in the four surveyed regions.

SONIC Study, A Longitudinal Cohort Study of the Older People as Part of a Centenarian Study, Fig. 2 Estimated number of survivors of SONIC participants in the longitudinal phase

We intended to include the same number of participants among regions irrespective of the total populations of each region. Therefore, we restricted the geographical region within which we sent out invitation letters to potential participants living in urban areas. The total population, aging ratio, and the invited and participating individuals in each region are shown in the Table 1. Regardless of the smaller total populations in rural areas, difference in number of older populations between urban and rural areas were quite small, especially in the 90s cohort. The participation rate for men was higher than for women in the 80s and 90s cohorts, but not in the 70s cohort.

The expected survival curves for the first wave of the SONIC study, separated by age group and sex, are shown in Fig. 2. The expected numbers of participants to reach 100 years old for the 70s, 80s, and 90s cohorts are 62, 69, and 39, respectively. Because there were fewer participants in the 90s cohort, we plan to recruit a new cohort of individuals in their 90s when we run the second wave survey for the 90s cohort.

Procedure

Recruitment of Participants

The data collection for each age cohort was performed in different years because of the large number of participants recruited. The first-wave survey began in 2010 for the 70s cohort, 2011 for the 80s cohort, and 2012 for the 90s cohort. Second-wave surveys began in 2013 in the same order. We are planning to conduct a follow-up assessment on each cohort every 3 years. As such, third-wave surveys are expected to start in 2016 with the 70s cohort.

All individuals invited to participate in the survey were recruited from residential registries. We obtained names, genders, birth dates, and addresses for individuals in the specific range of birth dates from the local government office. The range of birth dates was slightly different among the four study regions because of the differences in the schedule of creation of the registry database by the local government, allocation of the time slot which we can use to transcribe data at the local government office, and difference in the starting date of recruiting participants in each region.

The SONIC study was designed as an invitation-type survey. We asked invitees to visit survey venues located near their residences. Most of these survey venues were local community centers owned by the local government. The invitation letters sent out to invitees described the purposes of the SONIC study and its methodological details. We asked them to send back an agreement letter, wherein invitees indicated the appropriate date and time of participation if they were interested. About 2 weeks before data collection, we sent reminders to invitees of the place, date, and time of their survey. We also sent a questionnaire booklet comprising items on socioeconomic status, psychosocial variables, medical conditions of self and family, dental conditions, and food intake, which invitees were asked to complete in advance at home and bring to their appointment. In case participants could not fill booklet by themselves or with the help of family member, we asked all questionnaire items at the survey venue.

At the survey venue, participants were given an overview of the SONIC study and signed a consent form before taking part in the performance tests. At this point, participants were asked about their current physical condition, if they had a history of cardiovascular disease, and whether they had undergone hospitalization in the last 6 months. To ensure their safety, we then examined their body temperatures and body oxygen levels. For participants who showed high risks according to these measures, we began the investigation with a medical history (taken by medical staff), which resulted in exclusions for the performance tests. Most individuals with a history of cardiovascular diseases or who complained about pain did not participate in the physical examination.

Investigated Variables

Participants underwent the following examinations in a random order at the survey venue: a check of the prefilled questionnaire booklet and answering additional questions on psychosocial variables in face-to-face interviews; cognitive tests; interviews regarding work or household work to create a work complexity rating; current

leisure activity; short physical function tests; medical tests including blood samples, blood pressure, breathing capacities, carotid ultrasonography, and dental checkups including numbers of natural teeth, occlusal force, taste sensitivity, and masticatory performance. The main psychological variables collected in SONIC study are listed in Table 2. In total, examinations took about two and half hours to complete. If participants were unable to finish the tests within this time frame, we asked them to visit the survey venue again or asked if we could visit their homes to complete the questionnaire.

Preliminary Analysis of SONIC First Wave Data

Although the advantage of SONIC study is the longitudinal part of the data, we can report only on cross-sectional comparisons at present. Here we demonstrate age cohort differences in main variables of physical, cognitive function and well-being. Physical function were accessed by Short Physical Performance Battery (SPPB; Guralnik et al. 1994), cognitive function was accessed by Montreal Cognitive Assessment (MOCA; Nasreddine et al. 2005), and mental health was assessed by WHO-5 well-being index (Awata et al. 2007). Standardized scores for these variables among the three age cohorts are

SONIC Study, A Longitudinal Cohort Study of the Older People as Part of a Centenarian Study, Fig. 3 Comparison of standardized scores among three age cohorts

presented in Fig. 3. As shown in the figure, physical and cognitive function are lower in the 90s cohort. In contrast to these functional limitation, well-being of 90s cohort was at the same levels as in younger cohorts. As we mentioned in this entry, we cannot conclude that higher well-being in 90s cohort are characteristic of long-lived survivors or reflecting age-related change. This important question will be answered by completion of longitudinal follow-up phase of SONIC study. We believe that clarifying aging-related background factors that cause this type of dissociation must be possible by our case-control longitudinal study. The SONIC study will also allow to test many other important gerontological research questions not mentioned here. Future research progress in a variety of research disciplines is expected.

Spatial Cognition and Wayfinding

Scott D. Moffat

Georgia Institute of Technology, Atlanta, GA, USA

Synonyms

Navigation; Spatial orientation; Spatial visualization; Visual imagery

Definition

Spatial cognition is a term often used to refer to varied aspects of cognitive processing. It refers to spatial perception, spatial visualization, visual mental imagery, spatial memory, and spatial navigation. Most psychometric measures of spatial cognition emphasize the mental manipulation of geometric figures or forms. Spatial cognition in the context of wayfinding refers to the ability to

understand your position in the world and to use this knowledge to navigate to desired locations and destinations.

Introduction

Although, much less studied that some aspects of cognition (e.g., memory) spatial processing has important implications for the lives of older people. For example, Lord and Webster (1990) reported that elderly persons who had fallen in the previous year performed more poorly on a measure of spatial perception, compared to age-matched controls who had not fallen. In addition, we routinely tax our spatial computational skills in daily life when we attempt to find our car in a busy parking lot, travel to an unfamiliar location in a new city, or try to reverse directions to find our way back home. Older adults have self-perceived deficits in navigation and develop behavioral patterns to avoid unfamiliar routes and places (Burns 1999). Assessments of navigational/route-finding skills in older adults provide evidence of age-related differences in these skills. Moreover, impairments in navigational skills (e.g., “wandering”) are often apparent in the early stages of Alzheimer’s disease. The systematic study of spatial cognition has both important theoretical and practical importance in geropsychology.

What Is Spatial Cognition and How Is It Measured?

Spatial cognition is a relatively generic term that refers to a wide variety of cognitive measures sharing as a common feature the reliance on visual as opposed to verbal cognitive processing. Within this general cognitive domain, two traditions of study have emerged. In what I broadly identify as the psychometric approach, spatial cognition is typically measured using laboratory-administered tests involving the manipulation of either physical or imagined objects as stimuli. In a complementary approach, spatial cognition is studied from the ecological perspective of wayfinding or

navigation. The wayfinding and psychometric traditions tend to emphasize different aspects of spatial processing. Psychometric measures tend to be object oriented and static (do not require movement of the observer or the scene) and emphasize spatial manipulations of relatively small objects presented on the printed page (or computer screen). The wayfinding perspective emphasizes a more dynamic processing that takes place over a larger-scale space and tends to emphasize the movement of the whole body through the three-dimensional world (either real or simulated). Another unique aspect of the navigation/wayfinding perspective is that during navigation the whole spatial scene is typically not visible all at once and is encountered piecemeal, which requires integration of spatial scenes and views over time. This feature places demands on spatial working memory and episodic memory for items, landmarks, and cues encountered on a route. In both traditions, there has been robust consideration of individual differences, in particular in relation to sex and age of participants. Interestingly, scientific studies of these domains of spatial processing have tended to occur mostly in parallel with the wayfinding/navigation perspective often being more influenced by models of episodic memory encoding and retrieval than by the literature on object visualization. There is some justification for this parallelism, given that the psychometric and navigation tasks seem intuitively different, are only modestly correlated, and share somewhat different brain mechanisms. For these reasons, this paper will consider each of these aspects of spatial cognition in their own sections.

Aging and Psychometric Measures of Spatial Cognition

Spatial abilities are typically measured by tests that require the imaginary transformation, rotation, or visualization of everyday objects (e.g., hands, animals) or abstract shapes. Factor analytic studies of psychometric spatial measures have identified multiple spatial dimensions (Ekstrom et al. 1976), including, but not necessarily limited

Spatial Cognition and Wayfinding, Fig. 1 (a) In the mental rotations test (Vandenberg and Kuse 1978), participants choose the two figures from the four on the right that represent rotated versions of the target figure on the left. In the paper folding test, a series of drawings depicts a square

piece of paper being folded before a hole (small circle) is punched through all folds (b, left of vertical line). The participant must determine the resulting arrangement of holes when the paper is completely unfolded and select this from among the five alternatives (right of vertical line)

to, the spatial orientation factor best exemplified by mental rotation tests, (See Fig. 1a) and the spatial visualization factor exemplified by, for example, the paper folding test (see Fig. 1b).

There have been several meta-analyses of spatial cognitive performance across the life span and these have shown robust age-related differences in psychometric measures of spatial cognition. Most recently, Techentin et al. (2014) performed a comprehensive meta-analysis of the literature of age-related differences in psychometric measures of spatial cognition. These authors examined 138 effect sizes from 78 published studies. Importantly, they quantified separate estimates of age effects for both spatial orientation and spatial visualization factors and also examined the effects of possible moderator variables. Among the moderators considered were whether the age effects differed as a function of accuracy versus reaction time scoring criteria, sex distribution of the samples, education history, and year of publication (to examine change in effect size over time for secular/cohort effects). This meta-analysis revealed a substantial effect of age on spatial cognitive measures and identified the importance (or lack thereof) of possible moderator variables. Overall, younger adults outperformed older adults by approximately 1.0 standard deviation (SD),

with moderately larger effects when reaction time was used as a dependent measure (1.30 SD) than when accuracy was used as dependent measures (0.95 SD). The large effect size when accuracy was used as an outcome measure argues against a strictly processing speed account of spatial age differences. However, it should be noted that even when accuracy is measured in a study, the test is most often still timed (with a maximum time limit) and older adults may respond differently to speed-accuracy demands than younger adults. In addition, Techentin et al. (2014) found a small positive effect of higher education but no effect of spatial domain (orientation vs. visualization). Moreover, there was no evidence of change in effect size as a function of the publication years considered in the study (1958–2011). This latter finding suggests that the effect size has been robust through several decades of research.

A feature of the age differences observed across studies that must be emphasized here is that the effects are large by conventional effect-size criteria and are also among the largest effect sizes observed in the cognitive aging literature. For example, according to Verhaeghen (2003), the age-related effect sizes for short-term memory is 0.36 SD, 0.52 SD for more complex working

memory, and 0.67 SD for recall of story details. The age difference in spatial cognition is of similar magnitude to that of verbal list learning ($d = 1.0$) and seems to be exceeded only by the larger effects on perceptual speed ($d = 1.21$). It seems noteworthy that the magnitude of the age difference in psychometric measures of spatial cognition is among the largest of the age effects in cognitive aging, although the factors explaining this are poorly understood.

Of course, a meta-analysis can lose certain nuances of differences between studies by emphasizing commonalities rather than unique aspects of research designs. One of the most consistent and interesting findings in the domain of spatial cognition is the linear relationship between the degree of mental rotation and the time required to solve a mental rotation problem. That is, as the degree of misalignment between stimulus and target increases (say between 45 and 135°), the longer it takes a participant to arrive at a “same/different” judgment (Shepard and Metzler 1971). Indeed, this finding is often considered the quintessential evidence that a task requires mental rotation versus some other spatial or nonspatial solution strategy. Moreover, individual differences in the slope of this “mental rotation function” are also said to reflect individual differences in speed or efficiency of rotation. Several studies have investigated the nature and meaning of age differences in mental rotation reaction time slopes and a few are considered here to illustrate the main findings and to highlight some differences in perspective.

Several studies have found that mental rotation intercepts and slopes are greater in older than in younger adults (e.g., Jacewicz and Hartley 1987). Furthermore, steeper slopes in mental rotation tasks are often interpreted as evidence for slowing or reduced efficiency in the rate of mental rotation. That is, an individual with a shallow slope is relatively unaffected by the magnitude of the required rotation and is hence more efficient or faster at rotating. However, mental rotation tasks, like all complex cognitive tasks, are composed of separable components. Although full consideration to the literature on visual imagery is beyond our scope here, Dror and Kosslyn (1994) identify

image generation (generating a stored image from memory), image maintenance (maintaining the image in visuo-spatial working memory), image inspection (analysis of the image in working memory), and image transformation (e.g., mentally rotating the image) as essential components. In addition, post-rotation decision-making processes also play a role.

Hertzog and Rypma (1991) reasoned that age differences in mental rotation rates may not reflect mental rotation speed per se and designed a study to investigate age effects on encoding, rotation, and decision-making during a mental rotation task. Hertzog and Rypma (1991) presented a stimulus and target serially rather than simultaneously, as in most MR tasks in order to isolate the processes of interest. Replicating other studies, the authors found poorer performance by older adults at all three stages but only a weak rotation slope difference between age groups. The authors concluded that age-related differences in mental rotation rates may reflect decay of the stimulus from working memory and post-rotation decision-making processes. This study highlights the utility of considering even seemingly “pure” measures of spatial cognition (e.g., mental rotation) as complex cognitive tasks, the age effects for which may depend on specific and subtle subcomponents.

Age Differences in Navigation and Wayfinding

As seen above, there is a rich literature concerning the study of age-related differences in psychometric measures of spatial cognition. As noted in the introduction, these measures tend to be object centered and focused on a relatively small spatial scale.

These are important cognitive tasks that assess critical human faculties; however, the psychometric approach may overlook the dynamic nature of spatial cognition as it is utilized on a daily basis by most people. Arguably, the most important manner in which our spatial cognitive systems are challenged is during navigation where we must learn a route to a new goal or locate an object or person in our environment. The most obvious

difference between psychometric and wayfinding approaches is that navigation/wayfinding requires physical movement through space (and concomitant dynamic visual processing) and explicit memory for previously viewed scenes/routes, whereas paper and pencil tests require no movement through space.

There has been a tradition of wayfinding and orienteering studies in humans but these have mostly neglected possible age-related differences. This is partly due to the difficulty of studying human navigation because it takes place over a relatively large-scale space which exceeds what can be accomplished in the laboratory. As well, in the real world, it is difficult to gain experimental control over the features of the environment; there are inevitably between-subject differences in familiarity of the local environment and limitations of older people's physical function may compromise mobility. While some studies have examined older adults' capacities for navigating a large-scale space, this field of inquiry is experiencing something of a resurgence of interest due to the development of a virtual environment technology which has brought the systematic study of large-scale navigation into the laboratory and into the MRI scanner.

Age-Related Differences in Navigation and Orienting in the Real World

There is considerable evidence now for age-related differences in navigational/route-finding skills. One approach to the study of spatial navigation in older people has been to measure navigation in "real-world" settings such as supermarkets, hospitals, or university campuses. Kirasic (1991) assessed the navigational skills of younger and older women in supermarkets and found that younger women acquired the spatial information in the environment faster than did their older counterparts. Wilkniss and colleagues required participants to navigate through the hallways of a hospital after being presented with a map of the environment and route that they were required to follow. They found that older adults took longer to navigate through the hospital than

younger adults and that the older adults made more frequent turning errors. Interestingly, older adults recalled objects which were encountered along the route just as well as younger subjects, but compared to their younger counterparts, they were deficient at placing those objects in their proper temporal sequence (Wilkniss et al. 1997).

An often used measure of place learning in nonhuman species is the Morris water task. Briefly, this task requires an animal to locate a platform which is hidden beneath the surface of an opaque pool of water. Surrounding the pool are visual cues which aid the animal in pinpointing the location of the platform. Over successive trials the animal comes to learn the location of the platform as revealed by faster escape latencies and shorter path lengths to the target. One study has replicated the Morris water task on a human scale by requiring older and younger adults to remove then repeatedly replace a pole in a circular enclosure which was surrounded by visual cues. Across a series of learning trials, older adults showed greater displacement error in replacing the pole compared to younger adults suggesting age-related deficits in place learning in older humans (Newman and Kaszniak 2000). This type of measure is usually described as "place learning" and might be considered similar to locating your car in a parking lot by judging its distance and bearing from environmental cues.

Assessing Age-Related Differences in Virtual Navigation

Navigation in the real world is the most ecologically valid approach to studying navigation. However, as noted above there are difficulties associated with doing so and this has led to many studies now employing virtual environment technology to study age differences in navigation. As in most domains of cognitive aging, the methods are variable but these studies generally consist of computer-presented (or rarely head-mounted) displays depicting a first-person perspective and equipped with an interface device such as a joystick, mouse, and arrow keys to allow movement through the simulated world.

As one could imagine, this itself entails potential pitfalls in the assessment of older adults because they may have limited experience using computers and visual disturbances or may differentially suffer from the elimination of vestibular and proprioceptive feedback that accompanies real-world navigation. Nevertheless, with careful training and appropriate use of visuomotor controls, older people can interact quite effectively with the computer environment (Moffat 2009).

Moffat and Resnick (2002) developed a virtual MWT (vMWT) similar to the one described above. As with the real-world task, the results of the study confirmed substantial age effects on virtual environment place learning. These basic age differences in a virtual MWT have subsequently been replicated and extended by other authors (Driscoll et al. 2005).

In a task more similar to the hospital or supermarket studies listed above, Moffat and colleagues challenged older and younger adults to solve a computer-based route-learning task in which several intersecting corridors ultimately led to a goal point (Moffat et al. 2001). Participants were instructed to find a goal point and remember the route. An important distinction in scoring was made between “information errors” (the first visit to an error location in which the subject had no previous knowledge that a corridor did not lead to the goal) and spatial memory errors (repeat visits to error locations that they should have remembered did not lead to the goal). It was found that older participants made more spatial memory errors but did not make more information errors than their younger counterparts indicating that elderly individuals differed only in their tendency to revisit error locations and not in their initial exploration of the environment.

As noted above, one of the limitations of using VE presentations of navigation tasks is that it deprives the participant of vestibular and proprioceptive feedback that is normally available in real-world navigation tasks. Lovden et al. (2005) investigated the effect of age on spatial navigation through a VE using an interface which required participants to walk on a treadmill to initiate simulated movement through the environment, thus providing proprioceptive feedback. These authors

found that providing walking support on the treadmill attenuated (but did not eliminate) the age differences in navigation accuracy (Lovden et al. 2005).

Another approach to the examination of age differences in navigation has been to quantify the ability of younger and older individuals to spontaneously develop or use a map of the environment. A second component of the study by Moffat et al. (2002) described above required participants to draw a freehand map of the vMWT environment and to designate the platform location on the map. Older individuals showed evidence of impairment in cognitive mapping as revealed by their poorer map constructions of the environment and their impaired ability to locate the platform on the experimenter-provided maps of the environment. Interestingly, there was no age effect on the recall of the object cues present in the environment. Consistent with the results of Wilkniss et al. (1997), older individuals appeared to have comparatively spared object/item memory (at least if the number of objects to be remembered is low) but are deficient at using those objects to assist in navigational behavior.

Sjolinder et al. (2005) provided younger and older participants with an overhead map of an environment to investigate the effects of navigational aids on the age differences. Sjolinder found that although the older participants subjectively felt more secure with the map, it did not improve efficiency in navigating the environment (Sjolinder et al. 2005). Similar results were obtained in another VE study of cognitive mapping which showed that older participants required more time to form a cognitive map of an environment than young individuals and required more time and made more errors when subsequently using the map for orientation (Iaria et al. 2009).

Brain Mechanisms of Age Differences in Navigation

Behavioral age differences in spatial navigation have been consistent across studies. One major advantage of VE testing is that it makes

navigation tasks adaptable to the MRI scanner environment. Indeed, neuroimaging studies in younger participants have identified a network of structures that are involved in spatial navigation. These structures include the hippocampus, parahippocampal gyrus, parietal cortex, and retrosplenial cortex (Burgess 2008).

The role of the hippocampus and associated medial temporal lobe structures in human navigation have been of considerable interest, in part because of the very precise animal models of spatial navigation that localize “place” and “grid” cells to the hippocampus and entorhinal cortex, respectively (Moser et al. 2008). Likewise, in human aging there has been great interest in the role of the medial temporal structures in mediating age-related navigation impairments.

Three studies have now reported quite consistent results demonstrating reduced or absent hippocampal/parahippocampal activation in older as compared to younger adults during virtual navigation. Meulenbroek et al. (2004) had younger and older participants learn the layout of a virtual house by viewing and remembering a sequence of turns through the house. Compared to older adults, younger subjects showed stronger activations in the supramarginal gyrus and posterior parahippocampal gyrus.

Moffat et al. (2006) investigated the neural mechanisms of age differences in spatial navigation in an fMRI study. Fifty-one healthy individuals (30 young, 21 old) were scanned while performing a VE navigation task. The task differed from the Muelenbroek study in that participants actively navigated through the environment using a joystick, while the participants in the Muelenbroek study passively viewed the navigation task. The results showed that compared to their younger counterparts, older adults showed reduced activation in the posterior hippocampus, parahippocampal gyrus, and retrosplenial cortex. This study also demonstrated that increased activation in the hippocampus/parahippocampal gyrus was associated with more accurate navigation.

Antonova et al. (2009) provide further converging evidence that changes in the parahippocampal cortex may be a major component of the age differences in navigation

performance. As with virtually all navigation studies, these authors report a widespread neural network being activated in young and older adults. In addition, they report that only young adults significantly activated the bilateral hippocampus and left parahippocampal gyrus during encoding.

Of particular importance in these functional imaging studies of navigation and aging is the consistent observation of reduced activation in older adults in the hippocampal/parahippocampal complex and in the retrosplenial cortex of the posterior cingulate gyrus, despite quite different task demands across studies. These areas play a critical role in spatial navigation in both human and nonhuman species (Burgess 2008). In particular the hippocampal/parahippocampal area has been hypothesized to act as a cognitive map receiving egocentric and motion-derived information from other cortical regions and converting this input into an allocentric representation of the environment. This suggests a clear divergence in the neural systems devoted to spatial navigation in younger and older participants. It will be important for future studies to try to understand both the mechanisms and implications of the reduced medial temporal contribution to elderly navigation.

Do Spatial Strategies Change with Age?

Another dimension on which people differ in solving navigation tasks is in their strategic preferences. Although researchers have described navigation strategies using variable nomenclature, the most common terms are egocentric and allocentric. An egocentric strategy is one in which an individual uses a frame of reference centered on the self, for example, remembering left and right turns relative to your own body. An allocentric strategy is one in which the individual adopts an external frame of reference, for example, by developing a mental map of the environment in which the individual is one object with coordinate relations with other objects in the environment.

One approach to this question of deducing possible strategy differences between older and younger adults was to simply ask participants

how they solved a navigation task. Doing this, Driscoll et al. (2005) recorded spontaneous descriptions of people's own navigation strategies and subsequently coded them as either egocentric or allocentric and found that self-reported allocentric strategy decreased with age.

A more direct way to assess this issue is to perform specific environmental manipulations that may reveal more objectively strategic preferences. In an animal navigation study, rats were trained to locate a goal for a reward in a two-choice T-maze. There were multiple ways in which the rat could learn the location of the reward. One possibility was an egocentric strategy in which the rat always turned left while another possibility was an allocentric strategy in which the rat moved to the same absolute location designated by external room cues. Barnes and colleagues tested this by rotating the maze following training and starting the rats in a different arm. Barnes et al. (1980) showed that older rats were more likely to use an egocentric strategy to solve the maze while younger rats were more likely to use an allocentric strategy.

Rodgers and colleagues performed a very similar manipulation using a virtual two-choice Y-Maze in humans and found an overwhelming preference for the use of an egocentric strategy in older adults (83%) compared to a slight preference for allocentric strategy use in younger adults (54%). Harris and Wolbers (2014) extended these results by noting that in a given navigation task, it is often optimal to switch between strategies flexibly as the task demands change or as you gain more familiarity with an environment. These authors showed that older adults were impaired compared to younger adults specifically in switching from an egocentric to an allocentric strategy, suggesting that aging may also affect the dynamic strategic processing required for successful navigation.

Although no studies have specifically tested brain activation during egocentric versus allocentric processing in older adults, Iaria et al. (2003) showed in a sample of younger participants that while adopting an allocentric strategy, the hippocampus was activated and when adopting an egocentric strategy, activation was primarily in the caudate nucleus. This suggests that the overwhelming preference for egocentric

strategy in older adults may underlie and possibly explain their under-recruitment of the hippocampus and parahippocampal gyrus that has been observed in functional MRI studies.

Conclusion

Spatial cognition is an important and somewhat understudied aspect of cognitive aging. Nevertheless, important and consistent results have been observed across different labs employing varied study procedures. Psychometric measures of spatial cognition show robust age-related differences with effect sizes among the largest in the cognitive aging literature. There is currently a dearth of studies in this area investigating the possible brain mechanisms of the age differences in mental rotation or spatial visualization.

The study of spatial navigation is having something of a resurgence in cognitive aging as more researchers investigate both the behavioral and brain mechanisms of age differences. Under-recruitment of the hippocampus and related medial temporal lobe structures may underlie the navigation impairment in older individuals. This under-recruitment may be caused by or even interact with age-related changes in navigation strategy preferences. Among the advantages of spatial navigation assessment are its dynamic processing and ecological validity. By its very nature, navigation is an inherently complex cognitive task that depends on widespread brain networks and many component cognitive processes.

Spirituality and Religious Participation in Later Life

Holly Nelson-Becker and Kimberly Sangster
Loyola University School of Social Work,
Chicago, IL, USA

Synonyms

Faith; Belief; Creed; Religiousness; Practice of faith, belief, or ritual; Sacred matters; Mystical experience; Immaterial; Holism

Definitions

As older adults live to increasing ages, spirituality and religious participation form an important

source of meaning and purpose and relate to the ways older people choose to interact with what they deem as sacred. For many older adults, spiritual and religious participation include involvement in traditional world faith communities.

Spirituality

Spiritual awareness develops through relationships with one's inner self, others, nature, the universe, and ultimate reality, whatever a person understands this to be. Spirituality is the manifestation of the search for significance and purpose in life. Spirituality is an integrative, holistic component of life that can touch on physical, cognitive, emotional, and relational aspects. In the human services, spirituality is generally viewed as a larger domain that may or may not encompass religion.

Spirituality and Religious Participation in Later Life

As older adults live to increasing ages, spirituality and religious participation form an important source of meaning and purpose and relate to the ways older people choose to interact with what they deem as sacred. For many older adults, spiritual and religious participation include involvement in traditional world faith communities.

Religion

Religion is an organized system of beliefs, behaviors, rituals, and ethical principles or values shared by a community and transmitted over time. Religion is expressed through cultural lenses and traditions.

Spirituality and Religious Affiliation

Spirituality and most especially religion are of deep value to most older adults. While questions about the importance of religion have appeared in many national surveys, questions about the importance of spirituality are rare. In fact, the term spirituality is often less well understood by older people who as a group endorse religion over spirituality. For them, the meaning of these two concepts may be conflated, with spirituality

viewed as a component of religion, if seen separately at all. Sixty-nine percent of adults in the USA aged 65 years and older report that religion is very important to them; that differs from the 45.7% of those between 18 and 24 years who name religion as very important (Pew Forum on Religion in the Public Life 2008). However, the high rating of importance of religion has trended down by seven percentage points over the decade from 1998 to 2008. Further, 90% of older adults express belief in God (Pew Center: Growing Old in America: Expectations Versus Reality 2009). The fourth most common daily activity performed by older adults (behind talking with friends and family, reading, taking medication, and watching TV) was praying (Pew Forum on Religion in the Public Life 2008). Older adults not only report that religion is important to them but also they integrate public or private religious behavior into their lives. Increasing age has been related to higher levels of religious belief but not to attendance when health is controlled (Wang et al. 2014). Overall, like the rest of the population, older adults, too, report being religious only, spiritual and religious, spiritual only, or neither religious or spiritual. In the literature, these domains are referred to as R/S or S/R. In keeping with this tradition, this entry will use R/S to honor the more frequent use of the term *religious* compared to *spiritual* given by older adults.

Across all age groups, older adults (over 65 years) are the most religiously affiliated group. According to the US Religious Landscape Survey (Pew Forum on Religion in the Public Life 2007), about 84% of those ages 60–69 have stated that they hold membership in Christian religions; an additional 5% have membership in other world religions such as Islam, Hinduism, and Buddhism, bringing the full percentage to about 89 (Pew Forum on Religion in the Public Life 2008). There is a slight increase in these percentages for those over age 70. To a greater extent than the USA, the UK has long hosted a diverse population. This is demonstrated by greater numbers of older adults affiliating with world religions (72% report being Christian) and 15% of the population reporting to be atheist or agnostic (Association for Religion Data Archives: Religious

Adherents 2011). Globally, those who self-identify as part of a religious faith include the following: Christians (31.5%), Muslims (23.2%), unaffiliated (16.3), Hindus (15.0%), Buddhists (7.1%), folk religionists (5.9%), other religions (0.8%), and Jews (0.2%) (Pew Research Center 2012). *Folk religionists* comprise African traditional religions, Chinese folk religion, American Indian religions, and Australian aboriginal religions. The category of *other religions* comprises Baha'is, Jains, Sikhs, Shintoists, Taoists, and many other smaller faith groups (Pew Research Center 2012).

Descriptions

Spirituality. Psychology, social work, counseling, and other helping professions generally distinguish between spirituality and religion as being associated but conceptually distinct. Spirituality is often used as a broader more inclusive term that refers to the search for meaning and purpose. For many people, it is a process of dynamic discovery that unfolds over time with aspects that sometimes advance and other times regress as individuals face or choose not to face their own blockages and fears. Pargament, drawing on the work of Tillich and other theologians, refers to this as “a search for significance, in terms related to the sacred” (p. 32) (Pargament et al. 2013). Although he calls this a definition of religion, it more closely resonates with a spiritual understanding. The consensus conference to develop standards of spiritual care for palliative care suggested, “Spirituality is that aspect of humanity that refers to the way individuals seek and express meaning and purpose, and the way they experience connectedness to the moment, to self, to others, to nature, and to the significant or sacred” (p. 887) (Puchalski et al. 2009).

One of the views carried by a number of people who self-identify as spiritual, including indigenous groups, is that spirituality pervades everything, including inanimate objects such as rocks and stones. Thus everyone has an innate spiritual self whether this is acknowledged or not. Conceptually, the idea of the spiritual may be viewed in several forms: (1) as one aspect of the

biopsychosocial spiritual self, (2) as an inner center or core of the person, or (3) as something beyond everything that has a material/physical essence and transcendent to the self. These are not mutually exclusive ideas. Dependent on culture and worldview, the meaning of spirituality can expand to include presence of deceased loved ones, angels, guides, energies, and other forces (Nelson-Becker and Canda 2008). Connecting to nature for many older people remains a key expression of the spiritual. One older woman living independently reported that what she saw outside her window each morning was “a view of eternity” (Nelson-Becker 2003). The actual vista included a tiny corner of Lake Michigan which she later explained was her connection to spirituality. However, it is also important to note that the term spiritual applied to inner experience is not typically used by many older people (especially those residing in the Western world) who prefer the word religion as the umbrella term for all aspects. This seems to mark a generational difference in discourse between older adults and those born in the 1950s or later (Coleman 2011).

Religion. Religion is a marker for the Judeo-Christian social context in which many older people in Western culture were raised, although that is changing. With immigration and globalization, the number of older people expressing affiliation with world religions mentioned above, though small, is increasing. Religion refers to the organization, beliefs, ethical values, rituals, and behavior that are transmitted over time and shared by a community. Often, though not always, this includes belief in a divine power, transcendent being, or sacred source of meaning. Ancient sacred texts and modern devotional literature including stories about origins form part of most religions, although some have developed through oral traditions. Responsiveness to social injustice and moving synchronously with the rhythms of holidays and festivals are other aspects in the lives of older people of faith.

Religion as resource. Religion has been an important resource for social connection and for comprehending what is beyond ordinary understanding throughout history. For example, some

older Holocaust survivors wonder why God would allow the devastation of the Jewish people during World War II. Religion is embedded in nearly every culture, although with its own unique representations and manifestations. For older people who are beginning to lose social friendships through widowhood and death, the church, synagogue, mosque, or sangha offers an important source of connection and reconnection, especially with younger persons with whom they might not otherwise engage. *Faith* and *belief* are other terms commonly used by older persons in reference to the doctrine or teachings of a religion or their own thinking that is not based in substantive proof. Faith and belief are valuable because they express ideas about how the world/universe is and one's relation to it, assumptions based on deepest roots or foundations of being. Thus, religious tenets can offer reassurance to older persons. Most religious traditions offer a positive view of the cosmos and the place that humans have within it. Life especially is valued; it holds meaning and purpose. Further, religion can facilitate the expression of powerful emotions that lie beyond thought and include gratitude, peace, joy, and hope. Religion can provide comfort, the sense that one can turn to God or a sacred source when life becomes difficult or depressing. Religious rituals and ceremonies can offer renewal or recognition of transitions and life endings. Prayer in groups or alone (private prayer) and meditation facilitate a sense of nearness to the transcendent power as well as a sense of responsibility to a community and care for the earth, a sacred home for all beings. Religions offer general guidance for the best course of action taking into account needs of self and others, and most religious faiths have role models one can look to and reflect on for inspiration.

Spiritual well-being or spiritual strengths. The National Interfaith Coalition on Aging, with representatives from several religious faiths, described spiritual well-being in 1975 as an affirmation of living in relationship with self, community, environment, and God that cultivates wholeness (National Interfaith Coalition on Aging 1980). Spiritual strengths refer to specific aspects of religious faith and spiritual beliefs that serve as resources and anchors during times of

health crisis or transition. Many older persons report reliance on prayer as a tool to counter physical and emotional pain. Comments by older adults include statements such as "God made this world so beautiful. We've got to be thankful. Maybe I might not be thankful this morning [because of my pain], but I've got to get to it this afternoon." Religion alludes to basic principles that "develop heart, mind, soul, and body." "You treat people better. You have peace within yourself and peace and harmony among people" (Nelson-Becker 2003). Reading sacred texts also provides comfort and insight. Religion is viewed as an opportunity for tolerance and greater understanding of others. It is more often pondered in a positive light by older adults as something that offers benefit, though not always. Joy, hope, forgiveness, and acceptance are a few of the outcomes of spiritual strengths.

Spiritual suffering and spiritual struggle. Spiritual suffering concerns all the existential, religious, and spiritual conflicts people encounter during the life course that cause emotional pain or anguish. Spiritual struggles are active endeavors to either maintain or change spiritual views that are threatened. Spiritual suffering can ensue from discouragement, despair, abandonment, emptiness, detachment from self and others, fear, demoralization, and ambivalence or doubt about former beliefs. Spiritual pain also may emerge from a sense of separation from God, precipitated by illness or other loss. While older age may be a time for reconstituting the self and deepening, it may also be a time of sorrow over sensed failures, disappointment, and grief related to the meaning one assigns to one's experience of life.

Spiritual care. Even though somewhat less likely to use formal therapy than younger groups, older individuals do seek out and use formal psychotherapy supports. Spiritual care is the official province of pastoral care professionals, chaplains, and other spiritual leaders such as rabbis, priests, ministers, clerics, monks, nuns, imams, and shamans. Some of these leaders may have specialized study while others do not; some are ordained and some are lay (not ordained but possibly certified) ministers. Certainly, they should be

used as referral sources when feasible as well as sources of specific denominational or spiritual group knowledge resources. Generally there are fewer clergy than therapists, so frequently therapists are the ones available when psychospiritual crises or problems emerge. Also, fewer clergy have received the mental health education and training that licensed professionals have. Spiritual triage (beginning assessment of concerns) may be required from any first-line professional staff, especially those working on interprofessional teams. Mental health professionals should all have some training in assessing and addressing R/S needs of clients, with those who have particular affinity and comfort in this area encouraged to seek ongoing professional development.

Ethical Practice and Boundaries

Some mental health professionals feel uneasy about addressing religion and spirituality with older clients or choose to avoid it entirely because at times, well-intentioned professionals have attempted to privilege a spiritual or religious point of view. This section will identify those general concerns, discuss the reasons that assessing religious and spiritual needs is essential (especially those that are unmet), and provide guidance on working with spiritual issues and use of prayer with clients.

Concerns about proselytizing. One of the concerns mental health practitioners often have about discussing spiritual and religious issues with older clients is that they may be perceived as proselytizing or seeking to convert clients to a particular system of belief. In the past, people of goodwill, who thought they held the best answers, have stepped across boundaries. A risk for clients is that they are vulnerable and lack power in the relationship, so any assent would be manipulation and not freely given as an act of faith. Even though religious belief and practice have resulted in positive outcomes for many older people, that is not universally the case (Puchalski and Ferrell 2010). The level of intimacy is such that religion cannot be prescribed the way one might suggest exercise, certain reading material, or other “homework.”

Importance of assessing religious and spiritual needs. It is important to ask broad questions in assessment about whether these areas are important to the client and whether he/she would like them to form part of therapeutic work. If unasked, older clients particularly will often not mention what could be a significant source of comfort or distress. Taking cues from the practitioner about what is perceived as a level of discomfort, they may hesitate to reveal their spiritual or religious beliefs that are fundamental and integral to their constructed self. The unethical practice would be to avoid the area entirely. If it emerges that R/S is an area of interest or concern for the client, then the task for the practitioner becomes one of listening fully and holding in check one’s own assumptions and stereotypes. Although psychologists tend to rate religion as beneficial, when client beliefs shift farther from mainline beliefs and norms, these professionals demonstrate greater tendency to rate them as pathological (Post and Wade 2009). Even when affiliated with a particular religious faith, many older individuals may have developed their own unique understandings and expressions within that faith.

Professional work with older clients around spiritual issues. At moments when spiritual and religious issues emerge as a main concern, older clients can be referred to board-certified chaplains (available from many faith traditions) or leaders in their own faith community. However, there are occasions when the need is so immediate and the pain so profound that psychologists, counselors, and social workers should listen intently, no matter their own background or personal faith or non-faith preference. Some practitioners may feel unprepared and assume that it is best for clients to work with someone from their own religious or spiritual group. However, practitioners do not need to match clients on their spiritual genetics. In fact, at times a person from a secular or humanistic background may serve as the best resource because he/she can approach the problem with a fresh mind free of assumptions. The key requirement is that the professional be prepared to use all of his/her training and skill to listen deeply to what the client may find

extremely difficult to discuss or be conflicted about revealing.

Praying for or with clients. Holistic work with clients include integrating attention to many parts of the self. Although chaplains have had training in leading prayers after genuine invitation by clients, other mental health professionals have not. Unless there are exceptional reasons such as the client and therapist are members of the same faith tradition, there is a risk of abuse in participation in prayer. On some occasions, an older client may ask a professional to pray with them. Depending on the background of the professional, he/she might consider standing/sitting in respectful silence while the client prays. Because of risk of coercion, it is best when these requests are initiated by the client. Following the client's initiative, without engaging in behavior that would seem to cause harm to the professional's own belief system, seems like the optimal approach.

Spiritual Assessment with Older Adults

Assessment of spiritual and religious needs remains inconsistent in many agencies that work with older people. The Joint Commission as a health-care oversight agency requires some form of spiritual assessment in hospitals and other health-care organizations, but it offers little guidance in how these assessments should be structured. Classic measures of religiousness were whether an individual was affiliated with a religious faith and whether they prayed. More recently, a common question is how important religion and, separately, spirituality are in an individual's life or whether their spiritual needs are met. While the area may be checked off, there is little here to encourage a longer encounter. Better constructed assessment tools for therapeutic work cultivate a conversation about needs and desires by providing a framework that can point to later intervention. Quantitative tools explore specific areas such as coping, beliefs, values, and daily spiritual experiences (Fetzer Institute 1999). The health literature also has a number of qualitative assessment tools such as FICA (faith and belief, importance, community, address in care or

action). Before taking a full spiritual history or comprehensive assessment, it is helpful to ask a preliminary question about what gives an older person meaning and purpose (Nelson-Becker et al. 2006). If religion and spirituality surface here, these can be further explored, if the client wishes. If the individual indicates they have no interest, then that can be information noted and no further questions need be asked. Assessment of R/S should be directed by client needs and interests but can provide a prolog into intervention.

Spiritual Interventions

Spiritual interventions should be utilized cautiously with respect for all spiritual and religious positions but can be an empowering tool for older adults who may use R/S coping discussed below. Many older adults have spiritual portfolios or repertoires, strategies that have proved useful to them in the past for coping with stress. A mental health professional might assist someone in expanding their portfolio by helping them consider ways to deepen their spiritual practices or to try new ones. While these may include individual spiritual practices, learning to engage with spiritual communities in new ways may be another possible area for exploration. Making innovative use of pastoral care opportunities or small group meetings and support are other ways. Faith communities are growing older and they are beginning to explore ways to connect older and younger members as well as teach practices such as the recognition and inclusion of older people with mental health needs. There are some useful guidelines to consider in this area. Spiritual intervention should be preceded by client request. Practitioners should develop clinical expertise and cultural competency through education and training, respecting religious and spiritual diversity and any prohibitions within specific religious traditions. Finally, where available, this work should be research informed.

Spiritual resilience is a quality that enables people to mediate difficult circumstances and still flourish (Nelson-Becker 2013). It is present when an older person manages ambiguity

successfully by full immersion in and enjoyment of the moment. Similarly, benefit-finding is the ability to engender a positive outcome in the midst of severe health or other threats. Loss and grief are visible in personal histories that include stories of pain, but out of those stories, a reintegration and recovery of a new self can occur.

Spiritual reminiscence is a process that considers individuals' life stories and how meaning can continue to be understood or reframed from significant life events (MacKinlay and Trevitt 2010). Although useful with almost any older client, if they have some cognitive impairment, they can be paired with another person or their significant other to develop a dyadic story. This describes an in-the-moment process of meaning reconstruction and providing provisional purpose while addressing issues of vulnerability, reason to hope, and despair. Persons with dementia, like everyone, have stories to tell, but they will require assistance in structuring them in a way that returns meaning both to themselves and others. Spiritual stories are a validation of life lived experimentally without knowing the ending in advance and give witness to the woundedness and resilience of the storyteller. Storymining is the act of the professional who asks questions that can help highlight the meaning of a life, the wrong turns that were the right ones, for example.

Incorporating compassion, courage, fluidity, hope, trust, joy, and equanimity. Human values define the experience of being human, yet developing greater compassion, courage, fluidity, hope, trust, joy, and equanimity is seldom identified as a goal. Much therapeutic work takes a problem-focused approach instead of a spiritual development approach. Contemplation of the risks and benefits to full authenticity is another under addressed topic. Shame, guilt, greed, and other unsavory maladies also may remain unrecognized in a mental health lexicon that privileges standard complaints common in aging such as depression and anxiety. Forgiveness, too, is an important area of therapeutic work that can take greater significance in aging when a lifetime affords more opportunities for forgiving and being forgiven. Contemplating some of the ancient vices and

virtues anew may yield new places for enhancing the quality of life for older people.

Spiritual and Religious Coping in Older Adults

R/S occupies a unique space in the lives of people for whom it matters. The level of profundity and the core issues related to spirituality such as the quest for meaning and purpose, experiencing deep joy in recognizing the beauty of life and all beings, or dealing with doubt or sense of abandonment/anger toward an ultimate being/transcendent power/God touch on foundational beliefs central to a sense of personhood. Although religious beliefs and related ideals may falter in stressful circumstances of aging when older adults encounter chronic and acute illnesses, increasing frailty, and adapt to unwanted changes, religious coping has been found to offer benefit beyond social and psychological resources (Pargament et al. 2013). In a study of 79 older adults asked to identify their three most difficult life challenges and subsequent coping styles, the most common coping styles included tapping social resources (talking with friends or soliciting instrumental help), religious coping (attending church, praying, reading the Bible/Talmud/Koran, using resources provided by God/faith), personal coping (depending on oneself, accepting the situation, using humor), or idiosyncratic or avoidant coping styles (placing trust in physicians, crying, not coping) (Nelson-Becker 2004). The primary coping style was more salient than the type of problem, and older people used their preferred coping method on most identified problems. Religious coping was the dominant coping pattern for African-American respondents. Traditional religious practices of prayer, meditation, reading religious texts, and using religious teachings as a moral compass or guide and helping to banish loneliness through altruistic behavior of helping others are important aspects of religious coping. One older African-American woman spoke of placing her trust in God, "I'm helpless without God, that is where my help comes from." Another African-American woman who was a storefront minister exhibited a

strong belief in the benefits of using religious practices:

As I said earlier with prayer, Bible scriptures, meditation, seeking the answer from within, so I can do the will. I don't move too fast-I make the attempt to get an answer about what to do about a situation. I don't worry myself. It's like a touch on the shoulder. 'You're my child. You don't have to worry. It's going to be alright.' Then I adjust my mind to accept whichever way it turns out. In the end I find it to be the best.

A Caucasian woman detailed the manner in which she integrated her faith with her daily life. These rituals helped her achieve some important routines in her day and enhance life meaning since it was difficult for her to leave her home due to some physical limitations. Her preferred activity would have been to attend church frequently:

I have my daily practice of meditation, Bible reading and prayer. That's daily. I don't miss. My Bible reading has to be every day. In the morning I'll get up at 6:00 or maybe earlier and have my meditation and prayer, then reading. I have daily readings—three of them. I go back to bed and maybe sleep until 9:30. I have to listen to Joyce Meyer (a Christian speaker) on TV at 12:00.

Although spirituality was less often cited as a specific resource in this older age group, it was mentioned as something inside the self that provides courage and inspiration. An older Jewish American woman commented, "When you really feel very sad, you want to turn to something. This is when you use spirituality." Another older adult man spoke about the difficulties in managing interpersonal relationships, "You meet people who don't act right. My spirituality helps me leave them alone. I'm able not to get angry." A third individual spoke of spirituality as something mysterious that was difficult to fully articulate, "You use spirituality in the sense of you don't see but you know it's there. Just like the solution [to a problem]. All of a sudden it's there – aiding you and letting you know how to go about it." R/S are significant tools for many older people in managing increasing frailty, mental health issues such as depression, or simply maintaining a satisfactory quality of life.

Dementia and caregiving. Religious coping has been viewed as valuable to clients diagnosed

with early-stage dementia. When disconnection from others due to communication problems and loneliness disrupted their sense of identity and self-esteem, relationships with God were deemed important, regardless of varying attributes/descriptors assigned to conceptions of God (Beuscher and Beck 2008). Hope was expressed in living fully through daily experience rather than impractical hope for cure. Spirituality in later-stage dementias is evident in the power of ritual for communication when speech is no longer available. The body remembers when the mind cannot, and people with dementia are able to sing religious hymns or participate in religious chants and prayers that have been embedded in their being from young ages. Religious coping has also proved a valuable benefit to caregivers of older people and individuals with disabilities who experience great stress in provision of high levels of direct physical and emotional care. Caregivers under benefit in the reciprocity transactional measure when they give more than they receive. They often relinquish earlier dreams of what they wanted to accomplish or how they wanted to spend their time, sacrificing (making holy) a new project to devote themselves to the welfare of another person, often one who is deeply loved.

Religion, Health, Mental Health, and Aging

Considerable research over the past 20 years has examined overall physical and psychological well-being, a variety of specific health outcomes, mortality, health behaviors, and the role of faith communities in the prevention and impact on older adult health (George et al. 2013; Koenig et al. 2012). Research strongly suggests that R/S beliefs, behaviors, and religious participation influence older adults primarily in five specific ways: (1) development and maintenance of a meaning-making system, (2) social support and pro-social engagement with others, (3) social control of certain behaviors that affect health, (4) consolation, and (5) decision-making guidance around medical treatment and end-of-life

decision-making. The interaction of religion on health and mental health, however, is complex and not always explicit nor positive.

Specifically, mental health is maintained or enhanced by providing a sense of purpose and meaning in life. R/S beliefs have the potential to validate emotional suffering and provide an emotional “holding environment” for coping with life’s stressors and unanswerable questions. R/S communities foster a sense of belonging and opportunities for social relationships. They reduce social isolation. R/S beliefs encourage positive attitudes and emotions, such as hope, joy, and forgiveness that enhance well-being as well as neutralize negative emotions such as anxiety or depression. R/S beliefs and behaviors influence lifestyle choices that impact health, such as excessive alcohol use, sexual promiscuity, gambling, and drug abuse. Some R/S beliefs and practices affect one’s ability to cope with medical illness, loss, life stressors, and crises. The use of prayer, sacred texts, ritual, and congregational support can aid coping. R/S beliefs and the influence of faith communities guide medical decision-making, including whether or not to receive care. This can influence discussion and decisions regarding the development of an advance directive for medical care and decisions to begin, continue, or end medical treatment and provide definition to what constitutes “futile care” and assist with end-of-life decisions.

Not all R/S beliefs and practices are beneficial to health and well-being. Negative religious coping has been consistently linked with poor health outcomes. Those who believe their god has abandoned or is punishing them exhibit increased distress. Additionally, internal or external motivation for R/S beliefs, practices, and participation can strengthen or weaken the health effect. Older adults whose religious involvement is intrinsically motivated experience satisfaction from their beliefs and practices. Those who are externally motivated engage in beliefs and practices to receive something in return such as praise, respect, or social status. Internal motivation is linked with positive health outcomes, while external motivation is linked with negative health outcomes.

Religious Diversity and Struggle: An Example of LGBT Older Adults’ Relationship to Faith

Lesbian, gay, bisexual, and transgender (LGBT) elders have coped not only with the stigma and disregard of general society but also with spiritual violence meted out by authorities of various religious denominations. Religious leaders claimed the voice of sacred texts, the position of theological truth, and doctrinal mandate in relation to sexual orientation. Sacred religious texts have been used as weapons to legitimize harm and ostracism and make claims about one’s lack of worthiness to engage the divine and supportive religious community.

Spiritual identity occupies different levels of importance and contributes to self-understanding in varying degrees. For some, spiritual identity is core to who one is; it is a foundational aspect of self, central to how one views and approaches the world. To others, it is a part of the self that is accessed in times of distress or extreme gratitude, and yet to still others, spiritual identity is consciously not important at all. The process of integrating spiritual identity and sexual identity is complex and fraught with emotion. It is frequently a time of spiritual struggle. The outcome of this spiritual struggle can be positive, negative, or a combination. The historical time in which these elders came of age and the diversity of religious views regarding homosexuality can complicate this struggle. Some LGBT elders have developed a personal spirituality that supports a whole sense of self and provides strength and inspiration apart from their religious tradition (Witten and Eyler 2012). Those who have maintained a relationship with their religious tradition frequently have adapted their internal belief system to relieve the conflict between their sexual and religious identity.

An experience of deep grief is a common reaction for those whose spiritual identity is threatened. Anxiety can ensue as one tries to find one’s bearings and redevelop self-understanding. Individuals may feel that they no longer have access to God, their religious community, or spiritual home. A sense of what was known as true, good,

enduring, and nourishing might be shattered, at least for a time. Thus, there is loss of self-understanding and diminished access to the strength and coping assistance that was historically available and engaged. Out of this devastation, many LGBT elders have developed strong spiritual identities in the face of societal and religious discrimination. Many have emerged with a life-affirming spirituality that is a source of strength, comfort, and energy as well as the source of personal resilience.

The relationship between organized religion and LGBT elders is complicated at best. While dialog is currently taking place with religious authorities and lay people regarding religious participation, theological validation, and embrace of LGBT individuals within various faith communities, this is a newer development. Historically, LGBT elders have come to expect rejection from places of worship and religious institutions. Given this history and social context, many LGBT elders faced conflict as to how to reconcile these seemingly incompatible parts of themselves, a nonheteronormative sexual identity and a spiritual identity. Some choose to deny religious identity or deny sexual identity, compartmentalize their identity, or integrate their identity.

Many LGBT elders have experienced great pain and rejection from their faith communities. As LGBT adults age, feelings of vulnerability may emerge. Reliance upon existing spiritual resources and religious communities is common during times of stress and can aid in coping with these complex feelings. A large number of LGBT elders are committed to their religious and spiritual identities and have exhibited great resilience, strength, and growth in the face of homophobia, stigma, and rejection. Engaging their spirituality and accessing social support, including religious institutions, will help LGBT elders flourish through their later years. However, it is also important to understand that this vulnerability may impact LGBT elders in a detrimental way. Fears and concerns about being discriminated against when unable to care for oneself may become overwhelming. Some elders have expressed concern that they may be forced to move from an open, integrated sexual and

spiritual identity into a compartmentalized identity. They are concerned about being in a position of trying to “pass” as heterosexual for their own safety and ability to receive services. In essence, go back into “the closet.” This is a looming spiritual crisis for LGBT elders.

Conclusion

Religion and spirituality have formed part of the cultural landscape for older adults in communities across the world. They touch on many aspects of life which are nourishing: opportunities for social support and shared understanding, deeply held foundational beliefs, emotional richness, and strategies to bring personal peace or harmony in the face of intrapersonal and interpersonal conflicts. However, as societies change, older adults change with them. As their religious and spiritual sensibilities grow, diminish, or remain stable throughout longer life trajectories, there will be many possibilities for practitioners to enhance their understanding of a widening emergent field and of ancient resources for human flourishing. As research methods both expand and retain rigor, practitioners will be better able to recognize the complex associations of religion and increasingly with advancing generations of spirituality.

Stage Theories of Personality

Edward Helmes

Department of Psychology, James Cook University, Townsville, QLD, Australia

Definition

A stage theory of personality proposes a series of fixed developmental levels that are associated with different elements of personality, progress in the complexity of the expression of personality, and are experienced in the same way by everyone in a society and across different cultures.

History

The earliest stage theories of personality arose from the psychoanalytic writings of Sigmund Freud, and many of those who later went on to develop their own stage theories continued to do so in the psychoanalytic tradition. For the most part, these early theories were primarily concerned with developmental stages in children and considered the personality of adults in much

less depth, with even less consideration given to the personality of older adults. For a very influential example, Freud's theoretical stages of psychosexual development (Freud 1965) applied only to childhood and adolescence and were regarded as stable throughout the adult years. These developmental stages formed the core of the influences that formed the adult personality and its fundamental adjustment to life and its challenges. Another tradition in which stages are prominent is the developmental stage theory of Piaget (1954), who focused upon the cognitive development and resulting differences in observed abilities of children as they progressed in age. Adulthood in the psychoanalytic tradition was presumed to be stable and relatively unchanging except in response to strong environmental pressures. Later theories that built upon the psychoanalytic model retained the focus on childhood development, but some later theories focused more on personality differences among adults during the midlife and later-life periods and elaborated upon aspects of personality during adulthood.

Early Theories

After Jung finally split with Freud in 1913, his writings focused more on the influence of culture on the development of personality features in individuals and expanded on psychosocial developments in the second half of life without adopting a set of fixed developmental stages. Among his other contributions, Jung is credited with the idea of important developments in adult personality around the age of 40 that later evolved to become the concept of the midlife transition or midlife crisis (Jung 1971). It must be remembered that in general most stage theories of personality are based upon data collected from, and the resulting theories derived from, comparatively well-educated individuals from North American and European societies. Thus, Jung described a process of individuation during the adult years in which individuals became more clearly defined and differentiated from one another as individuals adopted different responses to the demands of adult life. Whether the implicit assumption in this

that all cultures and societies involve increasing differentiation among adults can be supported outside of well-educated Westerners is rarely addressed among early stage theorists. One of the distinct elements of Jung's work is his sensitivity to the issue of culture and its influence on developmental processes.

The appeal of stage theories is partially based upon the introduction of such additional secondary concepts as the midlife crisis. These ideas are often intuitively appealing but are also more difficult to support empirically. There is also the conceptual problem for a stage theory if empirical results do not support the secondary concept in question. This is the case of the midlife crisis, in which later research has shown not to be universal in all who reach midlife, not to appear at the same age in midlife, and not to necessarily involve significant emotional upset (Rosenberg et al. 1999). Despite such a lack of empirical support, concepts such as the midlife crisis remain popular in modern cultures and have seemed to acquire a life of their own independent of empirical evidence and the implications of disconfirmation for the parent theory. Indeed, little research on stage theories is being done currently. A PsycINFO literature search was done for this topic, using the terms "stage theory" and "personality" and "older adults." A total of only 52 hits were returned, many of them not relevant. In addition, many texts for adult development and aging courses give comparatively little space to stage theories in comparison to newer trait theories.

Lifespan Theories

The first comprehensive stage theory of adult personality change and development that covered the lifespan was that of Erik Erikson (1950, 1964) and Erikson et al. (1986). Erikson's theory emphasizes the interplay between the individual and society in developmental processes and can be seen as an extension of Jung's work. The eight stages proposed by Erikson are clearly articulated and intuitively appealing, including both significant relationships with other people in one's life and intrapersonal processes.

Widely influential, Erikson's stage theory was based on the idea that psychological development required the successful resolution of psychosocial crises. With a rich and clearly described base, the theory influenced many other writers and researchers in the area of personality development. At the same time, Erikson's theory primarily focused on childhood and adolescence, with five of the eight stages covering the first 20 years of life: basic trust versus mistrust, autonomy versus shame/doubt, initiative versus guilt, industry versus inferiority, and identity achievement versus identity diffusion. Issues arising during childhood and adolescence can recur under crises in later life, so the developmental sequence is not entirely fixed and rigid. Erikson devoted three stages for the remaining years of life that covered a substantially longer period of time. Of the three stages of adulthood, the first stage of young adulthood involved the psychosocial crisis of "intimacy versus isolation" and occurs during the 20s and 30s, while the second adult stage is based on the resolution of the crisis of "generativity versus self-absorption" that occurs during the period of the following 25 years from 40 to 65 (Whitbourne et al. 1992). This stage has perhaps attracted more research than any other in the accumulated studies involving the theory. The stage of generativity is predominant in midlife according to most research on the topic as many adults reach this stage of development (Sneed et al. 2006). Some studies have shown that generativity appears to be lower in both younger and older adults than those in their late 30s and early 40s, as predicted by the theory. The final stage that occurs during old age involved the crisis of "integrity versus despair," which covers the period of time from late adulthood to death (Erikson et al. 1986). This period of life can easily cover an additional 15–30 years of life for individuals whose health remains sufficiently robust to place them among those surviving beyond the average life expectancy. It seems to be a feature of most stage theories whose developers are in midlife in that later life is seen to be a relatively stagnant and unchanging stage of existence that begins with retirement and continues placidly until death.

Modern Theories

Despite its intuitive appeal and resulting broad influence, recent years have seen a relative decline in research on Erikson's theory in parallel with the increasing influence of trait models of personality and personality development. It is none the less evident that Erikson's stage theory has had a broad influence on others who have developed more focused theoretical and empirical accounts of the development of personality characteristics in adult life that do extend into later life. These include the theoretical developments of Levinson (1978, 1996) and Vaillant (1977). In common with Erikson's theory, such more recent theories are built upon the broad sequence of developmental events that are almost universally observed in modern Western societies, while retaining links of psychoanalytic theories. Early childhood, preschool days, the years or decades of formal education, employment and marriage, parenthood, and retirement are events and activities that are virtually universal in modern Western societies and are becoming more dominant in the societies of developing countries as Western influences continue to spread. Formal transition ceremonies, such as initiation rites, are far from universal in Western cultures and their survival is variable in developing countries. Individuals may exhibit substantial variation in how they progress in life across the cultural range of stages without considering the relatively consistent variation between cultures that can be exceeded by variation within a culture or society.

Much of the existing research on stages of personality development that does not deal explicitly with childhood and adolescence focuses on the middle period of life, the decades of adulthood. Several other investigators have focused their work on refining and elaborating upon Erikson's stage of identity and have expanded upon the original ideas of this level of development. Levinson's theory (1978, 1996) focuses on early to middle age (age 20 to age mid-40s) and incorporates six stages: leaving the family, entering the adult world, settling down, becoming one's own man, midlife transition, and re-stabilization and beginning middle adulthood.

Like many stage theorists, Levinson bases his theory upon situations and events that generally occur during relatively specific and consistent periods in a person's life. The theory was originally developed on the life situations of four occupational groups of men and thus lacked a certain amount of generalizability.

Modern Theories

As a psychiatrist, Vaillant (1977) had a rather different perspective on stages of personality development than most personality theorists, in that he was most concerned with the success adults had with the major issues of adulthood: forming an intimate relationship, establishing a career, and transmitting knowledge to the next generation. Vaillant was working in the predominant psychoanalytic tradition that has influenced much of the theoretical developments on the topic of personality structure. Unlike more rigid theorists about personality, and like Loevinger (1976), he does not assume that everyone progresses at the same rate or necessarily reaches the most advanced or highest level or stage. He is particularly interested in the manner in which adults adapt to life and in particular the role of defense mechanisms, a psychoanalytic concept for processes used unconsciously to deal with anxiety. He proposed six levels of defense mechanism, with the highest adaptive level being altruism; the highest adaptive level involves participation in society and care for others. It is in the maturity of the ego defenses that Vaillant's work can be seen as a stage theory. Successively less mature defenses include repression, omnipotence, denial, autistic fantasy, and help-rejecting complaining. The least mature level deals with stress by requesting help and then rejecting offers of assistance. Autistic fantasy involves image distortion, typified by daydreaming instead of taking action. Denial involves the disavowal or refusal to act or to acknowledge personal hurt. The omnipotence level involves minor image distortion by emphasizing one's special attributes. Repression reflects mental inhibition and dealing with stress by expelling thoughts and desires from conscious

awareness. From data collected through a series of longitudinal studies that are still ongoing, he was able to demonstrate the stability of individual personality characteristics over a 45-year period of time. Examples include the prediction of income during work life by extraversion scores obtained 45 years earlier.

A somewhat different stage model was developed by Harry Stack Sullivan (1953) who proposed seven developmental epochs, six of which occurred prior to adulthood. Sullivan proposed stage transitions in terms of psychological development rather than of the biological factors favored by most stage theorists working from a psychoanalytic perspective. Unlike many stage theorists, Sullivan felt that the majority of adults did not achieve the most advanced stage of development. Like that of Erikson, Sullivan's model has never been formally discredited by convincing empirical evidence but has fallen from prominence in recent years as other models have increased in popularity. Sullivan's focus on interpersonal relationships has, however, retained its utility into the present (Noller et al. 2001).

Ego and Moral Developmental Theories

Also classed as a stage theory, the work of Loevinger (1976) on ego development also is based upon psychoanalytic thinking. From this perspective with the dominance of the ego in adult life, viewing ego development as part of an individual's personality is relatively straightforward. Extending Erikson's model, Loevinger proposed eight stages of ego development with the last six stages occurring during adult life. At each stage, four areas are essential for the development of personality: character development, interpersonal style, conscious preoccupations, and cognitive style. The six stages of adult development proposed by Loevinger comprise conformist, conscientious-conformist, conscientious, individualistic, autonomous, and integrated. Most American adults operate at the second of these stages, conscientious-conformist. Relatively few adults achieve the level of the integrated stage, fewer

than 1% by one estimate (Cook-Greuter 1994) and between 2% and 3% by another report (Heaton 2011). Unlike the majority of stage personality theorists, Loevinger's theory relies upon evidence derived from an empirical source, the Washington University Sentence Completion Test, to evaluate the level of ego development, which provides stronger support for this approach than perhaps for older models of personality development that rely upon stages.

A related theory to those in the domain of personality is the stage theory of moral development proposed by Kohlberg (1981). For some, moral development is outside the domain of personality, while for others with a broader perspective, moral development is closely related to ego development and can be included among stage theories of personality. A feature of this theory is that a distinction is made between the form of thinking (the topic of thought) and the content of thinking (why one thinks that way). The reasoning behind the behavior is the important element. Moral development is typically assessed by a procedure in which the participant responds to a series of hypothetical moral dilemmas. In each one, different principles are in conflict. Based on responses to such dilemmas, three basic levels of moral development were developed, each of which can be divided into two further stages, resulting in six levels or stages in all. These stages are preconventional (punishment and obedience orientation and naïve hedonism), conventional morality (good-person orientation, social order maintenance orientation), and postconventional morality (social contracts and individual principles of conscience orientation). Kohlberg speculated about a seventh stage, unity orientation (confrontation with death), that developed in the second half of life (Kohlberg et al. 1983). The model has been a popular topic of research, and much of the research supports the general progression that is a fundamental aspect of the theory. In addition, the theoretical stages appear to occur in the proposed fixed order and in the proposed sequence, and that sequence appears to be widespread across different groups and cultures, something not always evident (Gardner and Macky 2012; Heaton 2011).

Summary

Stage theories of personality have an intuitive appeal. They simplify complex phenomena into discrete categories that are substantially easier to understand than the complexities of continuous development. At the same time, it must be recognized that human development does not involve the dramatic stages of development that are seen in nature. No human experiences the changes equivalent to those seen from caterpillar to pupa to butterfly that undoubtedly are clear and distinct stages of development. Human development is basically continuous with occasional major events, such as the sudden death of a loved one, that force changes. It would appear that in most cases stage theories arise from the imposition of artificial transitions upon a continuous process. Most stage theories are silent upon the issue of the necessary processes (see Connors and Richards 2002 for an example of a model of stage transitions). Conditions for transition from one stage to another and whether the same processes operate across all transitions or if different ones are involved at different stages are rarely, if ever, specified.

As with several other theories of personality development, the reliance upon psychoanalytic thinking about personality and its development by many theorists discussed here poses some difficulties with the decline in credibility and acceptance of much psychoanalytic thought. It cannot be denied that biological and social influences impose constraints upon possible developmental sequences and enforce others. Whether the human imposition of a limited number of categorical labels on a fundamentally continuous process advances scientific progress is arguable.

Narrow theories, such as Kohlberg's on moral development, are more likely to have stronger empirical support than very broad conceptualizations of human development in general. While Erikson's theory has broad appeal and substantial empirical support, it is relatively silent upon what is necessary for the progression from one stage to another and whether such processes remain constant across all stages.

While research on stage theories continues, it is clear that trait theories have become more popular over time while the popularity of research on stage theories has become notably less prominent. In part this may be due to most such stage theories ultimately being based upon psychoanalytic theory, and their decline in popularity may arise from their association with psychoanalysis rather than any inherent flaw of their own.

Definition

Stereotype threat is the concern that others are evaluating you through the lens of negative group-based stereotypes (Steele 1997). Over the past two decades, hundreds of laboratory studies

have demonstrated that stereotype threat disrupts performance when people attempt difficult tasks in domains in which they are negatively stereotyped, such as women in math and African Americans in academics (Nguyen and Ryan 2008). It has been over a decade since this research was extended to older adults. Here too the accumulated research evidence demonstrates that older adults are susceptible to the performance-impairing effects of stereotype threat (Abrams et al. 2006). Although the majority of stereotype threat research has examined performance decrements, a smaller body of research demonstrates stereotype threat can lead people to disengage from domains in which they feel stereotyped. Although every job involves being judged by other people, employees from negatively stereotyped groups such as older workers have the added concern of being judged on the basis of stereotypes about their group. Importantly, it is not necessary for people to believe the stereotype is true of their group to experience stereotype threat, nor is it necessary that they believe that the stereotype describes themselves. Stereotype threat effects emerge when people worry that others *might* evaluate them on the basis of the stereotype. This entry discusses the concept of stereotype threat and its relevance for older employees and the organizations who employ them.

Stereotyping and the Aging Workforce

Over the next few decades, the aging demographic will pose major challenges in the workforce in most industrialized nations. These developments have led policy makers and organizations to try to retain older employees for as long as possible. For example, in Australia the predicted labor shortage and pension burden have prompted the government to introduce financial incentives to delay retirement, with the pension age increasing to 70 years by 2035. While government inducements are undoubtedly important in helping to retain older employees, it is equally important to examine the

psychological factors that may affect well-being in the workplace and, ultimately, retirement decisions.

There are numerous stereotypes about older employees, and thus stereotype threat is a psychological factor that seems likely to be of particular importance. While some of these stereotypes are positive perceptions that reflect perceived gains in “wisdom,” more common are negative perceptions that emphasize reductions in “wit.” Older adults are often stereotyped as inflexible, frail, incompetent, out of touch, and slow, and consequently it comes as no surprise that older employees are susceptible to stereotype threat.

In the first demonstration of stereotype threat in late adulthood, older adults who were told that age leads to poorer memory performance did worse on a memory test than those who were told that older adults often perform just as well as younger adults (Hess et al. 2003). One reason stereotype threat disrupts older adults’ performance is that it consumes their working memory resources (Mazerolle et al. 2012). Interestingly, performance deficits under conditions of stereotype threat are more pronounced among the young-old (i.e., 60–70 years) than the old-old (71–82 years) and among those with higher levels of education (Hess et al. 2009). There is now more than a decade of accumulated research on aging and stereotype threat, and a recent meta-analysis revealed that these performance decrements emerged across a range of cognitive domains (e.g., memory and arithmetic) as well as physical tasks (e.g., flexibility and driving performance) (Abrams et al. 2006).

Stereotype Threat and Mature-Age Workers

Age-related stereotypes also exist about older workers: Although research has consistently demonstrated that workers’ age is generally unrelated to job performance (Ng and Feldman 2008), many people continue to hold negative opinions about older workers. Research has demonstrated that younger workers rate older workers as having lower job qualifications and less potential for

development. Older workers are also viewed as less productive, less flexible, and less willing to learn than their younger counterparts (Posthuma and Campion 2009). In short, stereotypes relating to older employees are consistently negative and generalize across most occupational settings. Although industries such as law and academia tend to value older employees for their experience and connections, in most vocational settings older employees report feeling that they have been put out to pasture and believe that their younger counterparts are given more training opportunities and are more likely to be assigned to high visibility projects. For all of these reasons, older workers are likely to experience stereotype threat, as they have good reason to worry that their colleagues are evaluating them on the basis of the “older worker” stereotype.

Beyond Performance Decrements

In the original theoretical description of stereotype threat, Steele (1997) described two types of consequences. First, he proposed that acute experiences of stereotype threat would lead to performance deficits, and this consequence is now well documented in laboratory studies (although this line of research has not been extended into the workplace yet). In contrast, the other consequence proposed by Steele has received much less attention. Specifically, Steele also suggested that chronic experiences of stereotype threat should lead people to disengage from the stereotyped domain over time. This possibility is of great potential importance for both organizations and older employees, as disengagement from work and the organization is associated with a variety of negative job attitudes (e.g., lowered job satisfaction) and greater intentions to quit.

To examine the relationship between stereotype threat and disengagement, job attitudes and turnover intentions were assessed among employees aged 50 or older in Australia and the USA (von Hippel et al. 2013). Across three diverse samples (i.e., traditional office environment, law enforcement, and a general internet survey), older employees who experienced

stereotype threat at work were less satisfied with their jobs, were less committed to their employer, and reported more work-related mental health problems. Negative job attitudes are important variables in their own right, but reduced job satisfaction and commitment are also associated with increased intentions to resign and retire. And thus it is not surprising that negative job attitudes were related to an increased interest in resigning and retiring among older employees. Interestingly, older employees who occupied higher status positions within their organizational hierarchy experienced less stereotype threat than their lower status counterparts, suggesting that not all older employees are equally susceptible to stereotype threat.

Negative workplace attitudes have been shown to impact performance, leading people to be less productive. If older employees who experience stereotype threat also show performance decrements (as seems likely given the robust effects of stereotype threat on cognitive performance in controlled lab-based studies), it could lead their colleagues to believe that stereotypes about older employees are true. Poignantly, the end result is a self-fulfilling prophecy and a self-perpetuating cycle of stereotype threat which has negative consequences both for the older worker and the organizations who employ them.

The Ubiquity and Subtlety of Stereotype Threat in Everyday Life

Stereotype threat is something that nearly everyone will experience at one time or another. For example, when a female driver makes a mistake and another driver beeps his horn, she may have a niggling feeling that the male driver attributed her driving mistake to the fact that she is a woman. These same feelings can arise for older employees in the workplace. For example, if older employees' recommendations are passed over in favor of suggestions put forward by younger colleagues, they may worry that age was a factor in this decision. It is these types of subtle experiences in the workplace that can make people wonder whether they *might* be being evaluated

on the basis of stereotypes about their group. Consider these comments made by older employees who reported sometimes feeling stereotyped at work based on their age:

Because I am now older than many of our clients, I get the impression it is felt that I no longer am 'in touch' with the clients, despite the fact my specialist knowledge means I have a good understanding of my area. Because my organisation is 'innovative', 'cutting edge' and encouraging of new ideas, it is sometimes assumed anyone over 40 won't have any ideas worth listening to. Or am I just old and paranoid and idealess?

I sometimes feel that I am invisible because of my age (at work). I have difficulty at times with getting people to include me and listen to me.

I believe that perceptions around my age tend to exclude me from the mentoring program and leadership development. Due to now being an 'empty nester' I have more than ample time to commit to my work – but I think that because of my age, I am not utilised enough.

I feel very comfortable in my position but I think that people sometimes view my age as a burden, especially young people that think you are too old to be working and that they should have all the opportunities over older workers.

In none of these examples is it clear that the subjective experiences these employees described reflect actual stereotyping on the part of their colleagues. Rather, it is their concern of being stereotyped that constitutes stereotype threat. These examples illustrate that overt discrimination is not necessary for older employees to feel stereotype threat. Rather, subtle events can occur in the workplace that make people wonder whether they *might* be being evaluated on the basis of stereotypes about their group. For example, a technologically capable older employee may worry that his preference for a paper diary will confirm the stereotype that older employees are less willing to learn new technologies, and that he will be judged as less technically skilled or valuable as a result. It is also important to note that the accuracy of the stereotype (about oneself or the target group in general) is irrelevant to whether people experience stereotype threat. Indeed laboratory research often reveals that it is the exceptionally talented members of the stereotyped group (e.g., female math majors at top ranked universities) who are most susceptible to stereotype threat.

Many workplaces are replete with reminders that certain groups are devalued, such as a small proportion of minorities or women in the upper echelons of the organization. For older employees, these reminders may even be well intentioned. For example, offers of help by younger employees to their older counterparts (e.g., to carry a heavy or unwieldy object or to help unjam the photocopier) may be interpreted as a sign of being stereotyped. Other cues may not be as well intentioned, such as patronizing tones or social exclusion – cues that appear in the earlier quotes from older employees who experienced stereotype threat. Regardless of the specific reminders, workplaces that contain many such cues are likely to lead to chronic feelings of stereotype threat for older employees. Under situations such as these, employees may experience stereotype threat from the moment they walk in the office door each morning until they leave at the end of the day. The end result would be the stringing together of a series of acute events into a chronically aversive state. It is easy to imagine how a situation such as this could lead to work-related mental health problems and ultimately premature retirement.

What Can Be Done?

The experience of stereotype threat at work may counteract efforts to retain older employees in the workforce. As a consequence, it is important to take action to neutralize stereotype threat in the workplace to avoid the unnecessary loss of older workers as well as to increase workers' satisfaction and well-being. Unfortunately, despite hundreds of studies documenting the negative effects of stereotype threat, there is far less known about the best ways to counteract the negative consequences and minimize experiences of stereotype threat. Although research will be necessary to determine the best approach, suggestions are provided based on previous research.

Organizations may be well served by making a concerted effort to promote *positive stereotypes of older employees*, which may help to counteract the existing negative stereotypes. Positive stereotypes of older employees focus on their

experience, wisdom, dependability, and conscientiousness and have had demonstrable positive effects on older adults' performance in previous research (Levy and Leifheit-Limson 2009). It may also be possible to address stereotype threat by *increasing positive intergenerational contact*. Laboratory research demonstrates that declines in cognitive performance after stereotype threat disappear when older adults experience positive intergenerational contact (e.g., quality of contact with people 35 years or younger during the week before the testing session) (Abrams et al. 2006). *Offering training and development* to older adults can make them feel more valued and less like they are being left behind by the organization. Older workers often feel they are missing out on training that younger workers receive, which is particularly problematic when the training is viewed as important to job performance. Finally, research suggests that *self-affirmation* may help diminish the negative consequences of stereotype threat (Cohen et al. 2006). Self-affirmation involves reflecting on one's important achievements, values, or traits. This kind of intervention would be easy to implement on both a personal and an organizational level and would not be resource intensive.

Conclusions

Most jobs involve being judged by peers, supervisors, or customers, yet older employees have the added concern of being judged on the basis of their age. It is the awareness that others may evaluate you through the lens of negative stereotypes that triggers stereotype threat, regardless of whether people believe the stereotype to be true of themselves. Given the prevalence of age-based stereotypes, it is likely that many older employees experience stereotype threat at least occasionally. Thus, although it is commonplace to experience evaluation apprehension when being judged, stereotype threat can result in additional concerns for older employees. It is therefore important for stereotype threat research to be extended into organizational settings more broadly, as the existing data suggest that stereotype threat is a concern for

organizations who desire to retain their older talent and help them reach their potential.

Strength and Vulnerability Integration

Susan T. Charles and Joanna Hong
Department of Psychology and Social Behavior,
University of California, Irvine, CA, USA

Synonyms

Aging and Psychological Well-Being; Mental Health and Aging; Emotional Development in Old Age

Definition

Strength and vulnerability integration (SAVI) is a theoretical model that describes how emotional experience varies across the adult life-span. According to SAVI, older age is related to greater use of emotion regulation strategies and a stronger focus on emotional well-being. As a result, older adults often report even higher levels of well-being than do younger adults. At the same time, however, age-related increases in physical vulnerabilities pose greater problems for older adults when regulating high levels of emotional arousal. Thus, when people can employ emotion regulation strategies to avoid negative experiences, they are more successful than younger adults. When they are unsuccessful at avoiding highly negative experiences that elicit high levels of arousal, however, SAVI predicts that older adults will have more difficulties modulating this experience (Charles 2010). SAVI was formed to explain the patterns of emotional well-being observed in the literature and builds on the work described in other models and theories in psychology and aging (Carstensen et al. 1999).

An Overview of the Three Main Tenets of SAVI

SAVI focuses on three overarching factors that determine age differences in emotional experience: (1) strengths of aging, (2) vulnerabilities or aging, and (3) current circumstances. The first component includes the thoughts and behaviors that influence how people experience and regulate their emotions. As people age, they increasingly engage in thoughts and behaviors that lead to more positive and fewer negative emotional experiences (Carstensen and Mikels 2005). Older age is related to greater frequency and ability to engage in these processes, so these processes are labeled in SAVI as strengths of aging. Despite these strengths, physiological changes occur with age that may challenge a person's ability to regulate high levels of emotional arousal. Throughout childhood, across adolescence and into adulthood, physiological systems develop that are critical for responding effectively to situations of high-emotional intensity. Across middle age and into late life, however, these physiological systems often experience decline. Physiological changes, then, serve as vulnerability factors for many older adults when regulating emotions that elicit high levels of arousal. The third component encompasses current life circumstances. This context determines the extent to which people can and do employ cognitive and behavioral emotion regulation skills effectively and the extent to which age-related vulnerabilities influence emotional experience. By assessing the demands of the situation, researchers can integrate information about the use of strengths and the impact of vulnerabilities to understand patterns of age differences in emotional experience. Below we discuss each of these components in detail, and how their interplay allows us to predict how emotional experience may vary across adulthood.

Strengths of Aging

Researchers have long documented the powerful role that thoughts and behaviors have on our emotional experiences. People experience less

negative affect (or emotional feelings) and more positive ones when they select environments that are more positive and less negative, focus their attention on more positive and less negative aspects of the environment they are in, appraise situations more positively and less negatively, and engage in actions that remove themselves from negative situations (Gross 1998). In multiple studies, researchers find that older adults engage in these processes more often than younger adults (Charles and Carstensen 2014). When exposed to negative, neutral, and positive emotional faces, older adults are more likely to focus on the picture showing more positive and least negative expression. When asked to interpret situations in their lives or when interpreting stimuli in the laboratory, older adults often appraise them more positively and less negatively than do younger adults. Finally, when asked to recall what they have seen in the laboratory or events from their lives, older adults often recall more positive and fewer negative aspects than do younger adults.

SAVI further includes the proposition that these strengths of aging are the result of how people perceive time, both time left in their own lives and the time that they have already experienced. This time perspective results in older adults having greater motivation to regulate their emotions (as described by socioemotional selectivity theory). Time lived also provides them with greater expertise to achieve their motivational goals. The importance of time left in life is taken directly from socioemotional selectivity theory, a theory that describes the importance of time perspective on emotional experience and its influence across people of all ages across the life-span (see entry for ► [Socioemotional Selectivity Theory](#)). This theory posits that as time left in life grows shorter, people increasingly prioritize emotion-regulated goals. Older adults, then, prioritize emotion-related goals more so than younger adults (Carstensen et al. 1999).

People are motivated to regulate their emotions given the time left in life, but researchers have also discussed the importance of time lived to explain why older adults often report similar, if not higher, levels of well-being than do younger adults (Blanchard-Fields 2007). Researchers have

posited that throughout years of practice and recognizing the situations that cause them the most distress, people have gained information that allows them to identify and avoid certain negative situations. For example, studies examining social expertise often find that older adults are better at knowing when to disengage from a contentious argument (Blanchard-Fields et al. 2007). Older adults prefer to back away from potentially negative situations, recommend these strategies to others, and report that doing so leads to better outcomes in their own lives. Together, the awareness that time left to live is growing shorter increases people's motivations to maintain enhanced well-being, and the past experiences from time lived provides them with information and knowledge to engage in thoughts and behaviors that enable them to achieve their goals.

Vulnerabilities of Aging

Across middle age and into late life, people often experience declines in biological and physiological processes. These declines can occur as a consequence of primary aging (genetically programmed biological declines) or from secondary aging (decline resulting from accumulated assaults from exposure or behavior). Secondary aging processes, although related to age, are not caused by biological aging, per se. For example, age is related to decreases in physical activity, and lack of exercise has been correlated with physical decline. Regardless of the source of decline, however, these age-related changes often result in a physiological system that is less flexible. SAVI posits that declines in flexibility will make both rapid responding to and recovering from high-intensity emotional situations more difficult with age.

High-intensity emotional experiences produce a cascade of physiological processes that influence both central and peripheral activity. Researchers have started examining age differences in the association between emotions and biomarkers, defined as physiological indices that often correlate with or predict worse health outcomes. For example, a review of studies has

examined cardiovascular reactivity to stressful experiences that occurred both in daily life and in the laboratory (Uchino et al. 2010). This review found that although older adults show less pronounced increases in heart rate – most likely the result of slower vagal withdrawal in response to the situation – their blood pressure was more reactive to emotional stressors than that of the younger adults.

In studies examining cortisol levels, the hormone biomarker related to stress, people with chronically high levels of negative affect have higher levels of cortisol compared to those with lower levels of negative affect. One study found, however, that the association between chronically high levels of negative affect and high levels of cortisol is greater among older adults than younger adults (Piazza et al. 2013). Specifically, the association between negative affect and cortisol levels was not significant among younger adults; only among people who were in their mid-fifties and older did overall higher levels of negative affect correlate with higher levels of cortisol. A similar age-related pattern is observed when examining the association between trait-like anger expression and metabolic syndrome (Boylan and Ryff 2015). The metabolic syndrome is a medical condition comprised of high levels of triglycerides, cholesterol, blood pressure, and glucose that predispose people to type II diabetes and other problematic health conditions. High levels of anger expression were related to metabolic syndrome among the oldest adults in the sample; levels or greater anger did not predict worse health among the younger adults who were in their mid-30s, 40s, and early 50s.

Integrating Current Circumstances

SAVI posits that by integrating knowledge about the strengths and the vulnerabilities of aging into the context of current circumstances, researchers can predict when older adults will exhibit higher levels of emotional well-being than younger adults, and when older age does not confer an advantage for emotion regulation or well-being. Specifically, in situations where people have the

time and opportunity to engage in strategies that allow them to avoid or mitigate exposure to negative experiences, older adults generally report higher levels of well-being than younger adults. This higher level of well-being reflects not only their actions but also circumstances that allow them to avoid negative situations more often than their younger counterparts. For example, when examining people in relatively good physical health whose financial situation supports their needs, older age is related to exposure to fewer daily stressors. Researchers posit that this reduction in daily stress is partly due to the benefits of retirement and no longer having children living in the house. In addition, however, this reduction is hypothesized to stem from older adults navigating their social environment to avoid potentially unpleasant experiences. When people are exposed to negative social situations, older adults more frequently opt to disengage from these situations by walking away or choosing not to continue the debate, whereas younger adults report continuing with the argument (Luong et al. 2010). These strategies are posited to explain why, when asked to think about life in general or the emotions that they have experienced in the past month, older adults are more likely to report more positive and less negative emotions. Older adults often report high levels of positive emotions in their daily lives, but studies suggest that their memories are even more biased toward positive emotions than their actual experiences and more positive and less negative than the memories of younger adults, as described by socioemotional selectivity theory (Reed and Carstensen 2012). Thus, in circumstances where people are given the time to either avoid negative situations or disengage from them quickly or when given the time to think back on their life and make general appraisals about their situations, older adults often report more positive and less negative emotional experiences than those of younger adults.

The avoidance of distressing situations, however, is not always possible. When confronted with an unavoidable negative situation, people experience high levels of distress and high levels of physiological arousal. At these times, SAVI predicts that older age will no longer confer

benefits to emotional well-being. When people cannot engage in thoughts and behaviors that allow them to avoid negative, highly arousing situations, they cannot benefit from these age-related strengths. At the same time, age-related changes in physiological processes are posited to make downregulating physiological arousal more difficult. Thus, when exposed to an inescapable, unavoidable distressing event where they are unable to use emotion regulation skills, older adults are not posited to show improved reactivity and recovery compared to younger adults. Studies have found, for example, that when faced with multiple stressors from different life domains, older adults report greater cardiovascular and self-reported emotional reactivity than do younger adults (Wrzus et al. 2013). In other studies, researchers have found that when adults report having avoided an otherwise negative social interaction, older adults report less reactivity to this mildly distressing event than do younger adults. When they actually engage in these events, however, older adults report similar if not higher reactivity than younger adults (Birditt 2014).

Stressful situations are unavoidable at all ages, but some types of stressful situations that are inescapable and prolonged increase in prevalence with age. These include living with a chronic condition with unremitting and unpredictable symptoms; caregiving for a spouse with a dementia where the course is sometimes unpredictable and the prognosis is bleak; losing people in your close social circle that provide a sense of belonging and security; having a disease that causes cognitive impairment so that engaging in thoughts and behaviors for emotion regulation purposes becomes more difficult; or facing a terminal illness and the decline in functioning that is often-experienced. These are negative events that can happen throughout the life-span, but often increase in prevalence with age. For people experiencing these unavoidable situations that are associated with high levels of distress and emotional arousal, SAVI predicts that age advantages are attenuated, if not completely absent. For people who are placed in chronically stressful circumstances, emotional well-being will decrease over time.

Conclusion

SAVI is a theoretical model positing that across adulthood, an increasing awareness that time is growing shorter and a lifetime of experience provides people with the information and the motivation to engage in thoughts and behaviors that benefit emotional experience. This has been used to explain why many older adults report higher levels of happiness and lower levels of negative distress than their younger counterparts. When faced with unavoidable situations that elicit prolonged physiological arousal, however, older adults will have a harder time modulating their response. The importance of current circumstances is vital, then, to predict emotional well-being and particularly age differences in well-being across adulthood.

Definition

Providing care to someone in need is usually a lasting situation associated with multiple demands, responsibilities, tasks, and events that have an impact on caregivers' life. All these conditions are considered stressors, as they have the potential to challenge the homeostasis of the caregivers. The degree to which the stressors impact on caregivers' life depends, among other variables, on the way caregivers respond, manage, or act to resolve the challenges associated with caregiving, that is, it depends on the caregivers' coping strategies. The complexities associated with caregiving have led to the development of theoretical models aimed to understand the processes that generate stress on caregivers, in which caregivers' coping strategies play a major role.

Introduction

Caregiving for an older adult dependent relative, especially those with dementia, is a highly demanding task. Caregivers often devote many years and many hours per day to looking after dependent family members, trying to cope with a wide variety of demands (supervision; behavioral and psychological symptoms in the care recipient; adjustments to one's personal, family, work, and financial circumstances; and so on). The often lengthy period over which caregivers are required to carry out the associated tasks makes it easy to understand why caregiving is considered a prototypical example of chronic stress (Vitaliano et al. 2004) and a natural experiment of extreme stress (Robinson-Whelen et al. 2001). Given the relationship between stress and health, it is not surprising that the majority of research carried out with caregiver populations relate caring for dependent persons with psychological and physical health problems in the caregiver (Pinquart and Sörensen 2003).

As early as the late 1980s it was suggested that the chronic stress to which family caregivers of persons with dementia are subjected had negative effects on the psychological and immunological adaptation of the caregivers (Kiecolt-Glaser

et al. 1987), a finding that would appear to be confirmed by longitudinal studies (Mausbach et al. 2008). Such circumstances may contribute to explaining the results obtained by Schulz and Beach (1999), who found that caregivers subjected to stress are at 63% more risk of death than noncaregivers and caregivers not experiencing strain. Nevertheless, despite the fact that many people experience negative consequences associated with caregiving, these vary from caregiver to caregiver, and some even report positive consequences. Thus, for example, Brown et al. (2009) reported that devoting at least 14 h per week to care was associated with reduced risk of death, suggesting the importance of considering the different psychosocial processes (e.g., coping) that characterize the task of providing care.

The recurrent observation that caregiving does not always affect people subject to similar demands in the same way has led to the development of theoretical models for explaining stress and coping in caregivers, models that try to account for the variability in the consequences of this process in this population. The variety of the models themselves reveals that caregiver stress is a complex and multi-causal phenomenon. Below are presented the principal theoretical models on stress among caregivers. The resulting classification of these models is intended to serve as a heuristic that facilitates a global understanding of the different factors that might be involved in the development and maintenance of caregiver stress. This classification does not pretend to be exhaustive, as there may be other conceptualizations of stress apart from those included here; nor should it be considered exclusive, since the models presented are compatible, and largely complementary.

Models with Major Emphasis on Research

Stress and Coping Models

Stress and coping models propose that the effect of stressors on outcomes (e.g., physical or mental health) varies between caregivers depending on variables such as coping or social support.

Perhaps the most widely accepted and influential theoretical models in the field of stress among caregivers of dependent older adults are Lazarus and Folkman's (1984) Transactional Model of Stress and Coping, adapted to caregiving (Haley et al. 1987), and the Stress Process Model (Pearlin et al. 1990). The two models are essentially similar and highlight the crucial role of people in the stress process, describing factors that mediate between stressors due to caregiving and the consequences of the caregiving for the care providers. Although there are arguments suggesting that looking after dependent persons means that difficult or stressful situations are maintained or accumulate, or even increase in their intensity and frequency over the course of the caring process (wear and tear model (Townsend et al. 1989)), the reality is that there also occur phenomena of adaptation to caregiving, and even improvements in distress levels associated with the effects of variables such as personal mastery (Mausbach et al. 2007a). Adaptation to the caregiver role can occur through the combined effect of the set of factors or dimensions involved in the process.

Stress and coping models identify first of all background and contextual variables such as caregivers' age, sex, kinship (to the care-recipient), or socioeconomic status. Caregiving processes and consequences have been found to vary depending on the sex or kinship of the caregiver (Romero-Moreno et al. 2014a). Second, these models recognize the importance of the stressors themselves, and most of the models differentiate between objective and subjective stress. Although there is no definitive way of distinguishing clearly between objective and subjective stressors, there does appear to be some degree of consensus that among the principal stressors facing caregivers are the behavioral and psychological symptoms associated with dementia (e.g., agitation or repetitive verbalizations). Behavioral and psychological symptoms of dementia or cognitive and functional status of the care-recipient are usually considered objective stressors. These symptoms are a main source of distress for caregivers and contribute significantly to the decision to institutionalize the care-recipient in a nursing home. But not all the behavioral and psychological

symptoms of dementia generate the same levels of distress. In fact, research findings suggest that the most common symptoms (e.g., memory problems) are not those associated with higher distress levels; on the contrary, disruptive behaviors (e.g., verbal aggression), the least frequent, actually cause the greatest distress (Fauth and Gibbons 2014). The scientific literature suggests the use of interventions such as behavior management as evidence-based therapies for reducing behavioral problems in care-recipients and that a reduction in stressful events is, in turn, associated with reductions in caregiver distress (Logsdon et al. 2007).

Pearlin et al. (1990) make a distinction between primary and secondary stressors. Primary stressors have to do with the needs and demands of the care-recipient (e.g., behavioral and psychological symptoms of dementia) and how these are satisfied by the caregiver. The effects of primary stressors on other areas, such as family or economy, are considered secondary stressors. Caregivers' appraisals of the stressors may generate the experience of burden or other feelings indicative of subjective stress, but they may also generate positive feelings such as finding meaning, fulfillment, or love.

The main contribution of the stress and coping models is the recognition that several variables may mediate between, on the one hand, caregivers' stressors and appraisals and, on the other, their psychological or physical health consequences. Social support, coping, and self-efficacy are some of the most widely studied mediators. These variables buffer the effects of the stressors on caregivers' distress and, as such, represent areas that are potential targets of interventions aimed at increasing caregivers' perceptions of mastery or self-efficacy for coping with care.

The last dimension identified by the stress and coping models is that referring to outcomes or consequences. Usually, these are classified in terms of psychological or physical consequences of caregiving, but others including time until institutionalization or family conflicts arising during the caregiving could be considered to fall into this dimension. Research findings are consistent in showing that caregivers, especially if the care-recipient has dementia, present more negative

mental and physical consequences, including those related to physiological health (Pinquart and Sørensen 2003). Although findings from longitudinal analysis, mostly analyzing depressive symptomatology, suggest no reduction in caregiving consequences over time, other studies have found an increase in risk factors for health problems (e.g., cardiovascular health) in caregivers (Shaw et al. 1999). In addition, caregivers' mood state seems to modulate physiological responses (Leggett et al. 2015), increasing the risk for developing physical health problems (Mausbach et al. 2007b).

Even though, as has been mentioned, several dimensions are included in the stress and coping models, feedback loops may be found between these dimensions or variables. For example, the use of maladaptive coping strategies for dealing with caregiving may increase the sources of stress or their intensity; a decline in physical or mental health may increase the appraisal of behavioral and psychological symptoms of dementia as stressful. Intervention studies have shown positive effects of interventions on variables such as caregivers' depression and delaying nursing home placement (Pinquart and Sørensen 2006). It is important to note that there is a general trend to identify caregiving with negative consequences (e.g., depression or anxiety). However, research has also shown that caregiving may be associated with positive aspects or outcomes for the caregiver, some studies reporting that up to 73% of caregivers identify one or more positive aspects related to caregiving (Cohen et al. 2002).

Sociocultural Stress and Coping Model

Although the Sociocultural Stress and Coping Model (Aranda and Knight 1997; Knight and Sayegh 2010) is an extension of the stress and coping models already mentioned, it is considered relevant to highlight it individually given the extensive research carried out showing the influence on the stress process of social and cultural variables, such as race, familism, or the cultural reasons why caregiving takes place (Pinquart and Sørensen 2005). According to this model (Knight and Sayegh 2010), there exists a common core model for different ethnic groups including

stressors and how these are appraised by caregivers, with higher appraisals of burden generating more negative psychological and physical health consequences. Ethnicity and/or cultural values seem to have an important influence on mediator variables such as use of coping strategies or social support. For example, cultural groups with a strong reliance on the family may perceive higher levels of social support than other groups that do not share a salient value of the importance of the family. However, it is also possible to find dark sides of the role of the family in the caregiving process, as perceiving the obligation to care and not seeking help outside the family due to culturally transmitted norms may contribute to caregivers' distress by reducing their chances of using adaptive coping strategies for such a demanding task (Losada et al. 2010). The inclusion of sociocultural variables in studies aimed at understanding caregiver distress is also necessary in order to develop interventions sensitive to the cultural values of specific groups of caregivers that may increase both their interest in participating in the intervention and the likelihood of strengthening the effects of these interventions for improving their quality of life (Gallagher-Thompson et al. 2003a).

Vulnerability or Diathesis Models

A substantial part of the explanation why caregiving is associated with negative consequences focuses on variables previous to the caregiving. Diathesis-stress models propose that negative consequences associated with caregiving result from a combination of prior vulnerability in the carer (personality factors, emotional disorders, etc.) and the stressful event that is caregiving. In this line, some studies show how people with a history of psychiatric disorders prior to caregiving were more likely to experience a recurrence of psychiatric problems after the onset of the care-recipient's illness, as compared to a control group (Russo et al. 1995). A study by Peter Vitaliano and colleagues (2014) shows that caregivers' distress could be partially explained through exposure to caregiving-related, genetic, and environmental factors (e.g., developmental history). Joling et al. (2015) provide longitudinal support for the

fact that predictors of caregivers' anxiety and depressive disorders are not characteristics of the care-recipient (e.g., neuropsychiatric symptoms) but rather of caregivers' mental and physical health at baseline. Personality dimensions, such as neuroticism or optimism, may also act as predisposing variables that can increase or reduce caregivers' chances of suffering distress (Hooker et al. 1998).

Life Events Models

Caregiver stress can be the result of having to cope with major life changes or life events. Caring for dependent persons, especially those with dementia, involves coping with numerous potentially stressful life events, several of which can pose a threat to caregivers through the stress process. The moment of receiving a diagnosis, institutionalizing the care-recipient in a nursing home, or the death of the relative are some of the most distressing events that caregivers can experience. However, research on mental and physical health consequences once care-recipients are institutionalized in nursing homes or caregiving ends due to the death of the care-recipient is not conclusive, with mixed findings having been reported (Knight and Losada 2011). Distress reductions may be explained through reduction in the number of demands or exposure to stressors (e.g., behavioral and psychological symptoms of dementia) associated with the institutionalization of the care-recipient, while increase or maintenance of symptoms may be associated with factors such as feelings of guilt or increase in financial strains associated with institutionalization or unexpected death of the relative (Knight and Losada 2011).

Models with Major Emphasis on Interventions

Behavioral Models

Behavioral models such as the one developed by Peter Lewinsohn and collaborators (1974) highlight the importance that pleasant activities or leisure have on well-being, by increasing the number of positive experiences (positive reinforcers). Research has shown that engaging in

pleasurable activities reduces caregivers' feelings of depression and chronic stress (Thompson et al. 2002). In contrast, a reduction in the number of pleasant activities or an increase in the number of aversive activities (punishment rates) contributes to distress. As already mentioned, caregiving generates many demands for caregivers, and this means a restriction in the number of activities they get to do. Nieboer and colleagues (1998) developed a model for explaining changes in depression over time, testing the role of activity restriction in this process. Through this model they confirmed that the demands associated with caregiving bring about disruptions in caregivers' life activities, increasing their depressive symptomatology (Nieboer et al. 1998). High levels of activity restriction may also increase cardiovascular risk in caregivers (Ho et al. 2014).

Mausbach and colleagues (2011) have developed a model that considers together the effect of pleasant activities and activity restriction: the Pleasant Events and Activity Restriction (PEAR) Model. According to these authors, the combination of the two dimensions permits better detection of psychological distress than considering them alone. They found that caregivers who reported low frequency of pleasant events and high activity restriction were those who reported higher levels of distress and use of negative coping strategies, as well as lower personal mastery and self-efficacy for obtaining support. Empirical support for behavioral models based on pleasant activities and activity restriction has also been obtained through interventions such as the one developed by Dolores Gallagher-Thompson et al. (Gallagher-Thompson and Steffen 1994). More recently an intervention aimed at increasing caregivers' behavioral activation has shown that, compared with a control group, participants in a behavioral activation intervention showed lower cardiovascular risk, as well as lower levels of depressive symptoms at the end of the intervention (Moore et al. 2013).

Cognitive Behavioral Model

Cognitive Behavioral Models (CBT) give a central role in the explanation of distress to people's beliefs or schemata. These beliefs or cognitions

are shaped by life experiences (e.g., cultural or family experiences) and determine the way the person perceives or interprets the world. One's emotional and behavioral responses are guided by one's way of thinking. Even though the literature analyzing the influence of caregivers' thoughts or beliefs is sparse, the available studies seem to support the association between dysfunctional thoughts or irrational beliefs and caregiver distress (Losada et al. 2010; McNaughton et al. 1995). CBT models also consider as central the link between thoughts and behavior. These models share with the behavioral models an endorsement of the importance of activities as a way of increasing the availability of reinforcers in caregivers' lives. However, CBT models consider that in order to promote the performance of pleasant activities by caregivers it is necessary to treat the cognitive barriers that prevent caregivers from doing such activities (Losada et al. 2006). For example, it is not uncommon to find caregivers who believe that asking for help is not a good way to cope with caregiving, because they are the ones that know best how to care. Also, doing pleasant activities without the care-recipient may be considered egoistic, and asking for help from one's children may not be considered an option because "they have their own lives and problems." In this context, CBT interventions include exercises for changing rigid thoughts such as those mentioned as a necessary step for promoting the performance of activities (Gallagher-Thompson et al. 2003b; Losada et al. *in press*). The strongest support for the cognitive behavioral model comes from the intervention literature, CBT interventions having been considered empirically based therapies for reducing caregiver distress (Gallagher-Thompson and Coon 2007).

The Third Wave of Behavioral Therapies

The so-called third wave behavioral therapies includes therapies such as Acceptance and Commitment Therapy (ACT), Mindfulness-Based Cognitive Therapy (MBCT), and Functional Analytic Psychotherapy (FAP). Although they involve clearly different interventions, they share an experiential style and highlight the importance of the context and functions of the problems.

For example, most caregiving intervention research (e.g., on cognitive-behavioral interventions) has addressed the issue of training caregivers in strategies for changing cognitions or behaviors that may increase their chances of coping better with caregiving. However, caring for a relative that has a chronic or deteriorating illness such as Alzheimer's is linked to stressors (e.g., cognitive deterioration), emotions (e.g., sadness), or thoughts (e.g., "why is this happening to me") that are often impossible or very difficult to change. Trying to change, avoid, or control these events may increase caregivers' distress; on the other hand, helping caregivers to accept them may increase their chances of coping in effective ways. Training in acceptance strategies and in commitment to personal values are two of the pillars of ACT interventions (Márquez-González et al. 2010). Interest in these types of therapies has increased enormously in recent years, and although the number of studies in the caregiving field is sparse, research suggests that variables such as experiential avoidance or cognitive fusion contribute to caregiver distress (Romero-Moreno et al. 2014b; Losada et al. 2014; Spira et al. 2007), while interventions involving Mindfulness (Whitebird et al. 2013) or Acceptance and Commitment Therapy (Losada et al. *in press*) seem promising in terms of their positive effects on caregiver distress.

Systemic and Interpersonal Models

There is a general consensus regarding the link between the family and interpersonal relationships in the immediate context and mental health problems reported by caregivers, and theoretical models based on the importance of the family in the caregiving process have been developed (Qualls 2014). Family structure and communication styles may contribute significantly to the generation of distress. For example, expressed emotion by caregivers, a variable that can increase the chances of interpersonal conflict, is predictive of negative care-recipient behaviors such as being uncooperative or angry (Vitaliano et al. 1993). Watching the suffering associated with the physical or cognitive decline of a loved one is also a mechanism through which caregiving generates mental or physical health

effects in the caregiver (Monin et al. 2010). Adequate adaptation of the family to the changes that occur in their life due to caregiving, through the redistribution of roles or improved communication styles, for example, may be crucial to the management of distress (Qualls 2014). Mitrani and colleagues (2006) found that the inclusion of family functioning in a stress process model contributes significantly to the explanation of caregivers' distress: objective caregiving burden effects on distress were mediated by family function. Considering this, it is not surprising to find family-focused intervention therapies aimed at empowering families, balancing burdens of care, or facilitating the restructuring of family members' roles (Monin et al. 2010). The inclusion of other family members in therapy has also been suggested as an important factor in obtaining positive outcomes in caregiving interventions (Mittelman et al. 2004), and evidence has been found suggesting that family therapy (e.g., Structural Ecosystems Therapy) may reduce caregiver distress but should be complemented with technological resources that help such interventions respond to caregivers' individual needs (Eisdorfer et al. 2003).

Conclusions

The main contributions of the reviewed models is that they allow an understanding as to why similar stressful or demanding situations do not generate similar mental or physical health consequences in caregivers, and this suggests potential target variables for interventions. The availability of empirically supported models or theories such as those reviewed here may contribute to the identification of factors or processes of special interest or that are key to the development of interventions.

Even though there has been a considerable increase in the number and quality of studies carried out with caregivers, we agree with Peter Vitaliano and colleagues (2014), who stated that "despite 50 years of formal caregiver research, we still need to find optimal ways to identify caregivers at the highest risk for psychological distress." This issue is complicated by the fact that research has provided findings to suggest that the

effect of stressors may vary throughout the caregiving process and that events may be perceived as stressors at some points of the process but not at others. Furthermore, coping strategies that are successful for dealing with demands or stressful situations at certain times in the process may not be successful at others. Research is also required for improving our knowledge of the sources of heterogeneity within ethnic or cultural groups (Pinquart and Sörensen 2005). These issues show that there is a clear need for more methodological sophistication in the study of the variables that influence caregivers' stress and coping resources, which could come in the form of longitudinal and experimental designs, as well as assessment procedures for complementing the use of self-report measures (Knight and Sayegh 2010; Zarit et al. 2014).

Stress and Coping Theory in Geropsychology

Jeffrey Proulx¹ and Carolyn Aldwin²

¹Department of Neurology, School of Medicine, Oregon Health and Science University, Portland, OR, USA

²Center for Healthy Aging Research, Oregon State University, Corvallis, OR, USA

Synonyms

Strain – psychological or physiological distress;
Stressor – environmental demand

Definition

Stress refers to person-environment transactions in which environmental demands outweigh the individuals' resources, resulting in psychological and/or physiological dysregulation.

Coping refers to effortful behavioral and cognitive strategies activated in response to actual or anticipated stressful situations that serve to regulate both the stressful context and its negative socio-emotional and physiological consequences.

Introduction

Stress and coping theory focuses on how people manage the adverse effects of stress (Lazarus and

Folkman 1984). People cope with stress in a variety of ways, depending on personal preferences and/or environmental demands (Carver and Connor-Smith 2010). Coping with stress is a dynamic process that may change from moment to moment, requiring reappraisal as to whether the stressor represents a threat, harm, or challenge, and whether there are sufficient resources to manage it. Therefore, stress and coping processes are not simply causal relationships between environmental threats and responses, but transactions between the individual and the environment.

The study of stress and coping is salient to geropsychology because stress is thought to accelerate the aging process due to the repeated activation of the stress response system across the life span (Seeman and Gruenewald 2006; Almeida et al. 2011; Dallman and Hellhammer 2011). Theoretically, coping strategies mitigate the adverse effects of stress and thus promote a longer health and life span, although most studies suggest that negative coping strategies, such as expressing hostility or religious alienation, increase the risk of mortality. The goal of this entry is to provide a basic primer on stress and coping and their health effects and then discuss how these process affect and are affected by aging.

Stress

Stress is defined as challenges or threats in the environment that tax a person's resources and may result in socio-emotional, cognitive, and physiological dysregulation (Lazarus and Folkman 1984). However, the effects of stress are not entirely negative and can be positive in both the short and the long term. Stress activates the physiological and cognitive resources necessary for dealing with environmental or intrapersonal demands. In the short term, stress can facilitate cognitive, psychological, or physiological functioning, as when individuals get "psyched up" to do well on a test or in an Olympic race. Dealing with stressors can also lead to long-term growth, if individuals develop better coping skills, which can to greater mastery for future stressors.

However, extreme stress, such as trauma or chronic stress, can rapidly deplete an individual's resources, leading to physiological and psychological dysfunction.

As Aldwin (2011) noted, there have been three ways of defining stress: as physiological or psychological reactions, also called strain; as environmental demands or *stressors*; and as transactions between the person and the environment that result in appraisals of threat, harm/loss, challenge, or benign.

Physiological Responses to Stress

Physiological strain is characterized by the activation of neuroendocrine stress networks, which are highly conserved across species. These networks mediate responses between stressors and physiology through a cascade of neurochemical signals that function slightly differently depending on the duration of the stressor (Dallman and Hellhammer 2011), which can be categorized as immediate, short-term, and long-term stress response. The immediate stress response system is characterized by rapid activation of the neuroendocrine system resulting in direct enervation of various organ systems. For example, the acting of standing up requires an increase in blood pressure, partially mediated through direct neuroendocrine enervation of arteries and the heart muscle. With aging comes impairment of the catecholamine system, which results in problems such as orthostatic hypotension (a failure of blood pressure to increase quickly enough upon standing), resulting in dizziness. A slightly more sustained neuroendocrine response is mediated through the sympathetic adrenal medullary (SAM) axis that releases catecholamines (i.e., epinephrine and norepinephrine) into the blood stream. For example, being threatened by a dangerous animal requires a burst of energy to either fight the animal or to flee. Catecholamines provide this energy by stimulating increases in respiratory and heart rates and increases in blood pressure. However, catecholamines are toxic and long-term chronic elevations can result in serious harm and even death, as exemplified when individuals go into shock due to extreme stress.

Thus, longer-term stress responses are mediated through the hypothalamic-pituitary-adrenal (HPA) axis. The detection of a long-term threat sets into motion a series of neuroendocrine responses starting in the hypothalamus that leads to successive responses in the pituitary and then the adrenal cortex, where glucocorticoids such as cortisol are released into the blood stream after a few minutes. Glucocorticoids mitigate the harmful effects of the catecholamines and provide a different energy source by releasing glucose from the liver for use by the muscles and brain in order to galvanize an individual for the stress management over a long period. Glucocorticoids also moderate the immune system through the release of cortisol into the blood stream, although long-term activation of the HPA axis can also result in chronic inflammation.

Cortisol fluctuates in diurnal rhythms that are characterized by sharp increases in the morning, called the cortisol awakening response (CAR), which is then followed by a general decline throughout the rest of the day. However, age, personality, and contextual factors may lead to flatter rhythms and higher levels of cortisol across the day, which, if chronically elevated, can also be deleterious to an individual. For example, high levels of cortisol over long periods of time are associated with immune system dysfunction, hippocampal shrinkage, and cardiovascular disease (Almeida et al. 2011). In turn, chronic inflammation may contribute to a host of chronic illnesses in later life, including cancer, heart disease, diabetes, and dementia.

Stressors

Aldwin (2011) identified four basic types of stressors, based upon severity and duration: trauma, stressful life events, chronic role strain, and daily stressors or hassles.

Trauma. Traumatic events include violent or life-threatening situations, which hold the potential of severe harm or death. These include combat, traffic accidents, domestic violence, rape, and natural disasters, such as earthquakes or tsunamis. One example of the long-term outcome of trauma is posttraumatic stress disorder (PTSD) in which individuals may continue to present with the

negative responses to a traumatic event and have altered physiology (e.g., dysfunctional cortisol levels) long after the event has ended.

Stressful life events. Stressful life events (SLE) are more common and include problems such as divorce, loss of a loved one, and job losses. Both SLEs and trauma are associated with long-term health consequences and dysfunctional stress responses. Aldwin et al. (2014) showed that older men who have chronically moderate or high levels of stress have about a 50% higher risk of mortality than those with consistently low stress levels.

Chronic role strain. Pearlin and his colleagues (2005) defined chronic role strain as enduring stress associated with major roles such as work, marriage, parenting, household maintenance, and chronic health problems. Role strain may be due to competing social roles, such as parenting, career, and caretaking for older relatives, which may lead to considerable distress. Currently, over 43 million Americans are providing care to older adults, and it is not surprising that caregiving, especially to physically or cognitively frail older adults, is a major source of chronic stress for many families (Knight et al. 2011).

Daily stress. Daily stressors, sometimes referred to as hassles, are challenges that arise out of everyday living (Almeida et al. 2002). Examples of daily stress include arguments with children, work deadlines, and the delays associated with commuting. Usually, daily stressors do not require major life changes in adaptation although these events may disrupt the normal rhythms of daily life. While traumatic events and stressful life events are known to affect physiology and mental health in the long term, daily stressors are associated with short-term physiological changes such as increases in cortisol levels and heart rate (Almeida 2005). However, the effects of daily stressors are not necessarily restricted to that day's well-being; Aldwin and colleagues (2014) showed that chronic elevations of hassles can also lead to elevated mortality risks. Not surprisingly, daily stressors are more common than SLEs and trauma; Almeida's review indicated that adults experience daily stressors 12 days within an average month (Almeida

2005). Nonetheless, cross-sectional studies suggest that middle-aged and older adults generally report fewer daily stressors than younger adults, but longitudinal studies suggest more complex patterns in exposure to daily stressors (see Aldwin et al. 2014).

Stress as a Transaction

For Lazarus and Folkman (1984), stress was defined as a transaction between environmental demands and individual resources. Stressful episodes, such as a car breaking down, may be simply a hassle for someone with the resources to fix the car, but a major crisis for a homeless person living out of the car and who simply cannot afford car repairs. Thus, how an individual appraises the stressfulness of the situation, and then copes with it, is not simply a matter of environment or personality, but a transaction between the two.

Lazarus and Folkman (1984) defined *primary appraisal* as an evaluation of the type of the stress, which can be appraised as a threat, a harm/loss, a challenge, or benign (that is, not involving any stress). These are important distinctions because some people may appraise an event as threatening, while others may appraise the same event as simply challenging, thus leading to differences in how one manages the event and the steps he or she will take in the next step of appraisals. Sometimes circumstances may lead a person to more than one type of appraisal. For example, the death of a spouse may involve not only the appraisal of a loss but is also the threat to future financial or social well-being. *Secondary appraisal* is an assessment of resources a person has to manage the stress and thus indicates how stressful the event is to that individual.

Lazarus and Folkman (1984) hypothesized that personality affects appraisal processes, and recent research confirms this (Mroczek and Almeida 2004). For example, neuroticism is associated with a higher likelihood of experiencing stressors, responding more negatively to stressors, and higher levels of stress hormone production as a reaction to stressors (Miller and Pilkonis 2006). However, consistently appraising minor events, or hassles, as highly stressful is associated with increased risk of mortality, independent of

neuroticism (Aldwin et al. 2014). Nonetheless, how individuals cope with stress may be more important to long-term outcomes than simple exposure to stress (Aldwin 2011).

Coping

Coping is rooted in the understanding that there are individual differences in how people manage stress. However, definitions of and approaches to assessing coping reflect different schools and theoretical assumptions. For example, early approaches from psychoanalysis assumed that adaptation processes were largely unconscious; in general, the evolution of coping theory has gone in the direction of greater flexibility and conscious effort.

Coping Theory

Defense mechanisms. Early psychodynamic theory focused on unconscious and protective defense mechanisms that were seen as attempts to alleviate internal conflicts arising from stress. Further, defense mechanisms were seen as both automatic and enduring aspects of an individual's personality. Defense mechanisms described by Anna Freud (1971) include denial, projection, and sublimation, among others. For Freud, defense mechanisms are inherently dysfunctional because they distort reality in order to decrease psychological threat.

In contrast, Vaillant (1977) found that patterns of defense mechanisms could become more adaptive as people matured. He examined long-term interviews with the Grant Study men, a major longitudinal study which has been following healthy Harvard male sophomores. Vaillant devised a widely used four-level hierarchy that indexed the developmental progression of defense mechanisms. Level I defense mechanisms were considered pathological and characterized by objective breaks from the actuality of a stressor. Level II included defenses such as passive-aggressive behavior, acting out, and projection. The defense mechanisms in Level III were considered to be neurotic and included intellectualization, disassociation, and

repression, which were thought to distort reality less than the defense mechanisms in the previous levels. Level IV defense mechanisms included sublimation and altruism, which were seen as the most mature coping responses. This view of defense mechanisms suggested that they address more than internal conflicts and can be used as strategies for engaging with external stressors. For example, a parent who cannot reconcile the death of a child may use denial or sublimation to convert unacceptable urges (revenge) into useful patterns of behavior, such as devoting time to a group like Mothers against Drunk Driving. However, Cramer (2015) noted that it was difficult to assess how well people used defense mechanisms because it is difficult to report on unconscious processes, casting doubts on the validity of self-report measures of defense mechanisms.

Coping styles. Coping styles theories were based on both social cognition and personality theory (Aldwin 2011). From a cognitive perspective, coping styles have traditionally been defined as either *avoiding* or *approaching stressors*. *Avoidance coping* diverts the focus away from stressors, which has also been referred to as suppressing or blunting. *Approach coping* refers to the cognitive process of information seeking to address a stressor and has also been referred to as sensitizing or monitoring.

Avoidance and approach coping were thought to inhabit opposite poles on a coping continuum. This polar relationship may have mapped easily on typical psychological scales and simplified coping measurement and therefore provided an attractive approach for measurement. However, more in-depth investigations revealed that coping was more complicated than polar structure styles suggested. People may use both avoidance and approach in reaction to the same stressor, either sequentially or for different aspects of the problem (Lazarus and Folkman 1984). For example, a woman may initially ignore a lump in her breast, but subsequently undergo a mammogram.

The concept of enduring coping *styles* posited that they are strongly related to personality characteristics. For example, Carver and

Connor-Smith (2010) found that approach styles of coping were associated with conscientiousness, extraversion, and optimism. On the other hand, they found that neuroticism was linked to disengagement coping. The results of these studies showed that coping styles could be more nuanced than polar measures of coping styles imply. For example, the span of time between when a person uses coping and when they report that event affected how people remembered the how they coped with stress. Further, age and stressor severity influenced how people coped with stressful events. These results indicated that coping styles were more variable than early explanations of coping styles hypothesized.

Coping processes. Coping processes refer to effortful cognitions and behaviors activated in response to actual or anticipated stressful situations that serve to regulate both the stressful context and its negative socio-emotional and physiological consequences. Coping is thought to be plastic, or responsive to situational demands and personal preferences, as well as sociocultural influences. Note that both problem- and emotion-focused coping can be cognitive (e.g., making plans or re-assuring one's self) or behavioral (e.g., acting to directly affect a situation or using exercise to manage stress).

For Lazarus and Folkman (1984), coping processes reflect primary appraisals which indicate the type of threat. Secondary appraisal involves identification of resources, including coping skills, as well as the level of stress. This is a dynamic process which changes across time, coping efforts may influence stress appraisals (perhaps the problem is easier or more difficult than initially thought), which in turn can lead to modification in coping strategies. Rather than reflecting stable coping styles, coping is plastic, or malleable, and can change depending on variation in situational demands or across time. How one copes with a work problem may be very different from coping with a death of a loved one. Because coping is plastic, it is also open to change – people can and do learn more efficacious coping strategies, either through therapy, stress management interventions, or the experience that comes with age.

While there is little consensus as to the exact number of coping strategies used, five of the more commonly assessed coping strategies assessed are: problem-focused coping, emotion-focused coping, social support, religious coping, and meaning making (Aldwin 2011). *Problem-focused* coping is the process of taking direct action to manage and remove a stressor. Problem-focused coping can also include seeking new information or exploring new options for handling the stressor than one otherwise employs. *Emotion-focused* coping is the process of managing the emotional responses a stressor elicits, which are often negative. These responses can range from ignoring the problem to substance use. Emotion-focused coping is often associated with negative outcomes, especially if this approach leads to rumination, catastrophizing, or engaging in poor health behaviors to handle a stressor. However, Austenfeld and Stanton (2004) showed that emotional processing, in which one tries to understand why one has these negative emotions, may lead to more positive outcomes.

Seeking social support is characterized by reaching out for emotional support and instrumental support. *Religious coping* involves turning to God, a higher power, or one's religious community for support, either through intercessory prayer or for understanding and support. *Meaning making* involves cognitively reframing stressful circumstances to come to an understanding of trauma or loss. Meaning making often compels a person to contemplate the reality of a stressor much more deeply, which may lead to more pain in the short term but have positive and adaptive outcomes later on.

Thus, it is important to be able to distinguish between the more immediate outcomes as a result of coping and the outcomes of coping that lead to long-term growth. Coping processes appear to be unrelated from situation to situation, reflecting a flexible approach tailored to different circumstances. However, patterns of coping processes tend to cluster together when data on coping processes are aggregated over time (Ptacek et al. 2006). These results do not necessarily support a personality-based approach to coping as

much as they suggest that adults are better at relying on strategies that have worked well in the past.

Finally, we tend to think of coping as something that individuals do, but coping is not solely a characteristic of the individual, but depends heavily upon contextual and social resources. Individuals, families, and other social institutions provide not only social support, but also influence how we appraise stress, what coping strategies are best suited to the situation, and can facilitate or provide barriers to effective coping.

Coping and Psychological Health

The effect of stress and coping on mental health is often a product of context and coping choices a person makes. This suggests that the psychological impact of stress and coping is highly variable between individuals, and possibly across ethnic groups. Jackson et al.'s (2010) provocative finding that African Americans who used poor health behaviors as ways of coping with stress, such as smoking and eating high calorie foods, had lower rates of depression than whites but higher likelihoods of poor physical health outcomes. Of course, this does not imply that psychologists and public health experts should promote poor health behaviors as coping choices, but it does illustrate the heterogeneity of relationships people can have with stress and coping and the importance of understanding context and individual differences as predictors of coping outcomes. Palliative strategies may be the only coping options when dealing with uncontrollable chronic stress.

Problem-focused approaches to coping are generally associated with better psychological health, and emotion-focused and support-seeking approaches to coping are associated with poorer psychological health (Aldwin 2011). However, coping outcomes can be more nuanced and have different effects depending on the circumstances. For example, a strong social network is usually associated with good mental health outcomes, but the act of reaching out to the network in times of need may lead to strained relationships and psychological distress. Similarly, Pargament's (Pargament et al. 2004) work shows that religious

coping is often associated with good psychological outcomes. However, negative religious coping, or religious alienation – e.g., blaming God or feeling deserted – can lead to a negative outcome if a person finds estranged from the congregation (Abu-Raiya et al. 2015).

Coping and Physical Health

How one copes with stress appears to be associated with physical health, yet conclusions as to the extent of these effects are somewhat mixed (Biondi and Picardi 1999). Some coping strategies are associated with direct effects on health, such as calming techniques that may lower blood pressure. Coping may also interact with a stressful event such that the coping strategy will have an effect on physiological outcomes only in the presence of a stressor. For example, calming oneself in a stressful circumstance may have significant effects on heart rate, but there may be little change when there is no stressor. Coping may also mediate between a stressor and health outcome. For example, a stressful experience may lead to a specific type of coping behavior, such as substance abuse, to blunt the emotional toll of a stressor, which leads to poor health. On the other hand, people may exercise when they feel stressed, which can lead to better health long-term health outcomes.

Some coping styles, such as defensiveness and repression, may be associated with higher levels of cortisol, but this association has proven to be difficult to reproduce. However, other data suggest that the effect of coping on the immune system can be very different depending on whether an individual uses emotion-focused coping or problem-focused coping. Patients who were positive for HIV that employed problem-focused coping tended to show increases in CD4+ cells, which are instrumental in immune system signaling but tend to be lower in HIV-positive patients. However, emotion-focused coping in HIV-positive patients was related to a reduction in immune response in an already besieged immune system, but other studies of individuals coping with cancer, e.g., Masters et al. (2009), have shown that emotion processing may be related to better inflammatory outcomes.

Thus, how one copes with illness may be important for well-being and even survival. Given the increased prevalence of chronic illness in later life, stress and coping processes may be of even greater importance for older adults.

Stress, Coping, and Aging

The following sections will address how stress and coping processes are affected by age and the influence they may have on the aging process.

Stress and Aging

Whether or not exposure to stress changes with age varies as a function of which type of stress is being measured (Aldwin 2011). Thus, we will address age-related changes separately for the different types of stressors identified earlier. However, we will first preface our remarks with a general discussion of age differences in vulnerability to stress.

There is little doubt that, in general, vulnerability to *physical* stressors increases with age (Charles 2010). For example, older adults are particularly sensitive to heat stress and new viral and bacterial strains, in part due to changes in the neuroendocrine and immune systems with age, but also due to underlying chronic illnesses such as cardiovascular disease or diabetes which may make them more vulnerable. In general, it appears that older adults are more vulnerable to stressors in laboratory settings, such as being injected with adrenaline or doing stressful tasks. However, older adults appear to be less vulnerable in some field studies – they often report fewer stressors and rate problems as less stressful (Aldwin et al. 2014). Older adults may have learned to distance themselves from stressors, either through taking a larger perspective or as a means of self-protection from the adverse effects of stress. However, this protection may fail if the stressfulness of the situation is too high.

Trauma and aging. Younger adults often have a higher prevalence of traumatic events, which tends to be associated with unexpected death and physical and sexual violence (Aldwin 2011). Older adults report fewer traumatic events than

younger and middle-aged adults, but older American adults are more likely to report more trauma associated with combat. However, the experience of trauma tends to be more of a function of cohort than of age, especially in those countries that have experienced war and civil unrest.

Stressful life events and aging. Early studies assumed that older age is a difficult and stressful stage of life. However, older adults routinely report fewer stressors on standard inventories. Most SLE inventories are often comprised of items that are more common among middle- and younger-aged adults (e.g., concerns with children, getting married, new jobs). However, even inventories which are more relevant to older adults show longitudinal decreases with age (Aldwin et al. 2011). In general, the types of SLEs change with age, with young adults more likely to report SLEs such as divorce, education, job loss, while older adults are more likely to report deaths of loved ones, health problems, such as chronic illness, and caregiving stressors. Nonetheless, the number of life events tends to decrease with age, with the exception health-related stressors (Aldwin et al. 2011).

Chronic stress and aging. It is widely assumed that older adults are more likely to experience chronic stress than younger adults, due to health problems, restricted incomes, and caregiving duties. However, to our knowledge, there are no studies examining age differences in chronic stress. Younger adults may also experience chronic stress, such as taking care of a disabled child, poverty, adverse working conditions, and the like. Thus, studies are needed which examine both types and the level of chronic stress in adulthood.

Hassles and aging. There are considerable individual differences in longitudinal patterns of daily hassles (Aldwin et al. 2014). Self-reports of exposure to hassles are highly variable across time and may be more related to cohort and situational factors than due to aging itself. However, the intensity or appraisals of stress ratings of hassles has been shown to follow a clear age-related or developmental pattern, with stress severity decreasing from mid to late life and then increasing again in very late life. Perhaps older adult's greater experience provides perspective on the relevance of stressors, or it may be that their health conditions

may worsen with stress (e.g., high blood pressure), and thus they have learned to appraise things as less stressful to avoid getting upset.

Appraisals and aging. There are age-related differences in some appraisals. Compared to middle-aged men, older men are less likely to appraise problems as challenges, but they are also less likely to report being annoyed by daily hassles (Aldwin 2011). Surprisingly, there are few age-related differences in the number of loss or threat appraisals. Thus, older men report fewer stress appraisals overall, which is, in turn, associated with lower reporting of stress ratings.

Summary. Clearly the relationship between stress and age is complex, varying by the type and severity of stressors. However, older adults may be adept at self-protective mechanisms, especially among those than are young-old (e.g., 65–75). In part, this may reflect survivor effects – men who consistently report moderate or high levels of stressful life events, or who consistently appraise their hassles as very stressful, are less likely to survive into late life (Aldwin et al. 2014). However, even for those who survive into very late life, those protective mechanisms may begin to fail, as indicated by higher stress appraisals among the old-old (75+). The increase in health problems and cognitive impairment and the decrease in functional health in very late in life may make it more difficult to cope with stressors.

Coping and Aging

Understanding age-related changes in coping is also complex. Early researchers thought that older adults were more passive copers (Gutmann 1974). For example, Folkman et al. (Lazarus and Folkman 1984) noted that older adults report fewer problem-focused coping strategies. However, there appears to be no differences in coping effectiveness between age groups (Aldwin 2011), and it is possible that older adults may be adept at conserving their resources while maintaining an equal sense of coping effectiveness as younger adults, suggesting greater efficiency. For example, a middle-aged person may address a fallen tree in the yard by assessing the problem and trying to mitigate it. That may mean spending all day chain sawing, disposing of the remains, and cleaning up

the shavings and bark left in the lawn – a very high level of effort. An older adult may be more likely to call a tree service to come and take the fallen tree away, which requires less expenditure of effort. So the older adult is technically using fewer problem-focused strategies, but is still efficaciously handling with the problem.

Other researchers have also identified positive aspects of older adults coping. As Vaillant (1977) indicated, older adults tend to use more “mature” defense mechanisms, allowing them to more graciously deal with stress. Older adults also use more religious coping, although it is unclear whether this is a cohort or an aging effect. Nonetheless, religious coping is often effective at staving off depression (Pargament et al. 2004). There are also indications that older adults may be more efficacious in coping with interpersonal problems (Berg and Upchurch 2007). They may be better able to regulate their own emotions and not accelerate or exacerbate interpersonal problems. We suspect that this may be part of a longer-term perspective. Older adults may understand the importance of maintaining good relations in general and become less upset over specific incidents.

Johnson and Barer (1993) studied coping among the very old (80+) in San Francisco and found that they utilized various strategies to avoid and/or minimize stress in their lives, including routinization and anticipatory coping. Most older adults in their sample had developed comfortable routines which minimized stress, such as eating the same thing for breakfast every morning or doing the food shopping at specific times every week. When faced with a new situation, such as going to an unfamiliar location, they would carefully plan out their route to avoid making a left-hand turn in big city traffic. They also used downward comparisons, acknowledging their own limitations, but using the problems of others to say that, “it could be worse.” Thus, they used a variety of strategies to successfully maintain psychological and social functioning.

Conclusion

In many ways, asking the question, does stress and coping change with age, is too simplistic and

does not address the substantial interindividual differences in intraindividual change. Further, the answer may vary by type of stressor and/or coping strategy. Nevertheless, we have found that, in general, stressful life events decrease with age, in part due to changing roles. Young people are more likely to get married, divorced, go to jail, etc., although older adults are more likely to report losses due to bereavement and health problems. But older adults also tend to appraise problems as less stressful.

Whether younger or older adults are better copers is also not an easy question to answer. On the one hand, older adults often expend less effort in problem-focused coping, which may seem to be more passive. However, this may actually conserve energy and reflect more efficacious coping. Older adults often have learned that many, if not most, problems solve themselves or can be helped to resolve with subtle encouragements. And there is much evidence to suggest that people use more mature defense mechanisms and are better at emotion regulation and perhaps at managing interpersonal conflict. But not all individuals develop these more sophisticated and nuanced coping strategies, and those with cognitive impairment may have a particularly difficult time managing the environment and regulating their emotions.

It is likely that stress can accelerate the aging process and that older adults are more vulnerable to the negative effects of stress. However, older adults have learned various strategies to avoid and/or minimize stress in their lives, including routinization, anticipatory coping, and taking a broader perspective. Older adults may have also learned what types of coping strategies are effective for them and becoming more efficient copers and achieving goals with less expenditure of energy. Thus, coping with stress can mitigate the harmful effects of stress and is an integral part of both optimal aging.

Stress and Well-Being: Its Relationship to Work and Retirement for Older Workers

Katey Matthews

CMIST, School of Social Sciences, University of Manchester, Manchester, UK

Synonyms

Effort-reward imbalance; Job demand-control

Definition

Well-being is defined as the overall mental and physical health of the individual. Work is defined as paid employment. The term ‘older workers’ is generally defined as those aged 50 and over, although studies sometimes use the term to refer to individuals of State Pension Age only.

Introduction

Understanding the health and well-being of older workers, and the influence stress may bear on this relationship, is currently an important issue. In response to increasingly aging populations, governments in many developed countries are seeking to increase the age of pensionable retirement to retain as high a proportion of the older population as possible within the workforce in order to overcome the financial and economic burdens arising from older people living healthier lives and therefore spending longer periods in retirement and in receipt of pensions. However, while encouraging longer periods of workforce participation may be of benefit to some older people, there is a high likelihood that extending the working lives of those employed in occupations which are characterized by high levels of stress will lead to a worsening of mental and physical health for those with existing issues or the onset of poorer health among those without.

In addition to the need to extend working lives for economic purposes, evidence consistently suggests that there are benefits to continuation of the working role in later life in terms of health and well-being, financial circumstances, and social integration. Role continuity theories promote the idea that continuing employment may provide a means of promoting good mental well-being by remaining socially productive, feeling valued, having adequate financial security, and maintaining social networks useful for both support and resources. Similarly, these theories suggest longer periods of work help combat the negative effects of role loss in later life, which bring about reductions in social identity, support networks, and feelings of purposefulness. However, again, while some occupations may easily lend themselves to the provision of these personal, social, and economic benefits for workers, others may not, and people continuing to work without these benefits are unlikely to observe any benefit of remaining in the workforce for longer periods of time.

Little is known about the effects of working in general in later life on the health of older people. Previous studies examining relationships between employment and well-being among older populations have produced mixed results, with some suggesting it might be beneficial to well-being, others that it is detrimental, and some that there is no significant relationship. There are many factors which are likely to be contributing to this variation in results, including definitions of “later-life employment” and “retirement” and the wide range of health and well-being outcomes, as well as the various means of measuring them covered by different studies. Studies which consider older workers as a homogenous group are likely to be masking effects which might be observed if workers were stratified on the basis of personal or workplace characteristics. Interestingly, when work is stratified on the basis of measures of stress, results consistently show a negative relationship between employment bearing characteristics of high-level stress and various well-being outcomes, and occupations which are characterized by low levels of stress are consistently associated with better health and

well-being. Additionally, the stress of work in later life has been shown to influence well-being not only in the period of later life employment itself but also across subsequent periods of transition into retirement as well as within early retirement. This work will outline some of the key evidences highlighting these associations and discuss the mechanisms through which work-related stress in older age potentially impacts the well-being and health of older people.

Theoretical Models of Stress at Work

Research concerning the relationship between stress and work across the entirety of the life course has focused on two key theoretical frameworks, both of which aim to reduce the complexity of common workplace interactions into key elements which may have subsequent consequences on health and well-being outcomes. The first of these frameworks uses the demand-control model (Karasek 1979), which refers to the levels of “job strain” to explain the relationship between the working environment and health. The second key framework uses the more recently proposed effort-reward imbalance model (Siegrist 1996) to demonstrate the importance of societal reciprocity within the role of a worker as a means of maintaining good emotional well-being across the working life course and beyond.

The Demand-Control Model

The job demand-control model aims to explain the relationship between work stress and well-being in terms of the balance between workload and the ability of the worker to handle this workload. The ability of workers to successfully manage their workloads by means of the opportunity to make decisions about the completion of job tasks is associated with positive workplace-based effects in terms of reduced job strain and higher job satisfaction, both of which in turn have beneficial effects on emotional well-being and subsequently on aspects of well-being which may affect the worker both in- and outside of the workplace.

The demand-control model breaks employment down into four key groups on the basis of

the balance between workload and control over workload and considers the effect these differences in balance may subsequently bear on well-being. The model proposes that the worst effects on emotional well-being are observable among those with “high strain” jobs characterized by high workload demands and low control over meeting these demands. The individual experiences increased mental distress which subsequently impacts on physical health through the mechanism of increased cardiovascular tension which increases the risk of further detrimental health outcomes (Karasek 1979). Conversely, individuals with high work demands but also high levels of control to manage these demands see better well-being, probably because these workers are those in good occupational grades and managerial positions with adequate resources to handle their workloads.

The Effort-Reward Imbalance Model

Critics of the demand-control model focus on the ambiguity of what may comprise the concepts of “demand” and “control,” with difficult workloads potentially characterized by either too small timeframes in which to complete high frequencies of tasks or tasks which are too challenging for the current skills of the worker. Additionally, control may be measured both in terms of the level of decision a worker has over how to handle his workload and his level of learned ability to deal with tasks in an organized and timely manner (Siegrist et al. 2004). Additionally, the model focuses on aspects of work which are specific to the workplace, rather than on aspects of work which may influence the circumstances of the individual outside of the working environment. In response to this, a more recently proposed framework of understanding the effects of occupational stress focuses on the idea of an effort-reward imbalance model (Siegrist 1996). The effort-reward imbalance model builds on the idea that the role of the paid worker is central to adult life and on the notion of social reciprocity on which paid employment is based. Social reciprocity is measured in terms of financial reward, self-esteem, career development opportunities, and job security (“gains”) offered adequately in return

for the effort made in completing the tasks required within the working role (“costs”). The model then proposes that imbalances in these costs and gains lead to emotional distress and impair successful self-regulation, which in turn lead to a higher susceptibility of the worker to further problems with both emotional and physical well-being. These negative effects are likely to be observed the most among workers who suffer lower levels of reciprocity but who are considered “overcommitted” to their job, encompassing a personality-based individual variation within the effect of imbalance on working populations. The effort-reward imbalance model might be especially relevant to older populations if it is considered that older workers are more likely to find certain types of work more physically and mentally effortful and to experience fewer opportunities for promotion, role alteration, or alternative employment if desired, all of which demonstrate examples of an imbalance between effort and reward.

Although the effort-reward imbalance model draws on the relationship between stress and health in terms of the occupational circumstances subsequent to the level of effort or demand required to be put into tasks at work, the reliability of the model may benefit from its inclusion of occupational-related concepts such as salary and job security, which are likely to influence an individual’s well-being in realms outside of those concerning work. For example, levels of salary have subsequent effects on the living conditions of individuals which then further impact on well-being. So, while negative effects of the demand-control model might be limited to time spent within the workplace, negative effects as specified by the effort-reward imbalance model are likely to radiate to wider areas of the individual’s life and therefore offer more persistent and stronger effects on health and well-being. However, both models are useful in identifying a group of workers who are likely to be most adversely affected by work circumstances such as low control and low reward (Siegrist et al. 2004), and as will be discussed in the following section, the literature has found significant associations between these workers and

poorer levels of a range of health and well-being outcomes.

Empirical Evidence

The majority of recent research into the effects of employment-related stress on the well-being of older workers and retirees draws heavily on the two aforementioned models of work stress. However, definitions of work stress are diverse, and observational data used to conduct such research may be limited in the ways in which it allows the researcher to measure stress at work. While many datasets contain measures to specifically compose scales of demand-control and effort-reward imbalance, this piece additionally considers research which examines well-being on the basis of work stratified by measures of stress such as occupational type, occupational grade, and worker satisfaction, all of which have been shown to demonstrate associations with imbalances between control and demand or effort and reward.

The relationship between stress and work and retirement can be considered from two perspectives. Firstly, work-related stress can be considered as a driver out of the workforce and into retirement, often due to stress-induced poor levels of health and well-being. Secondly, it can be considered in terms of its effects on well-being among the older workers who are still employed in stressful environments as well as on the well-being of the older people who have retired from them.

Stress as a Driver of Workforce Exit

Evidence has demonstrated that work-related stress impacts older individuals’ decision to leave the workforce early, often because of negative impacts on health and well-being. Siegrist et al. (2007) found an imbalance between effort and reward to be an independent predictor of intention to leave the workforce prior to normal retirement age even after controlling for health problems and physical disabilities which are often considered to have the strongest impact on the decision to take early retirement. Similarly, Elovainio et al. (2005) examined imbalances between job demand and control and again

found these to be significant predictors of early retirement. Furthermore, the relationship between poor demand-control balance and the intention to retire early strengthened with age and was particularly prominent in individuals aged 45 and over.

Another means of measuring stress in the workplace is by means of physically demanding tasks which older individuals might especially struggle to cope with. Banks and Casanova (2003) find a greater propensity for those in physical or heavy manual work to expect to have left the workforce prior to reaching the age of 65 due to disability or health limitations, and a survey by Humphrey et al. (2003) found 11% of men and 16% of women took early retirement because their work had become too physically demanding to manage.

Older people are also likely to be driven into retirement because of mental stress in the workplace. Barnes et al. (2004) found older people were more likely to decide to leave the workforce early because they found their jobs mentally more difficult to manage in their later working years, as a result of both increased time pressure brought about by company restructuring or changes within their own ability to manage tasks and workloads as they became older. Similarly, the aforementioned survey by Humphrey et al. found 8% of both men and women took early retirement because their jobs had become too mentally stressful.

The Relationship Between Stress, Work, and Well-Being

Research which has looked at the associations between work stress and health and well-being has found detrimental effects to exist across the life course on a variety of health outcomes including cardiovascular disease (Bosma et al. 1998), coronary heart disease (Kuper et al. 2002), poor mental health (Pikhart et al. 2004), self-reported health, and type 2 diabetes (Marmot et al. 2006). As mentioned beforehand, although research concerning effects of work among older populations in general provides mixed results, research which recognizes that work should be stratified on some measure of its quality consistently finds the relationship between higher levels

of work stress and well-being observed in midlife to persist into older age. In consideration of the effort-reward imbalance model, McMunn et al. (2009) found paid workers of state pension age (SPA) and over reported higher life satisfaction and quality of life as well as fewer symptoms of depression than those of the same age who were not in work, as long as they felt well reciprocated in terms of effort and reward. Older people who felt poorly reciprocated for their efforts saw no significant differences in well-being than older people who were not in the workforce. Similarly, Matthews et al. (2015) used a sample of workers and retirees of SPA and over matched on the basis of their background characteristics and found those who felt poorly reciprocated for their work had significantly higher levels of depression than both those who worked in well-reciprocated employment as well as those who had taken normal retirement at SPA. Similarly, those who continued to work in well-reciprocated employment saw significantly better self-reported health than those in poorly reciprocated work and those who had taken normal retirement. These findings have important implications for policymakers raising SPA as they suggest retirement would be more beneficial to the well-being of older people than the continuation of work which is stressful in nature. Volkoff et al. (2010) focused on the demand-control model of work stress and found that older workers with the highest levels of time pressure combined with the lowest control over the way in which they could manage their high workloads had the highest prevalence of several health disorders, including sleep disorders, experience of pain, and ability to recover from illness or injury. These workers also experienced stronger feelings of discouragement within the workplace. De Jonge et al. (2000) explicitly compared the demand-control and effort-reward imbalance models of stress and found that high levels of effort-reward imbalance were stronger predictors of poor mental and physical well-being outcomes than low levels of job control to deal with high demands. However, the study also accounted for level of worker commitment and found overcommitted workers with high demands and low control saw the poorest well-being outcomes.

This is consistent with Siegrist's (1996) notion that overly committed workers are likely to experience the strongest negative effects on well-being when there is a mismatch between reward and effort contributed to work-related tasks.

The National Statistics Socio-Economic Classification (NS-SEC) is another means of measuring work stress which relates to the notions implied by the effort-reward imbalance model on the basis of the inclusion of employment characteristics including levels of autonomy and control in the workplace, job security and salary, and the availability of opportunities to further one's career. On the basis of these characteristics, employment types can be described as one of three broad categories (each of which incorporate a range of smaller occupational descriptions): managerial and professional occupations, characterized by high autonomy and control, good job security, and good career prospects; routine occupations, characterized by low autonomy and control, poor job security, and fewer opportunities for career development; and intermediate occupations, which lie somewhere in between. Sacker et al. (2005) found those in routine occupations suffered poorer self-reported health than those in managerial and professional occupations and that differences in health widened with age, so that at age 21 there were no health differences, yet at retirement age the differences were at their greatest. The poorest health was observed among those who had worked in routine occupations throughout adult life, and effects were smaller if the individual's employment in routine occupations was preceded by time spent in occupational types characterized by lower levels of stress, suggesting the effects of work stress are accumulative over the life course and should be considered from a life course perspective. Similarly, Chandola et al. (2007) used NS-SEC and found people from lower-grade occupations saw faster declines in physical health over time than those in higher-grade occupations. For example, the study demonstrated that a 70 year old who had worked in a high-grade occupation prior to retirement saw similar physical health characteristics as that of a 62 year old who had worked in the lowest grade. The study also found that mental health improved

after retirement for all occupational groups, although the rate of improvement was lower for those from the lowest grades than for those from higher grades.

Warr et al. (2004) examined well-being on the basis of individuals' role preference and found those in work with a preference for being in the workforce had higher life satisfaction and affective well-being than those who would rather have been out of work. However, well-being was found to be a function of the working environment rather than just of role membership, and better well-being was observed among those with better control over their work as well as among those with better work-related environmental circumstances, such as job security, financial position, and social networks.

Finally, work stress may be measured by the level of physical activity involved, and this may be particularly relevant in terms of older workers who are likely to demonstrate lower levels of physical functioning ability than younger workforce members and so find occupations characterized by high levels of physical or manual labor particularly stressful. Among older populations, jobs characterized by heavy manual or physical labor might be particularly prone to imbalances between both demand and control, where the individual may struggle with the physical ability necessary to manage his workload, and between effort and reward, where the individual may feel his efforts to carry out physically demanding work are not particularly well reciprocated by means of salary and job security. Often, workers in manual employment are lower skilled and less able to experience promotion or move to alternative employment types despite worsening physical health (Siegrist et al. 2004). A study by Tuomi et al. (1991) used the level of physical activity included in individuals' occupations as a measure of work stress and found that older men in more physically demanding jobs had poorer health and higher disability mortality rates.

The Relationship Between Stress, Retirement, and Well-Being

Again, research which has examined the impact of work-related stress on the retirement experience

of older people consistently demonstrates associations between jobs characterized by higher stress and poorer well-being in retirement and, conversely, jobs which are less stressful in nature and better well-being. Westerlund et al. (2009) used markers of occupational grade, psychological and physical stress, and job satisfaction to determine individuals' working conditions and found the prevalence of suboptimal self-reported health decreased after retirement for all workers apart from those who retired from the highest conditions. Additionally among older people in poorer working conditions, the prevalence of suboptimal self-reported health increased at a faster rate prior to retirement than after despite the fact that suboptimal health is commonly associated with increasing age, suggesting retirement provides a substantial relief of the stress brought about by poor working conditions. Another study by Marmot et al. (2006) found civil servants from the lowest employment grades had more than three times the mortality risk than those in the highest grades before retirement and again that after retirement the impact of occupational grade on mortality lessened and became smaller than the impact of other social measures. Mein et al. (2003) found civil servants who retired from higher occupational grades saw a significant improvement in mental health thereafter, but those from lower occupational grades did not, suggesting the potential beneficial effect of retirement from stressful work on well-being is possibly counteracted by poorer financial circumstances limiting activities available during retirement.

Discussion

Both the demand-control and effort-reward imbalance models outline the means by which mismatches between certain aspects of workplace characteristics can impact negatively on mental well-being and, through physiological stress responses, subsequently on other aspects of health, and the literature in the field provides plenty of evidence that this is the case. However, it is important to understand the mechanisms

through which stress impacts on well-being and the ways in which these mechanisms might vary among different groups of older workers, not only throughout the later periods of employment but also over the transition into retirement and into the retirement period itself thereafter. If policies to extend working lives and retain as high a proportion of older people in the workforce as possible are to succeed, they need to be based on a knowledge of how different workplace stressors and characteristics are likely to both positively and negatively affect the health and well-being of the older workforce.

The evidence provided by the research outlined in the previous section of this work demonstrated the means by which work-related stress can lead to both early workforce exit and detrimental effects on health and well-being outcomes. Additionally, although the key models of work-related stress focus on imbalances of either demand and control or effort and reward, job stress might also be characterized by work which is too physically or mentally demanding in nature. Although not explicit measures of control or reciprocity, often in these instances, imbalances between control over workload and the gains received for commitment to physically difficult work are likely to be prominent. Overly physically demanding work is likely to be a form of workplace stress that is detrimental to the health of older workers in particular, and older people participating in such jobs are the most likely to have the intention of taking early retirement or actually exit the workforce before state pension age (Humphrey et al. 2003). Furthermore, increasingly physically demanding work among older populations might be particularly detrimental to both physical and mental well-being outcomes for two key reasons: Firstly, if it is considered that those who have worked in manual employment throughout adult life are more likely to have acquired disabilities or health problems as a result of their work, it may be considered that continuation of this type of employment in later periods of life will only exacerbate existing issues. Secondly, considering older people in manual employment are the most likely to want to leave the workforce early (Banks and Casanova 2003), when it is not

possible to do so, for example, because state pension age has not yet been reached and the individual cannot afford to take earlier retirement, the individual is likely to experience negative effects on both mental and physical well-being as an effect of the forced continuation of work which is difficult to carry out.

One of the key points to emerge from the literature is that individual well-being in later life is likely to be associated with the experience of stress over the life course, rather than specifically at the time retirement age approaches. The aforementioned research by Sacker et al. (2005) showed self-reported health to be poorest shortly before retirement age among those who had continuously worked in occupations characterized by higher stress levels, while those who had experienced periods of less stressful employment prior to entering a stressful occupation reported better outcomes as they neared retirement age. This idea is further backed up by the finding within the same study that there were no significant differences in self-reported health between those in high and low stress occupations at age 21, again suggesting the negative effects observed among those who have worked in stressful environments to be the result of cumulative stressful experiences. Similarly, the aforementioned increased rate of early labor market exit observed among those in manual employment due to limiting illness and disability suggests cumulative negative effects on health occur among those who participate in physically demanding work in earlier periods of their lives. This idea is strengthened again by the finding by Chandola et al. (2007) that physical health deteriorated faster among those in lower-grade occupations than among those in higher-grade occupations.

Furthering the life course perspective on the associations between older workers and retirees in relation to stress, there is evidence to suggest that participation in jobs characterized by higher levels of stress is the result of social inequalities which

often stem from childhood and persist throughout adult life. This idea is furthered by work by Dannefer (2003) which states that lifelong employment in good quality occupations and circumstances is usually preceded by high educational attainment which in itself is often associated with higher social status in childhood. Furthermore, as better health is observed across the life course among those with higher incomes and better social positions (Marmot and Shipley 1996; Chandola et al. 2007), this cumulative advantage of higher quality and less stressful work can persist into older age. Those who have worked in lower stress occupations are also those who are more likely to either benefit from prolonged periods of employment in later life, as well as those who are able to enjoy better well-being in retirement due to having a level of health and financial security which allows pursuit of meaningful and enjoyable activities in place of the paid worker role.

Conclusions

There is increasing importance in understanding the effects on health and well-being of the working environment as state pension ages rise to accommodate the financial burdens brought about by aging populations. Previous research into work-related stress among older people consistently finds detrimental effects on a range of well-being outcomes among those working in stressful occupations. This association is likely to persist across the life course and throughout the transition into retirement, as well as during retirement itself.

Definition

In vivo radiological examination of tissue, including the brain, for the purpose of identifying structural health and disease states.

Older adults are vulnerable to a variety of neurological and neuropsychiatric disorders in which diagnosis is facilitated by contemporary neuroimaging. With clinical presentations, magnetic resonance imaging (MRI) and other imaging techniques can assist in clarifying etiology, progression, and severity of neuropathological states. Given that early and accurate diagnosis is critical to optimizing treatment, imaging is increasingly being used to expedite diagnosis and to rule out other CNS-related conditions or to provide a baseline, since in the beginning of symptom onset for disorders in the elderly, the initial symptoms may be subtle. The following section of this *Encyclopedia* will provide discussion on the role of imaging techniques in older adults, with a particular emphasis on normal aging, acquired brain injury, and dementia.

Understanding the utility of neuroimaging among older adult populations first requires a discussion of the natural morphological changes that occur as healthy individuals age. Early development consists of a steady rate of increases in

brain volume, whereas by early adulthood, overall brain volume has reached its apex, which thereafter is associated with a steady rate of brain volume loss (Hedman et al. 2012). As shown in Fig. 1 from a meta-analysis of neuroimaging studies on brain volume and aging, a steady decline becomes rather evident by midlife. Some of this volume loss can be associated with cell death and cellular morphological change. Beginning at the fourth decade of life, adults inexorably experience myelin sheath deterioration, leading to a reduction of white matter volume. Concomitantly, there is also an increased gray matter loss, which is more responsible for driving the overall volume reduction (Mukherjee et al. 2002).

Figure 2 compares magnetic resonance imaging (MRI) linking age-related brain changes from childhood, adolescence, and early and older adulthood with a healthy nonagenarian that can be visualized on a brain MRI. What is distinctly viewable across the age span shown in Fig. 2 is the cortical sulci (the furrows on the surface of the brain) widen and the ventricular system enlarges. The ventricles are filled with cerebrospinal fluid (CSF) and are under pressure. Brain tissue, referred to as the parenchyma, prevents the ventricular system from expanding. Thus, as parenchymal volume is lost, whole-brain CSF increases leading to ventricular expansion and visible changes within the sulci and cisterns of the brain. In a practical sense, this means that every brain has to be assessed in reference to so-called age-typical “normal” aging.

The importance of the “normal” appearance of age-related changes as visualized in a scan is that “normal” atrophy is part of the natural aging process. Atrophy that is beyond what would be expected for someone given their age may implicate an underlying degenerative or some other disease process. For example, compare the two images in Fig. 3, one is from the coauthor (EDB) at age 67 compared to a 67 year old with probable Alzheimer’s disease (AD). Note in particular the hippocampal atrophy associated with AD compared to the author’s control brain.

As shown in Figs. 1 and 3, current MR technology provides excellent image resolution that mimics gross anatomy with the T1-weighted

Structural Neuroimaging in Geropsychology, Fig. 1 Image was derived from a meta-analytic study of brain volume by Hedman et al. (2012). Whole-brain volume is plotted by age in this life span view from age 4 through 88. The curves are dashed around age 18–21, indicating the uncertainty in this area, since only few data were available for fitting this age range. Two separate fits

were calculated for the younger (<19 years) and older (>19 years) group. Regardless of the unevenness of the earlier developmental data due to lack of consistent studies, by early to mid-adulthood, there is general stability in brain volume followed by an inexorable decline. See Fig. 2 for actual visualization of these changes

image. Current automated methods of image analysis also use the T1 image for computational purposes to derive volumes, surface area geometry, thickness, and shape/contour measures. In addition to the T1 anatomical sequence, from a pathology distinction, the other standard MR sequences including the fluid-attenuated inversion recovery (FLAIR), gradient-recalled (GRE) sequence or susceptibility-weighted imaging (SWI), and a T2-weighted sequence constitute the core clinical MRI studies typically performed. There are other MR sequences involving water diffusion especially important in assessing stroke and tumor patients, as well as diffusion tensor imaging (DTI) along with various methods for examining blood flow and contrast infusion, although these are not performed unless there is a specific referral to run such MR sequences.

The T1 images up to this point have focused on a general overall appearance of the brain from a gross anatomical perspective, but the FLAIR sequence is very helpful in identifying white matter pathology with the GRE/SWI sequences sensitive in detecting certain kinds of vasculature lesions. For example, a reduction in white matter integrity is a normal part of aging and in fact

accounts for reduced cognitive efficiency among healthy adults (Voineskos et al. 2012). In addition, normal aging is associated with significant microvascular changes that mitigate physiological and cognitive functioning and results in reduced cerebral blood flow and vascularization of brain parenchyma (Steketee et al. 2016). In the age-typical MR FLAIR sequence, abnormal white matter signals in the form of white matter hyperintensities (WMHs) begin to increase in appearance after the fourth decade of life (Hopkins et al. 2006). While some white matter pathology may just be the normal cost of the aging process, in the presence of vascular disorder, ischemic changes disproportionately affect deep white matter because the penetrating vessels that feed these regions constitute the most distal aspect of the cerebrovasculature and are therefore prone to microinfarction. Excess WMHs, as shown in Fig. 4, is a pathological indicator. When indicators of hemosiderin deposition with brain parenchyma are identified with GRE/SWI sequences, these are objective indicators that hemorrhage has occurred. The presence of WMHs and/or microhemorrhages has been associated with greater likelihood of being associated with

Structural Neuroimaging in Geropsychology, Fig. 2 Visual changes in the axial view of a T1-weighted MRI scan taken at the level of the anterior

horns from age 6 months to 66 years are depicted (The *top images* are from Vardhan et al. (2014) and reprinted with permission)

neurocognitive and neurobehavioral deficits (Wiegman et al. 2014).

Older adults also experience widespread cortical gray matter reduction with normal aging, which also impacts cognitive functioning (Thambisetty et al. 2010; Fleischman et al. 2014). As shown in Fig. 1, the rate of brain atrophy increases with age (Hedman et al. 2012), which is reflected in a reduction in cortical thickness. A most important image analysis advancement in the last decade is the automated image analyses, including measuring cortical thickness (Bigler 2015). These quantitative techniques for measuring thickness can be applied to any region, like in Fig. 5 that shows the changes in entorhinal cortex over the life span (Hasan et al. 2015). Entorhinal cortex is critically involved in processing short-

term memory and affected by many disorders, including Alzheimer's disease and TBI, and such quantitative imaging can be helpful in differentiating brain health from disease processes in clinical populations.

The fastest and most common brain imaging method is computed tomography (CT) which capitalizes on x-ray beam technology and tissue density to reconstruct an image of the brain. Because a CT scan can be completed within a few minutes from the time the patient is positioned in the scanner to when images are ready for interpretation, it is a quick screening method for detecting coarse brain pathology. In emergency departments, the CT is often relied upon because of its speed and disorders like brain tumor and stroke can be quickly ruled out.

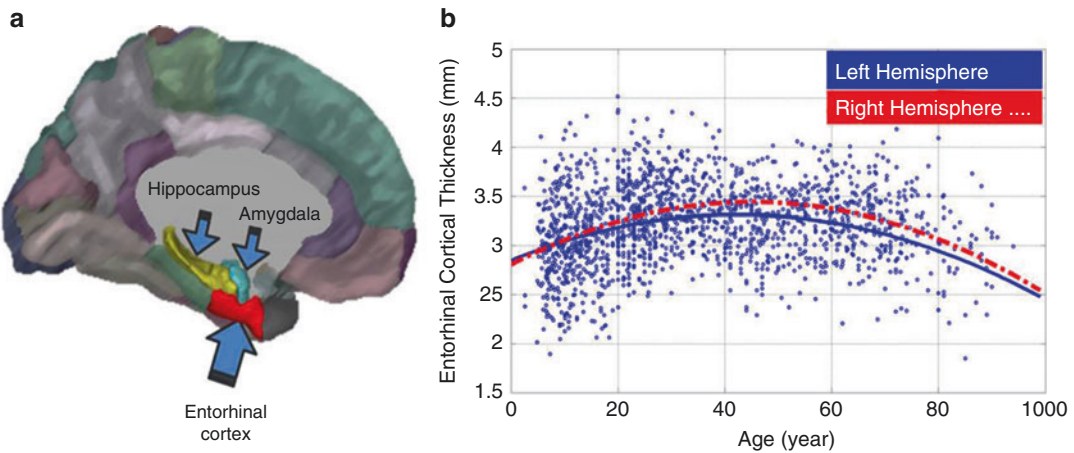

Structural Neuroimaging in Geropsychology, Fig. 3 The image on the *left* is a T2-weighted coronal MRI through the hippocampus in an 83 year old diagnosed with Alzheimer’s disease. This patient also had a history of cardiovascular disease and hypertension, and the axial fluid-attenuated inversion recovery (*FLAIR*) sequence shows

extensive white matter hyperintensities characteristic of microvascular disease. The images on the *right* are from a healthy 67 year old. *Red arrow* points to dilated temporal horn of the lateral ventricular system and hippocampal atrophy. Note in the control the fullness of the hippocampus tends to fill the temporal horn

Structural Neuroimaging in Geropsychology, Fig. 4 The *left* (axial) and *middle* (sagittal) images depicted multiple hemorrhagic lesions from sustaining a severe TBI based on susceptibility-weighted MRI. Note in the sagittal image the depth of the hemorrhagic pathology in the frontal white matter. Some of the hemosiderin deposition may be due to sluggish venous return and dilated

vessels also assumed to be the result of the TBI. The image on the *right* shows generalized white matter pathology. This TBI patient who had been injured approximately 2 years prior not only suffered from the severe traumatic injury to the brain but also extensive blood loss and hemorrhagic shock, which may have contributed to the white matter abnormalities

Structural Neuroimaging in Geropsychology, Fig. 5 The image shows the region of the entorhinal cortex, how it can be identified using advanced quantitative neuroimaging techniques, and how the entorhinal cortex changes with age. By knowing the normative size of the

entorhinal cortex, comparison can be made with any individual who may be having symptoms of medial temporal lobe pathology, such as memory impairment (Reprinted with permission from Hasan et al. (2015))

The limitation of CT is considerable, the most prominent being the lack of anatomical detail compared to MRI and CT's lack of sensitivity to certain types of pathologies. However, CT can be adapted for use in several functional neuroimaging techniques including fluorodeoxyglucose positron emission tomography (PET) and single-photon emission computed tomography (SPECT). Both of these techniques examine the uptake of a radiotracer, used to infer if metabolic activity is reduced, such as occurs in degenerative damage or infarction, or heightened, as what might occur at the site of seizure activity. Both CT and MRI can be adapted to examine the vasculature of the brain and various types of blood flow measures. Of particular importance for neuropsychology are the MR-based techniques that are capable of detecting blood oxygen level-dependent (BOLD) changes, such that regional differences in brain activation may be identified during certain cognitive tasks. Currently, this procedure is used most in preoperative cases to best outline regions related to cognitive processes that, if possible, should be avoided during surgical intervention.

Clinical research has examined whether imaging can differentiate between normal aging, mild cognitive impairment (MCI), and more advanced

states of dementia. As mentioned above, normal aging is associated with natural changes in both white and gray matter integrity and volume. Monitoring the rate of volume loss over time is one clinically meaningful approach to differentiate illness from normal aging. Specifically, a dementia process would have an accelerated rate of volume loss relative to non-symptomatic older adults (Thambisetty et al. 2010). In addition, the pattern of atrophy can help delineate different etiologies (i.e., Alzheimer's disease will have a different atrophy pattern relative to Lewy body dementia, frontotemporal dementia, etc.). For example, the case presented in Fig. 6 shows a 55-year-old female with onset of mild complaints of failing memory and language and her baseline scan, which was interpreted by radiology as within normal limits for her age. However, after a 10-year follow-up, there are clear differences, with temporal lobe atrophy, including hippocampal atrophy, more prominent cortical sulci, and ventricular enlargement. The patient's diagnosis is complicated at this stage because of sepsis and probably mild anoxic injury, but the clinical presentation appears to be FTD and the patient continues to be monitored.

Those with AD pathology will show differentially increased atrophy involving the

Structural Neuroimaging in Geropsychology, Fig. 6 In her mid-50s, this patient began to display cognitive and behavioral changes that raised the suspicion of behavioral variant of frontotemporal dementia. As seen in the image on the *left*, beginnings of left prominence of the Sylvian fissure can be visualized (*white arrow*) with some

early changes in the hippocampus (*black arrow*). A decade later the differences are more apparent; there is ventricular dilation and rather profound hippocampal atrophy on the left. This patient's history is complicated by also experiencing an ischemic infarct in the left globus pallidus

hippocampus and entorhinal cortex relative to other forms of dementia, such as dementia with Lewy bodies (DLB). There is also evidence from serial MRI that the rate of atrophy is increased in AD compared to DLB (O'Brien 2007). When diagnosis is unclear, the use of PET and/or SPECT appears to increase the sensitivity and specificity when comparing AD to other dementias (O'Brien 2007; Palmqvist et al. 2015). The use of MRI is also often used to distinguish vascular dementia from healthy individuals and those with other dementias. That is, those with vascular dementia will often show cerebrovascular disease as seen from multiple infarcts or widespread white matter disease. This is shown in Fig. 4, using the FLAIR MRI sequence. There are limitations to the use of MRI to diagnosing vascular dementia in that there is no consensus on the degree of white matter damage required to warrant a diagnosis, but the combination of prominent white matter pathology on MRI and neuropsychological indication of cognitive decline or frank impairment is the best current indicator (Prins and Scheltens 2015). There is also the observation that white matter damage as seen on MRI does not necessarily correlate to clinical outcomes and that other disease states often present with white matter

damage as well, so by itself white matter pathology is but a nonspecific finding in neuroimaging.

Imaging is able to distinguish AD from frontotemporal dementia (FTD) based on areas and patterns of atrophy; AD typically presents with bilaterally atrophic medial temporal lobes, whereas FTD will present with an anterior to posterior progression of atrophy to both frontal and temporal regions, often beginning unilaterally. Furthermore, there are now PET labeling techniques that assist in making the diagnosis of Alzheimer's disease and other dementias as well as the level of progression of the disease (Mattsson et al. 2014). The use of SPECT and PET demonstrates that FTD is often distinguishable from AD due to a unique pattern of hypoperfusion to frontal and temporal regions (O'Brien 2007). Voxel-based morphometry has been used to demonstrate frontal and anterior temporal lobe gray matter reduction in individuals with possible and probable behavioral variant frontotemporal dementia (bvFTD) relative to controls. Notably, even individuals classified as pre-bvFTD are differentiated from healthy controls in volume to the left superior temporal gyrus, the left medial frontal gyrus, and the right insula (Borroni et al. 2015). Imaging has also been

useful in identifying other rare degenerative processes with unique MRI markers including Huntington's disease, Creutzfeldt–Jakob disease, progressive supranuclear palsy, corticobasal degeneration, and multisystem atrophy (O'Brien 2007).

MRI studies consistently demonstrate that pathological changes occur in the brain even before illness onset. Specifically, MRI has been used to demonstrate that individuals with no cognitive complaints or subjective memory complaints but normal cognitive testing already show signs of atrophy similar to a pattern of atrophy seen in Alzheimer's disease (Peter et al. 2014). In fact, multiple studies have now demonstrated that a pattern of atrophy unique to Alzheimer's disease is seen volumetrically several years before the onset of clinical symptoms. In one longitudinal design (Tondelli et al. 2012), 148 healthy and cognitively normal older adults were measured at baseline and then later stratified by onset of either amnesic mild cognitive impairment (MCI) or Alzheimer's disease (AD). Here, all subjects were assumed to be healthy at baseline because researchers screened out those that were symptomatic four years after enrollment to ensure that subjects did not progress to clinical diagnosis shortly after enrollment. In this study, voxel-based morphometry demonstrated that relative to individuals who remained healthy after 10 years, those who later converted to either preclinical AD or MCI had a reduced gray matter density at baseline with a pattern of atrophy similar to that seen in AD.

Similarly, visual and volumetric analysis of atrophy to the hippocampus of individuals with amnesic MCI can be predictive of conversion from MCI to AD (Fleisher et al. 2008). In one longitudinal study of 130 patients with amnesic MCI, researchers used volumetric and surface morphometry analysis to examine the hippocampus over a three-year period. Relative to controls, researchers found that individuals with MCI had significantly reduced hippocampal volume and that those with reduced volume to the hippocampus and entorhinal cortex were more likely to convert to AD, even when controlling for demographics and cognitive functioning (Devanand et al. 2012).

In summary, although there are limitations, neuroimaging continues to be a powerful tool in both research and clinical settings, especially among older adults, who are uniquely vulnerable to acquired injuries and disease states. Imaging tools provide assessment of biomarkers that allow for early identification of disease, differential diagnosis, and longitudinal monitoring of brain health. Imaging has also provided a greater understanding of how disease states, such as AD and other dementias, develop and progress with time. As the general adult population continues to age, more research will without questions lead to additional advances in geropsychology and treatment of older adult populations.

Definition

Numerous measures exist, yet there is little consensus on the definition of subjective age (SA). Subjective age, unlike chronological age, is a multidimensional construct that reflects how old a person feels and into which age group a person categorizes himself/herself (Kleinspehn-Ammerlahn et al. 2008). It is a self-perception of age, and common to most definitions is the notion of how old or young individuals experience themselves to be (Montepare and Lachman 1989). According to the pioneering work by Kastenbaum et al. (1972), subjective age is a person's sense of age based upon: (1) the reflection of their own development and their interpretation of aging or how old an individual feels, looks, and acts, (2) with which age cohort the individual identifies, and (3) how old the person desires to be (Kaliterna et al. 2002). More recently, Diehl and associates conceptualize

subjective age as a specific form of self-knowledge and a part of the processes and conditions of the aging self (Diehl 2006).

Measures of Subjective Age

Kastenbaum et al. (1972) suggested subjective age largely reflected two components including how old a person looks and how old a person feels, assessed initially with single items. This was later expanded to four dimensions, leading to an often-used method of measuring SA, which was influenced by Barak (1987) and based on Kastenbaum et al.'s (1972) four dimensions of how they feel, how they look, how they act and behave, and what interests they have. Barak labeled this measure "cognitive age," and it has repeatedly demonstrated high levels of reliability (Barak 2009).

Although these four dimensions are important, most SA measures do not necessarily reflect all four dimensions. Rather, SA is often measured in various ways; in particular, using single-item assessments that reflect a global measure, multiple items which are intended to assess a single dimension and more recently multiple items that assess and reflect multiple dimensions or factors.

One-item measures. Single-item measures of SA are simple and straightforward, such as items that ask "What age do you feel?" or "Would you say that you feel young, middle-aged, old, or very old?" (Barrett 2005; Cleveland and Shore 1992; Cutler 1982) or using a single item that required employees to rate whether they feel younger, middle age, or older (Cleveland and Shore 1992). Single-item assessments of subjective age continue to be encountered in the research literature today. These items ask one of the following: (1) to specify in years how old respondents feel most of the time and then compute difference scores with actual age (Barnes-Farrell and Piotrowski 1989; Barnes-Farrell and Rumery 2000; Barrett 2003, 2005); (2) to specify what age do [they] feel, or what age do [they] feel most of the time, within a specific time frame (e.g., during the last year or month), or (3) how old individuals experience themselves to be with respect to various

psychological, physical, and social attributes (e.g., a lot younger than my age; Montepare 1991, 2006).

Multiple item/dimension measures. One multi-item measure is a 47-item assessment of personal aging experience that includes items relevant to subjective age (Steверink et al. 2001). These items refer to both positive and negative statements regarding aging in a number of life domains (e.g., health, personality, social contacts). Two pilot studies showed that the 47 items reflected three factors: physical decline, continuous growth, and social loss. These findings reinforce earlier conceptualizations of subjective as a multidimensional construct (Steверink et al. 2001). This measure supports Keller et al.'s (1989) structure of subjective age.

Drawing from Levanthal's self-regulation model of health and illness, Barker and colleagues (2007) developed a multidimensional assessment of aging perceptions. In this model, illness is viewed as a stressor, and people's perception and response to this stressor affects subsequent health and longevity. These illness perceptions have a number of facets including time-bound stressors and responses, consequences, and control. The Aging Perceptions Questionnaire (APQ) incorporates this approach and consists of 32 items reflecting seven dimensions: two timeline dimensions perceptions of aging (timeline-chronic and timeline cyclical); two consequence dimensions (positive and negative); two control dimensions (positive and negative); and a seventh, emotional representation that refers to negative emotional reactions to aging. Sexton et al. (2014) developed a short version of APQ, which combined negative control and negative consequences and eliminated the timeline cyclical dimension thereby yielding a 17-item, five-factor model.

Subjective Age at Work. Rioux and Mookkolo (2013) argue that subjective age at work is a separate construct from general subjective age. Their study also revealed subjective age at work to be a better predictor of certain outcomes related to work, such as satisfaction with professional life. Their measure includes items assessing specifically how old individuals feel, look, or act when they are at their workplace.

Other measures have taken similar approaches by assessing how old an individual feels in comparison with their work group (Cleveland and Shore 1992).

Related Constructs and Measures

Subjective age is, of course, related to many other age constructs. Examining these relationships helps to shed light on the precise meaning of subjective age.

Age identity, Psychological age, and Cognitive age. Age identity has been used interchangeably with subjective age. However, Kaufman and Elder (2002) suggest that age identity consists of four dimensions including subjective age, desired age, perceived old age, and desired longevity, with a related study tapping subjective age, other age, desired age, and perceived old age. Barak et al. (2001) suggest that age identity is a measure of cognitive age. Other researchers have assessed subjective age identity using subjective age scales (e.g., Montepare 1996; Montepare and Clements 2001).

Awareness of Age-Related Changes (AARC). Both AARC (Diehl and Wahl 2010) and successful aging (described below) are two constructs that are enjoying increasing attention in the age and aging literature and may reflect superordinate constructs of which subjective age, age identity, and so forth are subsumed. Diehl and colleagues posit that subjective age is a facet of self-knowledge. Awareness of age-related changes refers to all the experiences that a person encounters (e.g., own behaviors, level of performance or life experiences) that make him/her aware that his or her life has changed as a result of growing older.

Successful Aging at Work. A related construct is successful aging at work (e.g., Kooij 2015; Zacher 2015) and draws upon Baltes and Baltes' (1990) work on successful aging in general and extends this important work in important ways. Although its concrete meaning, assumptions, and underlying process remain unclear, successful aging refers to the conditions of the person and situations where an individual obtains a maximum

satisfaction and happiness (Birren 1958; Havighurst and Orr 1955; Zacher 2015). Success can be generally defined as the securing of desired and favorable outcomes. Rowe and Kahn's (1987, 1997) conceptualization of successful aging represented a significant milestone in defining and research of this concept, and they define it as including three largely objective outcomes including a low probability for disease and disability, continued high physical and cognitive performance, and engagement in social and constructive activities. Importantly, Zacher (2015) recently proposed that successful aging at work should have the following four elements: (1) a focus on both subjective and objective outcomes relevant and important to individuals and context; (2) focus on testing intraindividual age-related changes in success aging criteria over time and across life/work span; (3) investigation of age-related mediators, and (4) description of any positive (work) outcomes of older people/employees, regardless of the age-related processes and conditions that lead to an outcome (Zacher 2015).

Often successful aging is measured using both semiobjective assessments including health indicators and more subjective mental and emotional assessments. For example, Freund and Baltes (1998) used subjective well-being, positive emotions, and absence of loneliness as measures. Further, Kotter-Grühn and Hess (2012) used aging satisfaction as a measure of successful aging.

Theoretical Frameworks

Historically, the construct of subjective age has been theoretically underdeveloped (Diehl et al. 2015), and this may have led to the generation of numerous related terms including psychological age, age identity, self-perceptions of aging, attitudes toward aging, and cognitive age. Further, in the early research on subjective age, there were few instances where subjective age was linked with life span development or human development. However, numerous aging theories can and have contributed to our understanding of subjective age including (1) Bronfenbrenner's (1994) bioecological model; (2) selective optimization

with compensation theory and socioemotional selectivity theory (SST/SSC); (3) stereotype embodiment theory; and (4) life span and life-course theory.

Ecological model. Bronfenbrenner's biopsychosocial approach to aging and is an excellent organizing framework for understanding subjective age. According to this model, individuals learn, change, mature, and age by their interactions with multiple ecologies or environments. Four levels are identified in the model: microsystem, mesosystem, exosystem, and macrosystem. Perhaps the two most influential systems in terms of affecting SA are micro- and macrolevels. In terms of shaping SA, the individual's direct interactions with an environment are most influential in shaping SA. These include proximal processes (e.g., family, work) and influence the self-directed attitudes about aging held by an individual, including how satisfied the person is with his or her own aging process, and the awareness of becoming older.

At the mesosystem and exosystem levels, subjective aging is affected through interactions between two or more microsystems (e.g., family system and health care) with the latter involving at least one system that does not directly include the individual (e.g., availability of healthcare services information on aging and quality level of physician training). Finally, the macrosystem level includes each of the previous three systems (micro, meso- and exo-) and encompasses broad age stereotypes and values assigned to "being old," which may be widely held by members of a particular culture (sociocultural perspective on age stereotypes; Hummert 2011), including cultural structures and social policies.

Selection, Optimization, Compensation, and Socioemotional Selectivity Theory. The selective optimization with compensation (SOC) model conceptualizes how people cope with age-related changes, adapt throughout their lives, and use strategies to maximize potential for successful aging. The theory emerged from the gain/loss dynamic within life span development. This is the process of how humans both grow (gain) and decline throughout the aging process (e.g., Baltes 1987).

The SOC theory has three main parts that encompass the gain/loss relationship for successful aging: (1) *strategic selection* of focusing one's resources and adapting in terms of contexts, outcomes, and goal structures, which is important because it directs a person's behavior based on their hierarchy of goals, necessary because one's resources are often limited; (2) *optimizing* potential by maximizing the gains possible, and (3) *compensating* for losses (Baltes and Baltes 1990; Freund and Baltes 2002; Baltes 1997). The socioemotional selectivity theory (SSC) focuses upon the premise that as one ages, her/his perception of time shifts (e.g., Carstensen et al. 1999). Among younger people, the future seems more distant than among people who are older; therefore, motivations and goal seeking vary between these groups. For example, younger people are more likely to invest in the future, while older individuals may focus upon enhancing current relationships and events. SSC recognizes that these social interaction goals will not only shift throughout the life span due to distinct time limitations at hand, but the selection of goals will change as well. For example, younger people will be more motivated to have knowledge-related goals, while later in life, as they age, emotion-related goals will be more important. Further, an older person is more likely to reduce their social interactions with new acquaintances while increasing time with people who are more emotionally meaningful to them.

Although both SOC and SST have been primarily assessed in relation to chronological rather than subjective age, the approaches may apply to subjective age in terms of predictions, growth and maintenance orientation, as well as an open future time perspective.

Life Span Development. The life span development perspective of aging is concerned with the development of changes across the life span and is not one particular theory; many orientations are connected with these ideas and encompass the approach. Baltes and colleagues rooted their research deeply into the life span perspective (Baltes 1987; Baltes et al. 1980, 1992). They have put forth a number of propositions about the nature of aging. These propositions include

assumptions that (1) major differences occur among normal, pathological, and optimal aging; (2) course of aging shows much interindividual variability (heterogeneity); (3) old age shows much latent reserve capacity; (4) range of reserve capacity or adaptivity shows loss with increasing aging; (5) with age, the balance between gains and losses becomes increasingly negative; and finally, (6) the self in old age remains a resilient system of coping and maintaining integrity.

Accordingly, the age individuals perceive themselves to be (subjective age) involves the experience of time along multiple dimensions – including life-course transitions. The life span perspective illuminates variation across and within life stages by identifying developmental processes and age triggers that drive age identity (Diehl and Wahl 2010). The life-course perspective highlights other temporal issues including social, cultural, and historical factors that influence developmental processes and shape age-related patterns in subjective age.

Stereotype embodiment. An emerging prominent psychosocial theory that provides one explanation for the development of subjective age is the stereotype embodiment theory (Levy 2009). Research has shown that among older individuals, negative age stereotypes held earlier in life predicted poorer health (Levy et al. 2009). Based on a series of experimental and longitudinal research, Levy proposed that age stereotypes (1) become internalized across one's life; (2) may be activated and influential unconsciously; (3) develop greater influence or salience as they become more self-relevant (as a person ages); and (4) can influence expectations through psychological, behavioral, and physical means (e.g., via multiple pathways).

Antecedents and Outcomes of Subjective Age

Subjective age is a complex psychological construct and does not always systematically reflect changes in chronological age. One can more fully understand the concept by explicating the antecedents and outcomes of variations in aging perceptions.

Antecedents

To begin, there are general categories or perspectives behind explaining the most salient antecedents associated with subjective age. These more commonly are psychological factors, the social context, or a combination of both (Berg 2007). The first perspective, psychological, is comprised of research supporting the notion that personal factors (e.g., financial stability, personality, cognitive factors) and perceptions are the main antecedents of subjective age. For instance, Arnett (1998) contends that social events do not dictate the way one perceives youth; it is their psychological state. In other words, according to this perspective, the way someone feels about their stage (e.g., financial stability) in life is going to be more indicative of their age perceptions rather than the actual events or roles themselves. It has been shown that subjective age is influenced by certain psychological variables such as life satisfaction (Chua et al. 1990), internal locus of control (Hublely and Hultsch 1994), and so on. Also, within this perspective, it has been shown that certain personality characteristics (i.e., openness to experience) serve as predictors of subjective age irrespective of socioeconomic and health-related variables (Canada et al. 2013).

Many researchers consider health to be an individual difference driving age perceptions, thus falling into this psychological perspective. There is no doubt that many health variables (e.g., general health, physical health, functional health, mental health) and stress are related to subjective age differences (e.g., Bergland et al. 2014; Chua et al. 1990; Kotter-Grühn et al. 2015). Petery (2015) tested the directionality of these health variables and found health to be both an antecedent and an outcome of subjective age. She specifically found that health was an antecedent for subjective age in people older than 50, but not for those younger than 50 years old. Previous research has examined that certain stressors early in life (e.g., sexual abuse, financial hardship) influence subjective aging (e.g., Turner et al. 1999; Johnson and Mollborn 2009). In addition, subjective health perceptions are central predictors of subjective age more than many other influential predictors such as SES and/or education (Barrett 2003; Mutran and Burke 1979).

The second perspective, the social context, is mostly concerned with the environment around the person (e.g., the workplace) and the social roles people hold. Within this perspective, it is surmised that life events and social roles are the most important antecedents to subjective age (Mathur and Moschis 2005). Life events could include moving out of the house, having children, or transitioning into retirement, and these have been shown to influence age perceptions (e.g., Benson and Furstenberg 2003). It is important to note that social interactions are complex and these antecedents might not be consistent across different cultures. For instance, it has been shown that those in Western cultures will have younger age perceptions than those in Chinese cultures (Chua et al. 1990). Additional research is needed on this topic.

It is also important to consider the workplace as a domain that can provide a great deal of influence over age perceptions. Kunze et al. (2015) examine what aspects of the organizational context lead to changes in employees' subjective age. They concluded that perceived meaningfulness of work could shape age discrepancies for workers. In other words, when employees have high work-related meaning, they are more likely to benefit from experiencing a lower subjective age (Kunze et al. 2015) when age-inclusive HR practices are present. In addition, they found that average relative subjective age was negatively related to average individual goal accomplishment in companies, which in turn is related to company performance.

The third perspective acknowledges that both psychological and social variables together play a role in predicting subjective age. Shanahan et al. (2005) highlight that there are social variables and personal qualities that can influence age perceptions. For instance, there are social roles (e.g., being a parent), social domains (e.g., with friends, at work), and traditional transition markers (e.g., marriage) that interact with personal differences (e.g., cognitive maturity) to impact subjective aging.

Finally, chronological age (CA) is a significant predictor of subjective age. Along with one's health, CA shows a stronger relationship with SA than any other predictor (Cleveland and

Shore 1992; Mathur and Moschis 2005), with correlation coefficients between 0.44 and 0.81.

Outcomes

The subjective age of a person also relates to certain outcomes inside and outside of work. Within a sample of shift workers from a large manufacturing organization, older subjective age was associated with higher perceived stress at work and lower reported presence of support mechanisms (Barnes-Farrell and Piotrowski 1991). A study by Bobko and Barishpolets (2002) found increased physical tiredness in Ukrainian workers with an older subjective age, and workers with a younger subjective age generally reported better physical ability to work; the difference between felt age and chronological age was also related to self-ratings of stress factors. A younger subjective age is also related to the self-perception of achieving higher work performance and less tiredness after work days (Iskra-Golec 2002). Furthermore, Kaliterna et al. (2002) found that workers with a younger subjective age can feel more capable of mastering the mental, physical, and social demands of certain occupations. Organizations that employ workers with a younger subjective age have more beneficial performance if the company operates in a dynamic environment (Kunze et al. 2015). Rioux and Mokoukolo (2013) differentiate between general subjective age and subjective age at the workplace. They contend that both are linked to higher satisfaction with professional life, but specifically an older subjective age at the workplace is also linked to higher attachment to the workplace.

Segers et al. (2014) conceptualized a framework for age perceptions at work, called the Age Cube of Work. It has not yet been empirically tested, and the main purpose of the Age Cube of Work is currently to generate empirical questions regarding work and aging. The Age Cube includes a dimension capturing important work context variables (i.e., job, team, organization, industry, and country). Although it has been demonstrated that subjective age has been studied briefly in the workplace, much additional research is still needed to fully examine all relevant job related variables and outcomes (e.g., retirement timing).

Subjective aging has mostly been studied outside of the work context. The extent to which a person feels younger or older as her/his actual chronological age has shown to influence health outcomes. Barrett and Toothman (2014) found that a younger age identity is generally related to better health (i.e., if you feel young but are chronologically older, that is a predictor of positive health outcomes). Bowling et al. (2005) reported similar results in regard to both physical and psychological health and functioning. Furthermore, their study revealed that participants with a younger subjective age indicated higher self-efficacy and tended to rate their quality of life higher than participants with a lower subjective age. Additionally, Boehmer (2006) examined subjective age in cancer patients and found that patients who reported a younger subjective age, or feeling as old as they really were, perceived themselves to have higher health-related quality of life than patients who felt older than they really were. In another study, Boehmer (2007) also found that cancer patients with a younger subjective age indicated higher satisfaction with recovery after their surgery, as well as a lower perception of personal disability. These results indicate that subjective age is a relevant factor when considering the healing and recovery of people who are fighting with illness.

Other health outcomes of subjective age relate to mental health and depressive symptoms. Choi and DiNitto (2014) found that an older subjective age can have a negative effect on depressive symptoms, and Keyes and Westerhof (2012) demonstrated similar results by confirming that a younger subjective age is related to the increase of flourishing mental health and a decrease in major depressive episodes. Furthermore, a younger subjective age can lead to higher levels of subjective well-being, which is characterized by life satisfaction and positive affect (Westerhof and Barrett 2005). It has also been shown that a younger subjective age and therefore feeling further from death can lead to lower psychological distress (Shrira et al. 2014), and it has also been shown to lead to lower levels of C-reactive protein (CRP). CRP is associated with some physical functional limitations and quicker cognitive decline (Stephan et al. 2015b); a younger

subjective age therefore has positive effects on physical and psychological health.

Other outcomes of a younger subjective age include a higher intention to perform physical activities (Caudroit et al. 2012). Also, Stephan et al. (2013) achieved improved physical functioning measured by grip strength by inducing a younger subjective age in their participants. Teuscher (2009) found correlations between a younger subjective age and higher optimism, self-efficacy, and general satisfaction. Stephan et al. (2015a) also found that people with demonstrated accelerated subjective aging had steeper and nonnormative declines in the personality traits Extraversion and Openness. Participants with slower subjective aging on the other hand showed typical patterns of decline of these personality traits. People with an older subjective age had less tendencies to be sociable, energetic, and enthusiastic. Depending on the age group though, an older subjective age can also have advantages. First-year university students can benefit from an older subjective age in regard to positive and negative affect, particularly students with vulnerable self-esteem. Students with a higher subjective age may report higher positive affect and more self-enhancement and protection against threats to psychological well-being (Fang and Galambos 2015).

While there are several outcomes of SA, it is also important to consider that some of these are mediated by the social status older people hold in society due to their age (Marques et al. 2015). There is a negative relationship between age identification and health in countries where people of older age are devalued in terms of their social status. Mock and Eibach (2011) found that a person's attitude towards aging influences the relationship between subjective age and well-being. Less favorable aging attitudes can lead to lower life satisfaction and increased negative affect when a person demonstrates an older subjective age.

Cultural Considerations

A review by Barak (2009) showed that subjective age is an appropriate construct to use across

nations and cultures. It translates well and can be measured with reliability and validity in a cross-cultural research context. It was found that there is a generally consistent pattern across 18 different countries that people felt and desired younger ages than their chronological age. In addition, Barak found a consistent pattern of ideal age being younger than subjective age, which was younger than chronological age (as he illustrates as ideal age < subjective age < chronological age). However, additional research is needed to fully explicate these comparisons and compare nations statistically (e.g., Barrett and Montepare 2015), because there are still meaningful and prominent cultural differences that exist. For instance, although both Americans and Germans feel younger than their chronological age, this relationship is stronger among Americans (Westerhof et al. 2003). Also, Barnes-Farrell et al. (2002) revealed differences in age-perceptions, specifically components of psychological age (subjective age, act age, and preferred age) among five nations that were included in their study of healthcare workers. These differences are most likely due to differing cultural beliefs regarding age-appropriate behavior and the differing values that the USA, Ukraine, Brazil, Poland, and Croatia hold for youth and/or age. Furthermore, the relationships between felt age and work strains, specifically physical fatigue, mental fatigue, and tension, differed among all five nations.

Both social roles and the social environment shape an individual's aging experience (Diehl et al. 2015), and these variables are known to differ culturally both inside and outside of work. For instance, social experiences, such as age discrimination or stereotypes, differ across groups of individuals and present important influences on subjective age. Events that serve as social markers that trigger subjective aging perceptions also differ culturally (e.g., rites of passage, sexual maturity, retirement). Subjective age research is not always conclusive. For example, some researchers have found gender differences in subjective age (e.g., Peters 1971), while others have not (e.g., Baum and Boxley 1983). These inconsistent findings can also be found with other

variables such as educational level and marital status with subjective age (Barak and Stern 1986). These differences can be due to ethnic and cultural differences in the samples studied (e.g., Henderson et al. 1995).

Not only are there cultural differences cross-nationally, but there are cultural differences within similar societies. An example of this is generational differences. The cultural influences of someone in a much older cohort might not align with those of a younger cohort. Setterson and Hagestad (2015) illustrate this anecdotally by noting that a younger generation today might greatly emphasize their individuality and autonomy in their aging perceptions, whereas someone from a much older generation would not include this in their interpretation of aging as strongly and be more concerned with concepts such as "human agency." With increasing life expectancy in many countries, society is growing older, and this has implications for subjective age perceptions as well. These demographic shifts help to shape new age-expectations for individuals (Setterson and Hagestad 2015). For instance, people are healthier, family structures are shifting, life expectancy is longer, and people are staying in the workplace longer.

Future Directions

People in their 20s tend to believe middle and older age begin at a lower chronological age than do older individuals. People in their 60s often consider themselves to be middle age. Further, the gap between chronological and subjective age becomes wider as individuals become older. For example, older individuals often feel younger than their chronological age would indicate (Goldsmith and Heiens 1992). In addition, the gap between chronological and subjective age is wider for middle-aged and older women than it is for middle-aged and older men (Montepare and Lachman 1989).

Further, there is evidence from the gerontological literature that after childhood, where chronological age serves as a reasonable developmental milestone, one's chronological age increasingly

becomes a less useful description of one's "age." Historically, the initial alternatives to chronological age reflected one item or one-dimensional measures of some facet of subjective age. More recently, multidimensional measures of subjective age, awareness of age-related changes, and successful aging are all promising concepts to pursue in relation to understanding the links between age and important work outcomes.

There are a number of research questions that are important next steps. First, there is a need for clearer construct articulation and explication of subjective age or subjective aging. Research in this area is more measurement-focused currently; there is a pressing need to develop the theoretical relations among subjective age and related constructs and determine the convergent and discriminant validity of relevant age measures. Second too little is known about the psychometric properties of subjective age measures, AARC, and successful age measures. Are these overlapping measures and if so, by how much? Does the SA construct add to other constructs? Is it a part of other constructs or are other constructs facets of SA? Each of the many age constructs described here is based on similar core theories from the gerontology literature, although each uniquely draws from other theories as well. Yet few theories, if any, attempt to elaborate on the relationships among these age constructs.

Third, what work and well-being outcomes does each class of age measures predict? What unique contributions do various measures make to such outcomes and how do different measures operate jointly? (Cleveland and Hanscom [in press](#)). Fourth, what proximal (e.g., job, supervisor, coworker) and distal (e.g., stereotypes, climate) variables influence employee perceptions of their own age and the age of their co-workers? Fifth, one of the poorly understood aspects of this key construct is its malleability. The beliefs workers hold about their age and the age of others are important, but the source and determinants of these beliefs are not well understood especially within the work context. Can beliefs be modified to enhance adaptability and successful aging? For example, Diehl and colleagues have developed the AARC construct and initiated research and

pilot interventions to enhance and change people's age self-perceptions. One goal of these interventions is to enhance individual well-being and position health and exercise behaviors. This laudable stream of research is one that should be tested and applied to employee in the workplace, young and old alike.

Not only older people need to be examined, but also younger people to determine whether or not subjective age and well-being can be influenced in order to enhance both one's work and personal lives (e.g., Zaniboni et al. 2014). Given the clear evidence of the increasing chronological age of many members of the workforce, finding out how beliefs about what constitutes an "old" (and a "young") worker develop and change is important.

Definition

Subjective memory is one's perceived memory ability, independent of objective standards or performance. Subjective memory reflects one's perception about his or her personal memory functioning. It is a construct to be quantified, studied, and understood in clinical practice and can be referred to as subjective memory complaints (SMC), subjective memory decline (SMD), subjective cognitive decline (SCD), subjective memory impairment (SMI), and subjective cognitive impairment (SCI) (Edmonds et al. 2014; Stewart 2012).

The Construct of Subjective Memory

The precision and utility of the construct of subjective memory performance has been scrutinized since its introduction as a potential variable of interest for older adults at risk of dementia (Stewart 2012). Studies remain mixed regarding its reliability, its value in relationship to objective measures of memory performance, and its prognostic value for future memory or general cognitive decline (Crumley et al. 2014; Edmonds et al. 2014). The reliability of subjective memory has been questioned on the basis of variability in the source, which can include patients, informants, or skilled clinicians (Albert et al. 2011). Moreover, the diversity of terminology used within the construct provides opportunity for conflation of the reported concerns, be those specifically memory related abilities, nonmemory related abilities, or a combination of both (Edmonds et al. 2014).

Nevertheless, the construct of SMC has played a prominent role in the clinical appraisal of cognition, specifically as a diagnostic criterion of mild cognitive impairment (MCI; Diagnostic criteria for MCI include SMC to capture self-reported experience of change in cognitive performance and to exclude individuals with longstanding cognitive difficulties) (Petersen 2004). Edmonds and colleagues (2014) recently questioned the efficacy of SMC as an MCI criterion within a cohort of participants from the Alzheimer's

Disease Neuroimaging Initiative (ADNI) previously labeled as MCI. Using hierarchical cluster analysis they demonstrated that overestimation of self-reported cognitive complaints was more frequent in cognitive cluster-derived normal subgroup, while underestimation of self-reported cognitive complaints was more frequent in an amnesic cluster-derived MCI phenotype, which is associated with progression to Alzheimer's dementia.

To address the dissociation of objective and subjective memory, Dalla and colleagues (2015) recently proposed a cognitive model of subjective memory awareness, whereby memory performance is construed as first-order consciousness or "consciousness in action," and awareness of memory performance is understood as second-order consciousness or awareness of first-order consciousness. Within such a model, congruency between objective memory, performance, and subjective ratings of said performance is mediated by awareness. Poor awareness of memory performance in the context of good objective performance constitutes cognitive dysgnosia; on the other hand, poor awareness of memory performance in the context of impairment objective performance constitutes anosognosia.

Beyond cognition, the relationship between subjective memory function and aspects of well-being has also been investigated. Mol and colleagues (2007) reviewed a small sample of studies ($n = 5$) meeting inclusion criteria for SMC in the absence of objective memory impairment. They reported consistently diminished quality of life (QoL) in older adults endorsing SMC across studies incorporating different methodologies and measures of QoL. Mol and colleagues (2009) also investigated the presence of SMC on measures of QoL (satisfaction, mental well-being, anxiety, depression) over time. Older adults with SMC at baseline reported lower overall QoL and increasing amounts of anxiety over time when compared to those without SMC. More recently, Zuniga and colleagues (2016) found that community-dwelling older adults ($n = 179$) reporting fewer memory complaints endorsed lower perceived stress, fewer adverse physical symptoms, and higher levels of happiness.

On the other hand, as the awareness and accuracy of objective memory deficits diminish over the course of neurodegenerative illnesses, it is accompanied by higher QoL ratings (Trigg et al. 2011; Hurt et al. 2010). The relationship between patient and informant report of SMC has also been shown to be relevant. While healthy individuals without SMC often align with informant report on measures of memory concern, discrepancy between self and informant report is common. Gifford and colleagues (2014) found that among healthy control participants who later converted to MCI/dementia, mutual self and informant SMC was associated with the largest increase in risk for conversion, followed by informant only, and then self only SMC. For participants with MCI, only mutual self and informant SMC and informant only SMC were associated with increased risk of conversion to dementia. Thus, obtaining collateral report of memory complaints is valuable in distinguishing pathological aging trajectories and can play a role in early intervention planning.

Prevalence in Population

SMC are common among middle-aged adults and elderly. In a sample of 1,971 adults between the ages of 25 and 85 years old, 41% of people between the ages of 55 and 65 and 52% of people between the ages of 70 and 85 years old reported being forgetful (Ponds et al. 1997). Prevalence of memory complaints varied in other community-based studies with older adults, ranging from 22% in adults 65–84 years old (Jonker et al. 1996) to over 50% in adults 65 years and older (Blazer et al. 1997). Fritsch and colleagues (2014) reported that in a sample of 499 community-dwelling older adults aged 65 and older, 27% endorsed SMC. Jessen and colleagues (2007) reported that 30% of healthy older adults acknowledge difficulty remembering recent events, as well as where certain “belongings are kept.” Prevalence of subjective cognitive impairment in community adults 65 years and older ranged from 25% to 56% (Reisberg et al. 2010).

Relationship to Psychiatric Symptoms

Mood symptoms play an important role in understanding SCI. Self-reports of cognitive problems in older adults are often attributed to depression rather than being reflective of objective memory deficits, such as what would be seen in early neurodegenerative disease. Indeed, SCI is often the primary complaint in older adults with depressive symptoms, and difficulties with memory and attention are commonly reported in those who are depressed (Reid and MacLulich 2006). Several studies indicate that depression is highly correlated with memory complaints, and that SCI, as measured by self-referrals for memory evaluations and self-reported memory concerns, are more likely due to depressive symptoms rather than objective memory problems (Jonker et al. 2000). Several large studies have shown that SCI is not related to performance on objective cognitive measures and instead reflect mood symptoms and personality traits (Jorm et al. 2004; Kliegel et al. 2005). Further, Minett and colleagues (2008) also found that SCI is strongly associated with depressive symptoms in adults aged 50 or older, more so than with poor performance on objective cognitive measures. These findings suggest that mood functioning may be driving concurrent subjective cognitive concerns rather than cognition.

However, the majority of research examining the relationship between SCI and mood are cross-sectional studies or utilize healthy aging samples. Longitudinal studies of older adults suggest a more complicated relationship between mood, SCI, and cognition. While cross-sectional studies suggest that SCI is related to personality traits and depressive symptoms, when examined over time, several studies have shown that baseline SCI predicts which individuals went on to experience cognitive decline (Reid and MacLulich 2006). Similar findings suggest SCI is not just a symptom of depression, but may reflect an individual's realistic observation and self-appraisal of his or hers cognitive status, particularly with respect to the prediction of future cognitive decline (Schmand et al. 1997).

Taken together, these findings suggest an interesting interplay between mood, SCI, and

cognitive decline. There is evidence that depression is associated with worse performance on cognitive measures and SCI. But, depression may also be a by-product of a realistic awareness of subtle cognitive difficulties. Individuals who are aware of declining cognition may feel more depressed, and individuals reporting depression may describe worsening cognition, resulting in exacerbation of both depressive and cognitive symptoms (Schmand et al. 1997).

Relationship to Neuropsychological Performance

SMC may at times reflect very subtle changes in cognitive functioning that may not be recognized by neuropsychological tests. Some research indicates that people who report subjective cognitive changes are “worried well,” and therefore there is no relationship between SMC and objective memory performance on neuropsychological tests (Flicker et al. 1993; Ginó et al. 2010). However, other research has indicated significant relationships between SMC and cognitive performance on objective neuropsychological measures (Reisberg et al. 2010; Amariglio et al. 2012; van Harten et al. 2013). Amariglio and colleagues (2012) found significant relationships between people with SMC and decreased performance on neuropsychological measures of episodic memory, working memory, and semantic information. Longitudinal research revealed that people with SCD demonstrate a more rapid decline on immediate recall tasks (Reisberg et al. 2010).

Several studies have also revealed that SMC in cognitively intact older adults is related to an increased risk in dementia (Geerlings et al. 1999; Reisberg et al. 2010). Reisberg and colleagues (2010) found that healthy older adults reporting SMC are more likely to experience future cognitive decline than healthy older adults who do not have SMC. When controlled for age and other similar factors, older adults with SMC were 4.5 times more likely to develop MCI or dementia than adults who did not report decline (Reisberg et al. 2010).

Additionally, Reisberg and colleagues (2010) revealed that adults with SCI, whose performance on neuropsychological measures were lower, but still within normal limits, were more likely to have cognitive decline than adults whose neuropsychological performance remained stable at follow-up visits.

Predictive Value of Future MCI and/or Neurodegenerative Disease

Subjective cognitive impairment is very often seen in individuals with mild cognitive impairment (MCI). Individuals with MCI function independently on day-to-day tasks, yet show cognitive impairment in specific areas, often memory, that is beyond what would be expected during the process of healthy aging (Petersen et al. 1999). The role of SCI is important in Petersen’s conceptualization of MCI, but corroboration by an informant is also preferred. This is predicated in evidence that 35–75% of individuals with MCI have cooccurring neuropsychiatric symptoms, which also are correlated with subjective cognitive complaints and may not be as predictive as collateral reports, which are thought to be more strongly correlated with objective performance (Apostolova and Cummings 2008). Of course, Petersen’s criteria also call for objective memory deficits. Longitudinal follow-up shows that individuals with MCI convert to Alzheimer’s disease (AD) at differing rates. Fischer and colleagues (2007) reported a 49% conversion rate to AD for individuals with amnesic MCI after 30 months. This rate declined to 27% for individuals with nonamnesic MCI. For cognitively healthy individuals at baseline, the rate dropped further to 13%. Busse et al. (2006) estimated the maximum conversion rate to dementia in individuals with MCI to be approximately 65%. Notably, they reported that conversion rates to dementia are highest during the first 2–3 years of clinical observation (20%).

The combination of mild memory difficulties despite relatively intact general cognition often results in individuals being well aware of their cognitive decline, or even noticing subtle cognitive

changes before evidence is seen on objective measures. In point, individuals are often referred for memory evaluations after reporting subjective memory concerns to their physicians. Empirical findings on the overall accuracy of SCI to predict cognitive decline is mixed. Several studies not surprisingly show higher levels of cognitive complaints in individuals with MCI as compared to healthy older adults (Roberts et al. 2009). Specifically, individuals with MCI are often aware of experiencing decline in their general cognitive abilities, but are poor at predicting their actual memory deficits (Clément et al. 2008). Baseline SCI has been shown to be predictive of objective memory problems at a 3-year follow-up and associated with an increased risk for a future diagnosis of dementia even when baseline cognition was normal (Geerlings et al. 1999; Luck et al. 2014; Schmand et al. 1996; Tobiansky et al. 1995). Even more striking, a recent metaanalysis found that older adults with SCI are twice as likely to develop dementia as individuals who are not reporting SCI, with an annual conversion rate of 2.3% for dementia and 6.6% for MCI (Mitchell et al. 2014). SCI has also been associated with poorer functional autonomy and consistent with daily functioning problems associated with MCI (Clément et al. 2008).

Yet, other studies have shown SCI has little association for either present objective cognitive difficulties or future incidence of dementia, and a recent study found that subjective memory concerns do not predict mortality over an 8-year span (Kliegel et al. 2005; Jorm et al. 1997; Roehr et al. 2016). However, the majority of studies suggest that baseline subjective memory complaints predict future cognitive decline over a 2-year span, particularly for those already carrying a diagnosis of MCI (Jonker et al. 2000). The inconsistencies in extant literature for SCI to portend cognitive decline may be partially attributed to variance in individual's level of cognitive awareness (Roberts et al. 2009). There are also differences in sensitivity to change, with some being hyper aware to any changes in cognitive status, overestimating dysfunction and falling more in to a category of "worried well." Others may be less attuned and be unaware or nonchalant of deteriorating cognitive abilities. Further, an individual's

self-awareness of cognitive deficits likely depends on the level of objective cognitive difficulties. Individuals may report cognitive deficits in proportion to objective findings, but insight may deteriorate as cognitive deficits become more severe, resulting in a bell-shaped curve of self-awareness in relation to cognitive difficulties (Mitchell et al. 2014). Such variance in personality and self-awareness are difficult to control for within subjective cognitive constructs, making reliance upon SCI as both a research and clinical entity difficult. Nevertheless, while individual differences in subjective cognitive awareness may contribute to these mixed findings, the significant inconsistencies in defining the construct of SMC, along with how MCI has been operationalized, are likely the strongest contributor to the discrepancy among study findings.

Proposals for Established Criteria Informing the Construct of SMC

Concerns surrounding the definition and underlying framework of subjective memory have prompted proposals to establish uniform criteria for this construct. Abdulrab and Heun (2008) detailed the lack of consistency in current descriptions of SMC among 44 papers providing definitions of the construct. They outline essential criteria, course-specific criteria, and nonessential supportive criteria detailed in the table below (Table 1).

More recently, Jessen and colleagues (2014) have outlined a framework for studies investigating SCD in preclinical AD specifically, offering research criteria for pre-MCI SCD and features that increase the likelihood of preclinical AD in individuals with SCD (*SCD plus*). Pre-MCI research criteria include: (1) self-reported persistent decline in cognitive capacity compared to previous normal status and (2) normal normed performance on standardized cognitive tests. Both of these criteria must be present. *SCD plus* criteria that can be applied to collected data include: specific subjective decline in memory, onset within past 5 years, age of onset of SCD >60, worries and concerns associated with SCD, and subjective worse performance compared to

Subjective Memory, Table 1 Proposed criteria for subjective memory impairment (Abdulrab and Heun 2008)

Essential criteria	Course specific criteria	Nonessential supportive criteria
<ul style="list-style-type: none"> • Age at presentation (e.g., >50 years) • Presence of memory complaints in a specified length of time (e.g., past 6 months) • Belief that memory is worse compared to earlier periods of life (e.g., when one was in high school or college) • Valid example of memory problems in everyday life • Frequency of memory problems (e.g., at least every week) • Normal objective memory performance (not-demented) 	<ul style="list-style-type: none"> • Gradual onset (may indicate AD) • Sudden or staggered onset (may indicate vascular dementia) 	<ul style="list-style-type: none"> • The belief that memory is worse than others of similar age • Memory worsening affirmed by an informant (close relative or friend who is in contact with subject at least monthly) • Subject spontaneously mentions memory problems if asked about any general medical concerns • Seeking medical help for memory problems

others of the same age group. In addition, confirmation of cognitive decline by an informant, presence of *APOE* e4 genotype, and biomarker evidence for AD are suggested as conferring additional likelihood of preclinical AD in individuals with SCD. Each of these recent proposals provides much needed specificity to the construct of subjective memory and offer specific criteria for more reliably assessing self-reported memory performance.

Conclusions

Subjective memory remains a construct of great interest to clinicians, researchers, and individuals

themselves. While the utility of self-reported memory performance always received some scrutiny, it remains a useful clinical tool to characterize patient experience and awareness and critically is a part of the diagnostic criteria for. Recent proposals offer recommendations for narrowing the definition of self-reported memory difficulties and parsing out symptoms that may be more associated with specific neurodegenerative diseases such as AD. These proposals provide much needed clarification and definition to the construct of subjective memory and if adopted may help advance the clinical utility of this construct, which has proven difficult to grasp.

Definition

A substantial proportion of older adults use and misuse alcohol, tobacco, illicit drugs, and prescription medications, and there are several risk factors that increase an older adult's likelihood of engaging in such health behavior. Due to their particular life stage, assessing older adults for substance use or misuse presents unique challenges. Few existing treatments have been tested on older adults; however, treatments are known to be more effective when they are tailored to the older adult and take into consideration any learning difficulties or disabilities.

Background

Thirty percent of the adult US population is comprised of baby boomers, a generation of individuals turned 65 starting in 2011 (Kuerbis et al. 2014). Longer life expectancies and the size of this group contribute to estimates of the number of older adults almost doubling in size from 40.3 to 72.1 million between 2010 and 2030. In past generations, older adults reduced their substance use as they aged (Moore et al. in press). This trend was reflected in the shrinking prevalence rates of substance use disorder (SUD) across the life span. Indeed, current prevalence rates of SUD among older adults remain lower than their younger adult counterparts. Additionally, few older adults present to formal treatment programs. These two facts lead many to assume that older adults do not generally use substances and subsequently do not require in-depth assessment or treatment.

Unlike previous generations, baby boomers came of age at a time when attitudes toward alcohol, tobacco, and drug use were more permissive and accepting, leading to greater rates of alcohol and drug use overall and subsequent SUD (Kuerbis et al. 2014). SUD among this generation have remained high as they age, with a seemingly slower rate of aging out of alcohol and drug use than their predecessors. Both the increased numbers of the individuals within this population and their greater rates of use contribute to higher estimated prevalence rates. Numbers of individuals 50 and older with SUD are estimated to more than double from 2.8 million in 2006 to 5.7 million in 2020. While older adult prevalence rates are lower than their younger adult counterparts, differences between the groups are slowly shrinking. This closing gap is even more of concern when taking into account the special vulnerabilities (biological, psychological, and social) of older adults to the effects of mood-altering substances.

Terms and Diagnostic Challenges

Relying solely on formal diagnosis of SUDs and treatment utilization paints an incomplete picture

of the effects of substance use among individuals 65 and older. Given their vulnerabilities with even limited substance use, older adult substance use requires expanded description. As a result, there are a variety of terms describing various forms of substance use.

Alcohol use that exceeds limits recommended by the National Institute of Alcohol Abuse and Alcoholism (NIAAA) (i.e., \leq seven standard drinks per week, no more than three on any one occasion; a standard drink is defined as a 12 oz beer, 4–5 oz glass of wine, 1.5 oz of 80-proof liquor) (National Institute on Alcohol Abuse and Alcoholism 2013) has been termed *unhealthy use* (Moore et al. in press). Currently, there is no recognized safe limit for tobacco or illicit drugs. Use of these substances would be considered unhealthy regardless of amount. *At-risk* drinking refers to drinking beyond the safety guidelines and includes identifiable risks such as drinking with comorbid health or mental health disorders but has yet to result in harm. *Problem drinking* refers to drinking patterns that result in identifiable harm but are subthreshold for the *Diagnostic and Statistical Manual*, 5th edition (DSM-5), alcohol use disorder (American Psychiatric Association 2013). *Nonmedical use of prescription-type drugs* relevant for older adults is use without a prescription, in greater amounts, more often or longer than prescribed, or for a reason beyond the parameters of the prescription given by the doctor.

The term *substance use disorder* refers to the diagnostic criteria using DSM-5, of which an individual must meet or endorse at least 2 or more of 11 criteria in at least 12 months (American Psychiatric Association 2013) (see Table 1).

Criteria for SUD may not be relevant to older adults, due to specific biological and social factors unique in late life (Center for Substance Abuse Treatment 1998), potentially interfering with accurate diagnosis. Age-related physiological changes increase the effects of substances in older age, resulting in a reduction in tolerance to these substances. Thus, increased tolerance, one of the primary indicators of SUD, cannot be used to determine SUD in older adults. In addition,

Substance Use and Abuse, Table 1 Substance use disorder (formerly substance abuse or dependence) criteria, from the *Diagnostic and Statistical Manual, Fifth edition*, p. 491

DSM-5 criterion for SUD	Consideration for older adult
A substance is often taken in larger amounts or over a longer period than was intended	Cognitive impairment can prevent adequate self-monitoring. Substances themselves may more greatly impair cognition among older adults than younger adults
There is a persistent desire or unsuccessful efforts to cut down or control substance use	Same as a general adult population
A great deal of time is spent in activities necessary to obtain the substance, use the substance, or recover from its effects	Consequences from substance use can occur from using relatively small amounts
Craving or a strong desire to use the substance	Same as a general adult population. Older adults with entrenched habits may not recognize cravings in the same way as the general adult population
Recurrent substance use resulting in a failure to fulfill major role obligations at work, school, or at home	Role obligations may not exist for older adults in the same way as for younger adults, due to life stage transitions such as retirement. Role obligations more common in late life are caregiving for an ill spouse or family member, such as a grandchild
Continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance	Older adults may not realize the problems they experience are from substance use
Important social, occupational, or recreational activities are given up or reduced because of substance use	Older adults may engage in fewer activities regardless of substance use, making it difficult to detect
Recurrent substance use in situations in which it is physically hazardous	Older adults may not identify or understand that their use is hazardous, especially when using substances in smaller amounts
Substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance	Older adults may not realize the problems they experience are from substance use
Tolerance, as defined by either of the following: 1. A need for markedly increased amounts of the substance to achieve intoxication or the desired effect 2. A markedly diminished effect with continued use of the same amount of the substance	Due to increased sensitivity to substances as they age, older adults will appear to have lowered rather than increase in tolerance
Withdrawal, as manifested by either of the following: 1. The characteristic withdrawal syndrome for the substance 2. The substance or a close relative is taken to relieve or avoid withdrawal symptoms	Withdrawal symptoms can manifest in ways that are more “subtle and protracted” (Barry et al. 2002). Late onset substance users may not develop physiological dependence or non-problematic users of medications, such as benzodiazepines may develop physiological dependence

Table adapted from Barry et al. (2002), p. 109 (Reprinted from (Kuerbis et al. 2014))

reduced or restricted social and vocational roles that change as a result of life stage, such as retirement or mortality of age-group peers, may mask the consequences of or changes related to drinking and drug use. Finally, many older adults may misattribute problems resulting from substance use to aging. Thus, the criterion “continued use despite persistent problems” may not apply. While the new criteria may capture a greater proportion of substance-using older adults to be diagnosed

with SUD (Kuerbis et al. 2014), many will remain unidentified.

Prevalence Rates of Use and Substance Use Disorders

Alcohol continues to be the most commonly used substance in later life (Moore et al. in press). As described previously, the prevalence of abstinence

increases and the amount of alcohol consumed decreases as individuals age. Still, about 50% of older adults in the USA consume alcohol (Moore et al. 2005). Prevalence rates for unhealthy older adult drinkers are estimated to be 10% for women and 12% for men (Blazer and Wu 2009a). Only about 1–2% of persons aged 65 years and older have a current diagnosis of alcohol use disorder, according to DSM-IV abuse and dependence definitions, which are more conservative than DSM-5 criteria (Kuerbis et al. 2013). Prevalence rates are lower than younger cohorts due in part to a mismatch of diagnostic criteria, older adults maturing out, increased mortality among those with lifelong AUD, and difficulty with accurate diagnosis.

Tobacco use is a marker of vulnerability for older adults, and 12–14% of individuals over the age of 65 report using tobacco (Moore et al. [in press](#)). About 4% have a tobacco use disorder. It is common both in the general population and among older adults to use tobacco and alcohol simultaneously. For this reason, it is not surprising that 6% of older adults report using both. In fact, older adults who use tobacco are twice as likely to report binge drinking (Wu and Blazer 2011).

Illicit drug use is historically minimal among older adults compared to their younger counterparts. With the aging of the baby boom generation, however, prevalence rates of illicit drug use are increasing (Moore et al. [in press](#)). Between 2002 and 2012, use of illicit drugs in the past month among individuals aged between 50 and 65 years doubled to 7.2%. In 2012, 19% of adults 65 years and older reported ever having used illicit drugs, compared to 48% of those aged 60–64 that same year (Wu and Blazer 2011). Of those individuals who report ever using illicit substances, 12% meet criteria for an SUD in the past year. Cannabis is the most commonly used illicit substance (3.9% of those aged 50–64, 0.7% of those aged 65 years and older), followed distantly by cocaine (0.7% aged 50–64 years, 0.04% of those aged 65 years and older). With increasingly relaxed restrictions on the sale and use of marijuana, the prevalence rate of use among older adults may increase (Kuerbis et al. 2014).

Because older adults take more prescribed and over-the-counter medications than younger adults, they are at increased risk for harmful drug interactions, misuse, and abuse (Kuerbis et al. 2014). Nonmedical use of prescription medication is common among older adults. Many older adults do not view using a prescribed medication in ways it was not prescribed (i.e., for extended periods or in larger doses) to be a problem; nonmedical use of prescription medications is still generally thought to be underreported. In 2012, just fewer than two million adults 50 and older reported using prescription drugs nonmedically in the past year (Moore et al. [in press](#)). The current estimate of prescription medication misuse among older women is 11%. A national epidemiological study reported that 1.4% of adults aged 50 years and older used prescription opioids nonmedically in the last year, a rate higher than sedatives, tranquilizers, and stimulants (all < 1%) (Blazer and Wu 2009b). Despite contraindications for older adults, benzodiazepines are disproportionately prescribed to older adults (Kuerbis et al. 2014). Rates of benzodiazepine use among older adults range from 15% to 32%, potentially impacted by overprescription, misdiagnosis, or polypharmacy rather than intentional misuse or abuse.

Unique Vulnerabilities to Substance Use for Older Adults

While prevalence rates of use and SUDs are lower for older adults than their younger cohorts, there are specific risks for harm from substance use for older adults (Kuerbis et al. 2014). Some risks are due to aging itself, such as changes in substance metabolism and distribution in the body. Other risks are due to specific patterns of use (e.g., 1 drink a day for 7 days vs. 7 drinks on 1 day) (Moore et al. [in press](#)) or mixing prescription drugs and alcohol, or cognitive impairment, gait disorder, or another comorbid medical problem.

Alcohol. Due to biological changes to the body in late life, alcohol has a differential impact on older adults compared to their younger cohorts (Kuerbis et al. 2014). As the body ages, lean

body mass and total body water decrease, and the liver also loses the ability to process alcohol as well as it did in earlier age. The permeability of the blood-brain barrier and the neuronal receptor sensitivity to alcohol also increase. As a result of these biological changes, an older adult who imbibes the same amount of alcohol as a younger or middle-aged adult will experience higher blood alcohol concentration and greater impairment than the other two will experience, and with less awareness of that impairment. Thus older adults experience a greater vulnerability to the ill effects of alcohol even at moderate amounts. Furthermore, older adult at-risk drinkers are more likely to experience alcohol problems as well as impaired instrumental activities of daily living, such as shopping and cooking for oneself. Complications of drinking alcohol also arise with comorbid medical and psychiatric conditions that can occur in late life. Medication interactions increase the vulnerability of an older adult's health, even when he or she may be drinking at moderate levels.

It should be noted that despite this increased vulnerability to the negative effects of alcohol consumption, older adults can experience positive health effects from moderate alcohol consumption, such as drinking within the NIAAA safety guidelines. Drinking alcohol at moderate levels is associated with decreased morbidity and mortality among older adults (Center for Substance Abuse Treatment 1998), and moderate drinking older adults often experience better health (e.g., fewer falls, greater mobility) than their abstinent and heavy drinking peers. Positive benefits of alcohol consumption among older adults are limited to very specific conditions and in some cases have negative trade-offs. For example, with moderate drinking, the risk of ischemic stroke may decrease for an older adult, but his or her risk of hemorrhagic stroke may simultaneously increase. Thus benefits of drinking must be weighed against the individual's risk factors for such conditions, as well as his or her unique biopsychosocial context, age, gender, genetics, and comorbid illnesses.

Tobacco. Perhaps due to historical factors and level of cultural acceptance over time, older adults are less likely to perceive that smoking harms

health (Moore et al. *in press*). In fact, older adults who use tobacco have higher mortality, lung disease, coronary events, and overall physical functioning compared to younger adult tobacco users or their non-tobacco-using counterparts. Tobacco-using older adults also experience more smoking-related cancers, chronic obstructive pulmonary disease, greater decline in pulmonary function, development of osteoporosis, risk of hip fractures, and greater loss of mobility than their non-tobacco-using counterparts (Duru et al. 2010). Treatment for each of these conditions is further impaired or inhibited by continued tobacco use.

Medications and Illicit Drugs. Biological changes during the aging process also affect the impact of prescription medications and illicit drugs on the older adult body (Kuerbis et al. 2014). Benzodiazepines and opiates are processed much more slowly in an older adult body compared to a middle-aged or young adult. They should be prescribed and used with caution. Certain benzodiazepines are contraindicated for use with older adults as they tend to cause excessive sedation and the effects last far longer than for younger adults. An additional complication is that due to the sheer number of medications older adults tend to take, an older adult may not have an accurate list of the medications they are taking, including supplements. They may also see multiple doctors, each of whom is prescribing medications (often without knowing) that may interact poorly with the others or with alcohol or illicit drugs. An older adult who is prescribed a benzodiazepine, a barbiturate, or an opiate for a medical condition can expect to experience increased sedation with the simultaneous use of alcohol or marijuana. Finally, older adults may innocently or accidentally misuse a medication (e.g., taking another person's medication, confusing pills, or taking more than intended).

Cannabis' increasing acceptance, both medically and recreationally, may also pose unknown risks for older adults. In the general population, marijuana causes impairment of short-term memory; an increased heart and respiratory rate, as well as elevated blood pressure; and a fourfold increase in the risk of heart attack the first hour

after smoking (Kuerbis et al. 2014). For those older adults whose cognitive or cardiovascular systems are already compromised, cannabis may pose a notable risk. It is not yet clear which of the abovementioned conditions associated with tobacco use will emerge for marijuana.

Factors Associated with Late Life Substance Use and Abuse

Existing research on older adult risk factors for substance use and abuse is almost exclusively focused on alcohol use (Kuerbis et al. 2014). It is reasonable to assume that the factors associated with late life unhealthy drinking may also contribute to use of other substances; however, unique factors that may contribute to use of substances other than alcohol remain relatively unknown. Table 2 lists some of the potential risk factors associated with older adult unhealthy use of alcohol and, when known, other substances.

Demographics. Several demographic characteristics are associated with unhealthy drinking in

late life. Male gender, affluence, and Caucasian race are the most prominent characteristics associated with late life drinking (Kuerbis et al. 2014). Age is also associated with unhealthy drinking – such that those below the age of 75 are more likely to be unhealthy drinkers than those above 75. None of these factors are demonstrated to predict an increase in late life drinking except for wealth. Having more affluence, more financial resources, and longer financial horizons are predictive of increased alcohol use among older adults. For other substances, female gender is associated with misuse of prescription drugs. Finally, having no or little religious affiliation is associated with a greater quantity and frequency of alcohol use.

Medical and Psychiatric Morbidity. Both alcohol use and unhealthy drinking are associated with overall better health in older age (Kuerbis et al. 2014). This is likely not a causal relationship but instead suggests that those older adults in good health are more likely to drink more than their counterparts in poor health. It has been observed that as hospitalizations, disabilities, or depression increase, drinking tends to decrease among older adults. Poorer physical and mental health also has been observed at greater rates among older adult heavy drinkers compared to their moderate drinking counterparts. Finally, pain is a key long-term predictor of alcohol use in late life (Moos et al. 2010).

Co-occurring psychiatric (e.g., anxiety, mood disorders, and personality disorders) and substance abuse disorders are assumed to occur in late life, as they do often in earlier life (Kuerbis et al. 2014); however, little to no research has explored the prevalence rates of these comorbid disorders in late life. Within the studies that examined an older adult population, high correlations have emerged between specifically alcohol use and depression and other affective disorders. This co-occurrence can complicate diagnosis and treatment for both. Aside from the common co-occurrence of tobacco and alcohol use, there is almost nothing known about polysubstance use among older adults.

Many older adults experience sleep disturbance or sleep disorders (Kuerbis et al. 2014).

Substance Use and Abuse, Table 2 Risk factors related to substance use in late life

Physical risk factors
Male gender (for alcohol); female gender (for prescription drugs)
Caucasian ethnicity
Chronic pain
Physical disabilities or reduced mobility
Transitions in care/living situations
Poor health status
Chronic physical illness/polymorbidity
Significant drug burden/polypharmacy
Psychiatric risk factors
Avoidance coping style
History of alcohol problems
Previous and/or concurrent substance use disorder
Previous and/or concurrent psychiatric illness
Social risk factors
Affluence
Bereavement
Unexpected or forced retirement
Social isolation (living alone or with non-spousal others)

Reprinted from Kuerbis et al. (2014)

Older adults commonly use alcohol as a sleep aid, despite the fact that alcohol is known to interfere with sleep cycles overall. Older adults who combine alcohol and additional prescription or over-the-counter sleep aids are also likely to experience excessive sedation and/or cross-tolerance. Furthermore, older adults who use prescription medications with abuse potential or have had a history of a SUD or mental health disorder are more likely to misuse or abuse prescription medications. Finally, cognitive impairment and a variety of dementia types tend to be prevalent among older adults with an alcohol use disorder.

Style of coping with stress or tension may also predict having a late life alcohol use disorder (Kuerbis et al. 2014). Specifically, avoidance coping is associated with a drinking problem in later life. Similarly, older adults who report using alcohol to relieve tension or stress or to relax are also associated with late-life drinking problems.

History of Alcohol Problems. Not surprisingly, individuals who report having had an alcohol use disorder before age 50 and do not abstain from alcohol in late life are much more likely to drink at unhealthy levels in older age (Moore et al. *in press*).

Social Factors. While there may be gender differences, generally, divorce, separation from a spouse, or being single are associated with increased or unhealthy drinking in late life (Moore et al. 2009). Within a retirement community, having a larger social life with friends and family may increase one's risk of heavy or unhealthy drinking in later life (Kuerbis and Sacco 2012). While having sustained or increased social interactions from midlife into older age, particularly post retirement, tend to increase alcohol use in general, and in some cases problem drinking, social isolation is associated with prescription drug abuse among older adults. Late life transitions and events may also increase an older adult's vulnerability to substance misuse or a SUD. Loss in many forms has been shown to be associated with substance use among older adults. Loss can take the form of bereavement for a spouse or friends, living arrangement changes,

declining overall health, or loss of employment (Center for Substance Abuse Treatment 1998). Caregiving for a chronically or terminally ill spouse may increase the stress and subsequent vulnerability to substance misuse, and it may signal the loss of the relationship as it once was. Retirement can also impact substance use, depending upon preretirement conditions (Kuerbis and Sacco 2012). Preretirement job satisfaction, involuntary retirement, and workplace stress can negatively impact how the older adult copes with retirement and have been shown to increase alcohol use in general as well as drinking problems.

Screening and Assessment

Older adults are far less likely to be screened for substance use than their younger adult counterparts (Kuerbis et al. 2014). Older adults tend to be more private about their substance use than a younger cohort. As a result, often the first point of contact with an older adult substance user is within primary care. Several barriers may interfere with identification of unhealthy, at-risk, or problem use. In cases where an older adult may present with symptoms of substance use or abuse, physicians and the older adults themselves may be more inclined to identify those symptoms as a part of natural aging or another health problem. Clinicians may have insufficient time to fully assess the older adult who comes in with a clear presenting problem that may not be immediately relevant to substance use; they may avoid asking the older adult about substances for fear of embarrassing them or causing them to anger; and finally, the symptoms themselves may share similarities with other conditions. Finally, older adults tend to view their substance use behavior as normal rather than risky. They may be particularly reticent to discuss this behavior as they themselves see it as irrelevant to the problem at hand and potentially their "last pleasure." This perspective is known to be reinforced by some health care professionals, such as in nursing homes, where the substance use may be enabled to the detriment of the older adult's health.

Overall Approach to Discussing Substance Use with Older Adults

As with any person, older adults should be treated with respect. The overarching goal for any assessment should be the overall health and well-being of the older adult (Sacco and Kuerbis 2013), thus reducing shame and stigma around any particular behavior. Older adults are known to respond more fully to a supportive, nonconfrontational approach to assessment and intervention. Confrontation is not helpful or efficient in engaging an older adult to provide information about their substance use or to provide an intervention for such behavior. Efforts to identify a drug abuser rather than to assess substance use as a part of one's total health tends to cause defensiveness on the part of and stigmatization of the older adult. Questions about substance use should be asked matter-of-factly while keeping in mind that these questions may feel sensitive or intrusive to the older adult. Questions about quantity and frequency of drinking, any medications (prescription, over-the-counter, and those obtained from friends), and illicit drugs (e.g., marijuana) should be asked in a gentle, respectful manner with the assumption that the information is important whether the behavior itself is problematic or indicative of a SUD.

During assessment and intervention, it is important to keep in mind the potentially central role that substance use may play in the life of an older adult. For an older adult whose life is otherwise quite limited, he or she may view using a substance as the final vice – his or her last pleasure. Indeed, this may be reinforced by families, friends, or other health care professionals. A foreshortened sense of the future among older adults may also prolong substance use. Older adults have been found to be less motivated to change their habits around mood-altering substances compared to younger counterparts as they do not view their use as particularly severe or a problem – even when advised otherwise by a physician. In addition to differential motivation levels, a lack of self-efficacy may also be particularly problematic for an older adult. Self-efficacy is observed to decline with age when an individual perceives his or her life less and less in his or her

Substance Use and Abuse, Table 3 Potential indicators of substance misuse and abuse

Physical indicators
Falls, bruises, and burns
Poor hygiene or impaired self-care
Headaches
Incontinence
Increased tolerance to alcohol or medications or unusual response to medications
Poor nutrition
Idiopathic seizures
Dizziness
Sensory deficits
Blackouts
Chronic pain
Cognitive symptoms or potential indicators
Disorientation
Memory loss
Recent difficulties in decision making
Overall cognitive impairment
Psychiatric symptoms or potential indicators
Sleep disturbances, problems or insomnia
Anxiety
Depression
Excessive mood swings
Social symptoms or potential indicators
Family problems
Financial problems
Legal problems
Social isolation
Running out of medication early
Borrowing medication from others
Reprinted from Kuerbis et al. (2014)

control (Kuerbis et al. 2014). When older adults perceive the negative consequences of substance use to be a natural part of aging, this can also greatly affect self-efficacy to change. For many older adults, changing substance use habits may feel too late.

Potential indicators or symptoms of problematic use of mood-altering substances among older adults are reviewed in Table 3. Because older adults tend to dismiss use of mood-altering substances as problematic, assessment must focus specifically on behavior rather than the older adult's opinion (e.g., do you believe you have a drinking problem?) (Sacco and Kuerbis 2013). Questions should be included in a

nonjudgmental way. An important gateway to additional information about the older adult's use of substance is asking about whether he or she runs out of medication early, borrows medication from others, or takes an extra pill to fall asleep or cope with pain. It is also important to ask about any history of use or SUDs, as these may increase an older adult's risk for cognitive decline or psychiatric disorders in late life whether or not he or she is currently abstinent.

Screening Tools

Biological screening measures are not only intrusive but can also be misleading, as any damage to the liver (a common tool used to indicate heavy drinking or overuse of benzodiazepines) may be the product of prescribed medications. Thus, the best screening tools among older adults are those that are self-report.

CAGE-Adapted to Include Drugs (CAGE-AID). The CAGE-AID is a brief screening tool, adapted from the CAGE (Kuerbis et al. 2014), to indicate potential substance misuse across the general adult population. It contains four questions: (1) Have you ever felt that you should Cut down on your drinking or drug use? (2) Have people Annoyed you by criticizing your drinking or drug use? (3) Have you ever felt bad or Guilty about your drinking or drug use? (4) Have you ever had a drink or used drugs first thing in the morning to steady your nerves or to get rid of a hangover (Eye opener)? One or more positive responses to the four questions indicate the potential for a SUD. While there are no reported studies on the CAGE-AID's efficacy with older adults, the CAGE was demonstrated to have 86% sensitivity and 78% specificity for an alcohol use disorder among older adults (Kuerbis et al. 2014). The drawbacks of the CAGE are that it does not identify older adult heavy or binge drinkers, it does not perform as well within a psychiatric population, and it does not differentiate between current and lifetime use. Clearly, the CAGE or CAGE-AID, while useful, should not be a substitute for a thorough assessment.

The Alcohol Use Disorders Identification Test (AUDIT). The AUDIT is a 10 item, self-report questionnaire that assesses for current alcohol problems (Babor et al. 2001). Items ask about quantity and frequency of alcohol use, diagnostic criteria, and other consequences of alcohol use or abuse. Scoring on the AUDIT ranges from 0 to 40, with potential for an alcohol use disorder starting at a score of 8. Hazardous or problematic alcohol use among older adults can be detected using the AUDIT; however, a lower threshold of 5 is recommended.

The Comorbidity Alcohol Risk Evaluation Tool (CARET). The CARET (Moore et al. 2002) is a screening tool that identifies not only older adults who are at risk due to their alcohol consumption but also vulnerable due to comorbid diseases, risky behaviors (i.e., drinking and driving), and drinking while taking medications. Due to its broad focus, the CARET tends to be more sensitive to identifying hazardous, at-risk, or problem drinking among older adults than other measures.

Interventions for Older Adult Substance Users and Abusers

To match the spectrum of intensity of SUDs, there is a spectrum of treatment options available to older adults to help them achieve healthy moderation or abstinence from mood-altering substances. While popular assumptions that older adults are too entrenched in old patterns to make change persist, older adults at times demonstrate treatment outcomes as good or better than younger cohorts for the treatments that have been tested. Access to treatment remains a problem in the USA, as less than 20% of the substance abuse treatment programs offer tailored treatments to an older adult population (Kuerbis and Sacco 2013). Additional barriers to treatment for older adults include geographic isolation, difficulties with transportation, inability to pay, or stigma and shame around development or maintenance of a SUD in late life. As a result of these barriers, nontraditional settings provide unique opportunities for intervention with older adults, such as

emergency rooms, senior centers, and primary care offices (Sacco and Kuerbis 2013). There is a continued, relative absence of knowledge and research on older adults with SUD and treatments that are most effective for them. Interventions discussed below are based on initial empirical support within the substance abuse field or in other fields that have demonstrated efficacy.

Brief Interventions. Brief interventions that focus on alcohol and prescription medication misuse or abuse and vary in length from 15 min to an hour are shown to be effective for older adults (Kuerbis and Sacco 2013). They are usually performed in primary care, and they tend to focus on psychoeducation and normative feedback (i.e., levels of alcohol consumption by peers) about alcohol use or proper administration of medication. Interventionists, who include nurses, social workers, physicians, or other medical staff, provide the older adult with information about potential harms and consequences of substance use, attempt to enhance motivation to change, and, where needed, refer to more intensive services. These interventions, even at their most minimal intensity, are shown to be effective among individuals in late life.

Motivational Interviewing (MI) or Motivational Enhancement Therapy (MET). MI and MET are two very similar interventions that can be implemented as a part of a brief intervention, a stand-alone intervention, or a supplement to longer-term or more intensive substance abuse treatment (Kuerbis and Sacco 2013). Both are client-centered interventions that encourage a nonconfrontational, supportive approach to encouraging healthy changes, making it in this way an ideal approach for older adults. The primary focus of MI and MET is to reduce ambivalence to change by exploring with the client his or her ideas about the pros and cons of both making a change to one's substance use and sustaining current behaviors as they are (Sacco and Kuerbis 2013). Older adults may share motivations with their younger counterparts, and they may also have uniquely strong motivations related to their life stage, such as optimal health and mental capacity (Barry et al. 2001). Despite the seemingly natural fit of MI and MET with older adults,

very few empirical studies have been performed to explore whether it works with older adults in a similar fashion to younger adults. Most studies on MI or MET have excluded individuals over 65. A few studies have utilized MI with older adults addressing other health behaviors with some success (Kuerbis and Sacco 2013). However, no rigorous randomized controlled trials have tested how MI works with older adults.

Pharmacology. Pharmacological treatments used for SUD are growing for the population at large. Few medications currently approved by the Food and Drug Administration in the USA are thought to be safe for use with older adults. Disulfiram is a medication that is used as an aversive agent (Kuerbis et al. 2014). It increases the negative effects of alcohol, such that when alcohol is ingested it makes the person extremely ill. Thus the medication is only useful with rigid adherence to the prescription. Disulfiram has been used with adults 50 and older with some success, but it can also place additional strain on the cardiovascular system. Therefore it may be contraindicated for older adults. Naltrexone is an opioid receptor antagonist originally designed for treatment of opioid use disorder that has been applied to alcohol and other substances in the general population. It is thought to work by reducing craving or the pleasurable effects of the substance when it is administered. Initial research findings demonstrate a positive effect of naltrexone among older adults (Kuerbis and Sacco 2013). A major drawback of naltrexone is that it blocks the effects of opiate pain medications, limiting its application to older adults. In addition, it may enhance depressive symptoms or preexisting depressive disorders. Older adults taking this medication should be monitored closely.

Case Management. Case management models are services provided by primary care or community-based agencies that are useful and advantageous in engaging older adults with unhealthy substance use (Kuerbis et al. 2014). This comprehensive approach provides the older adult with more opportunities to address the full extent of medical and psychiatric complexities, rather than focusing solely on substance use reduction. It engages the older adult in working

toward what presumably he or she wants most: overall better health for higher quality of life. Due to the more holistic approach the older adult can feel less stigmatized for his or her substance abusing behaviors and feel that all of his or her problems are being addressed, not just the problems identified by the health care professional (Center for Substance Abuse Treatment 1998). These models are excellent for improving overall health and well-being of older adults and key in maintaining older adults in treatment.

Formal Substance Abuse Treatment. For the older adult willing to participate in the general treatment system, services range in intensity from detoxification and residential treatment to outpatient and aftercare, depending on the severity of the SUD and any comorbid medical complications (Sacco and Kuerbis 2013). Treatment and treatment settings are recommended to be tailored to the potential special physical and mental needs of older adult patients. In the relative absence of such treatments, older adults entering programs with patients of all adult ages should receive special attention when constructing treatment plans and services. For example, services should accommodate stamina for learning and physical abilities. While group treatment is often the modality of choice among treatment programs, as it serves to reduce isolation and shame, group therapy may instead enhance these feelings. Older adults may feel particularly intense shame at having these types of problems in later life, uncomfortable with speaking to persons younger than them about their personal problems, and may feel increasingly alone, such as in the case where he or she is the only older person in the group. Individual therapy should be provided in addition to providing a space for the older adult to explore issues related to recovery that are unique to him or her.

Psychotherapy. Only two types of psychotherapies have been empirically investigated in the context of substance abuse treatment with older adults: supportive therapy models (STM) and cognitive behavioral therapy (CBT) (Sacco and Kuerbis 2013). While now widely accepted that confrontational approaches to substance abuse treatment are less effective and in some

cases harmful for any group, STM grew out of the acknowledgment that older adults appeared to do particularly poorly in traditional, confrontational treatments. As a result, STM was developed as a psychotherapy that utilized a nonconfrontational, supportive approach to substance abuse treatment and also incorporated psychoeducation and support around issues observed to be more common among older adults: serious physical health conditions or disease, high rates of co-occurring depression, and social isolation (Center for Substance Abuse Treatment 1998). The focus of STM is to concentrate on helping build social support for the older adult's recovery, improve self-esteem, and similar to a case management model, take a holistic approach to treatment addressing all aspects of the older adult's life. While research is still quite limited in investigating the efficacy of this approach in comparison to traditional treatments, the studies that have been done demonstrate that older adults tend to have better outcomes when treatments have been tailored to their particular life stage as opposed to those settings in which those adaptations have not been made (Sacco and Kuerbis 2013). CBT is a type of psychotherapy that focuses on identifying faulty or self-destructive sequences of thinking, feeling, and behaving within the individual that lead to problem drinking or drug use (Kuerbis et al. 2014). CBT has empirical support for its efficacy and effectiveness across all ages and most population subtypes, including older adults. CBT has been used with older adults for smoking cessation and alcohol use with stronger, more positive outcomes than the comparison treatments (Kuerbis and Sacco 2013). CBT interventions are thought to be effective with older adults because of the structured nature; presenting topics that are particularly relevant to older adult life (e.g., coping with grief); and using written materials for all education levels, taking into account slower learning capabilities, cognitive impairment, memory difficulties or visual impairments; and a slower pace of treatment.

Self-help Groups. Twelve-step programs, such as Alcoholics or Narcotics Anonymous, and other mutual aid groups can help the older adult to reduce isolation, shame, and stigma

(Sacco and Kuerbis 2013). There are no formal studies of older adult participation in such groups; however, older adults may experience shame and stigma of dealing with addiction in late life with a younger generation – similar to what can happen in formal treatment settings. Previous generations of older adults may feel more discomfort with younger polysubstance abusers, as they may present primarily to a mutual aid group for alcoholism. Baby boomers may not experience this tension. Due to the variety of mutual aid groups, some may be better suited for older adults than others, depending on pace of the group, its general focus, or physical accessibility. Older adults, like their younger counterparts, should be encouraged to try more than one meeting before deciding whether it is right for them.

Synonyms

Minor psychiatric disorder; Subthreshold disorder

Definition

Subsyndromal psychiatric disorders (SPD) are characterized by the presence of elevated psychiatric symptoms that do not meet full diagnostic criteria for a specific disorder. Also commonly known as subthreshold or minor psychiatric disorders, SPD are difficult to qualify and quantify given the current categorical taxonomy of mental health disorders. By definition, they are not formally recognized as a diagnosis yet share many common features with their formal diagnostic counterparts (e.g., major depressive disorder). SPD are best viewed within a dimensional approach, with symptoms being present yet falling slightly below clinical cutoff within a diagnostic spectrum, often due to not meeting diagnostic criteria for level of symptom severity, duration, or frequency of symptoms despite causing significant distress.

Subsyndromal symptoms are fairly common in the general population, as well as in older adults, and are associated with a variety of negative factors including high cost to health care, poor physical health, poor quality of sleep, and a negative impact on the family. SPD is most commonly characterized and studied for depression- and anxiety-related symptoms, which will be the focus of this section. Description of psychological disorders and their associated criteria can be found in the *Diagnostic and Statistical Manual of*

Mental Disorders, Fifth Edition (DSM-5) (American Psychiatric Association 2013) and the *International Classification of Disorders, Tenth Revision* (ICD-10) (World Health Organization 2004).

Presentation and Prevalence

Subsyndromal psychiatric disorders are often described in terms of depression and anxiety symptoms. Subsyndromal depression (SSD), recognized in the DSM-IV-TR's Appendix B (criteria sets and axes provided for further study) (American Psychiatric Association 2000) as minor depressive disorder, is defined as one or more periods of depressive symptoms that are identical to major depressive disorder (MDD). However, these periods involve fewer symptoms, less impairment, and do not meet full diagnostic criteria for another psychiatric disorder. The DSM-5 has reclassified the proposed minor depressive disorder as other specified depressive disorder: depressive episode with insufficient symptoms (American Psychiatric Association 2013).

The occurrence of SSD in late life ranges from 8% to 30% depending on the setting and definition of SSD (Edelstein et al. 1999). A recent US representative sample of older adults found that 13.8% of individuals have experienced subsyndromal depression over his or her lifetime. In comparison, 13.7% of the sample met criteria for lifetime MDD, suggesting a similar prevalence rate between the subsyndromal and clinical disorders (Laborde-Lahoz et al. 2014). Even this high rate may be an underestimate, as another epidemiological study reported a 31.1% prevalence for SSD in adults over the age of 65 (Judd and Kunovac 1998).

Older adults with SSD are at higher risk for developing more severe levels of depressive or other psychiatric symptoms in the future and are at a higher risk for meeting criteria for MDD or an anxiety disorder both at 1-year and 2-year follow-up, with respective conversion rates of 10% and 25% (Laborde-Lahoz et al. 2014; Meeks et al. 2011). Conversion rates from SSD to MDD

are thought to be even higher in long-term care settings, displaying a 23% conversion rate at 1-year follow-up (Meeks et al. 2011). A multitude of factors are believed to increase the likelihood of an older adult developing depressive symptoms, such as low socioeconomic status, social isolation, recent loss of spouse, poor physical health, and serving as a caregiver. Remission rates for SSD vary widely based on the setting. Longitudinal epidemiological research suggests SSD has an 18–26% remission rate over a 3–6-year period, while primary care settings show approximately 50% remission rate at 1-year follow-up. Overall, SSD appears to have a fairly chronic course with intermittent improvements in symptoms, with 61–68% of individuals diagnosed with SSD showing some level of consistent chronic depression, often fluctuating between subthreshold depression and MDD over time (Meeks et al. 2011).

Similar problems are seen across other psychiatric disorders. Anxiety in particular is one of the most common types of psychiatric conditions seen in older adults with prevalence estimates between 1% and 15% in community samples (Bryant et al. 2008). The prevalence of subsyndromal anxiety is substantially higher, with rates between 15% and 52%. The onset of anxiety symptoms when examined over the lifespan appears to be a bimodal distribution, with two-thirds of individuals developing symptoms in adolescence and the remaining one-third of individuals developing symptoms for the first time in older adulthood (Lenz and Wetherell 2009). The etiology for the emergence of anxiety-related symptoms in older adults is likely multifactorial. The degeneration of brain regions associated with inhibiting anxiety, increases in life stressors, cardiovascular changes, and increased utilization of medications, some of which have secondary anxiogenic effects, may all contribute to new onset anxiety in older adults. Many of the risk factors associated with late-life anxiety are similar to those for depression and include being female, experiencing early-life stressors, and having a chronic disability (Lenz and Wetherell 2009).

Subsyndromal generalized anxiety disorder (GAD), also sometimes referred to as minor GAD, is another relatively common psychiatric disorder seen in older adults, characterized by chronic excessive anxiety or worry that is not due to the physiological effects of a medical condition. In older adults, subsyndromal GAD may present as concentration difficulties, poor sleep quality, irritability, muscle tension, and fatigue (American Psychiatric Association 2013). The focus of the worries varies by individual, but common themes include concerns about finances, health, or the well-being of family. As older adults are often faced with multiple anxiety-provoking life stressors (e.g., chronic health issues), when making a diagnosis, clinicians should consider the difficulty the individual has with controlling worry and the level of anxiety-related impairment. Subsyndromal GAD in older adults is associated with many of the problems seen in SSD, including a higher severity of health problems and disability as compared to those who report minimal generalized anxiety symptoms. Subsyndromal levels of panic disorder, social phobia, specific phobia, and obsessive-compulsive disorder are also seen in older adults, although with less frequency. Similar to SSD, the DSM-5 captures subsyndromal anxiety as other specific anxiety disorder, stating that the category applies to a presentation in which anxiety-related symptoms are causing significant distress and impairment in functioning, yet do not meet full diagnostic criteria for a specified anxiety disorder (American Psychiatric Association 2013).

Less is written about other subsyndromal psychiatric conditions in older adults, although they may be noted or recognized as clinical issues in an older patient. Trauma-related disorders, eating disordered behavior, subthreshold bipolar disorder, and subthreshold psychotic disorders are all seen in older adults and may warrant clinical attention. While older adults may not meet full criteria for a disorder at the time of assessment, symptoms may still cause significant distress and be clinically relevant. Older adults may experience cycling or fluctuations in symptom severity which influence the level of disruption in the life of the older adult. Subthreshold disorders, when

co-occurring with other disorders, are also likely associated with worse outcome. For some disorders, such as posttraumatic stress disorder, older adults may experience a spike in symptom severity correlated with major life adjustments, such as retirement or cognitive decline.

Also, little has been written on the impact of subthreshold personality disorders in older adults. Research examining middle aged adults suggests that subthreshold levels of borderline personality disorder (PD) are associated with many of the same symptoms seen in diagnostic levels of borderline PD (e.g., suicidal ideation), stressing the importance of utilizing a dimensional rating system during assessment and symptom monitoring, even when symptoms are at a subsyndromal level (Zimmerman et al. 2013). These findings do not necessarily generalize to other PDs, such as subthreshold levels of paranoid PD, avoidant PD, and obsessive-compulsive PD, which show variable correlations between subthreshold and threshold symptoms severity (Morgan et al. 2013).

Psychosocial Outcomes

While SSD often does not meet the clinical severity of MDD, it is frequently associated with increased risk for similar issues, such as higher rates of medical comorbidities, greater difficulty adjusting to co-occurring medical diagnoses, increased utilization of health-care services, and worse functioning on other aspects of successful aging as compared to nondepressed older adults (Laborde-Lahoz et al. 2014; Vahia et al. 2010). SSD is also associated with increased functional disability in older adults, slower recovery time among patients in inpatient rehabilitation, generally decreased levels of activity, and greater levels of impairment in activities of daily living (Meeks et al. 2011). Further, recent research suggests that depressive symptom influence on quality of life is not static and is associated with functional decline over a 6-month period (Charlson et al. 2008).

Depressive symptoms are associated with a lower general quality of life across multiple domains, including physical functioning, general health, vitality, satisfaction with life, and social

functioning (Diefenbach et al. 2012). Anxiety symptoms, which often co-occur with depressive symptoms, are not surprisingly associated with similar functional outcomes. Activity avoidance and anxiety symptoms are associated with increased levels of subjective pain and decreased physical functioning (Hermesen et al. 2014). There is likely interplay between psychiatric symptoms and general functioning in older adults, suggesting a cyclical relationship of increased depressive and anxiety symptoms correlating with decreased ability to function autonomously and lower levels of activity. Increased psychiatric symptoms also often lead to increased social isolation, lower levels of physical activity, and decreased frequency of participating in pleasurable activities, all which likely exacerbate mood problems.

Cognitive Correlates

Subsyndromal disorders are frequently associated with multiple negative outcomes. Elevated anxiety or depressive symptoms in older adults are often linked with poor sleep quality, increased rate of mortality, and a variety of unhealthy behaviors, such as smoking and substance abuse, which carry their own set of associated health problems. Research suggests a correlation between cognitive functioning and psychiatric symptoms, as depression and anxiety symptoms are believed to be associated with worse cognitive functioning and increased risk for future cognitive decline, nearly doubling the risk of conversion from mild cognitive impairment to dementia (Beaudreau and O'Hara 2008; Palmer et al. 2007). Similarly, depression and anxiety symptoms are common in individuals with even mild cognitive difficulties and often increase in prevalence in parallel with the severity of cognitive deficits. One possible explanation for this correlation of cognitive decline and psychiatric symptoms is that an increase in SPD symptoms is a by-product of early neurodegenerative processes and disruption of neural networks. It is also possible that depressive and anxiety symptoms may precede cognitive decline, with increases in psychiatric symptoms

resulting in a decrease in cognitive resources, thus leading to cognitive impairment.

Depressive symptoms in older adults are associated with worse performance on measures of episodic memory and executive functioning. In particular, depressive symptoms in older adults may interfere with the learning of new material. Anxiety symptoms in older adults are also associated with worse executive functioning, particularly in the context of set shifting and the utilization of executive skills to facilitate learning and memory (Yochim et al. 2013). Several other studies report consistent findings, with high levels of anxiety being associated with difficulties in memory (Lenz and Wetherell 2009). These cognitive deficits may be mediated by the type of anxiety symptom, with affective symptoms (e.g., irritability) being associated with memory difficulties, while cognitive symptoms (e.g., worry) are associated with difficulties in response inhibition (Yochim et al. 2013). These two symptom constructs may be associated with different cognitive deficits and represent dysfunction in different networks.

Clinical Considerations

The assessment and differential diagnosis of subsyndromal psychiatric disorders is difficult and especially complicated in older adults. For example, older adults have a high incidence of chronic health problems. Medical disorders common in older adults may present similar to, exacerbate, or even precipitate mental health concerns. Cardiac arrhythmias, hypothyroidism, cardiovascular problems, Parkinson's disease, and a variety of other neurological, gastrointestinal, and general medical conditions may present very similar to psychiatric symptoms. Common mood-related symptoms, such as decreased libido and changes in weight, are often seen in medical disorders and even in healthy aging, leaving the clinician in the difficult position of attempting to parse the etiology of specific symptoms. Related to medical problems, older patients are often on multiple medications and are increasingly susceptible to adverse side effect (e.g., sedation) and

drug-to-drug interactions, which may cause symptoms often seen in psychiatric disorders, such as poor concentration.

Further complicating the diagnostic picture, mood symptoms are often common in patients with medical diagnoses. Adjustment to a medical condition, bereavement, and changes in physical ability and quality of life may all result in an increase in depressive symptoms. These mood-related symptoms may be interpreted differently depending on the clinician and the age of the patient. For example, depression in younger adults may manifest through somatic symptoms, such as low energy, decreased sleep, or changes in appetite. In older adults, a clinician or patient may attribute the same symptoms to medical problems or the general process of aging, resulting in a misattribution of depressive symptoms (Edelstein et al. 1999). Older adults may not recognize their symptoms as psychiatric in nature or may be disinclined to accept mood issues as an etiology. Clinicians should not immediately attribute changes in mental health status to normal aging, especially in psychiatric changes that are subsyndromal. Older adults may have a strong, coherent sense of self that does not easily integrate with acknowledging mental health symptoms or need for treatment (Cohen and Eisdorfer 2011).

The life circumstances of many elderly individuals may also complicate the accurate diagnosis of a mood or anxiety disorder. Older adults are often faced with a variety of life stressors and existential concerns including, but not limited to, increased mortality salience, adjustment to retirement, assimilation of aging into his or her self-concept, and changes in level of autonomy. Conceding changes in physical and mental health may be difficult for many patients and may be a stark reminder of the aging process and a loss of youth. Some older adults may be inclined to underreport symptoms due to cognitive dissonance with the aging process and self-concept and concern about diminishing autonomy. The potential of losing driving privileges or the ability to live alone may be on the forefront of a patient's mind and causing significant distress. Determining if realistic concerns about health problems or financial stressors

cross a threshold into specific diagnostic and statistical manual of mental disorders-5 (DSM-5) diagnostic criteria may be difficult. For example, it may be challenging for a clinician to determine if a patient's level of worry is "excessive" to a level that would indicate generalized anxiety disorder or more parsimoniously explained as a natural reaction to profound life stressors.

Conclusions

In summary, the differential diagnosis of SPD in older adults is complex, particularly when considering the prevalence and clinical import of subsyndromal presentations. For instance, SPD may lead to negative outcomes such as increased psychiatric symptoms severity, decreased physical functioning, and lower reported quality of life in older individuals. Given the strict diagnostic criteria for psychiatric disorders, older adults experiencing subsyndromal symptoms may not seek treatment and may not be referred for follow-up mental health care by their primary care provider.

Suicide in Late Life

Amy Fiske¹, Elizabeth C. Price¹ and Jeffrey J. Gregg²

¹Department of Psychology, West Virginia University, Morgantown, WV, USA

²Durham Veterans Affairs Medical Center, Durham, NC, USA

Synonyms

Lethal self-harm; Self-inflicted death

Definitions

A well-accepted definition of *suicide* is: “a self-inflicted death with evidence (either explicit or implicit) of intent to die” (Silverman et al. 2007). Suicidal behavior with a nonfatal outcome is known as a *suicide attempt*. The term *suicide-related ideations* refers to thoughts about suicide, with or without intent to die. This category encompasses *suicidal ideation*, which refers to thoughts of taking one's own life, as well as *death ideation*, which refers to thoughts of death and dying without considering taking one's own life.

Introduction

Suicide, which claims the lives of nearly a million individuals globally each year, is a major public health problem. It is a problem of particular significance for geropsychology, as older adults, and especially older men, are at elevated risk of suicide. Although suicide risk increases with age, suicide is not a normal part of aging. The majority of older men and women who die by suicide suffer from depression or another mental health disorder.

Late-life suicide is a neglected topic. Suicide in late life, as at other ages, has profound negative consequences, including complicated grief for surviving family and friends. Nonetheless, surveys show that the suicide of an older adult is generally viewed as less serious than the suicide of a younger individual. Furthermore, resources for suicide-related research and prevention programs are generally targeted to younger populations, neglecting the problem of late-life suicide. Nevertheless, suicide in late life differs in many ways from suicide among younger individuals, including epidemiology, theory, risk factors, and protective factors. Thus, the need for age-specific research is especially important.

Epidemiology

Throughout the world, suicide rates tend to increase with age and peak in old-old age (age > 85 years). Older adults tend to be disproportionately affected by suicide compared to the general population. For instance, in 2013, individuals over the age of 65 comprised only 14.1% of the population in the United States, but represented 17.5% of all deaths by suicide (McIntosh et al. 2013). Though suicide rates are generally elevated in older adulthood internationally, significant variability has been noted between nations. For example, suicide rates are highest in adults over the age of 85 in Australia and the United States, whereas peak rates in Japan occur in middle age.

Elevated rates of suicide among older adults appear to be largely driven by men rather than women. In most countries throughout the world,

men are more likely to die by suicide than women across all age groups; however, this gap becomes even greater in old age. For example, men over the age of 65 in the United States are approximately five times more likely to die by suicide compared to women of the same age group. On the other hand, women's risk of suicide tends to decline after the age of 60. Notably, in the United States, the suicide rate among White men over the age of 85 represents the highest risk among any age-gender-race demographic.

Late-life suicide rates in most nations also differ as a function of rural versus urban residence. For instance, in China, suicide rates in older adults are significantly higher among rural-dwelling individuals compared to urban-dwelling individuals.

The epidemiology of suicide attempts versus deaths by suicide in older adulthood also is noteworthy. Estimates suggest a ratio of 25 suicide attempts per death in the United States' general population. Among older adults, however, this ratio is drastically lower, with only four attempts per death. Nonfatal suicide attempts are three times more likely among women compared to men. The increased lethality of attempts found in older adults is likely attributable to the more prevalent use of firearms in this demographic. Older adults also exhibit greater planning in fatal suicides compared to younger adults. Thus, the lower attempt-to-death ratio may also reflect greater intent to die among older adults versus other age groups.

Theory

Several prominent theories of suicide have been applied to the understanding of suicide among older adults (Fiske et al. 2015). These include sociological theories as well as psychological theories focused on cognitive, behavioral, and interpersonal factors. A few theoretical frameworks also incorporate a life span developmental perspective.

Durkheim's classic sociological theory explains suicide as a function of social integration and regulation (Durkheim 1897). According to

this theory, individuals with weak ties to society, described as having low levels of integration or regulation, are at risk of suicide primarily because they lack a feeling of belonging and are not bound by social norms. Excessively strong ties to society are also linked to suicide, through subordination of one's own interests to those of the society, but these cases are thought to be rare. Research on older adults confirms that lack of social connectedness is related to suicide in late life (Fässberg et al. 2012; Duberstein et al. 2004).

Cognitive theories by Beck and others explain suicide as a result of an individual's interpretation of events that are experienced (Beck et al. 1975). Pessimistic cognitions lead to a form of depression characterized by hopelessness, which is strongly linked to suicidal ideation and behavior in older adults as at other ages (De Leo et al. 2013).

A prominent recent theory of suicide, which incorporates social, cognitive, and behavioral components, is Joiner's interpersonal theory of suicide (Joiner 2005). According to this theory, suicide occurs only when an individual has both the desire to die by suicide and the capability of enacting lethal self-harm. The desire to die is conceptualized as stemming from a thwarted sense of belonging as well as the perception that one is a burden on others. Research generally supports the notion that perceived burdensomeness and thwarted belongingness are associated with suicidality in older adults, as in other age groups. Joiner's interpersonal theory also posits that the capability of engaging in suicidal behavior is a function of an individual's ability to tolerate pain and overcome the fear of dying, both of which are acquired through exposure to painful and provocative events. Given the fact that exposure to painful and provocative events is cumulative across the life span, the theory would predict greater capability of enacting suicide as one ages, consistent with the elevated suicide rates that are observed in late life.

There are other theories of suicidal behavior that have garnered empirical support among younger adults that may also be applicable to older adults. For example, suicide has also been conceptualized as an escape from unbearable

psychological pain by several theorists (e.g., Schneidman, Baumeister). Nonetheless, these theories remain to be evaluated in older adults.

The most relevant theoretical perspectives for explaining late-life suicide are those that integrate life span developmental theory with suicidal theory. Clark proposed a model in which certain behavioral predispositions are adaptive in youth and middle age, but maladaptive in late life, leading to suicidal behavior (Clark 1993). Specifically, this theory predicts that a heavy emphasis on independence may become problematic only in late life, when it may interfere with an individual's ability to adapt to age-related stressors such as a decline in functioning and lead to a suicidal crisis. Empirical findings in older adults are consistent with this theoretical perspective (O'Riley and Fiske 2012; Kjølhseth et al. 2009).

Caine and Conwell also proposed a developmentally informed theoretical model to explain changes in suicide risk across the life span and into late life (Caine and Conwell 2001). In this framework, some distal risk factors (such as inflexible personality or childhood trauma) influence suicide risk throughout the life span. Other distal risk factors (e.g., change in role status) may emerge for the first time in late life. Mental health problems serve as proximal risk factors for suicide.

Risk and Protective Factors

There are several well-established risk factors for death by suicide, some of which are specific to older adults. Because of the relatively low base rate of death by suicide, large prospective studies or psychological autopsies (thorough investigation including a review of records and interviews with family and health-care professional after a death by suicide) are typically necessary to identify predictors. Current theory proposes that risk factors can be divided into factors likely to influence *desire to die* by suicide and factors likely to influence the *ability to enact* lethal self-harm (Joiner 2005). Factors that influence desire to die will be discussed first, followed by factors that

may increase capability to engage in self-harm behaviors.

Among factors that increase the desire to die are mood disorders and related negative mood states. The vast majority of older adults who die by suicide meet criteria for a diagnosable mental disorder, especially mood disorders (Kiosses et al. 2014). Presence of a mood disorder is one of the strongest predictors of suicidal behavior (Conwell et al. 2011). Compared to younger and middle-aged adults, substance use disorders, anxiety disorders, and schizophrenia are less predictive of suicide in older adults (De Leo et al. 2013). Hopelessness is an affective state that also increases risk for suicide, even after resolution of a depressive episode (Kiosses et al. 2014).

Studies using twins have shown that genetics play a significant role in eventual death by suicide (Fiske et al. 2015). In older people, higher levels of neuroticism, lower levels of extraversion, and lower levels of openness to experience are personality traits that have been found to be related to death by suicide (Conwell et al. 2011). Poor emotion regulation and negative emotions such as anxiety are also risk factors for suicidal behavior (Kiosses et al. 2014). Physical illness, disability, and pain have also been linked to suicide in late life (Conwell et al. 2011). Physical health problems can also contribute to depression, which may explain part of the link (Fiske et al. 2015). Low social connectedness, or thwarted belongingness, is believed to increase the desire to die by suicide among older adults (Joiner 2005).

Among factors associated with the ability to enact lethal self-harm, history of suicide attempt is a consistently strong risk factor for death by suicide. Exposure to death and dying should also lead to habituation and thereby increase a person's capability of enacting lethal self-harm, although this proposition remains to be tested directly in older adults (Fiske et al. 2015). The availability of readily lethal means, especially firearms, will increase the individual's ability to enact lethal self-harm. Men's greater rates of suicide may be partially explained by their use of more lethal means (i.e., firearms). In addition to increasing desire to die, social isolation may increase suicide

deaths by reducing the likelihood that someone would be present to intervene.

Considering cognitive functioning, older adults in the beginning stages of cognitive decline may be most at risk for death by suicide because they are still capable of planning and carrying out highly lethal behavior, especially in the presence of a depressive disorder (Kiosses et al. 2014). However, older adults who attempt suicide show impaired decision-making, compared to other groups (Kiosses et al. 2014). The relations among aspects of cognitive functioning and suicidal behavior continue to be explored.

Protective factors for older adults include social connectedness and support, an absence of the above risk factors, and any personal “reasons for living” (Fässberg et al. 2012). These reasons may include religious beliefs, ties with loved ones, a desire to continue to accomplish or experience events (e.g., a grandchild’s graduation), and a view of suicide as morally wrong (Fiske et al. 2015).

Assessment

Given the high prevalence of suicide among older adults, the availability and use of accurate, practical assessment methods and tools represent critical public health issues. One avenue for increasing the accuracy of clinical assessment of late-life suicidality is to utilize contemporary, empirically supported models of suicidal behavior, which incorporate well-established risk and protective factors. The fluid vulnerability model provides a useful framework for suicide case conceptualization (Rudd 2006). Specifically, the fluid vulnerability model posits that an individual’s suicide risk at any given time is comprised of both chronic, baseline risk factors (e.g., male gender, mental health diagnosis) and acute risk factors (e.g., recent death of spouse, feelings of hopelessness). Protective factors (e.g., religiosity, positive social support network) are also important for consideration. In light of the fact that there are both developmental and cohort differences in risk and protective factors, it is widely considered crucial

that suicide assessment with older adults be tailored as much as possible to this specific population.

Though unstructured, informal clinical interviews are frequently used to assess for suicide risk in later life, specialized assessment instruments exist that can greatly enhance clinical decision-making. Such tools can assist in providing a more comprehensive understanding of an individual’s current suicide risk and protective factors. Further, a wealth of research has demonstrated the benefits of administering brief depression screening tools in settings frequented by older adults in order to identify depressed (and potentially suicidal) older adults who might otherwise go unrecognized. Primary care is an especially important example of such a setting, as three-fourths of older adults who die by suicide visit their primary care provider during the year prior to suicide (Luoma et al. 2002). Almost half visit primary care within the 1 month prior to suicide (Luoma et al. 2002). Available late-life suicide assessment instruments consist of both clinician-administered tools and self-report tools, including some tools that directly assess suicidal thoughts and behaviors and others that measure factors known to be related to suicide (e.g., hopelessness, reasons for living, depression).

Because suicide differs in later life compared to earlier life in many important ways (e.g., risk factors, protective factors, lethality), it is essential that assessment instruments exhibit adequate psychometric properties, particularly content validity, in older adult populations. For example, the Geriatric Suicide Ideation Scale (GSIS) is a 31-item self-report measure that assesses both direct suicidal thoughts and behaviors (e.g., suicidal ideation), as well as factors known to be associated with late-life suicide (e.g., death ideation, meaning in life; Heisel and Flett 2006). The GSIS has demonstrated promising psychometric properties among older adults, including internal consistency and construct validity. Instruments that indirectly assess suicide risk via related factors (e.g., hopelessness) also may be especially useful with older adults, considering that older adults are less likely than younger adults to endorse overt

suicidal ideation and, yet, more likely to enact lethal self-harm. A critical review of individual assessment methods and instruments for late-life suicidality is beyond the scope of this entry. However, the interested reader is directed to Dennis and Brown (2011) for assessment recommendations.

There are a number of factors that represent barriers to the accurate assessment of suicidality in later life. Many individuals are hesitant to discuss suicide with older adults due to concerns about potential iatrogenic effects (i.e., discussing suicide might lead to an increase in suicidal thoughts and behaviors). However, a plethora of research has discounted this myth. In addition, many clinicians lack training in managing the care of older adults with heightened suicide risk. Finally, ageism and age-related biases can impede accurate assessment of late-life suicidality. For example, individuals may be more likely to attribute suicidal ideation to normative aging processes in older adults and, thus, less likely to facilitate connecting suicidal older adults with adequate treatment services.

Intervention

There are relatively few empirically supported interventions for late-life suicide (LaPierre et al. 2011). In general, suicide prevention may be described as falling along a continuum of universal, selected, and indicated strategies (Erlangsen et al. 2011).

Universal strategies are applied to the entire populations. For example, legislation that restricts access to firearms in certain US states has been shown to reduce suicide deaths among older adults (Conwell et al. 2011). Several large-scale screening programs have been evaluated with respect to reducing suicidal behavior in Japan and Europe (Fiske et al. 2015; LaPierre et al. 2011). These programs involved screening of older adults for depression and then treating with combinations of psychosocial and psychiatric interventions. Existing evidence suggests that universal approaches can prevent suicides in older adults, but that older men may require psychiatric

intervention, not just psychosocial intervention, in order to reduce suicide deaths.

Selected preventive interventions are used for individuals at risk for suicide, before the occurrence of suicidal behavior, but are not specific to suicide-related outcomes. It may be difficult to identify and reach older adults in need of treatment. One way to identify older adults in need of intervention is to use gatekeepers. In the case of older adults, “gatekeepers” may be primary health-care providers, mail carriers, individuals delivering meals, clergy, or other workers who might be in a unique position of contact with older persons (Conwell et al. 2011). Other preventative interventions could be to encourage church or other community activities and to promote access to medical care to relieve disability and pain (Conwell et al. 2011). Telephone-based outreach programs have been shown to reduce suicide and suicide-related outcomes in older adults with psychiatric and medical problems (LaPierre et al. 2011). Because depression is strongly related to suicidal behavior, several large studies have shown reduced suicide-related ideation with the use of depression care managers in primary care (LaPierre et al. 2011). Pharmacological treatments, in particular lithium and antidepressants, are associated with reduced suicide deaths among older adults (Fiske et al. 2015). However, no pharmacological treatment has been developed to specifically target suicidal behavior.

Indicated preventative interventions are used to directly intervene with an individual who is deemed to be at high risk for death by suicide, based on the presence of suicide-related ideation or a suicide attempt (Erlangsen et al. 2011). Indicated interventions for older adults should include multimodal strategies that provide the ability to reach a provider during a time of crisis or for support and the involvement of significant others in treatment as well as address a range of social, emotional, and medical needs (Erlangsen et al. 2011). Because older adults tend to make highly lethal suicide attempts, intervening before an attempt (at the universal or selected levels) is desirable.

Psychotherapy that directly addresses suicidal behavior has generally been developed and tested

with younger samples. However, cognitive and cognitive-behavioral therapies, dialectical behavior therapy, and problem-solving therapy are effective for reducing depression among older adults and show promise for reducing suicidal behaviors (Fiske et al. 2015). Interpersonal therapy is another type of psychotherapy that may be useful for older adults because of its focus on relationships and role transition and has been shown to reduce suicide-related ideation and depressive symptoms among at-risk older adults (LaPierre et al. 2011).

Safety plans are often used with adults who report suicide-related ideation. Safety plans consist of a list of steps that the individual agrees to take if he or she is having thoughts of suicide. These plans generally include coping strategies that the individual has found helpful, phone numbers of supportive family and friends, phone numbers of providers, and contact information for crisis lines and emergency services. Safety plans should not be confused with no-harm contracts (i.e., oral or written agreements by which patients promise not to hurt or kill themselves), which have not been shown to be effective and are not recommended.

Overall, the evidence supporting interventions for suicidal behavior among older adults is minimal but building. Multimodal and comprehensive strategies are recommended in order to identify, support, and treat older adults at risk for suicide (LaPierre et al. 2011).

Conclusions and Future Directions

Suicide is an important issue in geropsychology, considering the elevated risk, particularly among older men. Late-life suicide is best understood by integrating theories of suicidal behavior with a life span developmental perspective. The interpersonal theory of suicide, which proposes that suicide can be understood as a joint function of desire to die and capability of enacting lethal self-harm, appears to have particular relevance for explaining late-life suicide. Risk factors for suicide in late life include genetics, depression and other mental disorders, certain personality traits,

poor emotion regulation, hopelessness, history of suicide attempt, impaired decision-making, and social isolation. Protective factors include social connectedness. Further research is needed to distinguish between factors that influence desire to die and factors that influence capability to enact lethal self-harm.

There are reliable and valid methods of assessing suicide risk in older adults, to include self-report and clinician-rated measures of suicidal ideation as well as instruments that assess depressive symptoms and hopelessness but can predict suicide. Because a majority of older adults who die by suicide present to primary care shortly before the death, it may be particularly useful to introduce suicide risk assessment into this setting. Training for professionals may be helpful in reducing barriers to accurate assessment of suicide risk in this population.

There is emerging evidence supporting several types of interventions to prevent suicide in late life. Universal preventive strategies with some empirical support include means restriction (especially related to firearms, such as laws implementing background checks and waiting periods) and large-scale screening for suicide risk. Selected approaches with empirical support include outreach programs (e.g., telephone outreach or gatekeeper training) and treatment for depression and other disorders. Indicated preventive strategies also show promise, but further research is needed.

Additional research on late-life suicide is urgently needed (Szanto et al. 2013). Discovery-related research that distinguishes between risk for suicidal desire and risk for acquiring the capability of engaging in self-harm would be particularly useful. Research is needed to provide additional well-validated, age-specific assessments of suicide risk, including measures that distinguish between normal thoughts of death and suicidal ideation (Szanto et al. 2013). Research is also needed to evaluate the feasibility of conducting large-scale screening and intervention for suicide risk, especially at care transition points within the health-care system (Szanto et al. 2013). Intervention-related research is needed to establish the efficacy of universal,

selected, and indicated preventive strategies within this age group. Finally, additional training is needed to prepare clinicians and others to detect and intervene when an older adult is at risk of suicidal behavior. Suicide is not a normal part of aging, but suicide prevention is part of the job of everyone who works with older adults.

Survey of Health, Ageing and Retirement in Europe (SHARE)

Axel Börsch-Supan

Munich Center for the Economics of Aging, Max-Planck-Institute for Social Law and Social Policy, Munich, Germany

Overview

The Survey of Health, Ageing and Retirement in Europe (SHARE) is a unique multidisciplinary and cross-national panel database of ex ante harmonized microdata on health, socioeconomic status, and social and family networks covering most of the European Union and Israel. To date, SHARE has collected five waves of data in 2-year intervals since 2004, including current living circumstances and retrospective life histories. A sixth wave is currently (2015) in the field. Four additional waves are planned until 2024.

More than 230,000 interviews conducted so far give a broad picture of life after age 50, measuring physical and mental health, both objectively and subjectively; economic and noneconomic activities, income, and wealth by sources; intergenerational transfers of time and money within and outside of the family; as well as life satisfaction and well-being. The data are available to the scientific community free of charge at www.share-project.org after registration.

SHARE is harmonized with the US Health and Retirement Study (HRS) and the English Longitudinal Study of Ageing (ELSA) and has become a role model for several aging surveys worldwide. SHARE's scientific power is based on its panel design that grasps the dynamic character of the aging process, its multidisciplinary approach that delivers the full picture of the individual and societal aging, and its cross-nationally ex ante harmonized design that permits international comparisons of health, economic, and social outcomes in Europe and the USA.

Due to their harmonization, the SHARE data and their international sisters encompass a worldwide "historical laboratory" to assess the effects

of different policies on health, socioeconomic status, and well-being after age 50. To date (May 2015), more than 1,200 SHARE-based publications assess the chances and challenges of individual and societal aging by exploiting the links between health, economic, and social conditions over the life course observable in SHARE.

Among the key findings is a European North–South gradient in many more dimensions than previously documented. In addition to the well-known income gradient, the health and well-being differences between North and South contradict mortality data and folklore about healthy Mediterranean lifestyle. SHARE has sparked an entire new area of research by revealing a strong correlation between early retirement and the loss of cognitive abilities, social contacts, and well-being. Equally impressive are findings that the large international differences in the uptake of early retirement and disability benefits are more strongly correlated with economic incentives than with health and age.

Background and Development

Population aging is one of the great societal challenges of the twenty-first century. Beginning in the 1990s, this trend mostly affected wealthy countries but is coming up in poorer nations due to their declining fertility rates. According to Eurostat, the rate of older people (65 years and above) in Europe, in relation to persons in their working age, is expected to almost double from 17% in 2010 to 30% in 2060. This is unparalleled in human history and poses big challenges to the welfare state. In 2060, for every one working person, there will be one retired person.

While the demographic trends and its two main causes (low fertility and increasing life expectancy) are clear, not enough is known about consequences and implications of population aging and its manageability through public policy. Understanding how the aging process will affect all of us and disentangling the influences of different cultures, histories, and policies is an important task for researchers in anthropology, demography, economics, epidemiology,

gerontology, history, and sociology in order to turn the challenges of population aging into opportunities.

In response to the European Commission's strong interest in obtaining scientific evidence on population aging in its member states, SHARE was created as a longitudinal survey infrastructure by and for researchers from multiple disciplines (Börsch-Supan et al. 2005). While its development started only in 2002, SHARE has already become one of the crucial pillars of the European Research Area. Since 2012, it is the first ever European Research Infrastructure Consortium (ERIC), with a new legal status and many of the advantages of major international organizations, as well as a long-term perspective up to 2024. The ultimate goal is to provide high-quality microlevel panel data of economic, social, and health factors that accompany and influence aging processes at the individual and societal level. In addition to its multidisciplinary and longitudinal nature, SHARE was set up to be a cross-national enterprise to enable researchers investigating how different European welfare state regimes moderate and mediate consequences and implications of population aging. The data from Europeans aged 50 and over from 18 European countries and Israel are provided free of charge to the scientific community.

Two more features make SHARE a highly valuable source for genuine cross-cultural comparisons. First, SHARE is closely modeled after and constantly harmonized with its sister studies HRS in the USA and ELSA in the UK. This model has sparked and informed exciting new survey research on aging all over the world, e.g., Japan (JSTAR), China (CHARLS), Brazil (ELSI), South Korea (KLOSA), and India (LASI) which puts SHARE into a truly global perspective. Second and as opposed to these global sister surveys, SHARE in itself is a multinational survey. The SHARE interview is *ex ante* harmonized, and all aspects of the data generation process, from sampling to translation, from fieldwork to data processing, have been conducted according to strict quality standards. Maintaining this *ex ante* harmonization in spite of national differences and decentralized funding poses great scientific and governance challenges.

Participation and Population Coverage

After five waves of SHARE, more than 230,000 interviews have been conducted with about 86,000 respondents aged 50 and over and their potentially younger partners in 20 countries (Austria, Belgium, Croatia, Czech Republic, Denmark, Estonia, France, Germany, Greece, Hungary, Ireland, Israel, Italy, the Netherlands, Poland, Portugal, Slovenia, Spain, Sweden, and Switzerland). A person is excluded if she or he is incarcerated, hospitalized, or out of the country during the entire survey period, unable to speak the countries' language(s), or has moved to an unknown address. In addition, current partners living in the household are interviewed regardless of their age. All SHARE respondents that were interviewed in any previous wave are part of the longitudinal sample. They are traced and reinterviewed if they moved within the country (for more information see the SHARE methodology volumes (Börsch-Supan and Jürges 2005; Schröder 2011; Malter and Börsch-Supan 2013)).

SHARE is a multinational survey, which involves differences in sampling resources between countries. Consequently, sample frames are chosen in accordance with the best available frame resources in the country to achieve full probability sampling. Most SHARE countries have access to population registers. SHARE provides sampling design weights to compensate for unequal selection probabilities of the various sample units. Without such weights it is not possible to obtain unbiased estimators of population parameters of interest.

Despite the complexity of the survey instrument and partially decentralized funding, most countries managed to stick to the schedule of having a SHARE data collection every second year. The major exceptions are the later fieldwork periods in Israel in Wave 1 and 2 and, due to funding problems, in Poland in Wave 4. Also, due to lack of sufficient funding following the economic crisis, Greece could not take part in the fourth and fifth waves but is joining again in Wave 6. After merging the Irish SHARE study with TILDA, the Irish Longitudinal Study on Ageing (Kearney et al. 2011), there will be no

Survey of Health, Ageing and Retirement in Europe (SHARE), Fig. 1 Average 2-year retention rates by sample and country

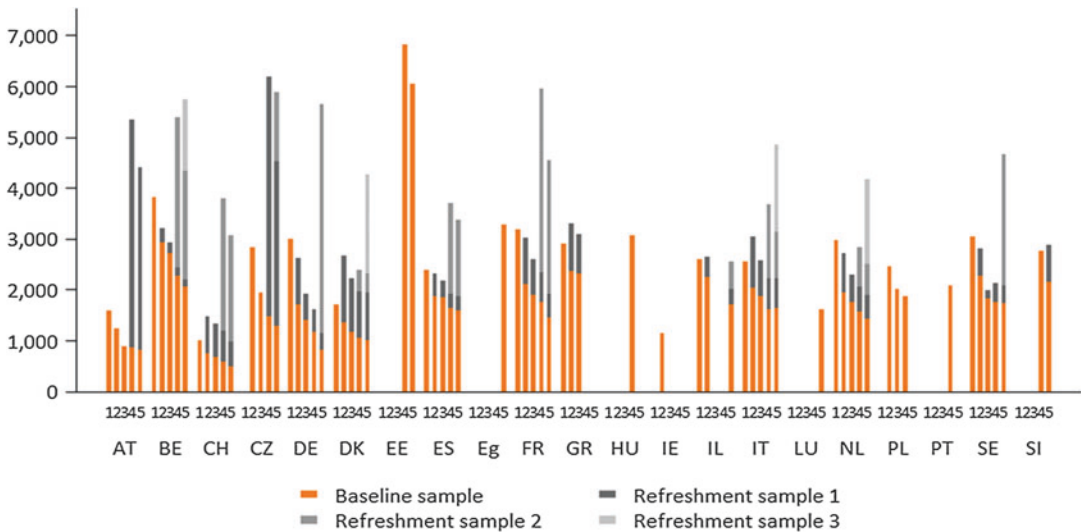

stand-alone SHARE in Ireland after Wave 3. However, TILDA has taken over substantial parts of the SHARE questionnaire into their study.

The gross samples for the initial wave in 2004 were locally drawn in each of the 12 participating countries. They have been based on sampling frames which acknowledged country-specific circumstances such as the availability of register information, need for screening, expected response rate, etc. This has resulted in more than 50,000 addresses overall. Response rates in the first wave, defined as the proportion of selected households including at least one eligible person from whom an interview was successfully obtained, were about 62% on average. In total, 31,115 interviews were conducted. Existing variation in performance over countries was for the most part consistent with previously known patterns from other international surveys. Cooperation at the individual level was only slightly lower than at the household level. Conditional on household participation an interview could, on average, be obtained from more than 85% of eligible household members.

In the second wave of SHARE, three new countries entered the study. Response rates for the new countries were on average very similar to Wave 1 (about 61%). Additionally, refreshment samples were drawn to increase net sample size and compensate for attrition in the longitudinal sample. Here, response rates were on average a

little lower than in the first wave (54%). Individual retention with regard to the longitudinal part of the sample was about 73%. Starting in Wave 2, end-of-life interviews on deceased respondents were administered to relatives or other close persons to the deceased. In total, 34,415 Wave 2 interviews plus 533 end-of-life interviews (EOL) were released, including 18,742 longitudinal interviews. For the third wave, the SHARELIFE study with retrospective life history interviews, no additional households were sampled. 26,836 interviews and 1,139 EOL interviews were conducted in panel households, including 1,158 first interviews with new or previously noncooperating spouses. The resulting individual retention rate was about 77%. In Wave 4, net sample size was substantially increased by including four new countries and drawing refreshment samples in most of the established countries. Altogether, 58,489 interviews, of which 21,566 were longitudinal, and 1,110 EOL interviews were released. Response rates in the baseline (56%) and refresher samples (49%) were on average lower than in previous waves. In this respect SHARE is no exception to the general decline in response rates in face-to-face surveys in Europe and worldwide (Matsuo et al. 2010).

Figure 1 depicts the average retention rate of panel members. It varies a great deal across countries. The average retention rate across all countries and waves is 81%, for the most recently

Survey of Health, Ageing and Retirement in Europe (SHARE), Fig. 2 Data released in SHARE by country and wave

sampled persons 77%. For those interviewed for the first time in Wave 1 (Wave 2, resp.) and reinterviewed in Wave 5, this rate reaches 87% (84%). This reflects the high retention of long-term panel members including the recovery of those respondents who missed a wave. Actually, for every person lost between Wave 4 and Wave 5, almost one person could be recovered from previous waves.

Since 2005, 11 scientific data releases of the SHARE data were compiled. Figure 2 gives an overview of the released interviews by country, wave, and sample.

Variables Collected

SHARE consists of normal panel waves (Waves 1, 2, 4, 5, and 6) and retrospective life histories (Waves 3, repeated for all new respondents in 7).

SHARE panel. Covering the key areas of life, namely, health, socioeconomics, and social networks, SHARE includes a great variety of information: health variables, physical measures and biomarkers, psychological variables, economic variables, and social support variables as well as social network information (see Table 1 for more details):

- **Health variables** include self-reported health, physical functioning, physical measurements such as grip strength, walking speed, peak expiratory flow, chair stand, and body mass index (BMI); health behaviors; and the use of health-care facilities. Wave 6 will add biomarkers extracted from capillary blood such as glycated hemoglobin (HbA1c), a marker of diabetes; C-reactive protein, a marker of cardiovascular disease; cytokines such as TNF-alpha, IL-6, and BDNF, involved in low-grade inflammation, frailty, and cognitive function; and Vitamin D.
- **Psychological variables** include mental health components such as depression, several tests of cognitive functioning, well-being, life satisfaction, and control beliefs.
- **Socioeconomic variables** include current work activity, job characteristics, job flexibility, opportunities to work past retirement age, employment history, pension rights, sources and composition of current income, wealth and consumption, housing, and education; in some countries linkage to administrative data on employment, labor income, and pension claims.
- **Social support variables** include assistance within and beyond families, transfers of income and assets, social networks including

Survey of Health, Ageing and Retirement in Europe (SHARE), Table 1 Information collected in the SHARE panel Waves 1, 2, 4, 5, and 6

Questionnaire modules	Examples
Coverscreen	Year and month of birth, sex, household composition
Demographics	Education, marital status, country of birth and citizenship, parents and siblings
Physical health	Self-rated health, diseases, weight and height, (I)ADL limitations [(instrumental) activities of daily living]
Behavioral risks	Smoking and alcohol, nutrition, physical activity
Cognitive function	Self-rated reading and writing skills, orientation, word list learning immediate and delayed recall, verbal fluency and numeracy
Mental health	Depression scales (Euro-D and CES-D), quality of life (CASP-12)
Health care	Doctor visits, hospital stays, surgeries, forgone care, out of pocket payments
Employment and pensions	Employment status, individual income sources (public benefits, pensions), job, work quality
Children	Number and demographics of children
Social support	Help and care given and received
Financial transfers	Money/gifts given and received
Housing	Owner (mortgages, loans, and value), tenant (payments), type and features of building
Household income	Income sources all household members
Consumption	Expenditures for food, goods, services, ability to make ends meet
Assets	Bank and pension accounts, bonds, stock and funds, savings
Activities	Voluntary work, clubs, religious organizations, motivations
Expectations	Expected inheritances, life expectancy, future prospects
Interviewer observations	Willingness to answer, understanding of questions, type of building, neighborhood
<i>New modules after Wave 1</i>	
<i>Since Wave 2: end of life</i>	Death reasons and circumstances
<i>In Wave 4: social networks</i>	Ego-centered network, contact, emotional closeness, geographical distance, satisfaction with network

ego-centered network size and intensity, and volunteer activities.

The interviewers used computer-assisted personal interviewing (CAPI) to collect most of the data in all waves. In addition self-administered questionnaires (drop-off) were handed out in Waves 1, 2, and 4 after completion of the CAPI. If respondents deceased, EOL interviews were conducted face to face (CAPI) or by telephone (CATI) with a proxy, collecting the information regarding the respondent's last year of life. Proxy interviews were also used when respondents were not able to do an interview, for example, due to health reasons.

Even though SHARE is a panel survey with a stable core questionnaire over time, innovative research questions, physical measurements, or modules have been incorporated in each wave. For example, in Wave 2, two physical measurements – peak flow and chair stand – were added (see next section for details). In Wave 4 a completely new module – the social networks module based on a name-generator approach – has been implemented to learn more about the social connectedness of respondents. In Wave 6 dried blood spots were taken to measure blood sugar, C-reactive protein, and cholesterol.

To assure an easy and fast entry into cross-national data and high convenience while working with the data, it is necessary that certain variables are readily provided, especially those that allow a valid comparison between countries, such as the International Standard Classification of Education (ISCED). Besides internationally standardized variables, SHARE datasets provide further generated variables that ease or enhance working with SHARE data as well as different kinds of weights and multiple imputations (see the documentation at www.share-project.org/data-access-documentation/).

SHARELIFE retrospective life histories. In SHARELIFE, retrospective data with respect to childhood living circumstances, partners, children, accommodation, employment, and socio-economic and health conditions were collected with the help of a “Life History Calendar” similar to the one applied in ELSA (Schröder 2011). The combination of the SHARELIFE with SHARE

and ELSA data thus gives a detailed picture of the current status of individuals in Europe with a view across their entire life courses (Börsch-Supan et al. 2011). Table 2 provides more details.

Physical measurements and biomarkers. Until today, physical measurements and biomarkers were mostly taken in smaller, nonrepresentative clinical studies. In the last couple of years, more and more large-scale surveys added physical measurements and biomarkers to their program since standard health questions in surveys are often subject to the respondents' own interpretation (of the question), own evaluation or perception (of health status), and own knowledge (of health status). The value of subjective health measurements is undeniable, but some research questions require objective measurements. Biomarkers enable researchers to validate respondents' self-reports and therefore to study the amount and determinants of under-, over-, and misreporting in large-scale population surveys. Biomarkers can help to understand the complex relationships between social status and health and allow identification of predisease pathways, since physiological processes are often below the individual's threshold of perception. From the first wave on, SHARE combined self-reports on health with physical performance measurements. Dried blood spots have been collected in Germany during Wave 4, and a full-scale collection of dried blood spots in all countries is taking place in Wave 6.

Linking survey and administrative data. Survey data can cover a wide range of topics. However, the information provided by respondents is often incomplete or inaccurate. Administrative data on the other hand are much more complete and accurate since they are process generated. The disadvantage of administrative data is that the information is limited to certain topics only. Linking survey data with administrative data is a way to combine the best of both worlds. SHARE thus cooperates with the German Pension Fund (DRV) and has linked the German survey data with administrative data held by the DRV in a pilot study in the third wave of SHARE. The administrative data consists of two parts: The first part is longitudinal and includes sociodemographic characteristics (such as age, sex, number and age of

Survey of Health, Ageing and Retirement in Europe (SHARE), Table 2 Retrospective information collected in SHARELIFE (Wave 3)

Questionnaire modules	Examples
Start of the interview	Year and month of birth, sex
Children history	Pregnancies, births, children characteristics, maternity leave
Partner history	Living arrangements, marriages, divorces
Accommodation history	Residences (country, region), moves, types of accommodation, ownership
Childhood circumstances (Age 10)	Accommodation features, number of books, school performance
Work history	Employment status, job characteristics, income
Work quality	Effort, demand, control, job circumstances
Disability benefits	Disability leaves, work reduction, disability pension
Financial history	Investments in stocks, funds, insurance uptake, retirement savings
Health history	Hospital stays, illnesses, diseases, current self-rated health
Health-care history	Vaccinations, doctor visits, preventive checkups, health behaviors
General life	Periods of happiness, stress, financial hardship, hunger, persecution, oppression
Interviewer observations	Willingness to answer, understanding of questions, type of building, neighborhood

children, and education) and detailed information about the working history as well as all activities which generate public pension entitlements. That data is implemented as a panel database beginning at age 14 which provides that information on a monthly base. The second part is cross sectional and only available for retirees. Included is information on the calculation of the pension benefits. The two datasets are updated every year (Korbmacher and Czaplicki 2013).

Data Usage

Access to the infrastructure via two data archives is free for all scientists globally, subject to European Union data protection regulations: <http://www.share-eric.eu>.

The scientific power of SHARE is based on three elements: its panel design which grasps the dynamic character of the aging process, its multidisciplinary approach which delivers the full picture of the aging process, and its ex ante cross-national harmonization which permits rigorous benchmarking and policy evaluation across countries. Such a data set takes time to build up. Since 2004, when SHARE was started, the number of countries almost doubled from 11 to 20.

SHARE has succeeded surprisingly fast to create a large user community. Since the first public release of SHARE data in April 2005, SHARE has attracted more than 4,300 registered users with an unbroken, more than linearly increasing trend. Since we count registrations not including work students and students in class, we estimate an approximate number of 10,750 actual users. While users include mainly scientists from Europe, researchers from the USA are now the second largest user group after Germany, before Italy and the Netherlands. We interpret the acceptance of SHARE by so many researchers, and particularly in the USA, as an indicator of SHARE's high scientific value.

Arguably the best indicator for the success of a research infrastructure is the number of published findings emanating from it. In addition to four comprehensive volumes of first results from the

SHARE baseline, longitudinal, and retrospective waves (2004–2012) which have been complemented by several national collections of findings, more than 50 books and 1,000 articles in peer-reviewed journals and volumes have been published based on SHARE data. This is the current state. Based on the experience of other panel data, their usefulness and thus user and publication numbers will increase steeply with the number of future waves.

SHARE has generated some surprising findings which have received wide-spread attention. Three examples may show the breadth and quality of successful SHARE-based research:

- Already the first wave of data revealed a European North–South gradient in many more dimensions than previously documented. While the income gradient was known, thanks to earlier Eurostat data, the health and subjective well-being differences between the North and the South of Europe were a surprise because they contradict mortality data and folklore about healthy Mediterranean lifestyle. These findings pose new fundamental questions, e.g., about the economic, social, and medical causes for a divergence between mortality and morbidity.
- Another surprising finding from SHARE has sparked an entire new area of research and a lot of controversy: SHARE data revealed a strong correlation between early retirement and the loss of cognitive abilities both within and between European countries. A fruitful cooperation between cognitive psychologists, gerontologists, economists, and sociologists has begun to identify the causes for this finding which range from the cognition-stimulating effect of work even if it is unpleasant to the social isolation experienced by many retirees. It sheds new light on the EU's strive for active aging.
- Equally surprising is the finding that the large international differences in the uptake of disability benefits are not at all correlated with health or demographic differences in Europe, such as those mentioned above between the North and the South. Rather, they are almost

completely explained by the different rules and regulations of the various disability insurance schemes in the member states and document how powerful economic incentives are for retirement behavior.

Many of the SHARE findings have strong policy implications for aging societies, such as tighter targeting rules for disability insurance or a stricter handling of early retirement pathways. SHARE has been successful in providing help for evidence-based policy making, both at the European Union and the member state level. SHARE is also intensely used by the Organisation for Economic Co-operation and Development (OECD) and the World Health Organization (WHO).

Acknowledgments

During the first three waves, the SHARE data collection has been primarily funded by the European Commission through the 5th framework programme (QLK6-CT-2001-00360 in the thematic programme Quality of Life), through the 6th framework programme (SHARE-I3, RII-CT-2006-062193, COMPARE, CIT5-CT-2005-028857, SHARELIFE, CIT4-CT-2006-028812) and through the 7th framework programme (SHARE-PREP, 211909, SHARE-LEAP, 227822). Starting with Wave 4, SHARE has changed to a decentralized funding model and became an international organization („SHARE-ERIC”) funded by its member countries. Substantial additional funding comes from the US National Institute on Aging (U01 AG09740-13S2, P01 AG005842, P01 AG08291, P30 AG12815, Y1-AG-4553-01, OGHA 04-064, IAG BSR06-11, R21 AG025169). The German Federal Ministry of Education and Research is funding the Munich-based international coordination of SHARE (AZA 01UW0908) while the EU Commission finances all coordination elsewhere (SHARE-M4, 261982). We gratefully

acknowledge these as well as all national funding sources (see www.share-eric.eu for a full list of funding institutions). This article is based in parts on an updated version of Börsch-Supan et al. (2013).

Adaptability; Career potential; Sustainable careers

Definition

Employability is the capacity of continuously fulfilling, acquiring, or creating work through the optimal use of competences. Sustainable careers are the sequence of an individual's different career experiences, reflected through a variety of patterns of continuity over time, crossing several social spaces, and characterized by individual agency, herewith providing meaning to the individual.

Over the past decades, substantial evolutions have taken place in the world of work which has important implications for the nature of careers. Careers have become more insecure, both from an organizational and an individual viewpoint. Employability has become a critical condition both for the sustainability of employees' careers and for organizations, which for their performance depend on the employability of their workforce. The aging of the workforce has brought these challenges even more to the forefront. Employees will have to work longer and thus will need to safeguard their employability also at older ages. For organizations, investing in employability of their aging workforce requires a shift in mindset which requires a different stance toward the meaning of age in careers. The goal of this entry is therefore to examine the role of age in employability models and to address the notion of sustainable careers.

Overview of This Entry

This entry consists of six main parts. First, we define the concept of employability. Second, we discuss the process of self- and other appraisal of employability and the challenges for organizations to overcome common age-related stereotypes about employability and performance. In the next two parts, we summarize empirical findings on the role of age in the relationships between employability, on the one hand, and career success and job search intensity, on the other hand. In the fifth part, we take a closer look at the notion of sustainable careers and its meaning from the perspective of employability throughout the life span. We close this entry by highlighting some important reflections on future research and practice in the domain of sustainable careers.

Defining and Operationalizing the Concept of Employability

Employability is a concept that is studied from different angles and defined on more than one level (individual, organization, industry, society). The concept came into use from about 1955 (Versloot et al. 1998) and has acquired different meanings over time. The particular context in which employability is used influences its definition. There has been a lack of studies integrating the different perspectives adopted in employability research. Business and management studies, HRM, HRD, educational science, and career theory are each examples of the use of the concept on different levels and the different meanings that are attributed to employability. This has led to the concept of employability remaining rather abstract and vague. Apart from the great variety in employability definitions, one could consider the concept as useful in pointing to certain historical work and organizational developments in Western countries. More specifically, one may detect a relation between the conceptualization and the transition of an industrial to a postindustrial society. Employability in that sense is a symbol to address work-related problems related to this transition.

Scholars have described the development of the concept from the 1970s to the 1990s (time span not the same for each country), and this development is characterized by a shift of ‘government’ to ‘organization’ to ‘employees’ as the most important party responsible with regard to employability concerns, here defined as deployment. Three time periods correspond to three different definitions of work from the perspective of those different parties, namely, full employment (government), putting people to work with a match between supply and demand (organizations), and attractive paid work (individual) (Thijssen 2000). A parallel shift in studied target groups occurs from “population groups” to “internal organizational segments” to “very specific target groups,” such as employees in their thirties.

Definitions of employability at an individual level are abundant (e.g., Versloot et al. 1998; Forrier and Sels 2003), each emphasizing different as well as similar career aspects on the part of individual employees, but all with employment as outcome: physical suitability, cognitive suitability, (career) development, learning, de-specialization, flexibility, adaptation to (fast) changes, and mobility (both external and internal). Employability is believed to accommodate several or all of these aspects, depending on the angle from which it is studied and consequently cannot be seen as a unidimensional construct.

In search of the core of the concept, various attempts have been made to capture and to categorize its constituent dimensions. We define employability as the capacity of continuously fulfilling, acquiring, or creating work through the optimal use of competences (Van der Heijde and Van der Heijden 2006). This definition is compatible with definitions like “the chance for employment on the internal or external labour market” (Forrier and Sels 2003) and “a form of work-specific active adaptability that enables workers to identify and realise career opportunities” (Fugate et al. 2004). It implies a permanent acquisition and fulfillment of employment within or outside the current organization, for present or new customer(s), and with regard to future prospects (Van der Heijden et al. 2009).

Several studies in the field of employability have used a thoroughly validated measurement instrument (Van der Heijde and Van der Heijden 2006), with high psychometric qualities, wherein domain-specific expertise (occupational expertise is defined as domain-related knowledge and skills.) is complemented with four more generic competences: (a) anticipation and optimization (anticipation and optimization is defined as preparing for and adapting to future changes in a personal and creative manner and striving for the best possible results), (b) personal flexibility (personal flexibility is defined as the capacity to adapt easily to all kinds of changes in the internal and external labor markets that do not pertain to one’s immediate job domain), (c) corporate sense (corporate sense is defined as the participation and performance in different work groups, such as organizations, teams, occupational communities, and other networks; sharing responsibilities, knowledge, experiences, feelings, credits, failures, goals, etc.), and (d) balance (balance is defined as compromising between opposing employers’ interests as well as one’s own opposing work, career, and private interests (employee) and between employers’ and employees’ interests). The first two dimensions are flexibility dimensions, discernible as one proactive/creative variant and one more passive/adaptive variant. Corporate sense represents the requisite increase in social competence. The dimension of balance is added, taking into account the different elements of employability that are sometimes hard to unite and which require fine-tuning, such as current job goals and career goals, to give an example (Van der Heijde and Van der Heijden 2006).

In the remainder of this entry, we will go into the role of age in the relationships between employability, on the one hand, and career success and job search intensity, on the other hand, and on the meaning of sustainable careers from the perspective of employability throughout the life span. However, in order to better understand the possible impact of employee age upon multisource ratings of employability (self-ratings versus supervisor ratings), it is of utmost importance to understand the phenomenon of age-related

stereotyping in performance ratings and possible ways for organizations to combat this.

Age-Related Stereotyping in Appraisals of Employability: Self-Other Disagreement in Performance Ratings

Age-related stereotyping is an important phenomenon where assessments concerning quality and performance assessments about the employee's current functioning or about his or her future career potential (employability) are made by supervisors. Every human being forms stereotypes in order to make his or her world more orderly and predictable, with supervisors in working organizations being no exception. However, many stereotypes are based on cognitive errors. These errors are most likely to occur where people do not have extensive contact with the subject in question and where they do not have any additional information about the individual members of a group. In judging employees whom we do not know very well, we may see them all mainly as members of one and the same group with a common set of attributes. The outcomes of previous research indeed confirm that supervisors have a more negative opinion of the functioning of the over fifties compared with that of starters and mid-aged employees (e.g., Van der Heijden 2001).

Moreover, the nature of the rater, self, supervisor, colleague, or customer (multisource ratings or 360° feedback methodology) produces very different information about the employee. One manager's idea of, for example, the worker's employability may be concretely quite different from another's. After all, any rating is only an indication of how the person (often the manager) applies a fuzzy criterion. Especially in the case of a poor operationalization of the performance indicator in question, rating systems give people a false sense of security, protection, and objectivity. Yet all assessments, of whatever kind and in whatever context, occur in the cognitive processing of an individual human being. As assessment occurs "in the head," it is always, necessarily, and by definition subjective (Van der Heijden and Nijhof 2004). Now, of itself, this is neither good nor bad.

That is just how it is. The important question here is how we respond to the inevitable subjectivity of assessment and to the fact that judgment depends on values and accordingly is subject to response sets, for example, due to stereotyping.

The accurate interpretation of differences in appraisal by different sources requires that one can assume that each set of raters uses the same metric. If, for whatever reason, one group of raters interprets the text of an item or a set of items differently from another group, the resulting differences in the ratings may be the result of not only the observations of the raters but also of the interpretative difference elicited by the item (Penny 2001). The findings of previous empirical studies on occupational expertise, being an important indicator of employability, indicate that employees "think" somewhat better of themselves than supervisors do or at any rate they give a rosier image (Van der Heijden 2001). The scale ratings given by the employees themselves are all significantly higher than the corresponding ones made by their supervisors. This is not thought to be caused by the measurement instrument itself, because the scale reliabilities and discriminant validity are high, both for the self-ratings and for the supervisor ratings. The tendency to present oneself positively, the so-called leniency effect, is common in performance ratings (Golden 1992).

Nonetheless, that an item can function differently for different groups of raters suggests the existence of a degree of measurement inequivalence between the rater groups, and this inequivalence may be indicative of systematic bias in ratings between particular groups of raters. This outcome raises important questions about the reliability and objectivity of performance ratings in general. It might be that self-ratings reflect a reliable but somewhat more differentiated self-image. Supervisors are more consistent in answering. If they are asked to account for their employee's performance, it seems that they are inclined to give unanimous answers, meaning that the scores for items are more accommodated to each other. That is to say, the ratings made by supervisors are more colored by the ratings for other items and, also, for other dimensions of the attribute that is to be evaluated.

Possibly, the supervisor ratings are strongly influenced by a response set, for instance, the degree to which they like or dislike the employee in question as a person. It is well known that such liking–disliking factors, or the “halo effect,” can have a strong effect where persons are required to give valid and dependable judgments of other persons, but are not well informed enough to base their judgment on observations of real-life behavior of these people or on relevant real-life events that they are involved in. Ratings by supervisors are based on a much smaller amount of information, leading to the so-called effect of under-sampling. The effect of under-sampling arises because of the fact that supervisors tend to be more superficially acquainted with their employees, due, for instance, to a lack of communication between the two parties (employee and supervisor), especially in the case of higher-level employees, whose work is highly independent and often solitary even. The effect of under-sampling is thought to give rise to the occurrence of response sets. An example of a response set that can be highly influential is stereotyping, for example, on account of age (Rosen and Jerdee 1976).

Based on the outline given above, we conclude that it is not sound from a statistical point of view to aggregate the scores from different sources: for example, the employee and the supervisor. In fact, this procedure may be very misleading. We should rather spend much more time in analyzing the exact meaning of data on performance assessments emerging from the 360° feedback methodology. If we do not take the time to do so, we are in danger of conducting “sophisticated” analyses before understanding the exact nature of perceptions about the employee’s current functioning or about his or her future career potential (employability), that is to say, before having established the measurement equivalence.

Specifically, there are two aspects of measurement equivalence: (a) conceptual equivalence, the comparability of constructs, and (b) psychometric equivalence, the comparability of psychometric properties of measurement scales (Cheung 1999). *Conceptual equivalence* exists when, for example, employees and their supervisors use the same conceptual frame of reference for

evaluating, for instance, the worker’s employability, that is, in case raters use the same items to represent dimensions and assign similar weights to items, appearing from factor form equivalence and factorial invariance. As regards *psychometric equivalence*, there have been many studies that examine the properties of self-rated performance, and response bias, such as measurement errors, low variability, and leniency error, to mention some frequently found aspects. When comparing self-ratings with supervisor ratings, response bias not only attenuates the power of statistical analyses, but non-equivalent psychometric properties (unequal response sets) also lead to biased results.

The same would apply to ANY appraisal instrument, whether one uses multiple sources or just a single manager. The fact is that we do not think about this as a problem where a single manager carries out the performance appraisal. However, if we consider five managers rating the same employee, we would run into the same problem of poor psychometric qualities. If the appraisal system that we use to make decisions on mobility, firings, promotions, pay raises, etc., can be demonstrated to have low psychometric qualities, for instance, due to age-related stereotyping, it may even confront the company with a variety of problems, like lawsuits and accusations of discrimination on the basis of illegal criteria. Lawsuits apart, decisions that are perceived as unfair will have negative consequences on the motivation, loyalty, and extra-role behavior of employees (e.g., Nijhof et al. 2000). Earlier research in the field of organizational justice theory shows that this kind of procedural unfairness indeed has strong effects on the performance and citizenship behavior of subordinates (e.g., Rutte and Messick 1995).

In order to truly make use of knowledge of perception differences and to openly share the information, employee and supervisor should have an elaborate base of information to talk about the differences in perception. Supervisors should do their utmost to gain greater insight into the potential of one’s workforce and should therefore bridge the gap that exists between them and their subordinates, especially as the supervisor’s opinion is to a great extent influential upon the

career of the individual employee. We also advocate more interaction between supervisor and employee, and in fact between all parties involved, given the expected buffer function of increased interaction in the light of stereotyping (*unknown ... unloved; known ... loved*), for instance, on the base of age.

However, ratings on their own do not convey sufficient information for people to improve. In order for staff to develop and learn, they need to know what they should change, where (specifically) they have fallen short, and what they need to do. In some cases, a personal coach may be the key to deal with the inherent discrepancies found in multisource ratings. Moreover, expert behavior is something that has to be learned on the work floor with feedback from supervisors and close colleagues. When skills are developed “on the job,” staff members function as codevelop partners, and the chances that self-perceptions of performance appraisals do not correspond with the perception of other parties will diminish (Stoker and Van der Heijden 2001).

Employees should not just learn by means of courses or training programs, but by working together with their supervisors. Supervisors can be “sponsors” of several assignments throughout these courses. In this way, they can help facilitate the development of their subordinates. Implementing 360° feedback for developmental purposes centers on communicating evaluation information to the focal employee. This process is aimed at increasing employees’ self-awareness, helping them to set goals, focusing on areas of development, and, ultimately, altering their behavior to improve job performance and to stimulate greater dialogue between all parties involved (Stoker and Van der Heijden 2001).

In the next two parts of this contribution, we will go into the role of age in the relationships between employability and two important outcomes (career success and job search intensity). Although age has often been included as a covariate or confounder in previous employability research, few researchers have explicitly studied age differences in the relationships between model variables.

The Moderating Role of Age in the Relationship Between Employability and Career Success

Career success refers to real or objective, and perceived or subjective accomplishments of individuals in their work lives (e.g., Judge et al. 1995). From an objective perspective, career success is evaluated using external reference points or norms and is operationalized by means of quantifiable employment history criteria that include promotion rate, income or salary, and attained organizational level. Obviously, performance appraisals about current or future functioning of individual employees play a major role in decision processes regarding their objective career outcomes.

Therefore, it is likely that employability (or career potential) is positively associated with career success (Van der Heijde and Van der Heijden 2006). Moreover, as decisions about career mobility appear to depend heavily on career and life stage considerations (Feldman and Ng 2007), it is expected that employee’s age moderates this relationship in case supervisor ratings are used.

Few career researchers have studied differences in relationships between model variables for distinguished age groups. However, differences in self-reported and supervisor ratings of employability and subsequent career outcomes, depending upon employee’s age, are plausible considering the prevalence of age-related stereotyping (Van der Heijden et al. 2009) and increased person–environment (P–E) fit for older workers (Wright and Hamilton 1978). Negative stereotypical beliefs about older workers may stem less from their current performance levels, yet more from fears of their supervisors as regards their future prospects. And equally distressing, just as immediate supervisors make relatively negative assessments of the “pay-off” period for career investments, older workers themselves also deliberately take into account whether the investment is worth the effort (that is to say, a self-fulfilling prophecy occurs; see also Van der Heijden 2001). As such, they confirm the negative differential treatment they receive in their work environment, and we may therefore expect a

stronger positive relationship between supervisor-rated employability and career success of the youngsters versus the over forties.

As regards the increased P–E fit for older workers, earlier career development theories focused on the idea that one’s self-concept becomes more clearly defined with age, and that career choice is a process of matching one’s self-concept with images of the occupational world (Watkins and Subich 1995). Similarly, the “job change” hypothesis (Wright and Hamilton 1978) states that due to experience, seniority, and skills, a selective group of active older workers will have obtained a relatively better P–E fit and higher occupational levels with more job control compared to their younger colleagues. The increased P–E fit for older workers may result in a relatively stronger relationship between self-rated employability and career success for the over forties, compared to their younger counterparts.

Indeed, in previous empirical work, it was found that for the younger workers self-reported employability contributes to both overall promotions and current gross income, while supervisor ratings appeared only to contribute to current gross income (Van der Heijden et al. 2009). For the over forties, on the other hand, highly different results have been found. Self-reported employability appeared to be positively related to overall promotions, while in case the supervisor ratings of employability were used, the relationship was negative (Van der Heijden et al. 2009). Possibly, our results reconfirm the prevalence of age-related differences in supervisory attitudes (e.g., Van der Heijden 2001). Moreover, it is conceivable that for the over forties in particular, the previously discussed “instrumental style of leadership” plays an important role (Van der Heijden 2001).

The Moderating Role of Age in the Relationships Between Occupational Expertise, Self-Perceived Employability, and Job Search Intensity

Job search intensity refers to the frequency with which job seekers engage in job search behaviors or activities (Blau 1994). One of the factors

leading employees to search for another job on the external labor market is their self-perceived employability. While employees’ perceptions of *internal* employability (i.e., the idea that there are alternative jobs available for them in their current organization) might reduce the likelihood of external job search, their perceptions of *external* employability (i.e., the idea that there are alternative jobs available for them in the external labor market) might increase the likelihood of external job search. Notwithstanding the opposing effects of internal and external self-perceived employability on job search intensity, both are likely to be positively affected by occupational expertise. Occupational expertise may strengthen employees’ labor market value, so that they become more employable, not only in the internal but also in the external labor market (Forrier and Sels 2003).

Although these relationships make sense from a theoretical viewpoint and can be supported with earlier empirical work, the question remains to what extent age may play a role in affecting these relationships. Most studies tend to focus on the main effects of age on outcomes like occupational expertise, employability, or job search. It is equally important however to understand whether the relationships between these variables hold across different age categories. For instance: Will an employee aged 55 plus be as likely to engage in job search when he or she has low perceptions of internal employability in comparison with an employee aged 25? There are several theoretical reasons to expect different dynamics depending on age which can be deduced from theories on life-span development, motivational theories, and literature on opportunity structures. More specifically, one can expect that these relationships will become weaker with increasing age.

An empirical study among employees working in private sector firms provides mixed support for the moderating role of age (De Vos 2009). In accordance with socio-emotional selectivity theory which posits that older employees are less driven by growth motives and more by socio-emotional motives (Carstensen et al. 1999), older employees were less likely to engage in job search when their perceived internal employability was

low, compared to their younger counterparts. However, age did neither moderate the associations between perceived external employability and job search nor the associations between occupational expertise and perceived internal or external employability.

Based upon these findings, we posit that it is important for organizations to understand that occupational expertise is a critical antecedent of perceived employability. However, referring back to the distinction between self and other appraisals earlier in this entry, these self-perceptions of employability will not necessarily be consistent with how others might perceive the employability of older workers – while it will still be these others who might affect older workers' actual opportunities in the internal labor market. As a result, organizations might risk to decrease the motivation and engagement of older employees who, despite their occupational expertise, do no longer perceive internal opportunities for further growth or development but yet stay in their current organization. This might have negative consequences for the sustainability of careers of the employees involved, for the dynamics and motivations in teams of colleagues, and for organizational performance in the long run.

Toward Sustainability Across the Life Span

Based upon this entry, we may conclude that there is indeed a broadly held and persistent view that older workers are less able to cope with the demands of the modern, complex, and competitive organization than younger employees and that older workers' ability or motivation to change jobs or to learn new skills and expertise has deteriorated. Moreover, the possible danger of a self-fulfilling prophecy even worsens the situation, referring to the emotional, attitudinal, and behavioral reactions of the older worker to the instrumental leadership style that is only focusing upon the here and now functioning and wherein supervisors ignore the strength and capacities of their senior staff members. These reactions might, for example, consist of a decrease in motivation and

engagement, a decrease in efforts from the employee's side to actively engage in their future employability enhancement, and increased immobility which is translated in "getting stuck" in their current organization wherein no further opportunities for growth and development are perceived, to mention but a few.

Enhancing workers' competences throughout their life span and adjusting their workplaces and tasks will offer these workers significant future career potential within the labor market. HRM policies should be rooted into a so-called "conservation" model, wherein employees, regardless of their age, are seen as long-lasting valuable organizational assets, instead of the long-adhered "depreciation" model. As older employees are not less motivated to acquire new knowledge and skills, compared with their younger colleagues, management, in particular one's immediate supervisor, should focus upon facilitating employability and career success across working life. With an age-conscious HRM policy, aging of the working population does not need to pose a threat.

Moreover, individual development plans are needed that are based upon valid and reliable multisource instruments and sufficient guidance and training for the raters, not in the least place aimed at detection rating biases. To our opinion, the employability measurement instrument that has been described earlier has high practical value and might be used for comparing current competences and future career potential of employees working in different organizational units or departments. The latter might produce an improvement in recruitment, staffing, and career mobility practices. Moreover, the instrument enables us to further investigate the relationship between individual, job-related, and organizational career activities, on the one hand, and employability, on the other. This might eventually lead to useful recommendations for enhancing lifelong career success, as age-related changes may be carefully detected as well.

However, in order to really help organizations with suggestions on how to protect workers' employability across the life span, we need a sound conceptualization of the concept of

sustainable careers. “Sustainable careers” is defined as the sequence of an individual’s different career experiences, reflected through a variety of patterns of continuity over time, crossing several social spaces, and characterized by individual agency, herewith providing meaning to the individual (De Vos and Van der Heijden 2015).

Different patterns of *continuity over time* (De Vos and Van der Heijden 2015; Van der Heijden and De Vos 2015) mean that in the sequence of different kinds of career experiences, periods of employment can be interchanged by periods of part-time work, volunteering, unemployment, sabbatical leave, care-giving, and so on. A career is, in essence, dynamic. It is a cycle of events and decisions that determine the work people are doing, the changes they make from one job to another (within or across organizations), or transitions between paid work and other statuses (e.g., nonpaid work, unemployment, temporary leave, and retirement). These events, decisions, and their outcomes (i.e., subjective and objective career success) are intertwined.

Also, the *social context* (De Vos and Van der Heijden 2015; Van der Heijden and De Vos 2015) wherein careers unfold has undergone significant changes. Careers are enacted within and across different types of social contexts (work, home, friends, leisure), and they increasingly take place across several different employers. Continuity here implies that influences of actors and factors in the social space, as well as the choices individuals make regarding (the combination of) the different social spaces they live in, may impact the sustainability of their careers.

By *agency* (De Vos and Van der Heijden 2015; Van der Heijden and De Vos 2015), we mean that how the career develops over time is the result of many choices made by the individual owner of the career, not the mere consequence of external influences and constraints stemming from this social space. Choices are made in line with the individual’s career and private needs and aspirations, yet, obviously, these have to be aligned with organizational (employer) objectives and cannot be separated from the individual’s broader life context in order to balance or compromise between (opposing) the individual’s work, career, and

private interests, on the one hand, and (opposing) the employer’s interests, on the other hand (Van der Heijde and Van der Heijden 2006; Van der Heijden et al. 2009).

Finally, careers entail a continuous need to produce new expertise, while, at the same time, they create new opportunities for development. The qualifications that are required for a job are becoming increasingly complex while, simultaneously, the “half life” of these qualifications is becoming increasingly shorter. Employees who are able to make their careers sustainable and who are able to survive the current needs are the ones with not only the most up-to-date knowledge and skills but also the capability to continuously build up the new expertise requirements while deriving *meaning* (De Vos and Van der Heijden 2015; Van der Heijden and De Vos 2015) from their professional activities.

This line of reasoning on the notion of sustainable careers brings age and employability at the core of careers. As careers have changed, the challenges for realizing sustainability throughout one’s career are particularly prevalent when one considers the demographics, that is, the aging workforce, yet in contradiction, the highly prevalent focus on employability and career success of employees in their early career stages. We need new empirical models and HRM policies and practices to safeguard employability throughout the life span, thereby considering that careers have a longer life span than what is often assumed in organizational career management approaches and individual career choices. In other words, employability is a critical criterion for ensuring that employees remain motivated and able to fulfill work-related roles at all ages.

Longitudinal studies

Definition

SWILSOO is a Swiss longitudinal study with a follow-up of 10 years (nine waves; 1994–2004) of 340 participants and 5 years (five waves; 1999–2004) of 376 respondents, all aged 80–84 years at baseline.

Description of the Study

Procedure and Sample

SWILSOO is a two-cohort longitudinal research study of octogenarians conducted by an interdisciplinary team directed by C. J. Lalive d'Épinay (principal investigator) and Dario Spini (assistant director) (Lalive d'Épinay et al. 2008), at the Center for Interdisciplinary Gerontology, University of Geneva. The research program started in 1992 and ended in 2008; the fieldwork took place from 1994 to 2004. The study was funded by several grants from Divisions I and IV of the Swiss National Science Foundation (No 5004-58534/58536, 1253-8261). A set of new analyses based on data from SWILSOO are currently developed in the framework of the Swiss National Centre of Competence in Research LIVES – Overcoming Vulnerability: Life Course Perspectives (www.lives-nccr.ch).

The first cohort (born in 1910–1914) was drawn from a cross-sectional study on the aging population (65+ years) conducted in 1994 (Lalive d'Épinay et al. 2000) and was followed for 10 years (1994–2004); the second cohort (born in 1915–1919) was followed for 5 years (1999–2004). The periodicity of the interview waves varied from 12 to 18 months, resulting in a total of nine waves for the first cohort and five waves for the second. The main objective of the study is to describe the heterogeneity of the elders' life trajectories and situations at a very advanced age. The first sample consisted of 340 respondents, the second of 377; all of the participants were aged 80–84 years and living at home at baseline. In total, 2890 interviews were completed. The SWILSOO data are archived and available at the Data and Research Information Services: <http://forscenter.ch/en/data-and-research-information-services/>.

The sample of the two cohorts was stratified by region (Canton of Geneva and Canton of Valais) and by gender. The two cantons were chosen to increase the heterogeneity of situations; Geneva is primarily urban, and Valais, located in the Alps, is semirural. The Canton of Geneva forms part of one of the main metropolitan regions in Switzerland; it has a high population density (1590 inhabitants/km² in 1990), a large proportion of foreign residents (notably because of the presence of international organizations), an essentially tertiary economy, and a sizeable public sector. In contrast, the Canton of Valais has a lower population density (84 inhabitants/km² in 1990). Its heritage is one of farming, mountain life, and Catholicism, and it currently has a rapidly expanding tertiary sector, notably in the tourist sector.

A major strength of SWILSOO is the random selection of respondents based on the cantonal register for Geneva and the municipalities' registers in Valais, which enabled the follow-up of a sample that was also heterogeneous in terms of socioeconomic background. Among the cohorts, in Valais, slightly less than half of the men (47%) and three-quarters of the women (77%) completed only compulsory school; in Geneva, these proportions were 21% and 43%, respectively. The elders from Valais were mostly manual workers: farmers, workers, and tradesmen; only 37% were white-collar employees, in comparison with 62% in Geneva.

At the end of the fieldwork in 2004, there were 59 respondents left of the first cohort (which started in 1994) and 173 from the second (which started in 1999). To monitor attrition, the civil registries of both cantons were periodically checked to control deaths, removals, and dropouts among the participants. This process allowed analyses of mortality predictors (Guilley et al. 2005; Spini et al. 2001). Analyses of attrition in terms of different variables (gender, geographical area, social status, income, education, and religion) showed that only the geographical area was significantly related to the risk of dropout; there were twice as many dropouts in Geneva as in Valais. Health did not impact dropouts. This result may be explained by the proxy procedure implemented since the start of SWILSOO, which resulted in

394 interviews (14%) conducted by proxy (mainly spouses, offspring or other family members, and eventually professionals in nursing homes) for 194 respondents who could have been lost otherwise (Lalivé d'Épinay et al. 2008; see also Ghisletta and Spini 2004).

Questionnaire

The questionnaires used in wave 1 were longer than those used in the following waves, notably because they included biographical questions and questions about socioeconomic background. Since the second wave, four forms of standardized questionnaires have been used, depending on the respondent's type of residence (private home vs. institution, mainly nursing homes) and the reporting person (self vs. proxy). The questionnaires used with proxies were shorter and logically did not include self-reported measures.

Trained interviewers administered the questionnaires during face-to-face interviews held in a place chosen by the respondent (in most cases, the respondents' homes). The basic structure of the questionnaire included questions about living circumstances (e.g., nature of domicile: private vs. institution, apartment/house, number of rooms, means of transportation), financial situation (e.g., assets, income, nonmonetary resources, insurance coverage and social benefits), health (e.g., illnesses, physical pain, functional health, sensory capacities, depressive symptoms, illnesses and accidents since the last interview; periods of confinement to bed; falls; hospitalizations; consumption of care; medical checkups; dental care; medication; alcohol and tobacco consumption; physical activities and exercise; functional status of cohabitants), institutional network (e.g., the nature and frequency of care received), family and friendship network (e.g., the family size and composition, proximity of offspring and siblings, existence of a close friend, frequency of exchanges, the nature and frequency of the support provided and received, neighborhood relationships), activities, social and cultural life (e.g., the nature and frequency of activities, media use, participation in associations, religious activity), and psychosocial dimensions (e.g., self-rated health, life satisfaction, social and temporal health

comparisons, beliefs and values, perception of important changes since the last interview, cognitive functioning). In addition to the wave-after-wave interviews using a close-ended questionnaire, 74 in-depth interviews were conducted to collect narratives of the lives of the very old.

Research Highlights

Fragilization and Frailty

The aim of SWILSOO was to describe and compare life trajectories in very old age. The research focused on the trajectories of fragilization and on frailty (Lalivé d'Épinay and Spini 2008; Spini et al. 2007a). Fragilization was defined as a universal process of losses in various functions and systems as a result of senescence, while frailty was defined as a state of vulnerability to various stressors that limits the capacity to recover previous levels of functionality and adaptability after exposure to a stressor.

Three health statuses were also operationalized: (1) ADL-dependent: a person unable to perform at least one of five activities of daily living (washing, dressing/undressing, eating, rising from/going to bed, moving inside home) without assistance; (2) ADL-independent but frail: with frailty defined as suffering from deficiencies in at least two of the following five domains: sensory capacities, mobility, memory, energy, and physical ailments; (3) Robust: no ADL incapacities and deficiency in no more than one of the five domains mentioned above. The results for the dynamics of health states showed that frailty is the health status that affects the majority of very old people (80–94 years old); for most of them, frailty was a long-lasting stage of their last years. The results also showed that progression from frailty to independence may occur (in approximately one case out of five), but is quite short-lived, and that most individuals who became dependent had gone through a period of frailty. Moreover, long-term ADL-dependence is not a normative conclusive stage of long lives. Women and people in lower social categories – notably manual workers – are at a higher risk of ADL dependency; however, it was not the primary health status, even

at the end of the longitudinal follow-up period. Finally, the analysis of health trajectories also showed that continuity in the status of robustness or frailty is the most frequently observed trajectory (Guilley and Lalive d'Épinay 2008, pp. 29–36; Guilley et al. 2008).

Family and Social Relationships

The research mainly focuses on the support elders receive from their networks. However, preserving the ability to give (or to exchange) is a crucial developmental resource across the life course, including old age (Antonucci and Jackson 1990). Studying the evolving structure of services that the elders provide and receive from their family revealed that, not surprisingly, ADL dependency drastically altered the capacity to provide services. At the same time, frail elders continued to provide support to their family members at the same level that robust elders did (with some adaptations in the nature of the services provided). This result highlights the subjective importance in very old age of preserving a positive, exchange-oriented status within the family for as long as possible (Guilley and Lalive d'Épinay 2008, pp. 85–92). The reverse longitudinal association between social relationships and health has also been investigated. The results showed that having at least one surviving sibling and paying regular visits to family members and friends has a positive impact on remaining independent (Guilley and Lalive d'Épinay 2008, pp. 93–102). Finally, the study by Ghisletta, Bickel, and Lövdén (2006) showed that increased media and leisure activity engagement slowed the decline in perceptual speed, but not in verbal fluency or performance, whereas cognitive performance was not associated with changes in activity engagement.

The Interface Between Formal and Informal Support

How does the interface between formal and informal support work and evolve in very old age, a context associated with an increased need for help and a declining number of potential caregivers (because of the decrease in contemporaneous family members and close friends)? Various theoretical models have been devised. Three were tested

in relation to instrumental help. The increase in formal support is associated with: (1a) an increase in or (1b) the stability of informal support (complementarity); (2) a relative decline in informal aid (adjustment of the informal network); and (3) the disappearance of informal help (radical substitution). The analyses were based on the changes reported during the nine waves of interviews with the community dwellers from the first cohort. Complementary support was observed in 72% of the interviews (1a: 47%; 1b: 24%), the adjustment of informal support in 21%, and radical substitution in only 7%. The concern that welfare state support through formal services may crowd out support from relatives and friends in the context of a post-industrialized country such as Switzerland is thus unfounded (Guilley and Lalive d'Épinay 2008, pp. 103–112). The results from SWILSOO are in line with the crowding in process described by Künemund and Rein (1999), that is, the generous welfare systems that provide resources for elderly people increase rather undermine solidarity.

Disruptive Events and Their Impact

From the second wave on, the interviews with the respondents were introduced in the following way: *Since our last meeting* (recording the date, if necessary), *have there been any major changes in your life?* This strategy had the practical goal of establishing the connection between the last and current interviews, but it also had the scientific goal of scrutinizing the individual's awareness of changes in the course of his/her life and the relationship between subjectively perceived changes and the range of objective changes that occurred between successive waves.

At the end of the 5-year follow-up, 80% of the survivors mentioned changes, with a mean of three changes; after 10 years, 88% mentioned changes, with a mean of six changes. The main domains of change were health and family, which accounted for over 80% of the mentions. When another person was involved in the change, he/she was almost always a close relative and, in one out of every two cases, the event was bereavement (Guilley and Lalive d'Épinay 2008, pp. 47–64).

In very old age, bereavement for a beloved one refers mainly to siblings (40%) and close friends (50%). A precondition for measuring the specific impact of a death on the survivor is to ensure that the bereavement is not the product of any other type of change, particularly health problems, that could have occurred during the same time span. Here, three categories of sequences were compared: the bereavement sequences with no mention of any other important changes, the health trouble changes sequences (with no bereavement), and the no-change sequences. Two temporal spans were considered: short term, when the event occurred between two waves of interviews, in which case the impact was measured at the second wave, and middle term, when the impact was measured at the third wave. Comparing the bereavement sequences to the no-change sequences revealed a slight and short-term impact on functional impairments and a very significant and long-lasting increase in depressive symptoms. Depending on the status of the person who died (e.g., a family member or a close friend), the adverse impact of the loss on the psychological health of the bereaved displays a distinctive process. The death of a family member stimulates a tightening of ties within the family that seems to buffer the negative impact on well-being. No such regulation comes into play with the loss of a friend. As a result, the bereaved suffers from a greater increase in depressive symptoms, with also a delayed disruptive effect on his/her sense of closeness (Lalivé d'Épinay et al. 2003; Cavalli et al. 2009).

Community Dweller Elders and Nursing Home Residents

In Switzerland in the year 2000, only 19% of elders aged 80+ were living in a nursing home (22% among women, 12% among men; statistics from the Swiss Federal Statistical Office), as a result of a “remaining at home” social policy. SWILSOO's longitudinal design allows comparisons of the trajectories of the elders who moved into a nursing home with those of the elders who remained in their private home.

The interaction of two sets of factors led individuals to move into a nursing home. On one

hand, accelerated fragilization resulting in severe frailty, often with ADL dependency, was a crucial factor associated with relocation. On the other hand, an increasing feeling of loneliness also favored a move to a nursing home. Such feelings were not necessarily related to social and family isolation but more to the awareness of a rapidly increasing imbalance between the care (medical, instrumental) the elder requires, the growing risks encountered in everyday life at home, and the insufficiency of the care that both informal and formal networks are able to provide.

Comparing the evolution of indicators between the wave before and the one after the move (the time span between the two waves was 12–18 months) into a nursing home shows that this period is very critical in terms of health and well-being and is marked with losses and risks in various domains. After the transition, a stabilization is observed, with a lower risk of accidents than during the last years at home, for example.

Two widespread preconceptions are (1) that nursing home residents have a low level of exchanges (visits, phone calls, etc.) with their family and (2) that living in a nursing home affects morale and well-being. Neither the first nor the second was observed in this study. During the transition and the first period in the nursing home, the residents benefitted from a higher level of interactions with family members than they had at home; after the first year in a residence, there was no significant difference in the level of interaction or in well-being between residents and community dwellers (Cavalli et al. 2007; Cavalli 2012; Lalivé d'Épinay and Cavalli 2013).

The Paradox of Well-Being in Later Life

Older individuals have many strategies for maintaining their well-being at a relatively high level despite objective health losses (Spini et al. 2007b). This phenomenon, usually described as the well-being paradox (Kunzmann et al. 2000), shows that despite an accumulation of losses during older age, individuals maintain a relatively stable and positive level of well-being. This paradox has been observed in numerous studies and is typically considered a robust finding.

Research from Girardin Keciour and Spini (2006) considered the specific health transitions that individuals experience and how these transitions were related to well-being. At the mean level, the paradox of well-being again emerged; while the number of incapacities increased across waves and with advancing age, the level of well-being was relatively stable and did not vary with age or time at the intraindividual level. However, when individual transitions from different states of health (independent, frail, and dependent) were considered, a different result was observed. Those who experienced a trajectory that included independence (stable independence, independence to frailty, or frailty to independence, 54% of trajectories) showed relatively high levels of well-being. Those who were frail at two successive waves (33% of trajectories) showed moderate levels of well-being. Interestingly, those who experienced a period of dependence (stable dependence or frailty to dependence, 13% of trajectories) showed low levels of well-being. Notably, 72% of the observed health trajectories remained in the same state (stable independence, frailty, or dependence) across two waves. Thus, stability and high levels of well-being occur because a majority of aging individuals experience a relatively stable and positive health trajectory, even in old-old age (Guilley and Lalive d'Épinay 2008). Moreover, when health has deteriorated, the levels of well-being are relatively lower. Thus, the paradox of well-being may not be as paradoxical as previously suggested.

elderly participants are discussed as well as future directions for the project.

Introduction

The global centenarian population is rapidly increasing (Richmond 2008), which has raised concerns about the burden this demographic change might have on health-care systems. At the same time, there is growing enthusiasm about the attainability of exceptional old age as well as longer productivity in the workforce and a focus on the role of modifiable, environmental factors in aging. As part of a growing wave of research into the very old, the *Sydney Centenarian Study* (SCS) was launched in 2007 at The University of New South Wales (UNSW), Australia. The SCS was developed to explore the genetic and environmental factors that contribute to successful aging among the very old with a particular focus on brain health. It included both centenarians (i.e., those 100 years of age or more) and “near-centenarians” (i.e., those 95–99 years old), henceforth referred to collectively as “centenarians.”

Sydney Centenarian Study

Definition

This entry discusses the history, protocol, methodology, and initial outcomes of the Sydney Centenarian Study, a longitudinal study of cognitive and physical function of people aged 95 years or more. Difficulties of research involving very

Theoretical Orientations

Successful Aging

Individuals who have survived to extreme ages, particularly those who have not developed dementia and who remain functionally independent, provide an excellent model of successful brain aging. This unique population may potentially yield insights into protective factors for brain health which are applicable for younger individuals.

Differential Aging

The “oldest old” could be expected to exhibit different characteristics to the “younger old.” Further, differences have been demonstrated between male and female centenarians (Hazra et al. 2015)

as well as significant cohort effects (Cho et al. 2012). The SCS allowed for the examination of differences between centenarians and the comparison of centenarians to younger populations.

Cognitive Aging

There is poor understanding about what represents “normal” cognition among the very old. It is known that dementia is not inevitable for centenarians (Perls 2004); however, impairments are common, and assessment is often hindered by sensory impairments and general frailty. Defining a “cognitive phenotype” and developing normative data for this age group will assist future researchers to disentangle pathology from natural aging processes.

Study Objectives

The SCS was launched in 2007 with the following stated aims: (i) to determine the cognitive profile of exceptionally old individuals; (ii) to relate cognition in this age group to brain imaging parameters; (iii) to examine centenarians from neuropsychiatric, medical, nutritional, and lifestyle perspectives; (iv) to determine the incidence of dementia in centenarians; and (v) to examine health-care needs and level of functional autonomy among centenarians.

Study Overview

A cohort of men and women aged 95 years and above were recruited from seven local government areas in the East and Inner West regions of Sydney. Participants underwent an initial cognitive, medical, and psychiatric assessment in their own homes and were invited to undergo an MRI scan and provide a blood sample. They were also asked to provide a detailed medical and nutritional history and an overview of their current and past levels of physical, mental, and social activities. Participants completed a brief follow-up assessment 6 months, 12 months, and 18 months after baseline to assess rates of incident dementia and monitor changes in cognition, physical health, and functional independence.

Recruitment and Study Timeline

The SCS was conceived in 2006 by Professor Perminder Sachdev (neuropsychiatrist). It was initially led by Dr. Charlene Levitan (psychologist) and funded by a research grant from the National Health and Medical Research Council (NHMRC). Recruitment began in 2007, predominantly via a targeted mail out to Sydney residents aged 95 years or above living in the targeted geographical regions. Addresses were obtained from both the Australian Electoral Commission (AEC) and Medicare Australia (all Australian citizens are registered with the AEC and Medicare, and noncitizen permanent residents are registered with the universal Medicare). A second mail out was conducted in 2010. This recruitment method was supplemented by other strategies to make the sample as complete as possible: local media campaigns, approaching directors of aged care facilities, attending community senior citizen groups, advertising through local surgeries, and approaching participants from another longitudinal study, the Sydney Memory and Ageing Study (Sachdev et al. 2010). Between 2007 and 2013, 345 participants completed a baseline assessment (Wave 1). Two hundred and thirty-two participants completed a 6-month follow-up assessment (Wave 2), 174 completed a 12-month follow-up assessment (Wave 3), and 124 of the cohort went on to complete a fourth assessment (Wave 4) 18 months after their baseline assessment. Blood samples were taken from ~70% of the cohort, while 8% underwent an MRI scan. A further 54 individuals aged 95 or more who lived outside the immediate catchment area were recruited to give blood samples. Twenty eight of these additional participants had MRI scans bringing the number of participants with brain scans to 57. A new wave of recruitment is planned for 2016 with the aim of increasing the sample to 600 participants. However, since the second wave of recruitment is 9 years after the first, there may be cohort effects which will be taken into consideration in the analysis. Lifestyle and neuropsychological data for the existing sample is undergoing review and is expected to be released in 2016.

Sample

The SCS sample included 345 individuals (247 females, 98 males) aged between 95 and 106 years with a mean age of 97.4 at baseline. Inclusion of “near-centenarians” (i.e., those aged 95–99) allowed for a much larger sample to be developed; at baseline, 88% of the sample was near-centenarians, while 12% were aged 100 years or more. Approximately one quarter (27%) of the sample was from a non-English-speaking background. Half of the sample was recruited via the targeted mail out, with other strategies contributing the remaining 50% (Sachdev et al. 2013). Participants were not screened for cognitive, physical, or sensory impairment; all individuals who met the age requirement and agreed to participate were included. When an individual was unable to provide consent, their next of kin were approached. Each participant was asked to give details of a family member or friend to act as their “Informant,” i.e., someone with whom they had regular contact and could answer questions about their cognitive and physical function.

Assessment Protocol

Baseline assessment comprised three separate home visits, typically spaced 1–2 weeks apart (Sachdev et al. 2013). The initial visit captured demographics, medical history, family medical history, current medications, fall history, subjective cognitive complaints, a brief cognitive screen – the Addenbrooke Cognitive Examination Revised (ACE-R), which includes the Mini-Mental State Examination (Mathuranath et al. 2000) – and a dietary questionnaire. A brief medical exam was also conducted which included height and weight measurements, blood pressure, lateral stability, visual acuity, grip strength, and lung function. The second visit comprised a comprehensive neuropsychological battery including tests of memory, processing speed, visuospatial functioning, language, executive function, and premorbid function. The final visit included measures of autobiographical memory, mood and

anxiety, satisfaction with life, social integration, and physical and mental activity. Diet, physical activity, and mental activity questionnaires captured both current lifestyle as well as lifestyle behaviors at various stages in their lives (e.g., between the ages of 40 and 50).

Biannual follow-up assessments (6, 12, 18 months) were brief and confined to one session. They included the same cognitive screen (ACE-R), interval medical history, interval fall history, and an abbreviated medical exam. Questionnaires about diet, social activity, physical activity, and mental activity were repeated across all four assessments.

Informants were approached at each wave to gather information about participants. They were asked to confirm the participants’ demographic details and medical history, as well as complete questionnaires about functional impairment, cognitive decline, and level of independence.

Diagnosing Dementia in Centenarians

The prevalence of dementia increases exponentially with age, with the oldest old population at the highest risk of developing dementia. The approaches for diagnosing dementia in centenarians vary widely as do the subsequent prevalence estimates (Gondo and Poon 2008). The challenges for diagnosing dementia in centenarians have been described elsewhere (Slavin et al. 2013) and include a lack of normative data, sensory and physical impairments affecting cognitive performance, as well as contentious definitions of “normal” in this population. This makes it difficult to define notions of “impairment” and “pathological decline” within this age group.

The essential elements of a dementia diagnosis (or major neurocognitive disorder), according to the DSM-5, include a decline from previous levels of cognitive performance to a level at which functional independence is compromised (American Psychiatric Association 2013). In the SCS, a diagnosis of dementia was given to those with both impaired cognition and function. Impaired cognition was defined as having a score less than or equal to 23 on the Mini-Mental State Examination

(MMSE). Impaired function was defined as having a score of greater than or equal to 3 on the Bayer Activities of Daily Living Scale (Hindmarch et al. 1998) that was adjusted so as to represent problems judged by informants as being due to cognitive rather than physical causes (Anderson et al. 2007). Cases in which there was concern about performance, discrepancy in results, or limited information were presented to a consensus panel for assessment. This panel consisted of a neuropsychiatrist, a psychogeriatrician, a neuropsychologist, and other research staff. An additional subgroup of participants was brought to the consensus panel to ensure the reliability of this approach.

At baseline, 120 (35%) participants were classified as having dementia, 208 (60%) were considered to not have dementia, and in 17 cases, there was not enough information to make a diagnosis.

Neuroimaging in the Sydney Centenarian Study

Neuroimaging studies involving exceptionally long-lived individuals are scarce but important for understanding the neuroanatomical basis of successful brain aging. Past studies of normal aging in “young” elderly have revealed that brain aging is heterogeneous and follows a “frontotemporal” pattern, i.e., brain loss with aging is greatest in the frontal and medial temporal lobes (Fjell et al. 2014). It is not known if this pattern of brain loss remains consistent as individuals approach 100 years of age.

A cross-sectional, non-demented cohort was drawn from the SCS and the Sydney Memory and Ageing Study (MAS) (Sachdev et al. 2010), and the profiles on structural magnetic resonance imaging (MRI) of the oldest old were compared with the younger old, by repeated measure analysis of covariance (ANCOVA) (Yang et al. 2016). The greatest loss of brain volume at advanced age was found in the medial temporal lobe (including the hippocampus) and parietal and occipital cortices, indicating that the “temporo-posterior” regions of the brain are particularly

vulnerable in exceptional longevity, even in those who aged successfully. This topographic distribution is distinct from the “frontotemporal” pattern in the younger elderly or the “temporoparietal” pattern typical of Alzheimer’s disease (Fjell et al. 2014).

White matter hyperintensities (WMHs), considered as surrogates of small vessel disease of the brain, were found in almost all of the SCS participants. Relationship of age with WMHs was examined using the general linear model and was found to be stronger at older age, suggesting that the accumulation of WMHs accelerates with advancing age. Despite the high prevalence and the extensive accumulation of the WMHs, their pathogenesis, progression, and impact on cognitive and motor function in exceptional longevity remains poorly understood. The clinical implications, including issues of prevention and treatment, warrant further investigations.

MRI Markers of Dementia

Examining the markers of pathological brain aging in the oldest old was another important aspect of neuroimaging in the SCS. Neuropathology is common in non-demented individuals at advanced age, and the conventional neuropathological markers are found to be weaker predictors of dementia in the oldest old than in the young (Savva et al. 2009). Data from SCS provided a unique opportunity to examine the association between structural MRI and clinical dementia. A wide range of MRI markers of neurodegeneration and vascular pathology were examined in the oldest old using logistic regression, with dementia being the outcome variable. Similar to neuropathology studies, our data showed that the association between MRI markers and clinical expression of dementia is not as well demonstrable in the oldest old as in younger old, in particular for vascular lesions. This suggests that while very old individuals do demonstrate considerable brain pathology, its presence is consistent with normal cognitive functioning. Factors underlying the brain reserve in this population need to be better understood to inform strategies for dementia prevention.

Blood Collection and Biochemistry

Peripheral blood samples were collected for biochemical analysis and DNA extraction for genetic analyses. Routine blood analyses performed include assessment of levels of lipids (total cholesterol, HDL- and LDL-cholesterol, and triglycerides), sodium, potassium, chloride, bicarbonate, homocysteine, urea, creatinine, estimated glomerular filtration rate, urate, glucose, C-reactive protein (CRP), and a full blood count. Blood samples (EDTA plasma, serum, buffy coat) have also been stored at -80°C for future work. For a small subset, a blood sample in a PAXgene tube (PreAnalytiX GmbH, Switzerland) was also collected for RNA extraction.

A particular group of plasma proteins, the family of apolipoproteins, play a crucial role in lipid metabolism and are implicated in age-related cognitive decline, Alzheimer's disease and longevity (Song et al. 2012; Yu and Tan 2012; Shadyab and LaCroix 2015; Atzmon et al. 2006). Hence, it was of interest to determine levels of these plasma proteins in the very old to establish any potential links of these proteins to physical and cognitive health in this age group. Levels of seven apolipoproteins (A-I, A-II, B, C-III, E, H, and J) were measured in a subset of EDTA plasma samples ($N = 147$) using a multiplex immunoassay (WideScreen™ Human CVD Panel 1; Novagen, EMD Chemicals Inc, WI). The data indicated that plasma apolipoprotein levels, in particular apolipoprotein E, differed in the very old compared to “younger” old age groups (<95 years) and were associated with cognitive performance.

Genetics

Prior studies have demonstrated that longevity is influenced by genetic factors and its influence appears to strengthen at the upper limits of the lifespan (Newman and Murabito 2013; Sebastiani and Perls 2012). Therefore, studying the genetics of exceptional longevity may shed light on the genetic and biological factors that lead to successful aging.

DNA from SCS participants was extracted from donated blood samples using conventional methods by Genetics Repositories Australia. One of the genes most consistently associated with longevity across different studies is the apolipoprotein E (*APOE*) gene (Shadyab and LaCroix 2015), which is also linked to late-onset Alzheimer's disease. Genotyping of the *APOE* $\epsilon 2/3/4$ polymorphism was undertaken using TaqMan assays (Applied Biosystems Inc, Foster City, USA) for the two *APOE* SNPs rs7412 and rs429358. In the SCS subsample with *APOE* genotyping data available ($N = 280$), only 13.5% of participants carry at least one copy of the $\epsilon 4$ allele, which is the major risk factor for late-onset Alzheimer's disease. In addition, genome-wide genotyping has been performed using the Illumina Omni Express array (California, USA) at the University of Queensland Diamantina Institute, Brisbane, Australia. Currently, after quality control procedures, we have genome-wide genotyping data for 256 participants. This data has also been imputed to the 1 K genome panel. For a subsample of participants, genome-wide DNA methylation has been assessed using the Illumina 450 K array (California, USA). In the near future, whole genome sequencing is planned for a subsample of participants aged 100 years and over.

Gene expression changes have been reported across the lifespan; however, few studies have examined the transcriptome comprehensively in long-lived individuals. In the SCS, RNA has been extracted using the Qiagen PAXgene blood miRNA kit (PreAnalytiX GmbH, Switzerland), and the transcriptome has been assessed using RNA sequencing for 24 participants.

Inherent Difficulties of Centenarian Research

Research involving the very elderly poses significant methodological challenges.

Proof of Age

Determining the age of participants in centenarian research is critical. Self-reported date of birth is

not necessarily reliable, especially for participants with cognitive impairment. Birth certificates were sought for each participant, but given that year of birth for the cohort ranged from 1902 to 1918, before many countries maintained accurate records, convergent sources of information were also requested. These included marriage certificates, passports, driver's licenses, military certificates, baptismal certificates, birth certificates of children and siblings (if any), and other corroborating documents.

Establishing a Representative Sample

Recruitment for the SCS was restricted to areas of Sydney proximate to the research center for reasons of convenience, and attempts were made to recruit as comprehensively as possible within this geographical area. Centenarians living independently were contacted by mail, centenarians in aged care were often approached through staff, and media advertising was also employed. Despite these efforts, many centenarians in the area declined to participate or were too impaired to give consent, and their families were unwilling. Those who volunteered to participate and were able and willing to complete all assessment tasks, particularly the comprehensive neuropsychological battery, represent the higher functioning centenarians, representing a healthy volunteer bias. This makes the establishment of normative data difficult.

Assessing Cognition

Assessment of cognition in SCS participants was plagued by a number of difficulties. Sensory impairments were common. Some participants had limited or no vision, and the majority of participants had at least mild hearing difficulties. Test materials were adapted where possible (e.g., using large print, assisting participants to complete self-report questionnaires); however, many participants still had difficulties seeing or hearing the material, and thus valid data could not always be gathered. Interpretation of performance was made more difficult by the lack of normative data as the majority of tests have been developed for a younger demographic.

Managing Fatigue

Fatigue was commonly noted during assessments, even among those who appeared to be higher functioning and in relatively good health. Baseline assessment was split across three home visits so as not to overburden participants, although each session was still at least 1 h in length. Breaking sessions into smaller periods, providing regular breaks, and prioritizing the more crucial elements of the assessment were all important in obtaining maximum valid data.

Reliance on Informants

Given that a large proportion of the SCS sample exhibited cognitive impairment, data collected from informants (family members or close associates) was critical to obtaining an accurate profile of a participant's physical, cognitive, and functional abilities. However, informants were not always willing to answer questions or may have exhibited cognitive difficulties themselves, particularly when the spouse of a participant was the nominated informant. The objectiveness of friends and family members is also variable. For example a family member may be concerned that their relative will be placed in aged care if they are assessed as being impaired and thus overrate their functional capacity. Finding reliable informants who have regular contact with participants and then keeping them engaged throughout the study is a crucial aspect of centenarian research.

Future Directions

The SCS provides an exciting and unique opportunity to explore the oldest old population. As well as providing normative cognitive, functional, psychological, and physiological data for this group, the SCS endeavors to identify risk and protective factors for dementia and successful brain aging. It is hoped that the output of this project will inform models of aging, consequently informing service planning, health burden estimates, and care delivery strategies.

The longitudinal design of the study affords researchers the opportunity to track the emergence and progression of pathology and successful

aging across a number of measures. This enables various relationships to be explored and tested over time and at specific time points. Among other topics, the psychological landscape of centenarians, the inevitability of dementia, and the association between cognitive and physical frailty are of particular interest to the research group.

The inclusion of biomedical data enables the biomarkers of dementia to be examined and collated with clinical diagnostic data, providing greater accuracy while normative data is lacking. Similarly, genetic data have been collected for the majority of participants and are in the process of being analyzed in attempts to assess the genetic contributions to successful aging and dementia in the oldest old. Finally, brain imaging for a subset of participants, combined with the brain donor program, provides information on the gross and microscopic structure of the brain at the extreme end of the lifespan. Continued research will focus on these measures.

The SCS is a member of the International Consortium of Centenarian studies on Dementia (ICC-Dementia <https://cheba.unsw.edu.au/group/icc-dementia>), a collaboration which seeks to harmonize centenarian and near-centenarian studies across diverse ethno-racial and sociocultural groups, to describe the cognitive, functional, and psychological profiles of the oldest old. In addition, it is hoped that the SCS's involvement in this consortium will aid efforts to ascertain the age-standardized prevalence and incidence of dementia, internationally.

Definition

Technology

Technology definitions cluster around the concept of the application of knowledge to solve practical problems, with many definitions including words such as technical knowledge, product, equipment, engineering, applied science, and tools. Here we will restrict consideration of technology to information and communications technology (ICT), technology aimed at facilitating communication of information, usually between distant sources. Typically, ICT devices contain microprocessor chips that support programmable behavior. The archetypal example is a digital computer system linked to a communication network, with that system having surface forms such as desktop, laptop, tablet, and smartphone.

Older Worker

It is always difficult to define or provide an age cutoff for an “older worker” as there is no

consensus about the term. It varies according to occupation and context. For example, a report by the National Research Council focusing on the health and safety of older workers (Wegman and McGee 2004) adopted the age of 45 as the arbitrary cutoff, whereas currently maximum US Social Security benefits begin at age 67 for those born after 1960. Also in the general literature, someone aged 65+ is generally referred to as older. Further, perceptions of aging are changing with the aging of the baby boomers, so the meaning of the term “older worker” is likely to change in the near future. Generally, we feel that although chronological age is important and has meaning with respect to functional abilities, what is most important is the health of the individual, their attitudes and preferences about remaining employed in their older years, and their abilities relative to the demands of the job in question.

The Role of Technology in Older Worker Participation in the Labor Force

How does the widespread diffusion of technology into the workplace impact the older worker’s participation, productivity, and well-being? Sub-questions include whether older workers are more reluctant to engage with technology (see entry on “► [Work Motivation and Aging](#)”), how both self and manager perceptions may affect older worker training opportunities (see entries on

Technology and Older Workers, Fig. 1 US labor force participation rates and projections by age group (Data from Toossi 2013)

“► [Job Attitudes and Age](#),” “► [Age Discrimination](#),” and “► [Recruitment and Selection of Older Workers](#)”), and what role technology plays in older worker productivity, in training older workers (see entry on “► [Training at Work and Aging](#)”), and in older worker withdrawal from the labor force (see entry on “► [Timing of Retirement](#)”). We begin with the latter.

Demographics of Older Workers and Trends for Work and Retirement

As the general population ages, so too does the labor force, depending on participation rates and number of workers in the various age categories. One demographic feature common to many industrialized nations is the presence of the baby boom cohort, the large group of children born in the two decades following the end of the Second World War. That large birth cohort continues to affect long-term projections for labor force participation of older adults, as depicted in Fig. 1.

As shown, younger workers are expected to continue their trend of declining labor force participation rates over time. By contrast, those in age groups of 55+ years are expected to show increasing participation rates over time. That is, over the next decade, a much higher percentage of such older workers can be expected to remain in the

labor force, suggesting that current trends of increasing technology deployment may not be a significant psychological barrier to participation. The median age of the labor force is expected to continue its increase from age 37.1 years in 1992 to 42.6 years in 2022, with workers aged 55+ years representing nearly 26% of the labor force by 2022 (Toossi 2013).

There is a similar trend in other developed nations of increased labor force participation of older workers. Many European countries have recently implemented policies aimed at promoting later retirement by increasing the age of entitlement to full pensions, in part to cope with current and projected growing government expenditures for pensions (OECD 2011) and the need for skilled workers in many occupations.

A second historically recent trend in developed countries is the growing labor force participation rates of women as compared to men (see entry on “► [Women and Retirement](#)”). Prior to late in the twentieth century, and even today in many less-developed nations, women would not typically engage in paid work outside the home, or if they did when young, they usually left the labor force permanently when they had children. Thus, the aging workforce is also going to be an increasingly female one, with US men aged 55 years and older expected to decline slightly in participation rates from 46.8% to 46.2% from 2012 to 2022, but

Technology and Older Workers, Fig. 2 Percent ownership of portable computing devices by age group (65–69 years, 70–74 years, 75–79 years, 80+ years) in the United States in 2013 (Data from Smith 2014)

women expected to show an increase from 35.1% to 37.5% in that same time interval (Toossi 2013). In terms of levels, men aged 55+ are expected to increase from 17.2 million in 2012 to 21.6 million in 2022 compared to same age women increasing from 15.2 million to 20.2 million. Given differences in anthropometric characteristics such as strength and body size for women compared to men, there is much to be done in the area of workplace design to ensure that it safely accommodates both sexes. Finally, given the growth in minority populations in the United States and in the older population, we can expect that the labor force will be more ethnically/culturally diverse.

How best to ensure productivity, safety, and comfort for an aging workforce will be a significant challenge to many nations. Technological innovations are seen as one way to address productivity and safety challenges. For example, technology-based jobs are generally less physically demanding which is beneficial for older workers. Technology and telework applications also allow those with mobility problems to work from home. Assistive technologies may also allow workers who have some type of functional disability to remain productively employed. However, for these promises to be realized, the technology will need to be designed properly to ensure effective use by older workers whose perceptual, cognitive, and psychomotor capabilities are likely to be undergoing

normative age-related decline (Fisk et al. 2009; Salthouse 2010) though they may be advantaged in general knowledge (see entry on “► [Expertise and Ageing](#)”). Furthermore, designing effective training strategies will be crucial to addressing comfort with and adoption of new technology.

General Population Technology Use by Age/Cohort and Implications for Older Workers

Older adult cohorts, aged 65+ years, generally lag younger ones in terms of ITC technology adoption (Charness and Boot 2015). The lag is particularly noticeable for older cohorts aged 75+ years, as seen in Fig. 2.

Although even those 80+ years were likely to own cell phones (61%), very few of those devices were smartphones (5%). In the general US population, cell phone ownership was 91% and smartphone ownership was 55% in 2013. The bring-your-own phone device to work trend is accelerating and smartphones are increasingly likely to be considered necessary items for work settings. Although it is difficult to generalize from the older population’s general technology use, considering that few of them are still working, it seems reasonable to conclude that reluctance to adopt technology might be a barrier to later life

work participation, despite a desire to remain in the work force, perhaps in part-time work, past the normal retirement age.

Theories of Technology Adoption and Use in the Workplace

Several theories and models of technology adoption and use have focused on uncovering and specifying the factors that predict technology use in a variety of contexts, including the workplace. These models can help identify and reduce barriers to technology adoption that might interfere with participation in the workforce later in life, by enumerating the costs and benefits of adoption. Two of the more popular models are the *Technology Acceptance Model* (TAM) (Davis 1989) and, the more complex extension of TAM, the *Unified Theory of Acceptance and Use of Technology* (UTAUT) (Venkatesh et al. 2012). At the core of both models and their variants is the idea that a new piece of technology will be adopted to the extent that a potential user believes it is easy to use (low cost) and useful (high benefit).

Within the TAM model, perceived ease of use and perceived usefulness have a significant impact on decisions regarding technology use in the workplace. A worker who believes a software package will allow him or her to perform their job better is more likely to choose to use it compared to a worker who perceives that the software is difficult to learn and use. Within this model, these factors influence attitudes toward use and use intention, ultimately determining actual use behavior. Updates to TAM (TAM2 and TAM3) highlight important attitudinal and contextual factors that influence perceived ease of use and usefulness. Of particular relevance to predicting acceptance in older workers are the factors of computer anxiety and computer self-efficacy, which tend to be related to age. An older worker with high computer anxiety and low computer self-efficacy will be unlikely to perceive a new piece of technology as easy to use, discouraging acceptance. Empirically, personality characteristics, attitudes, and technology

experience have been found to predict perceived ease of use and usefulness within an older adult sample, suggesting that interventions focused on changing attitudes and increasing technology experience (e.g., training) may increase technology use and acceptance by older adults in the workplace (Mitzner et al. 2014).

Similar to TAM, the *Unified Theory of Acceptance and Use of Technology* (UTAUT) highlights performance expectancy (degree of belief that the technology will improve job performance) and effort expectancy (degree of belief that the technology will be easy or difficult to use) as major factors influencing the intention to use technology. However, actual use is also influenced by the perception of facilitating conditions or the belief that the workplace has systems and procedures in place to support use (e.g., training, technical support). Social influences also play a role in shaping the intention to use technology, with individuals more likely to use technology when they believe other important people (e.g., supervisor) expect them to use technology. Importantly, age (and also gender) is theorized to moderate the relationship between predictor variables and intention to use/actual use, with these factors generally being more important for older workers compared to younger workers. For example, the effect of effort expectancy, social influence, and facilitating conditions tends to be larger for older workers compared to younger workers in their model, and these moderating effects have been confirmed empirically (Venkatesh et al. 2012). UTAUT and the results that support it suggest additional steps that might be taken to ensure that older adults benefit from available workplace technology (e.g., ensuring that older workers feel well supported in their technology use). However, ultimately it is critical that the technology is designed so that it is easy to use and useful to diverse user groups.

Issues in Designing Technology for Older Workers

To ensure meaningful engagement with technology by older adults in the workplace, technology needs

to be designed well, taking into account the needs, abilities, and preferences of older workers. Normative age-related changes in vision (acuity, contrast sensitivity), hearing, attention, memory, fluid ability (reasoning), movement control, and cognition can make using technology, and learning to use technology, more challenging for older workers compared to younger workers (Fisk et al. 2009). For example, cognitive abilities are an important predictor of both technology use and breadth of technology use. When designing technology for older workers, normative age-related perceptual and cognitive declines need to be considered, or else technology that has the potential to improve efficiency and productivity may not be adopted by older workers, or if it is adopted, it may not be used to the fullest extent and have the desired benefit due to usability issues (see entry on “► [Work Design and Aging](#)”).

There are a number of strategies that can be taken to design technology for older workers (Boot et al. 2012). For example, improving the physical stimulus that the worker has to respond to can help offset age-related perceptual declines. A technology display that uses black text on a white background is much more suitable compared to black text on a gray background due to age-related changes in contrast sensitivity. Large or adjustable fonts can also help to compensate for declines in acuity. To decrease cognitive load and reliance on memory, important information should be placed in the task environment and should be easily accessible. Rather than expect an older worker to remember a complex sequence of actions to complete a goal within a piece of software, the software might be designed to automatically highlight the next field to be entered or the next menu item that requires selection. Crystallized knowledge, or knowledge of facts, is often found to be age invariant until old age. This can be taken advantage of by designing technology to be consistent with what an older worker already knows. Consistency across different technologies can also benefit the process of learning a new technology (e.g., always having the same icon in the same location to access the “help” function). Interoperability across systems can also reduce the challenges associated with using technology. Consistency across versions of applications, such as

software updates, is also important. These human factors principles are discussed here in the context of benefiting the older worker, but following these design principles should also make technology easier to use for younger workers as well.

In addition to normative age-related declines in perception, cognition, and motor control, increasing age is also associated with a variety of disease processes that could make technology use in the workplace more challenging. For example, arthritis may make the interaction with small technology and handheld technology a challenge. Cataracts, glaucoma, and macular degeneration can have a much more profound impact on vision compared to typical changes in acuity (Owsley 2011). When designing for older workers, design should anticipate the needs of a broad range of older workers with different abilities to reduce barriers to adoption and to ensure that technology has its intended effect on efficiency and productivity.

Issues in Training Older Workers for Technology Use

Clearly another critical factor with respect to the uptake of workplace technology among older workers is the availability of training and technical support. In today’s work environment with the continual diffusion of new technologies, training and retraining of older workers is critical to organizational effectiveness. The literature on aging and skill acquisition generally indicates (Charness 2009) that older adults are able to learn new skills though it usually takes them longer than younger adults and they typically require more practice and more instructional support. The job training literature that focuses on older workers though somewhat scarce generally supports these findings. The structure of the training program also impacts on training success. It is also important to note that older adults are not technophobic and are interested in learning new technologies.

There are guidelines regarding design of training programs for older adults (Czaja and Sharit 2013). These general guidelines take into account the characteristics of adult learners. However, it is important to note that few interactions between

age and training technique have been found such that a particular technique works better for older as compared to younger workers. There does not seem to be one training technique that is best for older adults as in any training situation it depends on the characteristics of the trainee population (e.g., amount of prior experience, skill level), the task or the skill to be trained, the setting, and the available resources.

In general, the pacing requirements of a training program are critical for older people to accommodate age-related changes in information processing speed; sufficient time must be allowed for older adults to process the training material and to complete any associated practice tasks or evaluation activities. In addition, it is generally advisable for the learner to be actively involved in the learning process and be exposed to and provided with practice on a wide variety of examples. Feedback should be provided in a timely manner so errors do not become engrained and as far as possible linkages between new material and material that is familiar should be made. In addition, instructional support should be readily available, and training support materials should be easily accessible, well designed, and easy to use. Finally, the learning environment should be as distraction free as possible and where possible trainees in a group training situation should have similar skill levels. Of course, training opportunities must be available for older workers. There are some data to suggest that employers invest less in training older workers because of stereotypes that older people can't learn (Pitt-Catsouphes et al. 2007). Similar to findings regarding adoption of new technology, older workers are more likely to participate in training programs if they believe they are capable of learning new skills and they perceive training participation as beneficial.

The emergence of new technologies is not only creating a continual need for worker training and retraining but also influencing how training is being conducted. Technology-mediated training or "e-learning" is rapidly being adopted by many organizations as it provides opportunities for training to occur any time and any place and presents a viable option for distance learning. However, a

potential disadvantage is the lack of face-to-face interactions with an instructor. This emphasis on "e-learning" is coupled with an increased emphasis on workers assuming responsibility for continuous learning. In other words opportunities for formal job training in classrooms with an instructor may become less available, and there will be an increased emphasis on "online learning or training" arrangements. The implications of this for older workers are not yet understood.

Prospects for Prolonging Work Life with Technology

There is considerable pressure to have older workers delay retirement in order to support the social welfare obligations for health care and pensions in most developed countries. Many older adults are also choosing to remain in the workforce longer as they are healthy and have a desire or economic need to remain productive. There are some industries where heavy physical demands and high-risk work environments could make this goal of a prolonged work life an unreasonable one for some older workers (Wegman and McGee 2004). The general economy has diversified in the past century beyond agriculture and manufacturing to sectors involving clerical work, such as office work, that are generally less physically demanding. However, these jobs often incur greater mental demand, particularly for using and learning to use new technology. So, why work at an older age?

Surveys have indicated a positive association between age and job satisfaction (Glenn et al. 1977). Those who remain in the labor force at older than normal retirement ages seem to do so in part because they "really enjoy going to work" with affirmation for that item rising from 88% at age 55–59 to over 95% for those age 65+ (National Institute on Aging 2007); other factors for remaining in the labor force are opportunities for financial gain and for socializing benefits. Also, some forms of work may be protective for maintaining cognition. Complex work is associated with beneficial effects for older worker

cognition (Schooler et al. 1999), so continued participation in technologically advanced work environments may provide benefits for both the financial and cognitive health of an aging workforce. Further, technology use can potentially compensate for normative age-related changes in functional capacity and provide direct support for impairments that occur more frequently as people age thereby accommodating older workers with disabilities. Further, to the extent that older, experienced workers in aggregate receive appropriately designed technology products and training for their use, they are likely to be productive contributors (Allen 2001). Generally, meta-analyses have shown that age and productivity show little relationship at the level of the individual (Ng and Feldman 2008).

Greater longevity in the workplace past age 55 is linked to higher education levels, higher wages, working in smaller firms, working in industries that do not have high physical demands (not working in manufacturing and construction), and having younger coworkers (Juhn and McCue 2012). Well-implemented technology addressing ergonomic concerns can help reduce physical demands (lifting devices), but a concern is that some technology products may increase mental demands particularly for inexperienced users, leading to slower adoption, as seen in population-level age lags in technology adoption particularly at older ages (Smith 2014). Aside from lack of relevance (34% of reasons), usability concerns (32% of reasons) were cited by non-Internet users in the United States (15% of the population) for not adopting the Internet, including the attitude “too old to learn” (Zickuhr 2013). Addressing usability barriers for technology adoption, including attitudinal, social/institutional, and physical ones, will be central to encouraging and enabling older workers to prolong labor force participation. In addition, training support must be available and designed to accommodate older adults. If technology is designed properly and accompanied by appropriate training, it can improve the health, safety, productivity, and longevity of an aging workforce.

Telemental Health

Zvi D. Gellis

School of Social Policy and Practice, Center for Mental Health and Aging, University of Pennsylvania, Philadelphia, PA, USA

Synonyms

Gerontechnology; Telecare; Telehealth; Telemedicine

Definition

In gerontechnology, the term *telemental health* is considered a subcategory of commonly

interchangeable terms such as *telecare*, *telehealth*, or *telemedicine*. These terms are three examples of information and communication technology for health and mental health service delivery. The field is reemerging in health care with a wide array of telehealth terms; thus, there is a lack of consensus in terminology.

Telehealth and Older Adults

The global population is aging rapidly. In the U.S. A., over 20% of adults will be 65 years or older by 2030 with the greatest expansion in the “oldest old” (85 years+) age-group. These demographic trends will have significant impacts on an aging population in terms of health and mental health care. The use of telehealth technology services designed to meet the physical and mental health needs of older people at home has attracted increased attention. Telehealth can monitor the patient remotely to detect changes in health status thus enabling service providers to intervene “just in time” to improve quality of care. It provides instant health/mental health status feedback to patients offering them the opportunity to develop self-management or remedial behaviors and can increase knowledge about diseases and medication.

The significant rise in older adults will result in a substantial increase in chronic medical conditions (congestive heart failure, chronic obstructive pulmonary disease, hypertension, diabetes) and prevalent mental health comorbidities such as depression. Untreated depression increases the risk of further disability, limits mobility, increases suicidality, and deters recovery. Cognitive impairment can also increase the risk of depression.

Due to financial constraints, health care industry will likely shift health policy priorities from acute to management strategies that may include preservation of independence, health and mental health symptom control, and improved quality of life. Psychological interventions and symptom monitoring will become a key focus of treatment plans for many older adults suffering from health and mental health problems. Currently, numerous technological solutions are being developed or

implemented to meet these physical and mental health needs. Delivering telemental health services to at-risk older adults may provide a cost-effective method to assess and monitor symptoms, improve communication with treatment providers, and offer evidence-based mental health treatments in order to reduce unnecessary hospital readmissions.

Telehealth and telemental health have been around for over five decades but have reemerged as a viable health service due to communication technology advances. *Telehealth* is a broad term described by the Health Resources and Services Administration as the use of electronic information and telecommunication technologies to support long-distance clinical care, patient and professional health-related education, public health, and health administration (Health Services Resources Administration: Telehealth. U.S. Department of Health and Human Services 2013). The American Telemedicine Association describes *telemedicine* as the use of medical information exchanged from one site to another via electronic communications to improve a patient's clinical health status (American Telemedicine Association: What is telemedicine? 2013), limiting its core function to providing medical services, that is, use of electronic communication and information technologies to provide or support primary care, medical specialties, intensive care services, emergency departments, and medical education programs. Telehealth is beneficial for older adults who cannot access specialists in their community, who prefer to receive care at home, are from differing ethnic, cultural, and linguistic backgrounds, and are institutionalized.

Telemental Health

Telemental health is a subset of telehealth using communication technology to provide behavioral health services from a distance (Myers and Turvey 2013). Telemental health services have frequently used the modality of real-time videoconferencing since it is most similar to traditional face-to-face mental health practice. Telemental health also uses other technology modalities such as mobile

technologies (e.g., mHealth), online therapy, and electronic communication and health information technology (e.g., eHealth). Telemental health can overcome distances and alleviate imminent gaps in the availability and accessibility of mental health services. Telemental health has the potential to support health care systems serving older patients with chronic diseases and co-occurring mental health disorders. Telemental health requires only audio or visual modalities. It provides greater accessibility to mental health services to isolated older adults, those receiving home health services, and rural and remote communities that frequently have few services or specialty care. Telemental health services may be cost effective due to reduced need for professionals to travel to these areas. With improved communication technologies such as telephone, Internet, tablet, smartphone, and videoconferencing, the practitioner can use nontraditional methods for mental health assessment and treatment. Currently, Internet Protocol network technology with reliable security and service quality may offer further cost reductions in service delivery. Telemental health services can be delivered in two ways. Synchronous mode encompasses live real-time interactive two-way communication. Asynchronous mode is the transmission of health information that is not in real time (e.g., email, psychological reports) to review at a later time.

The American Telemedicine Association has developed practice guidelines for video-based online mental health services (Turvey et al. 2013). It includes clinical, technological, and administrative considerations of professional and patient identity verification, patient appropriateness for telemental health, informed consent, physical environment, communication and collaboration with the patient's treatment team, emergency mental health management, and medical, referral, and cultural competency.

Telemental Health Practice Settings

Telemental health services are offered to older adults in various settings: community-based home health care, primary care, long-term care,

Veterans Health Administration, and rural or remote communities. Much of what is known in the community-based telehealth field is based on descriptive data with few definitive trials demonstrating effectiveness for telemental health interventions. In the United States, the National Association of Homecare and Hospice estimates that 21% of Medicare-certified home health agencies offer telehealth services for homebound older patients diagnosed with cardiovascular disease, pulmonary disease, hypertension, and diabetes with the mission to independently “age in place” and reduce health costs (National Association of Homecare and Hospice 2010). Preliminary evidence has been reported for patients with various medical conditions. Integrated telehealth and telemental health services targeting chronic disease (heart failure, pulmonary disease) and comorbid depression have been demonstrated to be feasible, acceptable, and effective for geriatric homebound medically ill patients (Gellis et al. 2014; Sheeran et al. 2011). Web-based telemental health has been shown to improve depression and psychosocial well-being of older diabetes patients. Telephone-delivered depression interventions show promise in improving depression symptoms and quality of life in older prostate cancer survivors, in older Latinos with heart failure, and in primary care patients. Telephone-based interactive voice recording home monitoring has been successfully used to include regular depression screening in a heart failure program (Turvey et al. 2007). However, in a large British trial study, home-based telehealth provided through primary care and hospital clinics was not found effective in improving quality of life, depression, or anxiety in older adults with heart failure, diabetes, or pulmonary disease (Cartwright et al. 2013). A variety of telehealth technology strategies are used for chronic disease management protocols, symptom monitoring, guideline-based assessments, and evidence-based interventions for depression care. Frequently, they include telephone, computer videoconferencing, and Internet-based applications with wireless capability.

In long-term care settings, models of telepsychogeriatric care have taken the form of telemental health consultation services via

videoconferencing for affective disorders, cognitive impairment, and dementia. Telemental health clinical components include diagnostic assessments, dementia screening and psychiatric consultations, depression screening, psychoeducation, and family support. Culturally appropriate telemental health services have also been reported with encouraging outcomes (Poon et al. 2005; Yeung et al. 2011). Preliminary reports of these services suggest that they are acceptable to staff and nursing home patients and are potentially time and cost efficient. Some of the challenges for telemental health in the long-term care setting include patient visual or hearing impairment, somatic complaints, instability of consciousness, and medication side effects. Overall, telepsychogeriatric care is an emerging field, though with mixed results and unknown effectiveness.

In the United States, the Veterans Health Administration provides free health and mental health services to all individuals who have served in the military. The Veterans Health Administration has a large and robust telebehavioral health rural service program using computerized videoconferencing technology and continues to develop new hybrid models of telemental health services. Mental health care for older veterans has received attention due to high prevalence rates for depression, suicidality, anxiety, and PTSD disorders. Older veterans make up nearly 45% of those enrolled in the Veterans Health Administration. It is the largest telehealth provider in the U.S.A. and has offered telemental health services over the past decade to aging veterans with multiple chronic and mental health conditions who are living in rural areas where transportation and services are scarce.

In the Veterans Health Administration, telehealth was found to be an efficient strategy for delivering health and mental health services and enhanced collaborative care within an integrated service delivery system. Telemental health provides preliminary support in the use of computerized videoconferencing for individual and group therapy with high levels of patient and clinician satisfaction (Morland and Kloezeman 2013). Evidence on psychological outcomes is moderately strong for Internet and telephone

applications in the Veterans Health Administration health system. Telemental health has been found to be generally as effective as face-to-face care for treatment-seeking veterans (Ruskin et al. 2004). In addition, the Veterans Health Administration has found significant reductions in hospital admissions (Jia et al. 2009), urgent-care or emergency room visits (Chumbler et al. 2005), and primary care visits while using telehealth services (Barnett et al. 2006).

Tablet and Mobile Phone Technology

Tablet computer and mobile smartphone technologies are well positioned for health and mental health information dissemination and psychotherapy and are now being used in health service delivery. Users of tablet devices and smartphones are prevalent, and these devices are comprised of Android or iOS platforms. Tablets and smartphones can also be used to extend the reach of mental health practice from the office to home. These devices offer numerous applications including direct patient services via audio or video applications, health information, self-monitoring activities of mood and symptoms, relapse prevention notes, patient journaling, behavioral activation record keeping, homework completion reminders, adherence to medication and treatment regimens, appointment reminders, and psychoeducation. Mobile phone, tablet devices, and software applications are ubiquitous in monitoring mental health care. These devices have many advantages including accessibility, low cost, portability, low power requirements, immediate and important “push” notifications, and search capability. They can offer access to low-income populations, individuals with mental health diagnoses, ethnic minorities, developmentally challenged, and older adults. These devices can build skills in improving mental health to foster self-determination and healthy independence. Barriers to using these devices in mental health care are similar to telemental health videoconferencing and include issues of security, privacy, service availability, reliability, adherence, and efficacy of assessment and interventions.

The Veterans Health Administration is a leader in the mobile technology field and is currently using videoconferencing smartphones to provide psychotherapy in live video sessions with veterans diagnosed with depression, anxiety, and post-traumatic stress disorders. The advantages of these devices include bringing mental health care to the veteran, reduction in stigma, reductions in delays in care, and increased continuity in care. Currently, little is known about how these devices are used with older adults. Further, there is a paucity of scientific evidence on the efficacy of mobile and tablet devices for mental health applications.

Future

Telemental health services for older adults are diverse ranging from home health care to chronic disease management, psychogeriatric consultation, dementia diagnostic assessment, remote primary and specialty care, and psychotherapy. Telehealth technology has revolutionized the mental health sector in an attempt to improve or maintain the quality of care while curtailing costs. The use of telehealth and telemental health technology, such as two-way audio-video biometric monitoring, interactive televideoconference counseling, electronic disease management devices, email and text, smartphone, tablet, and the Internet, has been instrumental in conducting patient assessment, depression interventions, psychoeducation, psychotherapy, and providing remote patient monitoring on a real-time basis.

The advantages of telehealth and telemental health technology may include reductions in barriers to services access, an increase in efficiency for providers, reductions in overall health care costs, reductions in delays in care, preservation of resources locally, reductions in mental health symptoms, and increase in patient satisfaction in health care delivery. With a telemental health approach, there are service implementation barriers including patient adherence to the technology and training of professionals in the use the devices for integrated chronic care and mental health management. Training of patients in the

use of telemental health applications and telehealth remote monitoring devices is of importance in assuring robust data, increasing self-efficacy, and treatment adherence. Further, there is always a need to maintain ongoing resources and personnel who possess the skills to provide care while managing electronic medical records, providing technology support to the patient, and transmitting data to other health and mental health team members to facilitate just-in-time communication.

Overall, empirical evidence to support telehealth and telemental health interventions for cardiac disease, COPD, diabetes, and mental health conditions is increasing. These interventions have become accepted forms of health services. However, there is only preliminary scientific evidence for its effectiveness and cost. (Chaudry et al. 2010) However, the few telehealth controlled trial studies generally demonstrate primarily positive outcomes independent of diagnostic category. Studies predominantly use personal contact (either by telephone or videoconferencing) as a main component of telehealth intervention. Personal interactive contact between service provider and patient offer better outcomes compared to studies without personal contact. Nurses generally play a key role in telehealth patient monitoring, though social workers, psychologists, mental health therapists, and physicians are also telemental health providers. These professionals provide some combination of psychoeducation, psychotherapy, chronic illness care, depression care, and/or medication support. With regard to behavioral outcomes, telehealth studies provide moderate evidence toward positive outcomes of medication or diet adherence, depression improvement, physical activity, quality of life, and disease self-management (Kang-Yi and Gellis 2012). The future will witness further mobile and tablet applications for psychotherapy with broad acceptance of these modalities.

Time Perception and Aging

Patrizia S. Bisiacchi¹ and Giorgia Cona²

¹Department of General Psychology, University of Padova, Padova, Italy

²Department of Neuroscience, University of Padova, Padova, Italy

Time perception, or more extensively time processing (i.e., time perception, estimation, reproduction and monitoring), refers to the ‘subjective’ experience of time.

Time processing is one of the most pervasive and essential aspects of our mental functioning since it is involved in all motor, perceptual, and cognitive activities. Timing of intervals ranging from seconds to minutes is crucial for representing the external environment (Buhusi and Meck, 2005, Grondin, 2010). Many everyday circumstances indeed involve short duration estimation. For example, while driving a car or crossing a street, time and speed estimates provide vital information.

It is worthwhile to notice that, despite there are no dedicated sensory receptors for perceiving time and although there is often no awareness of it, this ability is extremely precise. It is recruited in a widespread number of activities, for example,

synchronizing movements, predicting and anticipating events (or estimating durations).

In fact, it has been stated that the ability to monitor time and to be prepared for future events are part of the peculiarities of human beings. Nevertheless, there are persons, in particular aged persons, who show systematic biases in time perceptions that may put them at risk for independent daily living.

It is well known indeed that older individuals show changes in a multitude of cognitive and sensory domains and particularly in functions that rely upon those neural structures which show a decline with age, namely, prefrontal systems and hippocampus.

Recently, there has been growing interest in understanding cognitive mechanisms and neural bases of our sense of time (Gibbon et al. 1984), and this may shed some light on time perception in the life span.

In order to understand age changes in time processing in the present paper, it will be described the most influential model of time processing and the evidence on the neural basis of this human ability.

Mechanisms of Time Processing

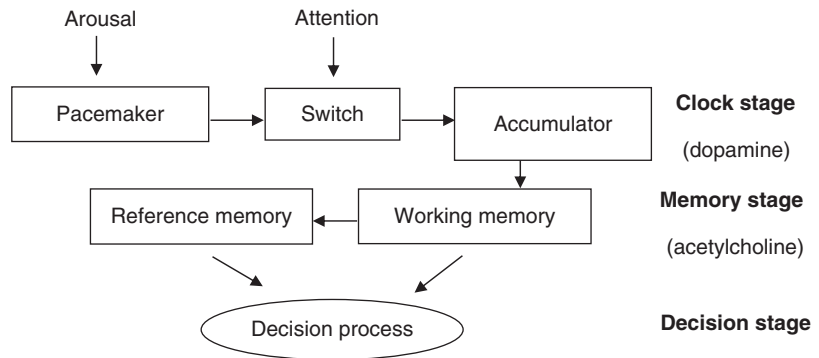

From a cognitive point of view, one of the most influential models of time processing, the scalar expectancy theory (SET), assumes that individuals encode durations by means of a specialized mechanism, the so-called internal clock, which is involved in all timing operations and for various timescales (Rubia and Smith 2004). Such mechanism is multicomponential and acts by means of a three-stage process: a clock stage, a memory stage, and a decision stage (Fig. 1).

According to the SET, durations are judged by a modular information processing system composed of clock, memory, and decision processes. The clock consists of one pacemaker, a switch, and an accumulator.

The pacemaker emits pulses that pass through an attention-controlled switch into an accumulator, which counts the pulses (clock stage) and stores the result in a “current time” working

Time Perception and Aging,

Fig. 1 Schematic representation of the scalar expectation theory model for time processing (Adapted from Gibbon et al. (1984))

memory (WM) (memory stage). The current stored pulses are then compared with those in the reference memory system, which contains a long-term memory representation of pulses accumulated on past trials (decision stage). The rate of the pacemaker is influenced by arousal level, as increasing arousal led to a faster internal tempo and to longer duration judgments.

The most recent theories proposed that attention processes affect the latency and the “wideness” of the switch mechanism. Attentional factors may influence these features and thus the number of pulses entering into the accumulator. When attention is directed away from time, the switch remains less open and some pulses are lost, leading to an underestimation.

Although the internal clock model can explain most of the behavioral data, it is still difficult to exactly define the function of each stage as well as to identify the relative neural correlates. Moreover, each stage of time processing requires the intervention of specific cognitive functions. Encoding an interval, attending to time, keeping the representation of a duration in working memory, and deciding differentially involve subcortical and cortical areas (Coull et al. 2004). Therefore, the range of intervals’ length or/and the nature of the timing task are critical to any statements about which brain areas are recruited.

One way to bypass such a limitation is to study the neural basis of such model by neuroimaging techniques, neurological patients, and healthy aged persons.

Neural Basis of Time Processing

Some of the first clearest evidence of a specialized brain network for interval timing comes from a functional magnetic resonance imaging (fMRI) study (Stevens et al. 2007). In this study, authors obtained the selective activation of brain areas by varying the attention toward temporal and nontemporal features of visual stimuli. Namely, participants were asked to direct their attention to the duration or to the color of the circle presented in a screen, which was parametrically modulated. Areas in the visual cortex (V4) showed a linear increase in activation when participants paid more attention to the color of the stimuli. In turn, the pre-supplementary motor area (pre-SMA) showed a linear activation when participants paid more attention to time, thereby identifying this area as part of the timing circuit.

Recently, Coull and Nobre (1998), using an independent component analysis (ICA) approach on fMRI data, identified four main brain circuits that are active during the performance of timing tasks – the frontoparietal, the frontostriatal, the cerebellum, and the motor one – that are highly probable to be implicated in different aspects of temporal information processing. Within these, the frontoparietal network has been consistently found to be involved in the discrimination of temporal durations.

Neuroimaging studies have found multiple brain structures to be involved in time processing, including the cerebellum, the basal ganglia, the insula, the dorsolateral prefrontal cortex

(DLPFC), the supplementary motor area (SMA), the inferior parietal cortices (IPC), and the ventral premotor cortex. Specifically, a frontoparietal cortical network has been consistently reported to intervene in a large number of tasks, including the right DLPFC, the SMA, the IPC, and the premotor cortices. Importantly, a distinction has been made between neural circuits dedicated to the processing of sub-second durations and circuits dedicated to the processing of supra-second durations and between explicit and implicit timing (Macar and Vidal 2004). Explicit timing is engaged whenever subjects make a deliberate estimate of discrete duration in order to compare it with a previously memorized standard. Conversely, implicit timing is engaged, even without a specific instruction to time, whenever sensorimotor information is temporally structured and can be used to predict the duration of future events.

Besides the neuroanatomical bases of interval timing, event-related potential (ERP) studies have tried to shed light on the functional correlates of time processing.

Given their resolution in the milliseconds range, electrophysiological methods represent the elective method in studying how brain processes time. Specific ERP components were shown to index processing of short interval durations. There is increasing evidence that a negative slow wave, the contingent negative variation (CNV), observed in frontal regions, is significantly modulated by interval length (Tarantino et al. 2010). More specifically, this wave, classically considered an expectancy wave, marks time on the basis of previous memorized durations. More recently, indeed, CNV morphological features, including peak and slope inversion latency, have been shown to mirror the duration of a previously encoded target interval when it has to be reproduced or discriminated (Mento et al. 2015; Battelli et al. 2007). Remarkably, the neural generators of the temporal CNV have been located in the SMA, confirming the crucial role of this area for timing. Researchers suggest that the CNV may be considered an index of the clock as well as of memory and decision.

Several fMRI, ERP, and neuropsychological studies emphasize the involvement of the right inferior parietal cortex (IPC) in the perception of current time durations that last from milliseconds to seconds. This associative area, by means of its integrative properties, subserves the timing of events in both visual and auditory modality. Patients with neglect tested on tasks requiring the estimation of short durations have shown to consistently overestimate stimuli presented in the neglected space and underestimate stimuli presented in the good field. Patients with lesions in the right IPC have shown deficits in perceptual abilities that require the analysis of time. The contribution of the inferior parietal cortex is very interesting when considered in the light of recent theories which postulate time perception to be strongly linked to the perception of space. Some authors (Belin et al. 2002) have recently proposed that the right parietal lobe, other than subserving spatial functions, has a dominant role in controlling attention over temporal information of events. This area has been considered as the key structure of a “when pathway.” Differently from the contralateral control on spatial information, the parietal control over temporal information is bilateral.

An earlier PET study (Malapani et al. 1998) has highlighted the contribution of a common neural network, including the right frontoparietal/left cerebellum areas, in tasks requiring the discrimination of duration and intensity of sounds. In this work, the authors have suggested that duration discrimination tasks are performed in the human brain by the combination of two cortical networks or groups of areas working in concert: (i) a “sensory attentional network,” which is active in discriminating quantity, such as duration and intensity, probably highly specific and supramodal since its activation is often reported irrespective of the sensory modality and sensory feature being attended to, with components in the right frontal and parietal lobes and (ii) a “temporal processing network,” more specifically involved in the temporal aspects of the discrimination task, involving the activation to varying degrees of the basal ganglia, cerebellar hemispheres, and right lateral prefrontal cortex.

Time Perception and Aging,

Fig. 2 Frontoparietal (*red*) and frontostriatal (*blue*) brain areas functionally connected during the performance of timing tasks. *PFC* prefrontal cortex, *SMA* supplementary motor area, *PPC* parietal posterior cortex, *NB* basal nuclei

Data also support the role of frontostriatal circuits in interval timing. Patients with Parkinson's disease who suffer from a degeneration of nigrostriatal dopaminergic projections have been found to be impaired in perception and production of time intervals. Off-therapy patients tend to overestimate the shorter intervals and to underestimate the longer ones. This "migration effect" has been interpreted as a dysfunctional representation of memory for time, which intervenes in comparing the current elapsing time with an earlier learned interval, and could be eliminated by administering L-DOPA (Salthouse 1996).

Figure 2 illustrates the main circuits involved in time processing in order to summarize the principle findings on neural basis of time processing

Aging and Time Processing

As described previously, time processing involves multiple different cognitive functions and, particularly, attention and working memory (WM). Since both attention and WM abilities are known to decrease with increasing age, it might be hypothesized that time processing may also decrease with increasing age. Moreover, time processing, attention, and WM share the same brain structures and neurotransmitter systems, which are the most sensitive to aging. Hence the

study of time processing may provide very sensitive measurements of age-related differences in cognitive functioning.

According to SET, an internal pacemaker generates pulses at a regular rate, which are then recorded by an accumulator. To estimate time, information from the accumulator is processed by the working memory and compared to reference values stored in long-term memory.

Several researches suggested that the setting of people's internal clocks is affected by age. This might be explained by the speed of processing hypothesis (Baudouin et al. 2006). According to this explanation, aged individuals have a general slowdown in information processing; thus they would have a slowdown at the clock stage. Some studies tried to estimate the speed of the internal pacemaker as a function of age. Participants were asked to produce regular finger tapings at the fastest possible rate or at a paced rate. It was found that increasing age was associated with slower tapping for both fastest and spontaneous rates.

Based on these results, it might be concluded that people's internal clocks run more slowly with advancing age and become less accurate.

Other studies reported differences in time estimation and in time reproduction. It was found that older adults performed longer verbal estimates and shorter productions than younger participants.

In a time reproduction task consisting in the presentation of an increasing number of durations requiring the reproduction of only one of them, older participants showed more errors with increasing task complexity than younger participants.

This pattern of results changed when attention and WM load were manipulated.

When divided attention was required for successful performance, larger effects in the older than the younger participants were observed. This may be explained by an attentionally modulated accumulator that links attention and clock-speed accounts of timing results. This pattern of results is not explained by a clock-speed model, since such a model would propose an accelerated clock in aged participants, which is contrary to slowness of physiological and cognitive processing speed with age.

Baudouin et al. (2006) argued that different mechanisms were involved in duration production and duration reproduction. They found a double dissociation: production was correlated with spontaneous motor timing and reproduction with working memory measures. These findings support a role of WM in the modulation of the internal clock rate.

Perbal et al. (2002) used temporal production and reproduction tasks in young and older participants with either a concurrent counting or reading task. These dual-task conditions resulted in shorter reproduction and longer production durations in both age groups. The elderly showed a higher coefficient of variations in the reproduction task in the concurrent reading condition, and this led to lower temporal precision compared to younger participants due to dual-task requirements in terms of attention and working memory load.

In the previous paragraphs, we described time-related processes that reside almost always under our awareness and intentional control. In most situations, indeed, although we perceive time, we do not think about it. Nevertheless, a situation in which the matter of time becomes critically evident and salient in our mind is when we are late, for example, for an appointment or a deadline. This represents a failure of a cognitive

ability typically called time-based prospective memory (PM). PM refers to people's ability to perform an intended action at the appropriate time in the future. The time-based PM activities include, for example, remembering to take medication at noon, or to take cupcakes out of oven after 30 min.

In time-based laboratory paradigms, participants are engaged in an ongoing task (e.g., lexical decision task), and they are required to remember to complete intentions (e.g., pressing a key) at a particular moment or after some duration has elapsed, such as remembering to perform an action every 5 min or after 8 min (Einstein et al. 1995; Henry et al. 2004). Their watches are removed, and they can monitor time by pressing a particular key or by looking at a clock that is outside the field of view. Since ongoing activity is not related to the PM task, there are no external reminders or cues embedded in the ongoing activity that trigger PM intention. Given this, time-based PM tasks are thought to be heavily dependent on self-initiated retrieval and monitoring processes (Henry et al. 2004).

In old age, an efficient PM was found to be the major prerequisite for independent living. Nevertheless, the picture arisen from the studies on aging is mixed with some studies showing age decline in PM performance and others revealing no age differences or even a better performance in older adults (Einstein et al. 1995; Cona et al. 2012b).

PM seems to be particularly sensitive to aging because it is characterized by less environmental support (e.g., explicit aids or reminders), and it depends more on self-initiated retrieval processes. As older adults exhibit a reduction in the availability of such attentional and self-initiated resources, they would have insufficient resources to accomplish PM tasks successfully.

Notably, older adults tend to perform worse in time-based PM tasks compared to younger adults, when they are tested in laboratory settings (Cona et al. 2012b). On the other hand, it is quite surprising that older adults perform as well, or even better, than their younger counterparts in PM tasks when these are carried out in naturalistic and

realistic settings. These experiments usually include, for example, remembering to telephone the experimenter at a specific time over 5 days or 2 weeks, following medication schemes, or attending appointments. The higher performance of older adults in naturalistic tasks, called age-PM paradox, has been attributable to several distinct factors such as more experience of older individuals with time management, generational differences in attitudes to politeness and punctuality, fewer distractions, greater awareness of memory failures, or better utilization of reminder aids. However, current understanding of the role of motivation, memory reminders and aids, and lifestyle busyness in PM tasks is still poor and requires to be further addressed.

Remembering to accomplish time-based intentions relies upon multiple processes. Among these, time estimation and monitoring seem to play a crucial role. According to the test-wait-test-exit (TWTE) model (Mäntylä et al. 2009), in time-based PM tasks, individuals intermittently test time (by checking the clock) to see whether the target time has come for executing the intended PM action. If the correct time is still not reached, individuals wait for a period of time until another test seems appropriate. The exit of this loop happens when the target time occurs and the intended action is executed. In line with the TWTE model, most of the studies showed that the overall pattern of clock-checking frequency can be represented by a J-shaped function (Henry et al. 2004; Maylor et al. 2002). Such studies indeed revealed that the number of clock checks is not constant during the task but increases as target time is approaching. Furthermore, for both younger and older adults, a relationship between time-based performance and number of clock checks has been consistently found (Henry et al. 2004; Maylor et al. 2002). Interestingly, an increase in the number of clock checks in the time interval just preceding the target time has been shown to predict an improvement in the PM performance.

Several studies showed that the frequency of clock checking was lower for older adults compared to younger adults and highlighted that such effect was accentuated during the time interval

just preceding a PM action (Henry et al. 2004). The reduced number of clock checks in older adults seems to reflect impairment in time monitoring, which might be considered one of the factors responsible for the poorer PM performance evidenced in older adults (Einstein et al. 1995).

Some studies analyzed the frequency of clock checks occurring before a failure and before a success in PM response (Mioni and Stablum 2014). Specifically, in the study by Maylor and collaborators (2002; Experiment 1), participants were engaged in watching a movie (i.e., ongoing task) for a successive recognition memory task, and, simultaneously, they were required to stop a clock every 3 min (time-based PM task). In general, young participants showed a better time-based PM performance compared to older participants. The PM accuracy was found to be associated with the frequency of clock checking. In particular, before a successful PM action, older participants checked the clock more often as compared to young participants; on the other hand, before unsuccessful PM actions, older adults showed a flat monitoring function even in the last 3-min interval. According to the authors, this pattern of results would suggest that time-based PM deficits in aging are mainly due to momentary lapses of attention.

Mäntylä and collaborators (2009) showed that the frequency of clock checking varied as a function of the cognitive resources required for the ongoing task in older adults. Specifically, the frequency increased across age in the low-demanding condition (i.e., listening to a brief story), with older adults checking the clock more frequently than their younger counterparts. Such monitoring strategy allowed older participants to obtain the same accuracy in PM performance shown by younger participants but led to an additional cost in ongoing performance. Conversely, when the ongoing task demands were higher (i.e., a series of cognitive tests), older participants checked the clock less frequently and, consequently, had an impairment in PM performance. In this condition, older adults would not have sufficient attentional resources to adopt the same compensatory strategy used under the

low-demanding ongoing task condition, and this determined a decline in PM accuracy.

Another study drew similar conclusions (Cona et al. 2012b) using event-related potentials (ERPs). So far, this is the only study that explored age-related neural changes underlying time-based PM processes. The authors found age-related alterations in a sustained ERP activity over prefrontal regions, which seem to suggest a decline in maintaining of intention. Notably, they found a higher frontal P3 in older adults, reflecting the allocation of additional resources to the ongoing task. This, however, led to a cost on PM performance, given that fewer resources were available to keep the intention in mind. Indeed, older participants who exhibited a higher frontal P3 were those who had poorer PM performance and lower number of clock checks. In line with Mäntylä and collaborators' (2009) idea, this study suggested that age-related decline in PM is the result of the reduced amount of resources available for the PM processes – as clock checking – given that older adults tend to allocate many resources for the ongoing task.

A further study highlighted that, when participants were allowed to execute a limited and fixed number of clock checks, a different pattern of clock checking was evidenced between younger and older participants (Mioni and Stablum 2014). Indeed, younger adults checked the clock less frequently in the time intervals far from the target time and started to monitor more frequently as approaching the target time. This pattern reflects the recruitment of a time monitoring strategy. By contrast, older participants did not exhibit such strategic pattern of clock checking and did not use all the clock checks available.

Taken together, these studies showed that an inefficient use of clock-checking strategy contributes to failures in time-based PM performance in advancing age.

In conclusion, we tried to outline the major findings on age differences in interval timing, in time-based prospective memory, and on the neural basis of such processes.

To summarize, great interest in the literature has been directed toward cognitive processes

involved in time processing, in both young and older persons. However, the literature is misleading about the contribution of different cognitive processes to time processing and their relation with aging. Specifically, one matter of debate concerns the role of attention and clock speed in accounting for the changes in temporally controlled responses. Indeed, based on the findings from different age groups and in conditions with different levels of cognitive resources requirements, it appears clear that attention and working memory play an important role in time processing in the elderly. Nevertheless, such relation is still unclear and needs further investigation. Also, the age-related changes on the neural bases underlying those processes that strictly require time processing and monitoring, such as the time-based PM, deserve a deeper exploration.

Decision to retire; Labor market exit; Labor market pathways; Older workers; Pension reforms; Retirement decision processes; Retirement pathways

Definition

This contribution focuses on the act of retirement, that is, exiting the labor market, and the potential processes involved prior to an older worker's retirement decision. Employee and employer perspectives are discussed.

Introduction

To minimize the growing economic burden caused by population aging, there has been an increasing focus on prolonging older workers' careers. Internationally, recent pension reforms and initiatives to prolong working life have led to multiple retirement options and possible pathways among which older workers can choose (Furunes et al. in process).

In spite of pension reforms and initiatives to prolong working life, obstacles to prolong working life exist at the individual level (e.g., motivation to continue or bridge careers; Feldman 2007), at the organizational level (e.g., manager attitudes; Furunes and Mykletun 2010), and at the labor market level (e.g., finding appropriate alternative

jobs; Alcover et al. 2014). In this entry, research related to understanding the timing of retirement is differentiated according to whether it refers to timing of retirement as seen from the employee perspective or timing of retirement as seen from the employer perspective. It is important to include both perspectives, as timing of retirement may not always be a matter of individual choice or preferences, but instead may result from a negotiation (or conflict) between the employee and the employer.

Retirement Is Contextual

Retirement may be defined as exiting the labor market permanently. Here, timing of retirement is understood as the transition to retirement originating in paid work, either full time or part time. If the transition to retirement originates in long-term disability or extended unemployment, the situation will be very different and falls outside the scope of this entry.

It is important to stress the probable influence of retirement systems on employee behavior and employer practices. This implies that retirement and the timing of retirement should be interpreted in a context (e.g., national retirement system, labor market situation). Nevertheless, there are commonalities across retirement systems and countries.

Retirement Systems

Until European countries started to reform their pension systems, the main pathways to retirement were disability pension, old age retirement, or contractual early retirement as negotiated in some countries. Pension systems differ in terms of what levels of wage replacements are offered through public pensions. High levels of wage replacement and attractive early retirement schemes tend to encourage early retirement, whereas lower levels of pension benefits and moderate early retirement schemes do not (see, e.g., Blöndal and Scarpetta 1998; Engelhardt 2012). Pension reforms were mainly introduced to

reduce incentives to retire early in order to prolong older workers' careers.

In some countries in continental Europe, initiatives to prolong working life have been mainly focused on bridge employment through motivating older workers to take alternative jobs to prolong their working lives (see Alcover et al. 2014), whereas other countries in northern Europe (e.g., Denmark, Norway, Sweden, Finland) have chosen to involve the social partners in working life through campaigns and/or tripartite agreements. Some countries have reformed their pension systems by eliminating the mandatory retirement age (see, e.g., Manfredi 2011), whereas other countries have kept the mandatory retirement age but changed the incentive structure to allow withdrawal of pensions while still at work. These retirement reforms have expanded the opportunities for individual choice and increased the number of trajectories retirement can take.

Because retirement can follow different trajectories, the timing of retirement may be a matter not only of when but also of how. In countries with mandatory retirement, the main exit routes prior to reaching the mandatory retirement age are disability pension or early retirement. For employees who are still working when they reach the mandatory retirement age, several trajectories are available: (1) retiring completely, (2) retiring partially while continuing to work in the same job, (3) retiring partially while working in a different job with the same employer, (4) retiring partially and working with a new employer, (5) retiring partially from the current employer and becoming self-employed, and (6) retiring completely and getting an unpaid/volunteer job.

Any paid work after an individual retires or starts receiving a pension, either with another employer or as self-employed, falls in the category bridge employment (Ruhm 1990).

As retirement ages and patterns vary across countries and industries, it is unlikely for the timing of retirement to be the same for all workers. According to Ekerdt (2010, p. 69), "every cohort retires in the context of its times." Studies of the transition to, event of, and timing for withdrawal from work are the most extensive genre of retirement research; however, as retirement is an

ever-evolving institution, matters are never settled and there is always something new to say. Moreover, there is considerable variability in how people age (Hansson et al. 1997), which is also likely to be reflected in how individuals approach and time their retirement.

Theories on Timing of Retirement

Different theoretical frameworks have been applied to study the timing of retirement. One of the most influential theoretical approaches in scientific debates about early retirement is the *Economic Theory of Retirement*, which assumes that older workers are rational, utility-maximizing individuals who time their retirement by considering their maximal financial opportunities and constraints so that lifetime income is optimized (Engelhardt 2012). According to this theory, individuals value leisure over work and will leave the labor market at the earliest time possible – that is, when pension payments compensate sufficiently for potential labor income.

Another construct that has received attention in relation to retirement timing is *future time perspective*. Future time perspective has at least two connotations that are relevant to the timing of retirement. The first is whether individuals focus on the future or the past (i.e., whether they have a short or long planning horizon). Future time perspective is found to be positively associated with preparedness for retirement (e.g., Hershey and Mowen 2000). This implies that individuals who are oriented toward the future are better prepared financially than those who have a short planning horizon. A second connotation of future time perspective is the “individual’s perception of his or her remaining time to live” (Kooij et al. 2013, p. 88). Kooij et al. (2013) distinguished between open-ended and limited future time perspective and found that limited future time perspective was positively related to age, implying that older workers see their future as less open.

Considering retirement as an individual behavior may be a limitation, as most older workers live

in households with other persons who may influence their retirement decisions and the timing of their retirement. There are two main competing hypotheses on how a husband or wife’s retirement behavior affects the spouse’s labor market participation. On one hand, it has been hypothesized that couples will choose to coordinate their retirement in order to get “complementary leisure” (see, e.g., D. M. Blau 1998). This hypothesis assumes that older retirees will enjoy their leisure time more when their spouses are with them and thus will attempt to exit working life jointly. On the other hand, the “added worker effect” mechanism (Lundberg 1985) suggests that one partner will increase his or her labor efforts when the other partner disengages, in order to compensate for the household’s income loss.

Both hypotheses have received empirical support. For instance, early studies by Hurd (1990) and Gustman and Steinmeier (1994) found that complementarity of leisure is a key factor in explaining why husbands and wives often retire simultaneously. Conversely, studies by Cullen and Gruber (2000) and Maloney (1987) support the hypothesized added worker effect. One possible reason why both these hypotheses have received support is that retirement is contextual. Different retirement and social security systems have different incentives. Further, the spouse and household income are only two among many possible factors influencing the timing of retirement.

In a more recent contribution, Ekerdt (2010) proposes a more complex model, including four social structural contexts that should be taken into account when analyzing retirement behavior: the welfare state, the family, the labor market, and cultural norms and values about age, work, and leisure (i.e., the normative age of retirement, later-life entitlement to leisure, moral assumptions, and solidarity between generations). All four of these contexts are likely to play a role in an individual’s retirement timing. It is thus important to remember that the timing of retirement is rarely a result of experiences proximate to retirement but rather is related to individual experiences throughout the course of the worker’s life.

A Process Perspective on Retirement Timing

Scholars have started to acknowledge that retirement planning is a complex phenomenon or process (Topa et al. 2009) that occurs over a span of time and involves a series of reflections and decisions concerning the timing and form of retirement (Moen 2012). One process approach to understanding how older workers gradually approach retirement is the retirement process model (Beehr 1986; Feldman and Beehr 2011). Feldman and Beehr's (2011) three-step model of retirement describes how workers progressively disengage from work by (a) imagining the possibility of retirement, (b) assessing when it is time to let go of long-held jobs, and (c) putting concrete plans for retirement into action. This model distinguishes between preferences, intentions, and the act of retiring, and it describes a process of increasing decisiveness toward the timing of retirement. These three steps are so broad that most employees approaching retirement will likely fit into at least one of them at some point. As such, Feldman and Beehr's three-phase model may be useful in understanding "how far from retirement" a worker perceives himself or herself to be. However, this model seems to assume that all workers at a certain age or stage in life have started to make retirement decisions. In contrast to this assumption, recent studies have provided more detailed information on the retirement decision-making process, suggesting that not all individuals disengage in the way proposed by Feldman and Beehr. For instance, a study of academics suggests five different ways of orienting oneself toward retirement: "reflections, explorations, assessments, discussions, and planning regarding retirement-related choices and alternatives" (Furunes et al. 2011b, n.p.). Individual variations in retirement orientations were found to covary with competencies, work enjoyment, and work identification, thus creating variations in how workers relate to retirement (e.g., their retirement intentions). A seemingly homogenous group of white-collar workers were classified into five

groups: (1) those *in love with the job*, who had very high competence, had very high work engagement, were job engaged, and planned to continue; (2) those *in the middle of a work project*, who had high competence, had high work enjoyment, were engaged in their project, and had considered but not yet planned for retirement; (3) those who retired to do new work tasks with their *pension as a stipend*, had high competence, and were so engaged in their topic that they sought alternative careers; (4) those whose competence was obsolete, whose work enjoyment was declining, and whose engagement was lost, who were barely *hanging in there* and planned to retire soon; and (5) those who lacked updated knowledge, had lost enjoyment, were disengaged, and were ready to retire or had already done so, because they were *done with the job*. Groups 3, 4, and 5 seemed to have determined that their options were better outside their current employment relationship, and the timing of their retirement seemed related to both their work and life experiences. Although this study adds details and new pathways to retirement, it says little about when timing or retirement starts, as the lowest age of interviewees was 58, an age at which it was assumed that they had started timing their retirement.

At What Age Does Timing of Retirement Start?

Calculating average retirement ages is easy, as most nations have accessible public data. Assessing the starting point for retirement timing, however, is considerably more difficult. As stated above, research increasingly acknowledges that retirement is not a discrete event but rather a messy and often disrupted process (Loretto and Vickerstaff 2012) involving hesitation and doubt (Ekerdt et al. 2001). Research has also established that retirement pathways are initiated long before retirement (see, e.g., Kloep and Hendry 2006) and acknowledged that the timing of retirement is a long process, with older workers developing expectations, intentions, and plans for retirement

long before the actual labor market exit (Zaniboni et al. 2010). Thus, there has been little focus on when timing of retirement starts.

On the one hand, it is well documented that a number of factors are associated with retirement timing. Survey data show that health, finance, marital status, caring commitments, job satisfaction, employer policy, and benefit status influence the timing of retirement (see, e.g., Phillipson and Smith 2005). On the other hand, practice shows that individuals with equal health and financial status may time their retirements differently (Loretto and Vickerstaff 2012). To explore retirement timing more closely, interactions between health, partners, and gender have received attention.

Wang et al. (2011) suggested applying a resource-based dynamic perspective to improve our understanding about the form and nature of the retirement process and adjustment to retirement. Furunes et al. (2015) argue that individual resources influence older workers' late career decision-making and retirement timing in the same way that they influence retirement adjustment.

Solem et al. (2014) found that labor market resources (i.e., health, education) influenced not only the timing of retirement but also the connection between intention to retire and retirement behaviors. Workers with low education and those with poor health tend to have fewer opportunities to remain in the workforce as long as they prefer. Additionally, blue-collar workers retire earlier than planned more often than white-collar workers; thus, the former have fewer opportunities to implement their decisions when they decide to retire late.

Nilsson (2012) found a distinction between those who left working life early and those who extended their working careers; specifically, "stayers" felt important to others and socially included at work and had meaningful tasks and a functional state of health, whereas those who left working life before 65 years of age considered their possibilities to be better outside working life and thus left as soon as they had a sufficient pension.

Ekerdt et al. (2001) found that retirement decisions among older workers in the United States involved a process of hesitation and doubt. Similar findings from Norway found that retirement

decisions frequently changed and were postponed close to the time of actual retirement among persons with ambivalent feelings toward retirement (Solem 1989).

In a meta-analysis, Topa et al. (2009) showed that poor health, negative working conditions, and positive attitudes toward retirement were positively related to both retirement planning and retirement decisions, whereas job involvement and job satisfaction were negatively related to retirement planning and retirement decision-making. Additionally, retirement planning was positively related to bridge employment, life satisfaction, and retirement satisfaction. An explanation for this finding may be that individuals who feel that they are in control of their retirement process are more satisfied compared to those who feel that retirement is forced upon them and thus have not planned for it. Likewise, those who have made plans have been found to adjust better to retirement (see, e.g., Anderson and Weber 1993; Wöhrmann et al. 2014). Below, some studies on the influence of family and health on retirement timing are presented.

The Influence of Partners and Families

Acknowledging that the timing of retirement is not only an individual decision, some research has taken partners and families into account as likely to influence the retirement decision. One of the reasons for this may be that for individuals linked to the retiree, the change in status may have counterpart effects (Ekerdt 2010).

American research has produced empirical evidence for joint retirement (i.e., couples choosing to retire at the same time). The desire for complementary leisure, as mentioned earlier, is often argued to be the reason for this phenomenon. Similar findings also resulted from a recent longitudinal study in Norway (Syse et al. 2014), where a spouse's work exit was found to be a strong predictor of a respondent's work exit, suggesting that spouses tend to coordinate their retirement. These findings differ from those of a study in the UK that found joint retirement to be less common than expected (Loretto and Vickerstaff 2012). In the UK study, joint retirement was found in cases of the sudden ill-health of one of the partners

(which made them recognize their own and others' vulnerability and mortality and thus led them to choose to retire together) and among couples who approached retirement in a more passive way (e.g., after long-term unemployment).

These studies call for the importance of studying retirement as household behavior. Also, they illustrate why it is important to study the timing of retirement in its complex context, which points not only to the retirement system but also to differences in characteristics such as social class, marriage, ethnicity, and race. For instance, in Norway, educational homogamy among married couples is highly prevalent (Birkelund and Heldal 2003) and thus likely to make it possible for couples to retire jointly. Conversely, in countries with low female labor market participation at higher ages, it is more likely for husbands to continue working to reduce the loss of income of the non-active wives.

The Relationship Between Health and Timing of Retirement

The relationship between health and retirement is bidirectional; health is central to the timing of retirement, and retirement may have varying effects on health (Oksanen and Virtanen 2012). Healthier workers remain at work longer than those with reduced health or working capacity (see, e.g., Harkonmäki et al. 2006). Finnish longitudinal studies show that improving health and work ability within the work context is possible (see, e.g., Tuomi et al. 2001) and may thus prevent early retirement.

When discussing whether it is ethical to prolong older workers' careers, it is often stressed that the work should not hamper the health of the worker; hence, it is important to know both the costs and the benefits of such efforts for the individual worker (Coe and Zamarro 2011). A large European study found a significant positive effect of retirement on general health. Another recent study of workers' health prior to and after retirement (Syse et al. [in peer review](#)) suggests that retirement may provide substantial health benefits. Those retiring were more likely to experience health improvements and less likely to

experience health deteriorations compared to those at the same age who continued working. Retirees were also more likely to increase their levels of physical activity and experience weight loss; thus, the study suggests that exiting working life may be beneficial for some. However, there is reason to believe that different kinds of retirement will have different health outcomes. For instance, a study comparing individuals retiring on disability pension to those retiring on early retirement or old age pension and those still working (Furunes et al. 2012) found that those retiring on disability pension experience a decrease in self-esteem that were not found in the other groups.

Effect of Gender on Timing of Retirement

Loretto and Vickerstaff (2012) stress that, for the generation that is now retiring, the retirement process may be very different for women versus for men. Women's entry into the labor market in the 1970s, especially in northern Europe and the UK, makes the now-retiring baby boomers the first generation to have high participation rates for both genders. However, it is common for women to have different work and life experiences than males (Sargent et al. 2013), as more women than men have experienced the "double burden" (Bratberg et al. 2002) of housework and paid work, as well as interrupted careers and part-time work due to caring for children and/or older family members. Discontinuous work histories or late labor market entries influence their pension earnings (Price and Nesteruk 2010) and thus may influence the timing of their retirement.

Timing of Retirement and the Role of Leadership and HRM Policies

While family and health certainly play a role in the timing of retirement, the retirement decision is also related to the work environment and workplace management. Recent pension reforms and initiatives to prolong older workers' careers have created new conditions for managing an

aging workforce. Leadership can take many forms and involve a series of processes related to employees' timing of retirement. Leadership strategies, for example, are likely to be different in countries that have a mandatory retirement age compared to those countries that have abolished the mandatory retirement age. Even in countries that have had strong national initiatives and tripartite agreements, such as Norway, the degree to which organizations have implemented strategies and actions to prolong the careers of their employees varies across organizations and leaders. Manager attitudes toward older workers are found to play a role in how eager they are to implement age-friendly HR practices and whether they think it is possible to postpone retirement (Furunes et al. 2011).

In order to influence employees' timing of retirement and manage older workers successfully, employers and managers may need to consider work ability and timing of retirement for each individual worker. This does not always seem to be the case in practice, however, as a study from the UK found that some line managers would turn a blind eye to poor staff performance among seniors approaching retirement to avoid conflicts, hoping that the older underperforming worker would retire soon anyway (Manfredi 2011). In countries in which the mandatory retirement age has been removed, Manfredi suggests that employers will need to focus more on performance management so as to avoid age biases and claims of age discrimination (Manfredi 2011).

Is it possible for employers to influence employees' timing of retirement? The answer to this question is yes – not for all employees, but for many – by understanding the multifaceted process and the role of the organization and the closest leader(s) in the timing of retirement. As employee motives and abilities change with age (e.g., Kanfer and Ackerman 2004), it is also likely that the utility and effects of human resource (HR) practices will change with age (Kooij et al. 2010).

Research shows that older and younger workers differ in terms of what motivates them to do a good job. For older workers, having an interesting job, being able to use their skills and

abilities, and feeling that they contribute, have autonomy, help others, and have a secure job are important (i.e., internal motivation). Younger workers, on the other hand, are motivated by challenging work tasks, career development, teamwork, and being recognized and rewarded (i.e., external motivation). On average, research suggests that the importance of internal motivation increases with age, while the importance of external motivation decreases with age.

According to the social exchange theory (Blau 1964), the degree to which employees return positive attitudes and behavior to the organization will be dependent on the perceived value of the offered HR activities. Kooij and van de Voorde (2015) suggest that organizations tailor their HR practices to the needs of older workers. In a study of HR practices, Kooij et al. (2010) identified four different HRM bundles of HR practices: (1) development, (2) maintenance, (3) utilization, and (4) accommodation.

Bundle 1, development, includes HR practices such as training to enable the employee to increase his or her level of functioning. Bundle 2, maintenance, includes HR practices aiming at maintaining the employees' level of functioning to enable him or her to meet new job tasks and challenges. Bundle 3, utilization, includes HR activities such as horizontal job change, job redesign, and mentoring that can help the employees to develop other relevant job resources. Finally, bundle 4, accommodation, includes HR practices such as reduced workload and part-time work that can help employees with reduced work ability when maintenance or utilization is not possible.

So far there has been little research conducted in this area. Initial research has found that Dutch and British organizations primarily used accommodative HR practices (e.g., additional leave, exemption from shifts, reduced workload) to retain older workers, suggesting that these organizations' managers may have a tendency to promote HR practices that release the pressure to older workers, whereas younger workers are offered developmental HR activities. One of the main roles of a leader is to make the person-environment fit as good as possible, so that the employee can continue to work as long as he or

she desires; hence, HR bundles should be selected according to their function.

Although to date relatively few empirical studies have actually demonstrated the importance of retention measures for the timing of retirement, there has been some initial investigation. In Norway, for instance, the most common entitlement age for retention measures is 62 (Hermansen 2014). Additional leave seems to be a widespread retention measure among European employers (see, e.g., van Dalen et al. 2009), for instance, it is by far the most commonly used retention measure by Dutch employers. One limitation is that there are few studies of whether these measures have the intended effect (i.e., influencing individuals' timing of retirement). A study by Hermansen (2014) shows that there has been an increase in the overall relative risk for 61- and 62-year-old workers to retire on contractual early retirement (AFP) in Norway in the period between 2001 and 2010. However, for older workers employed in companies offering additional leave, there has been a decrease in the relative risk of retiring early. In the analysis so far, it is difficult to know whether the small effects found it to be due to the HR practices per se or due to the organizations' general increase in attention toward older workers (i.e., a symbolic effect).

Although some initial work has been done on the role of leadership on the timing of retirement, there is a need for further studies. There is enough evidence for large individual differences in aging to claim that HR practices should be based on individual needs rather than collective goods that need to be negotiated by labor unions (see, e.g., Midtsundstad and Bogen 2014). There are also sufficient indications to suggest that organizations and managers can influence the timing of retirement (see, e.g., Furunes et al. 2015).

Definition

In this entry, we report the aims, methods, and findings of the Tokyo Centenarian Study (TCS) that was completed in the urban area of Tokyo in 2000–2002 and the Japan Semi-supercentenarian Study (JSS) that is being carried out for centenarians aged 105 and over in the whole area of Japan since 2003.

Aim and Recruitment

Tokyo Centenarian Study

In Japan, against a background of a rapidly aging population, the number of centenarians has increased notably. According to the Japanese Ministry of Health, Labor and Welfare, this population has continued to increase by 10% in recent years. When the Tokyo Centenarian Study (TCS) was initiated in 2000, there were 13,036 Japanese centenarians, 83.4% of whom were women. In 2014, the Japanese centenarian population increased to 58,820, with the female proportion increasing to 87.1%. The proportion of centenarians in total

Japanese population is about 0.05%, and about 7.6% is elderly people aged 80 and over. In the future, Japan will unavoidably become a “super-aged” society. There is a high probability the extreme elderly can have multiple disabilities and risk losing their ability to live independently.

Accurate descriptions of what happens to individuals’ health and independence at the tail end of the human survival curve have assumed an important role in accurately estimating future disability trends and health-care demands, which has enormous social, economic, and medical implications in an aging society. Research focusing on very aged people and centenarians helps inform how to extend a healthy life expectancy and how to adapt to functional decline. In addition, the achievements from research can contribute to the reconstruction of the social system in relation to coping with a “super-aged” society and to offer possibilities for a way of living an extended life. It is thought that studying the population of centenarians may inform best about how to achieve these aims.

The aims of the TCS were to (1) describe the status of centenarians and characterize ultimate aging in humans (i.e., When we live until the limit of the human life span, what do we become?), (2) identify the factors associated with longevity and healthy aging, and (3) examine the mechanism of adaptation to functional decline, based on the assumption that centenarians are a model of healthy longevity. Psychological factors, including personality, cognitive function, and subjective well-being, were also evaluated.

For sampling, we used an annual list of centenarians in Japan published by the Japanese Ministry of Health, Welfare, and Labor until 2003. (Unfortunately, it was stopped to be published since 2004.) According to this list, 1,785 centenarians lived in 23 wards of metropolitan Tokyo between 2000 and 2002. Addresses of 1,194 centenarians were identified from the basic registry of residence, and individuals were sent a letter inviting them to participate in the study. A total of 513 centenarians agreed to participate in the study, of which 304 (21.7% male and 78.3% female) participated in both the visits and mailed survey. The remaining 209 centenarians participated in mailed survey only

(Hirose et al. 2004; Gondo et al. 2006; Takayama et al. 2007; Inagaki et al. 2009).

Japan Semi-supercentenarian Study

While conducting the TCS, the researchers came to the conclusion that centenarians are no longer an ideal model for investigating human longevity. One of the reasons for this was the rapid increase in the number of centenarians. In Japan, the number of centenarians in 2014 was approximately 58,820, ten times higher than in 1994, and this number is expected to increase in the future. Additionally, centenarians are a heterogeneous group, from bed-ridden individuals to those having complete autonomy. Most centenarians are not in good health, experiencing declines in cognitive function, as well as being physically frail. Therefore, the study focused on individuals aged 110 years and over, known as supercentenarians (SCs). However, SCs are extremely rare, despite the overall increase in centenarians. National census results in 2010 indicated that 1 in 2,500 people were centenarians; however, semi-supercentenarians (SSCs), defined as people over 105 years of age, accounted for 1 in 45,000 people and supercentenarians (SCs) just 1 in 1,500,000 people. In addition, mortality rate for those aged 100 years and over was calculated and the rate did not rise after 105 years of age. Therefore, it was decided that SSCs and SCs were a more realistic model of healthy longevity than centenarians. Previously SCs had been considered as the best model for health and longevity, but it was difficult to collect data from sufficient numbers for adequate statistical analysis. The number of SSCs and SCs has been increasing recently. In 1991, there were 133 SSCs and five SCs; however, by 2010, the numbers increased to 2564 and 78, respectively. The larger SSC and SC population has made it possible to collect enough samples for more reliable statistical analysis. Therefore, the Japanese Semi-supercentenarian Study (JSS) was launched, in which a nationwide survey of SSCs was conducted, involving examinations using a standardized procedure (Arai et al. 2014).

JSS is a nationwide longitudinal survey, mainly consisting of individuals aged 105 years of age or older. Since 1963, a list of centenarians had been

compiled annually by the Ministry of Health, Welfare, and Labor, associated with the resident registration system and periodic census. According to the list, 849 SSCs were living in Japan in 2002 including 23 SCs. Names and addresses of 543 individuals (82 men and 461 women) among the 849 SSCs listed were identified, and individuals were sent a letter inviting them to participate in a home visit examination. 135 SSCs (20 men and 115 women) consented to participate in the visit. The list was discontinued in 2002; therefore, the recruitment strategy changed and SSCs were identified using one of the following methods: (a) subjects that had participated in the TCS in 2001–2002 and had reached 105 years of age by March 31, 2003, (b) individuals on the Basic Resident Register on the 23 Tokyo wards, and (c) individuals with their name and a part of an address published in a newspaper or other media. Of those identified and contacted, 161 replied, 17 declined to participate, and 51 were deceased. Of the 93 who agreed to participate, 20 (2 men and 18 women) participated in the mailed survey and 73 (14 men and 59 women) participated in the visit. Additionally, local government and the nursing homes, covering the whole country except Okinawa, were requested to introduce SSCs by mail (Arai et al. 2014). This is the current recruitment strategy for the study. A total of 591 SSCs, including 33 SCs, were enrolled in the JSS by the end of March 2015.

Data Collection

The mailed survey collected sociodemographic data, medical history, family history, subjective visual and auditory dysfunction, and basic and instrumental activities of daily living (B-ADL and I-ADL). After the mailed survey, a geriatrician, a psychologist, and a nurse visited a subset of centenarians in their current residence, such as their home, nursing home, or hospital. The geriatrician completed a medical examination, which included blood pressure measurement, an electrocardiogram (ECG), and a blood sample. Circumstance of care was reported to a nurse, from a centenarian's family member or care staff.

A psychologist rated several psychological variables including cognitive function using the Mini-Mental State Examination (MMSE) (Folstein et al. 1975), personality using the NEO Five-Factor Inventory (NEO-FFI) (Costa and McCrea 1985), subjective well-being using the Philadelphia Geriatric Center (PGC) Morale Scale (Lawton 1975), and depression using the Geriatric Depression Scale (GDS) (Sheikh and Yesavage 1986). Additionally, researchers asked about the centenarian's most important life events. After the visit, a psychologist and other expert gerontologists assessed the degree of cognitive impairment using a Clinical Dementia Rating (CDR) (Morris 1993) based on videotaped interviews of the centenarians and activities and state of daily living provided by the participant's family or caregiver.

Results

This section reports the psychological findings from the TCS and JSS.

Comprehensive Functional Status

In the TCS, 304 centenarians were classified using four phenotypes based on three functional dimensions: visual and auditory function, physical function, and cognitive function (Gondo et al. 2006). Only five centenarians (2%) were classified as "exceptional," meaning all functional dimensions were assessed as excellent. 56 centenarians (18%) were classified as "normal," meaning they had good physical and cognitive function and were maintaining an independent life. 167 centenarians (55%) had a problem with either physical or cognitive function; therefore, they were classified as "frail." The remaining 76 centenarians (25%) had a dysfunction with both physical and cognitive aspects and were consequently classified as "fragile." Therefore, based on biomedical or functional aspects, only 20% of centenarians in the study achieved successful aging.

Cognitive Function

The prevalence of dementia in centenarians varies, with reported prevalence ranging from 50% to 70% (Inagaki et al. 2009;

Gondo et al. 2014a). Using the Clinical Dementia Rating (CDR) (Morris 1993), dementia was defined as CDR1 and over; CDR1 is defined as cognitive function with mild impairment, and CDR2 and CDR3 are defined as moderate and severe impairment, respectively. Consequently, the prevalence of dementia in Japanese centenarians was estimated as 61.9%. This prevalence is similar to previous studies. In some of previous studies, MMSE has been applied to estimate prevalence of dementia in centenarians. However, by using the cutoff point applied for younger elderly, we may underestimate centenarians' cognitive function. Consequently, we assessed CDR (dementia or not) as external criterion and then used receiver operating characteristic (ROC) analysis to estimate appropriate dementia cutoff points of MMSE for centenarians. Applying this method, we found a MMSE cutoff of 17/18 points for the centenarians, compared with 23/24 points in the younger elderly (Gondo and Poon 2007). In addition, to determine which cognitive functions decline with aging or are maintained regardless of aging, we used the MMSE to evaluate the performance regarding specific cognitive domains in cognitively intact centenarians. Specifically, centenarians with CDR 0 (no impairment) were selected. Compared with young-old and old-old, the total MMSE score for centenarians was lower, indicating that general cognitive functioning declined in centenarians. Cognitive orientation and memory declined; however, language and praxis, as well as concentration, did not significantly differ from the younger elderly (Inagaki et al. 2009). Compared to the elderly with mild cognitive disability (CDR 0.5–1), decline was mostly dominated by deterioration of primary memory in centenarians. Long-term memory and orientation also were reduced; however, their functioning was maintained at a normal level. Working memory is likely to deteriorate more easily compare to other cognitive domains. Language and praxis also declined, but this decline was only small.

Personality

To identify personality characteristics specific to centenarians, a new method was used that

compares actual personality test scores of centenarians with a predicted test score for a 100-year-old, which was calculated based on younger controls (Masui et al. 2006). We conducted regression analyses for each personality score with age as an independent variable using scores of younger individuals. As a result, we adopted either a linear or a quadratic regression model that best fitted the data for each personality trait. Then, we calculated the predicted value for each personality trait for a 100-year-old based on the selected model and the actual mean scores and compared each score. The subjects of this analysis were 70 cognitively intact centenarians aged 100–106 years old and 1812 elderly persons aged 60–84 years old. Five personality traits (neuroticism, extraversion, openness, agreeableness, and conscientiousness) were assessed by NEO-FFI (Costa and McCrea 1985). Openness scores were higher in both male and female centenarians, and conscientiousness and extraversion were higher in female centenarians, compared with the predicted centenarian's scores. Thus, centenarians seem to have specific personality traits, and the traits of openness, conscientiousness, and extraversion are potentially associated with longevity through health-related behavior, stress reduction, and adaptation to the challenging problems of the extreme elderly (Masui et al. 2006).

Psychological Well-Being

As described above, our study documented deterioration of comprehensive functional status among most of centenarians. However, a disparity was found between functional status and psychological well-being in centenarians. In the TCS, psychological well-being among different functional subgroups was evaluated and compared using the Japanese version of the PGC Morale Scale (Lawton 1975). Centenarians who were physically frail but cognitively intact (i.e., a "frail" subgroup) demonstrated the same levels of psychological well-being as the "normal" (i.e., not frail) subgroup in centenarians. In addition, psychological well-being in centenarians was higher than in the young-old and old-old subgroups with physiological deterioration (Gondo 2002; Gondo et al. 2013). As a theory to explain these positive levels of psychological well-being

in the extreme elderly, further studies are focusing on gerotranscendence, which is defined as “a shift in meta-perspective, from a materialistic and rational vision to a more cosmic and transcendent one” (Tornstam 1989). The Japanese version of the scale was developed to measure gerotranscendence and data collected from the elderly, including centenarians (Masui et al. 2010).

Additional Contributions of the TCS: CAQ Questionnaire Development

In some situations, it is difficult to assess a centenarian’s cognitive function using performance tests, because most centenarians may have visual and hearing impairment, physical disability, or low levels of arousal. Estimation of the cognitive function by others who know the centenarian well may therefore be an effective method of assessing this competence. Based on this concept, a cognitive assessment questionnaire was developed (Masui et al. 2005; Gondo et al. 2014b). The CAQ aims at assessing the cognitive functions indirectly, by measuring the cognition-related daily activities. Although it is not possible to completely disentangle cognitive and physical capacity using this approach, the CAQ includes selected activities of daily living which can be considered to relate more strongly to cognition rather than physical functions. The item selection process was based on discussions of three psychologists who compared different existing scale for ADLs/IADLs. The final questionnaire consisted of 19 items which are shown in Table 1. For its validation, the CAQ was distributed to the family members of 233 centenarians or their care staff. Findings indicate that the CAQ had a high internal consistency (Cronbach alpha was 0.94) and great concurrent validity based on high correlations with the MMSE ($r = 0.85$, $p < 0.01$). In addition, this questionnaire was able to evaluate the functional level of participants below the lower limit assessable by the MMSE and was not affected by vision or hearing impairment. Because CAQ does not assess cognitive functions as directly as performance tests, such as MMSE, HDS-R, etc., it has some limitation regarding the

Tokyo Centenarian Study and Japan Semisupercentenarian Study, Table 1 Table items of CAQ

1	When someone greets him/her, he/she can greet them
2	He/She can express feelings, for example, delight, anger, sorrow, and pleasure
3	He/She can say thanks to someone's services to him/her
4	He/She can understand his/her age roughly correctly
5	He/She can reminisce his/her happy past story
6	He/She can correctly say his/her date of birth
7	He/She can reminisce his/her sad past story
8	He/She can behave in mind of others' evaluation
9	He/She can correctly understand what season it is now
10	He/She can understand his/her relatives' recent history and dwelling place roughly correctly
11	He/She can understand the program roughly correctly when he/she is watching TV or listening to a radio
12	He/She can turn on the TV or the radio and change the channels on his/her own
13	He/She can listen to someone's problem and give advice to them
14	He/She can smarten up his/her belongings in his/her own way
15	He/She can absorb ideas of book or magazine when he/she is reading them
16	He/She can remember about episodes which appeared a few days ago
17	He/She can calculate easy hanging money
18	He/She can stay home alone without any worry
19	He/She is working or doing the housework daily

degree of exactness with which the CAQ can assess cognitive functioning. However, we still consider that the CAQ is a very useful measure, because it does not require much expertise to apply this test compared to the previous observation methods such as CDR and it can apply to subjects who can no longer respond to the performance tests.

Summary

The TCS started in 2000, followed by the JSS in 2002. Data collection in the JSS is ongoing. In order to describe the status of centenarians, characterize ultimate aging in humans, and identify the

factors associated with longevity and healthy aging, some psychological factors including personality, cognitive function, and subjective well-being were assessed and evaluated, under the assumption that centenarians and supercentenarians are models of healthy longevity. Cognitive function showed an overall decrease; however, some cognitive functions maintained the same level, while others hardly decreased. Centenarians have specific personality characteristics. We speculate that this specific personality of centenarians contributes to longevity through health-related behavior and effective stress management. Despite centenarians' decline in physical and cognitive function, their subjective well-being is higher than expected from younger elderly. A psychological adaptation model for the extreme elderly, such as gerotranscendence, could be used as a mechanism to describe this phenomenon.

Acknowledgments The authors would like to extend their sincere appreciation to all the centenarians, their families, and caregivers involved in the studies. Data presented in this chapter are because of their kind and willing corporation. The authors also express their sincere gratitude to the research team members of TCS and JSS: Dr. Yukie Masui, Dr. Michiyo Takayama, Dr. Kazunori Ebihara, Dr. Ken Yamamura, Dr. Susumu Nakazawa, Dr. Ken-ichiro Shimizu, Ms. Yukiko Abe, and Ms. Miho Shimura.

Employee development; Learning; Skill acquisition; Worker education

Definition

Training is defined as a collection of organizational activities that presents employees with job-relevant information with the intent of yielding permanent changes in job-related knowledge, skills, and attitudes. The objective of work-related training is to increase job performance and ultimately work toward organizational goals. Aging employees in the workplace experience developmental changes in cognitive ability and motivation that can affect their performance during training programs. Below, considerations for age-related training are discussed.

Training Older Workers

In 2013, adults aged 55 years or older comprised about 61% of the U.S. workforce (Bureau of Labor Statistics, 2014). Other countries across the world are also experiencing upward shifts in the median age of their workforce population, with some countries (e.g., Japan) projected to have over 40% of their workforce older than 50 years of age by the year 2020 (Skirbekk

et al., 2012; Van Katwyk, 2012). As older adults continue to comprise an increasingly large portion of the workforce, they will require training for new jobs and continuous updating of their current skills in existing jobs. Understanding how to best design training for older workers necessitates a focus on understanding age-related changes in abilities and goals that impact performance in, and motivation for, training.

Training is defined as activities planned by an organization that lead to a permanent change in employees' job-related behaviors (Wexley & Latham, 2002). The primary purpose of work-related training is for employees to acquire new skills that they can use to positively impact job performance. Organizations recognize the value of good training as evidenced by the significant annual investment of resources toward training. In 2012, the average direct learning expenditure per employee for Fortune Global 500 organizations in the U.S.A. was \$802, with an average of 31.5 learning hours spent per employee annually (American Society for Training and Development, 2013). The demand for training is expected to continue into the foreseeable future, with technological advances and an increasingly global workforce placing higher premiums on keeping skills up-to-date and expansive enough to work successfully around the globe (Burke & Ng 2006). Though this may prompt various organizations to focus on rapidly changing market demands in their respective fields, there should also be a focus on the characteristics trainees bring to training situations that may dictate their success in training (e.g., motives, goals, and abilities).

Factors related to trainee characteristics have been shown to be influential before, during, and after training programs. Research suggests that two of the best predictors of training performance are cognitive ability and motivation (Colquitt et al., 2000). Both of these variables change as adults age in ways that can affect work-related issues (i.e., engagement in training programs and performance during training). Age has been shown to be negatively related to training performance and positively related to training time, meaning that as people age, they tend to take longer in training and do not perform as well

(Kubeck et al., 1996). Nonetheless, training programs can be designed to account for age-related changes in abilities and motivation, which create environments where older adults can perform well (Callahan et al., 2003).

Here, the current research on age- and work-related training is reviewed. Person-related attributes in relation to aging (i.e., cognitive ability and motivation) will be described and discussed within the context of the situational demands for trainees that arise from training environments. Future directions of aging and training research will also be discussed.

Person-Related Attributes

Cognitive Ability

Cognitive ability is one of the strongest predictors of training performance, accounting for approximately one-third of the variance in training performance (Beier, 2008); people who are generally higher in cognitive ability tend to do better in training relative to those who are lower. Research has commonly delineated components of cognitive ability into two types: fluid ability and crystallized ability (Horn & Cattell, 1967). Each type of cognitive ability is related to different, specific mental functions and each develops differently over time. As such, they have different age-related trajectories that provide implications for designing training given to older workers.

Fluid ability is associated with generating, transforming, and manipulating information. It is highly related to working memory capacity and is generally considered the raw reasoning ability that people possess. In training situations, fluid ability is important for learning novel tasks, processing information, and retaining newly learned material (Carroll, 1993). Some scholars posit that the amount of fluid ability a person has limits the amount of cognitive resources and attention a person has available to dedicate toward learning new tasks, such as those presented in training environments (Kanfer & Ackerman, 1989). As such, fluid ability is considered an essential determinant of learning in training.

Crystallized ability is associated with domain-specific knowledge obtained through life experiences and education. It is generally measured using verbal comprehension, vocabulary, and general knowledge tests (e.g., assessing information that is available to a general population). Fluid and crystallized ability are positively correlated (i.e., people who have higher levels of fluid ability are also likely to have higher levels of crystallized ability), which is reflective of the idea that crystallized ability develops as a function of the investment of fluid ability in learning (Horn & Cattell, 1967). However, these two abilities have different trajectories that develop with age.

Fluid ability increases from birth and peaks in early adulthood (around age 20 or so). Once a person ages beyond young adulthood, fluid ability steadily declines throughout the remainder of a person's life. This leaves older adults with fewer cognitive resources available for allocation toward learning novel tasks, as would be necessary in many training environments. Indeed, research has found that age-related differences in training performance follow expected trends for fluid ability. In particular, older adults have more difficulty learning new things compared to younger adults (Kubeck et al., 1996).

Similar to fluid ability, crystallized ability increases during the early portions of a person's life span, specifically from birth to young adulthood. But instead of declining after young adulthood like fluid ability, crystallized ability remains stable or even increases until approximately age 70. Consequently, crystallized ability is likely to remain stable throughout a person's working years. Research also suggests that crystallized ability in the form of domain knowledge is positively related to new learning in that particular domain (e.g., prior knowledge about investment products was positively correlated with new learning about retirement accounts for an age-diverse sample; Ackerman & Beier, 2006). This implies that learning is facilitated – even in the face of declining fluid ability with age – in training environments that build upon pre-existing knowledge. That is, in these types of situations, crystallized ability can compensate for some losses in fluid ability.

Cognitive ability is an important determinant of success in training. Although older adults are likely to have more difficulty reasoning through novel problems compared to younger adults, they are likely to benefit from the vast array of knowledge they bring to bear on the training situation. For example, in a training program on a new software program for architects, a less experienced and younger architect might rely more on her attentional and memory capacity to encode and remember the information presented in training. Conversely, a more experienced and older architect might rely more on his knowledge of the current tools used in his job to integrate and remember the trained material. Though cognitive ability is a strong predictor of performance, age-related differences in motivation can also speak to an employee's success in a training program.

Motivation

As adults age, their motivation for performing certain tasks or behaviors changes. One of the most common theoretical frameworks for examining motivation in work contexts is expectancy theory. Under expectancy theory, a person's level of motivation for a given task is determined by a combination of (a) the *valence* or value a person places on outcomes resulting from engaging in the task, (b) the *instrumentality* of a task to yield desired outcomes, and (c) the *expectations* that the effort dedicated toward the task will produce desired results. When applied to the context of training, this means that older adults will decide to engage in training opportunities if they value the outcomes associated with the training (e.g., outcomes such as a promotion or a more efficient way of doing an old task), believe that the training is useful to achieve the outcomes they value (e.g., skill enrichment), and believe that effort will lead to successful performance in training (Beier & Kanfer, 2010).

Because goals and values influence motivation for engaging in training, it is important to understand how they shift with age. In particular, shifts in goals are thought to be related to perceptions of time left (i.e., at work or in life); older people are thought to perceive that they have relatively

limited future time compared to younger people (Kanfer & Ackerman, 2004). This perspective that time is limited will lead people to choose goals that satisfy social or emotional needs over those that emphasize professional development (e.g., people with this perspective are more likely to be focused on building meaningful relationships than achieving a promotion). Conversely, when time is perceived as unlimited, professional development goals are favored as the person strives to advance at work. These changes imply that older adults will be less motivated relative to younger adults to engage in training opportunities that further professional goals, but would continue to be interested in training opportunities aligned with social or emotional goals. For instance, older workers may not be as motivated as younger workers to participate in training that would teach them computer programming so they could earn a promotion, but older workers may be just as motivated – or even more motivated – than younger workers to participate in training related to managing and coaching subordinate employees. Perhaps because much of the training research has focused on technical tasks, there is evidence that older workers are less willing to take part in training activities relative to younger workers (Beier, 2008).

In addition, because learning completely novel information (i.e., information that cannot be easily integrated into existing knowledge) becomes increasingly difficult with age, older workers may choose to operate in the environments that are most aligned with their existing skills and focus on developing those talents they already have. When necessary, older workers would also be expected to use strategies to compensate for skill deficiencies when they encounter difficulties in the training environment (Kanfer & Ackerman, 2004). These choices have implications for training because they determine whether older adults will engage in training opportunities and how they will behave during training. For example, as older adults realize that their cognitive resources associated with memory and learning are becoming limited, they will choose to focus their attention on learning in domains with which they are already familiar, rather than to explore new

pursuits in a broad range of domains. During training sessions, older adults would also be expected to engage in strategies to counteract losses in fluid ability such as mnemonic devices, note-taking, and moving at a slower pace. If these strategies are successful, age-related differences in performance may not be evident. That is, compensatory strategies – if effective – can serve to reduce age differences in training performance.

In summary, both cognitive abilities and motivation change as people age, such that older adults have fewer cognitive resources available for allocation toward novel tasks and begin to value social and emotional needs over professional development needs. These age-related changes in cognitive ability and motivation affect older adults' willingness to engage in training and their training performance. Nonetheless, the way training is designed can also affect performance. The following section will examine a variety of situation-based training demands that can yield differences in performance for older workers compared to younger workers.

Training Intervention Demands

Cognitive Demands

The basic purpose of training is to learn new skills. Theory and research suggest that learning a new task is effortful at first and will place demands on fluid ability (i.e., fluid ability being implicated in learning novel information). After a skill has been practiced over time, using the skill becomes less effortful and less reliant on fluid ability (e.g., riding a bike or driving a car, Kanfer & Ackerman, 1989). As the skill is learned, performance increasingly becomes a function of crystallized ability (i.e., task-related knowledge). Because fluid ability is somewhat limited for older adults, it is likely that the initial stages of effortful learning will be especially taxing, which would lead to poor performance and decreased motivation for training.

For instance, learning how to parallel park would be incredibly cognitively demanding for a person who has never driven before. That is, the task would require focused attention such that the

driver would not have any extra cognitive capacity to process extraneous information (e.g., they would likely turn off the radio or not participate in a conversation). Conversely, the same parking task should be significantly less demanding for a person who has practiced driving for 6 months because the task of parallel parking builds upon the experienced driver's pre-existing knowledge. As such, training can be designed to scaffold knowledge, building upon existing experience and knowledge. Training that builds upon existing knowledge should benefit older learners given the vast amount of knowledge they possess.

As described above, a trainee's expertise in an area can influence how cognitively taxing training is, but features of training design can also affect the cognitive demands associated with it. For example, the pace of training, the mode of delivery (e.g., lecture, electronic), the trainee's ability to control how quickly he or she moves through the training (i.e., learner control), the training materials, and the amount of instruction provided during training can all affect the cognitive demands associated with the training. Specifically, training environments that provide trainees minimal instruction and the opportunity to explore (e.g., discovery learning) can be more cognitively demanding than training environments that provide a more guided approach to the training content. An example of a training environment with minimal instruction is building a puzzle with only the image of the final product as a guide, whereas a guided approach would provide the image of the final product, but also instructions for the placement of each piece. Although discovery-learning environments have been shown to be effective for training – particularly for retention of trained material over time – these approaches can be cognitively taxing and difficult for people with limited fluid abilities. As such, people higher in cognitive ability, particularly fluid abilities, should be relatively more successful in these training environments than people lower in fluid abilities. Thus, it would seem to be particularly important to design training interventions for older workers that scaffold on existing knowledge and that provide extensive instruction,

particularly at the beginning of training when a task is new. There is some evidence that training that is relatively higher in structure is more effective for older learners than training that is relatively lower in structure (Carter & Beier, 2010). Nonetheless, the results of this literature remain equivocal and very few research studies have been published on the topic to date.

Another important consideration for designing training for older workers is its pacing. A meta-analysis of the training features affecting success in training for older adults found that older people learned more when training was self-paced versus instructor-paced (Callahan, Kiker, & Cross, 2003). Moreover, this study found that pacing of training was more important for success than the mode of delivery (lecture versus online, etc.). This is likely because older learners take longer than younger learners to process new information. Thus, self-paced training permits learners to take the time they need to encode training content into memory. Furthermore, self-paced training is higher in learner control – that is, the learner is responsible for determining when they have learned the content in one training module enough to progress to the next training topic. Consequently, self-paced training can be more meta-cognitively engaging than instructor-paced training as it forces learners to think about what they are learning during the training intervention. This thinking about one's own thinking also leads to increased performance in training.

In summary, success in training is a function of cognitive abilities, motivation, and the design of the training intervention. Because abilities and motivation are likely to change with age, the relationship between training design and performance in training is also likely to be moderated by age (i.e., the effectiveness of training interventions will differ depending on a trainee's age). Interactions between individual attributes and training treatments are called aptitude by treatment interactions (Campbell & Kuncel, 2001). Aptitudes are defined as any stable person-related trait, including cognitive ability, that is correlated with training outcomes and that interact with the training environment (which is the treatment). As described above in the context of training

structure and pacing, aptitude by treatment interactions is an important consideration when designing training for older workers.

Future Directions for Research on Training and Age

Due to the aging of the global workforce and worker needs for continuous skill development, research on the training interventions that are most effective for older people is imperative. But unfortunately, this research is also sparse, most likely due to the cost and availability of samples of workers between the ages of 20 and 70 who are willing to participate. Thus, one of the first things researchers can do is to move beyond undergraduate samples in training research and to examine the effectiveness of work-related training with working-aged people (including younger, middle-aged, and older workers). This will provide insight into those elements of training design that are most effective for working adults. Moreover, training conducted in the context of normal organizational training can also provide insight into the factors affecting motivation for training. Examining motivation for a training program is difficult in laboratory environments when the training content is not especially relevant to work-related concerns.

An additional research need is related to the study of motivational and self-regulatory processes implicated in training success. Relative to what is known about changes in abilities throughout the life span, little is known about changes in motivation, goals, and self-regulatory processes relevant to training. Theory suggests that people shift from achievement to emotionally fulfilling goals later in life and that older people will value generative versus achievement outcomes associated with training (Kanfer & Ackerman, 2004). It would be beneficial to confirm these ideas with additional empirical evidence. Specific topics ripe for research include the predictors of interest in training and development activity (e.g., Maurer et al., 2003) and understanding how framing training and development activities may influence interest (e.g., Cox & Beier, 2009). Future research

would also benefit from examining whether training interventions could be designed to boost self-regulation for older adults during training (e.g., Carter & Beier, 2010).

Conclusion

The aging of the global workforce will require that some people work past those years normally slated for retirement, either in their same jobs or in new roles. Moreover, the fast pace of business development will require workers of all ages to constantly update their work-related skills. As described above, research suggests that age-related changes in abilities and motivation can affect performance in training. But research also shows that training can be designed to facilitate learning for older workers. In particular, structured training that scaffolds onto existing knowledge and training that is self-paced can benefit older learners. In the coming years, it will be increasingly important for researchers to understand more about the training designs that affect learning in, and motivation for, training. It will also be increasingly important for training designers in organizations to consider the developmental changes in cognitive ability and motivation that influence training success. Designing training with the unique needs of older learners in mind will benefit not only the trainees, but the organizations who will increasingly rely on older workers in the coming years.

Definition

The process of developing the attitudes, knowledge, and skills to become a proficient professional geropsychologist. Training occurs at the undergraduate, graduate, internship, postdoctoral, and post-licensure level.

Background

As the number of older adults has grown, the field of geropsychology is advancing to meet their evolving needs. For example, as of 2011, over 100 clinicians in Europe have studied in the European Master's Program in Gerontology (EuMaG), which involves studying in various cities in Europe (Aartsen 2011; Heijke 2004). Yet, there remains a worldwide shortage of mental health professionals with specialized training in working with older adults. For example, there is a shortage of psychologists and psychiatrists with expertise in aging in Europe (Fernandez-Ballesteros et al. 2007; Ribeiro et al. 2010) and Australia (Snowdon et al. 1995) and a shortage of clinicians with expertise in dementia in Asia (Chiu and Chiu 2005). As of 2010, there were two graduate programs with specialty tracks in clinical geropsychology and five institutions with a gerontology department in Australia; Canada had no graduate programs with specialty geropsychology tracks, but had at least 12 institutions that had gerontology programs (Pachana et al. 2010). In Portugal, the awareness of the need for knowledge and experience with older adults is still emerging within clinical psychology, although the importance of a life course perspective in psychology courses and programs is starting to be recognized (Ribeiro et al. 2010).

Most information regarding geropsychology training focuses on American training, and that will be the focus of this chapter. The American Psychological Association (APA) adopted an official policy on psychological practice with older adults in 2003, and this was followed in 2010 by the establishment of geropsychology as a specialty of professional psychology (American Psychological Association 2004; Molinari 2010). Yet despite these advancements of the field, there is a well-documented shortage of qualified mental health practitioners to provide treatment to our aging society (Qualls 2010). At the start of the new millennium, a survey of over 1000 members of APA revealed that while only a small percentage identified older adults as their primary clientele, two out of three reported regularly providing care to older adults (Qualls et al. 2002). Of those

providing care to older adults, few had received formal training in geropsychology, with the most frequently cited training opportunity being informal clinical experience or on-the-job training. Furthermore, approximately half of those sampled identified a need for additional training in order to achieve competence in working with older adults. There has since been a steady growth of geropsychology training programs as well as the development of a formal, cohesive model of geropsychology training, the Pikes Peak Model for training in professional geropsychology (Knight et al. 2009).

Pikes Peak Model of Training in Professional Geropsychology

The Pikes Peak model of training in professional geropsychology serves as a framework in which all aspects of training can be organized. Several national (EUA) geropsychology conferences led up to their creation. In 1981, the “Training Psychologists for Work in Aging” conference was held in Boulder, Colorado. This conference (now known as “Older Boulder”) worked to define the state of geropsychology knowledge and also produced specific training recommendations for geropsychologists (Knight et al. 1995). “Older Boulder” was followed up in 1992, with a second national conference held in Washington, DC. The focus of “Clinical Training in Psychology: Improving Services for Older Adults” (now known as “Older Boulder II”) was on further refinement of geropsychology training themes and discussion of certification of competence (Molinari 2010; Knight et al. 1995). This produced the “Three E’s” model of training: Exposure, Experience, and Expertise. In this model, the level of training recommended is matched to the goals of the trainee, i.e., the degree to which the trainee will work with older adults in a professional capacity. All psychologists should have some *exposure* to working with older adults. For those psychologists who wish to have some older clients in their clinical practice, *experience* working with older adults across different settings is necessary. Finally, to gain *expertise* in clinical

geropsychology or become an advanced practitioner of geropsychology, a psychologist should have the requisite knowledge and skills within many aging-related areas (Molinari 2010; Devries 2005; Hinrichsen et al. 2010).

In 2006 a third conference, the “National Conference on Training in Professional Geropsychology,” was held in Colorado Springs, Colorado, near Pikes Peak. This conference, known as the Pikes Peak, sought to develop a comprehensive training model and articulate competencies for the practice of professional geropsychology. The primary product of this conference is the listing of the Pikes Peak Competencies in Professional Geropsychology, which are a collection of competencies organized around attitudes, knowledge, and skills essential to work with older adults as well as training recommendations for those seeking to meet these competencies (Knight et al. 2009). While aspirational in nature, these competencies provide a comprehensive model to assess the training needs of those who work with older adults. It is noteworthy that the model recognizes that specialized training in geropsychology is not essential for all psychologists who work with older adults; however, as the patient issues become more complex, the need for specific training increases. As such the competencies are most applicable for those who wish to primarily work with older adults.

In their seminal paper, Knight et al. (2009) define the attitudes, knowledge, and skill competencies for geropsychology practice. The competencies list is meant to be an aspirational list to be used for programs and clinicians seeking training in geropsychology to create and evaluate a plan of training at different levels, including graduate, internship, postdoctoral, and post-licensure levels. Core attitudes include (1) the goal of practicing within one’s competence, (2) recognizing how one’s attitudes and beliefs about aging will affect her or his work with older adults, (3) being aware of individual diversity in all its forms, and (4) continually increasing one’s knowledge, understanding, and skills related to working with older adults. Four domains of knowledge in the Pikes Peak Model include normal adult development and aging; the interaction of life span

development with increased neurological and health problems in later life; assessment methods and tools suitable for assessing older adults; and using knowledge of developmental, cohort, contextual, and systemic issues to inform interventions with older adults. There are six aspects of training that are considered critical parts of a training program for a geropsychologist: (1) understanding of normal aging; (2) supervision by professional geropsychologists; (3) gaining of self-awareness about one's responses to aging that vary by health status, cultural and individual identities, and diverse historical cohort experiences; (4) training in a variety of settings; (5) interprofessional team training; and (6) ethical and legal issues and practice standards that are involved in work with older adults.

Readers are encouraged to review Knight and colleagues' (2009) article in *American Psychologist* for a complete overview of the Pikes Peak competencies in geropsychology.

Council of Professional Geropsychology Training Programs (CoPGTP)

In addition to these comprehensive competencies, the Pikes Peak conference also produced the Council of Professional Geropsychology Training Programs (CoPGTP), which includes universities, internship training sites, and postdoctoral training sites. The purpose of CoPGTP (often pronounced "COG-TIP") is to further the advancement of geropsychology through promotion of geropsychology-focused education and training that is consistent with the Pikes Peak model of geropsychology. CoPGTP also provides a forum for training programs to share resources among themselves and with those interested in pursuing specialized geropsychology training.

In 2009, CoPGTP formed the Task Force on the Assessment of Geropsychology Competencies to develop an assessment tool for training programs and supervisors to evaluate trainees' development in the Pikes Peak competencies as well as for those psychologists that wish to engage in a self-assessment of their own training needs. As such, professionals who use the tool are able to

address the needs of many at different points in their training and careers (i.e., graduate school practicum, internship, postdoctoral fellowship, and post-licensure) (Karel et al. 2010a). The Pikes Peak Geropsychology Knowledge and Skill Assessment Tool includes detailed behavioral descriptors of the Pikes Peak competencies, which are then rated along a continuum that spans from novice to expert (Karel et al. 2010a). It is currently freely available through CoPGTP.

CoPGTP also provides extensive resources for those who wish to pursue training in geropsychology. Through its website (www.copgtp.org), CoPGTP provides a directory of undergraduate, graduate, internship, and postdoctoral training programs with a geropsychology emphasis. Resources for post-licensure psychologists include listings of aging-focused APA videos and web-based trainings as well as recommended readings, websites, and related training opportunities for the Pikes Peak competencies.

Levels of Training in Geropsychology

Given the growing number of older adults, the number of future geropsychologists in the "pipeline" will likely continue to be insufficient. The field thus relies on established providers to seek out specialized training in geropsychology so as to best meet the needs of their diverse older clients. Formal training is one of the best predictors of practice patterns, as those who received formal training in geropsychology are most likely to practice with older adults (Qualls et al. 2002; Hyer et al. 2005). To provide the greatest exposure to geropsychology and increase the likelihood a trainee will specialize in geropsychology, training should occur across the educational continuum beginning in undergraduate coursework, then to graduate studies, predoctoral internships, and postdoctoral fellowships. Training should not end after licensure, as there are numerous continuing education opportunities designed to meet the needs of practitioners who desire additional training in geropsychology (Hyer et al. 2005).

Undergraduate Coursework. Geropsychology is firmly rooted in a lifespan development theory

and as such has much overlap with developmental perspectives (Qualls 2010). In addition to the traditional coursework in human development, colleges and universities now offer certificates or degrees in adult development and aging. Universities often offer courses in adult development and aging or lifespan development. In addition to specific courses in aging, it is recommended that aging topics be interwoven into a variety of psychology courses, such as Introductory Psychology, Sensation/Perception, Human Sexuality, and Cognitive Neuroscience (Vacha-Haase 2010). Readers are encouraged to review Whitbourne and Cavanaugh (2003) for detailed instructions as to how to incorporate aging throughout undergraduate psychology coursework.

For those students who wish to seek out graduate training in psychology, their undergraduate coursework should be augmented with opportunities for clinical practice and/or research. Clinical experiences are of great benefit as they can help trainees decide if they would like to seek careers in mental health and also provide an opportunity to select a population of interest. Many graduate programs require the trainee to apply to certain tracks (e.g., health psychology, geropsychology, adult clinical). Thus, by gaining some clinical experience prior to applying to graduate school, the trainee is best able to make an informed decision regarding her or his choice of graduate training programs. In addition to gaining clinical experiences prior to graduate school, a competitive trainee will also obtain research experience. As many if not most graduate programs are based in a scientist-practitioner or scholar-practitioner model, research training makes an applicant more competitive. Opportunities for participation in research can typically be found through faculty in psychology departments, and some universities offer class credit for research experience. Trainees are encouraged to consult with faculty in Psychology, Gerontology, and Social Work departments for research training experiences. Ideally these experiences would lead to peer-reviewed posters and presentations at local, regional, or national conferences or peer-reviewed journal publications.

Graduate Studies. Psychologists that receive specialized training in aging are more likely to provide services to older adults (Qualls et al. 2002); thus, graduate training in professional geropsychology is an important piece of the field's efforts to meet the needs of the aging society. The APA's Division 20, Adult Development and Aging, maintains a current listing of doctoral training programs that offer training in geropsychology (<http://www.apadivisions.org/division-20/publications/graduate-studies/index.aspx>). As of 2015, there were 115 doctoral training programs listed in the United States and 15 international programs.

Currently, there are two primary models for graduate training in geropsychology. The first of these is training in a generalist psychology program with extra coursework available in aging, which is by far the most common model of training. More recently, doctoral programs focused on professional geropsychology have been developed. Both types of programs provide opportunities for trainees to obtain training and experience in working with older adults, but the programs differ in the types of training experiences offered as well as the opportunities to work with faculty who have a shared interest in working with older adults (Qualls et al. 2010).

Generalist Programs. Traditionally, options for training in professional geropsychology were limited to those provided within a generalist-training program. These training programs may have a few geropsychologists on faculty, or adjunct faculty, who provide mentorship to students with an expressed interest in geropsychology. These generalist-training programs may be driven by a mentorship model of admission in which trainees are recruited to work with a specific faculty member; thus, having an expressed interest in geropsychology at the time of program entry is beneficial. Alternatively, a generalist-training program may recruit strong applicants without an expressed interest in geropsychology and then incorporate work with older adults into the curriculum to promote the study of geropsychology. Generalist

programs may offer aging-focused coursework, such as Adult Development and Aging or Psychology and Aging. Other courses, such as Neuropsychology, Lifespan Development, and Cognitive Psychology, will include aging-relevant topics, though that is not the focus of those courses. Generalist programs may offer practicum experiences that specialize almost exclusively in older adults, such as a long-term care setting or a geriatric memory disorders clinic. If specialized practicum experiences such as these are not available, trainees are encouraged to tailor their practicum experiences to the older adult population whenever possible. For example, a trainee in a community-based mental health clinic may choose to focus on treating clients aged 65 or older or younger adults experiencing caregiver stress. Opportunities for research with older adults are also a possibility in generalist program, and trainees may be encouraged to choose an aging-related dissertation topic.

Specialist Geropsychology Programs. These programs offer formal training in geropsychology that is guided by the Pikes Peak competencies. While a generalist-training program may have one or two geropsychologists on faculty, programs with a formal geropsychology track have numerous faculty with expertise in aging that form a core of mentors for trainees in the track. Trainees are recruited specifically to the geropsychology track and matched to one of the core faculty mentors. Matching several students to geropsychology faculty at a given time provides the opportunity for a cohort of trainees that share similar professional interests (Qualls et al. 2010). As these programs follow the Pikes Peak model, courses are designed to provide trainees with the foundational knowledge, skills, and attitudes for the practice of professional geropsychology. Similarly, practicum experiences are selected to further develop competencies defined by the Pikes Peak model and provide opportunities for advanced training with older adults. Research in this track is aging specific, and trainees often conduct research with their faculty mentors, in

addition to their aging-focused dissertations. Whether a trainee chooses a generalist program or one with a specialty track in geropsychology, they should actively participate in clinical, research, and professional development activities throughout their graduate career so as to be most competitive for doctoral internships. In 2014, 20.2% of applicants did not match to an internship (Association of Psychology Postdoctoral and Internship Centers 2015). Successful applicants have broad clinical training experiences in treatment *and* assessment, a strong track record of publications and presentations at professional conferences, and participation in professional societies as student members or even student representatives. To achieve these benchmarks, trainees are encouraged to consult with their faculty mentors and seek out training opportunities early and often.

Doctoral Internships. Doctoral programs in clinical and counseling psychology require the completion of a yearlong internship prior to the awarding of the graduate degree. Doctoral internships represent an opportunity for advanced clinical training across a variety of settings including community-based clinics, university settings, private hospitals, academic medical centers, forensic facilities, and Veterans Affairs Medical Centers. Each of these settings has options for trainees to work with older adults as part of structured clinical rotations; thus, most trainees will complete internship having gained some experience working with older adults (American Psychological Association 2004). This infusion of older adults throughout clinical rotations reflects the growing number of older adults in healthcare systems that are receptive to mental health services (Karel et al. 2010b).

If training is viewed sequentially, geropsychology training at the internship level should build upon the competencies (i.e., attitudes, knowledge, and skills) that began in undergraduate training and were further developed in graduate school (Hinrichsen et al. 2010), a view that is consistent with the Pikes Peak model. Internship represents a unique opportunity for trainees to

work with older adults in new settings with greater independence, though while still under supervision of experienced providers. There is variability among internship training programs in terms of training model (e.g., scientist-practitioner, scholar-practitioner, clinical scholar) and structure of the training year. Trainees may work half time or full time on rotations that are 3, 6, or 12 months long. These advanced clinical experiences are augmented with regular didactics and the promotion of trainees' professional development through faculty mentorship.

While most internships offer options for work with older adults within clinical rotations, some internships have a specific geropsychology track within the larger training program. These track-specific programs offer clinical rotations that focus on older adults, such as community living centers or nursing homes, home-based primary care, and geriatric neuropsychology clinics, as well as possibilities for trainees to work in settings that are complementary to their geropsychology training, such as behavioral medicine or palliative care. Programs such as these may also have clinical-research rotations focused on aging-related issues, which may suit those interested in an academic or research career. Internships with a geropsychology track often have regular aging-focused didactics and case conferences with the geropsychology faculty.

Several factors may influence a geropsychology trainee's decision to apply to an internship program including number and type of clinical rotations, number of geropsychology faculty, availability of aging-related research, didactics offered, desire to pursue future board certification, location of internship and cost of living in the area, and a number of other personal factors. No matter which type of internship program is selected (i.e., generalist vs. track-based), trainees with an interest in aging can use the Pikes Peak competencies assessment tool to inform their selection of clinical rotations as well as provide a metric to evaluate their development in the competencies throughout their internship year.

As trainees begin their internships in the summer and fall, their thoughts invariably turn to the next step in their professional career, which for

many is a postdoctoral fellowship. Trainees who have completed geropsychology training at the internship level will be competitive for a geropsychology postdoctoral fellowship (Hinrichsen et al. 2010).

Postdoctoral Fellowships. The goal of postdoctoral fellowships is to prepare trainees for independent practice and provide the supervised experience necessary for licensure in most states. Over the past two decades, numerous geropsychology fellowships have been developed for those who desire clinical and research training in geropsychology at the fellowship level. Most APA-accredited geropsychology postdoctoral fellowships are based in VA hospitals that also have APA-approved internship programs. Thus, there is often a sharing of resources, similar clinical experiences, and the opportunity for continued mentorship with geropsychology faculty. Postdoctoral fellowships differ from internships in the increased autonomy of the fellow as well as an increased emphasis on professional development and leadership skills (Hinrichsen et al. 2010). Many clinical fellowships also provide some amount of protected time for the pursuit of clinically relevant research.

In addition to traditional clinical postdoctoral fellowships, there are growing numbers of APA-accredited postdoctoral fellowships with a focus on aging-related clinical research. Many of these clinical research fellowships are hybrids, for example, with 75% of time spent in clinically relevant research and 25% of a fellow's time spent in the delivery of direct clinical services. Fellowships such as these are essential to the field of geropsychology as they provide protected time for trainees to refine a programmatic line of research that will lead to independent funding, thus continuing the tradition of geropsychologists leading in aging-related research.

Continuing Education. Most psychologists that treat older adults are not specialized in geropsychology and may have not been exposed to training opportunities with older adults. Continuing Education coursework in aging is becoming more commonplace to address this need. For instance, there has been a workshop titled "What You Need To Know About Working With Older

Adults” continually offered at the past several American Psychological Association conventions, with a high turnout. There are several professional societies that focus on older adults who often take the lead in organizing workshops similar to these, including the Society of Clinical Geropsychology (APA Division 12, Section 2), APA Division 20 (Adult Development and Aging), Psychologists in Long-Term Care, the Gerontological Society of America (GSA), and the APA Committee on Aging. These workshops are available at national or state conferences or in webinars. Most states require continuing education for licensed psychologists, and psychologists can fulfill these requirements by obtaining continuing education coursework in professional geropsychology. Psychologists can seek particular workshops that meet their own training goals as suggested by the Pikes Peak Geropsychology Knowledge and Skill Assessment Tool. In Europe, geropsychologists can become involved with the Standing Committee on Geropsychology within the European Federation of Psychologists’ Associations. Countries within Europe also have national organizations, such as the Portuguese Psychogerontology Association (Ribeiro et al. 2010). In Australia, geropsychologists can find professional opportunities within the Psychology and Ageing Interest Group of the Australian Psychological Society, and in New Zealand, geropsychologists can find similar opportunities with the New Zealand Psychologists of Older People (Pachana 2015).

Board Certification in Geropsychology

The field of geropsychology reached a significant milestone in 2014, when it was granted board specialty status by the American Board of Professional Psychology (ABPP). Board certification demonstrates an expertise in a specialty area as determined by a series of peer evaluations by specialists in the field. This expertise is acquired through formal education and training in geropsychology as well as experience working with older adults. Interested applicants first complete the initial eligibility screening for

consideration by ABPP. Those applicants which pass this first level then must submit practice samples, which include a professional self-study statement and work examples, for peer review by those in the field. Finally, those who pass this second level of consideration are then approved to participate in an oral examination based partly on information in the practice sample. A complete listing of these requirements can be found on the ABPP website (www.abpp.org).

While board certification is not required for the practice of Clinical Geropsychology, it represents an important benchmark by which others can judge a professional’s expertise. As such, it is expected that more geropsychologists will seek out the training opportunities necessary for board certification in the field. During the development of the geropsychology board certification process, the intent of the American Board of Geropsychology (ABGERO) was to be as inclusive as possible. Thus, board certification should be possible for those with the essential education, training, and experience working with older adults.

Traumatic Brain Injury

Thomas J. Farrer

Department of Psychiatry and Behavioral Sciences, Duke University Medical Center, Durham, NC, USA

Synonyms

Acquired brain injury; Brain injury; Concussion

Introduction

Traumatic brain injury (TBI) constitutes a significant public health concern at all ages. Among older individuals, it is particularly problematic given the increased risk of mortality and morbidity in this age group. Understanding the impact of TBI on the aging brain is important, particularly given the increasing advancing age of the US population. Recent population-based data confirms that as age increases, patient disability, medical costs, and rates of hospitalization following

acquired brain injuries also increase (Chan et al. 2013). The following section of this *Encyclopedia* will provide a general discussion of TBI as it uniquely impacts older adults.

Definition

Traumatic brain injury can be defined as damage to the brain after insult from being struck by or against another object or following rapid deceleration. This might include such mechanisms as assaults or motor vehicle accidents (MVA). However, among older adults, falls constitute the most common mechanism of injury.

TBI severity is on a spectrum from mild to severe. Classification of severity is typically characterized by clinical state, as reflected by Glasgow Coma Scale (GCS) score, the presence or absence of post-traumatic amnesia (PTA), and degree of loss of consciousness (LOC). Briefly, the GCS is a scale that measures behavior following a head injury (i.e., spontaneous eye opening, verbalization, and motor behavior upon examination). The score ranges from 3 to 15 and lower scores indicate more severe injury. Classification of mild, moderate, and severe TBI is summarized in Table 1. The GCS is typically assigned at the scene of the injury by medical personnel. PTA and LOC are often documented as well to characterize injury severity. Patients often do not know the history of their GCS scores at injury and in recovery, but may be able to answer questions about PTA and LOC.

Most TBIs are classified as mild, especially among older adults who are more likely to experience a ground-level fall as the source of injury. There is a distinction in the literature between *complicated* and *uncomplicated* mild TBI (mTBI) based on day of injury brain imaging

(CT or MRI scan). Abnormality on imaging is classified as complicated, whereas a negative scan is uncomplicated. Outcomes are typically worse for complicated injuries compared to uncomplicated.

Pathophysiology

Understanding the pathophysiology of TBI among older adults begins with an appreciation of the natural morphological changes that occur as people age. Specifically, starting at the fourth decade of life, individuals begin to experience gradual cell death and cell morphological changes (Peters 2006), which leads to gradual volume reduction in the brain. This in turn results in reduced efficiency of neurotransmitter systems and synthesis of other brain chemicals important to cellular health and functioning. In addition, there are also substantial cerebrovascular changes that affect physiology and cognitive functioning via attenuated cerebral blood flow, reduced blood/oxygen delivery to brain parenchyma, and increased cerebrovascular burden. All of these changes to the brain occur naturally and account for some of the declines in cognition that occur with normal aging. These changes also result in a unique impact of TBI in the older adult brain and could account for worse outcomes for TBI in this age group.

Due to the nature of TBI, significant biomechanical force is placed on the tissue of the brain, which can impact the delicate cytoskeleton and long coursing axons of the neuron. Thus, brain parenchyma is susceptible to axonal injury from shearing and straining of the tissue. This disruption affects the ions of the cell and, therefore, the physiological functioning of the neuron (Bigler and Maxwell 2012). If injury is mild with minimal morphological change to the cell, the disrupted physiological functioning can normalize with no lasting consequence. However, more severe injuries will damage the cell and lead to loss of function and gradual degeneration of the cell (Maxwell 2013). In fact, traumatic axonal injury, or diffuse axonal injury, is the hallmark injury in TBI and has been documented in all injury severities (Bigler 2015). The effects of this type of

Traumatic Brain Injury, Table 1 Classification of TBI severity

Severity	GCS	PTA	LOC
Mild	13–15	<1 day	0–30 min
Moderate	9–12	1–7 days	30 min–24 hr
Severe	<9	>7 days	>24 hr

injury are also understood in terms of brain region vulnerability. Bigler (2007) illustrates that the frontal and temporal poles of the brain are differentially affected in TBI due to the position of the brain in the anterior and middle cranial fossa. These areas of greatest biomechanical force in TBI make surrounding white matter and adjacent networks more vulnerable following TBI, including the corona radiata and corpus callosum (Bigler 2015). TBI also has an impact on the vasculature of the brain and capillaries are especially delicate and vulnerable to injury following TBI. Injury to the microvasculature of the brain has a downstream effect of reduced glucose and oxygen delivery and, therefore, attenuated hemodynamic functioning (Bigler 2015).

Etiology and Epidemiology

The annual cost of TBI in the USA is approximately \$60 billion (\$45,000 per person) (Corrigan et al. 2010). Although relatively little is known about the cost of TBI among older adults, there are higher costs associated with increased complications and utilization in this age group. Specifically, age is associated with increased post-injury medical complications, with older adults having two times the incidence of seizure and urinary tract infection and three times the incidence of cardiopulmonary arrest. Older adults also have an increased length of stay (LOS) with an average of 5 additional days in acute rehabilitation relative to their younger counterparts and more in-hospital procedures (Frankel et al. 2006; Dams-O'Connor et al. 2013). TBI also has a significant long-term impact on functioning. Selassie et al. (2008) reported that 43% of TBI patients continued to have lifelong TBI-related disability. Increased age is associated with higher rates of discharge from acute care to a long-term care facility rather than home.

The etiology of TBI in the general adult populations includes falls (28%), MVA (20%), struck by/against an object (19%), assault (11%), others (13%), and unknown (9%) (Langlois et al. 2006). As noted above, falls are the most common cause of TBI for older adults (61% for

those ages 65+). Research on these mechanisms indicates that as age increases, TBI due to falls increases, while TBI due to MVA declines (Chan et al. 2013). General incidence rates of TBI in the USA are between 1.5 and 2 million new cases per year. Of the 1.4 million emergency room visits for TBI annually, approximately 140,000 constitute older adults age 65+ with a majority being age 75 and older (Coronado et al. 2013). Population data from 2002 to 2006 indicates almost 30% of TBI-related hospital admissions were from older adults age 65+ with a 20–25% increase in trauma center admissions for individuals age ≥ 75 years old (Dams-O'Connor et al. 2013). Chan et al. (2013) found a steady rate of increased hospitalization based on age. That is, for ages 65–74, 11% of patients are hospitalized while 50% are hospitalized for ages 75–84 and 63% for those age 85+. In the general population, the annual incidence of TBI-related mortality is approximately 51,000, 27% of which are older adults (Coronado et al. 2013). Mortality risk following TBI increases with hypotension, lower initial GCS scores, and age 85 and higher (Dams-O'Connor et al. 2013). There are several other factors that moderate the incidence and impact of TBI among the general population. Specifically, males are two times more likely to sustain a TBI than females (Frost et al. 2013). Regardless of age, alcohol increases the risk of TBI. Despite lower rates of drinking among older adults, blood alcohol levels are similar among younger adults and older adults who survive TBI (Frankel et al. 2006). Other epidemiology studies indicated that American Indian/Alaska Natives and African Americans sustained higher rates of TBI relative to other groups (Corrigan et al. 2010).

TBI outcomes are largely based on the severity of injury, lesion location, and the general health and comorbidities of the patient. Almost 43% of adult TBI patients will go on to have long-term disability, including changes to cognitive and emotional functioning, activities of daily living, and motor and sensory abilities. TBI also appears to increase the risk of other conditions, including dementia. For older adults in the workforce with TBI, disability status is related to age and gender. Selassie et al. (2008) demonstrated that older

cohorts age 65 and older are nearly four times more likely to have disability than younger individuals age 15–64 and that women are 10% more likely to suffer disability than men. Taken together, this suggests that women age 65 and older are most likely to have long-term disability following TBI. The rate of improvement is also slower post-injury for elders than it is for younger adults. Frankel et al. (2006) compared older adults ages 55–89 to adults age 16–44 and demonstrated that older adults with TBI have reduced cognitive independence and slower recovery of functioning during hospitalization.

Age also seems to impact long-term care and discharge planning for older adults. Older adults are more likely to be discharged to long-term care facilities rather than home (Chan et al. 2013). Similarly, older adults are less likely to discharge to community settings (81%) compared to younger adults with TBI (94%) (Frankel et al. 2006). Multiple factors impact discharge planning for this age group. First, greater length of stay (LOS) from the TBI-related hospitalization is associated with greater chance of discharge to long-term care. Next, the etiology of the injury is also related to discharge in that injuries related to falls suggest pre-existing functional changes, whereas injuries related to MVA suggest higher premorbid functioning. That is, patients who sustained injury due to falls are more likely to be released to long-term care facilities compared to injuries related to MVA. Females are also more likely to be released to long-term care rather than home, ostensibly because they often outlive their male partners and thus do not have a caregiver at home (Brown et al. 2012).

Diagnosis, Presentation, and Outcomes

A diagnosis of TBI is typically based on clinical variables, such as level of consciousness, which occurs on a continuum of coma, vegetative state, and minimally conscious state (Kwasnica et al. 2008), and imaging variables that reveal acute injury (e.g., hemorrhage/hematoma, skull fracture, and diffuse axonal injury). The severity of the injury is based on GCS, PTA, and LOC, as

discussed above. Educating the patient and family about the nature and severity of the injury is critical to setting realistic expectations for outcomes.

Given that older adults, by a function of age alone, are vulnerable to disorders of aging that affect cognition, it can be challenging for clinicians to differentiate new TBI-related symptoms from a latent degenerative process or whether cognitive decline from a dementia process is being exacerbated by a more recent injury. A careful history of premorbid cognitive and functional status will be essential to determine the time course and possible contributions to cognitive weaknesses.

In younger patients, TBI outcomes are often related to functional goals, such as a return to work or level of independence. Because many elders are retired or already dependent on others for care in some manner, functional outcomes after TBI will again have to consider social, medical, and psychiatric history prior to injury. Careful delineation of demographic variables such as age, education, occupational status, and history, combined with lesion location and size, medications and comorbidities, and substance use history are important when attempting to determine contributing factors and outcomes over time (Moretti et al. 2012). The clinical presentation of TBI is highly variable and is largely dependent on the mechanisms of injury and injury severity.

Neuropsychological Outcomes

The diffuse nature of axonal injury in TBI often affects the efficiency of network connectivity and results in slowed processing speed. As noted above, the differential impact to frontal and temporal pole regions can lead to focal neurocognitive changes. Briefly, those with orbital and medial frontal lesions often present with sharp changes to affect social/emotional functioning. More dorsolateral frontal lesions can result in changes in attention and executive functioning. Traumatic brain injury is also often associated with irritability and agitation (Flanagan et al. 2008). Individuals with parietal and right

hemisphere lesions may present with anosognosia or lack of awareness of their condition. Sensory and motor changes can occur with focal lesions to either hemisphere, and individuals with left hemisphere lesions may have aphasia or more subtle language changes such as dysnomia, inefficient repetition, or semantic retrieval. Regardless of the injury, acute presentation often results in changes in mental status and reduced decision-making capacity. Patients may also present with hemiparesis, decreased tone, and/or weakness, which can affect critical placement and supervision planning post-discharge. Mental status and PTA can also fluctuate dramatically in the acute stage of injury and stabilize and resolve in part over time. Noncognitive mediator variables such as fatigue, pain, medications, and rehabilitation demands should also be considered in monitoring cognitive and functional outcomes.

As noted briefly above, there is compelling evidence that TBI increases the risk of dementia in elders. Recent research shows that a history of TBI increases the risk of early-onset Alzheimer's disease (Mendez et al. 2015). TBI increases the susceptibility of the brain and may accelerate the onset of dementia (Moretti et al. 2012). In a large study of 164,661 TBI patients, the rate of new dementia diagnosis and age of diagnosis were compared between a TBI group and an orthopedic injury (OI) control group. Here, adults were age 55 or older at baseline and follow-up was done at least one year post-injury. Overall, those with TBI were more likely to have a diagnosis of dementia at follow-up and were more likely to receive a diagnosis at an earlier age of onset relative to the OI controls (Gardner et al. 2014). Also, the severity of injury predicted age of onset with moderate to severe injuries having an earlier impact than mild injuries. In a follow-up study, this same research group found that TBI also increases the risk of Parkinson's disease (PD) and that moderate to severe injuries had increased risk relative to mild injuries and that as the number of injuries increases, so does the risk of PD (Gardner et al. 2015).

In summary, TBI among older adults is unique in terms of etiology, epidemiology, pathophysiology, and impact. Older adults are at an increased

risk of TBI from falls and have a greater risk of long-term physical and cognitive disability and increased risk of dementia following TBI. Given our aging population, additional research is warranted to establish sound risk and prevention measures, as well as evidence-based treatments to manage the sequelae of TBI.

Synonyms

Binswanger's disease; Multi-infarct dementia; Poststroke dementia; Vascular dementia; Vascular cognitive dysfunction; Vascular cognitive impairment; Vascular neurocognitive disorder

Definition

As indicated by the number of synonyms, the definition of vascular dementia (VaD) is yet to be agreed across the world. There are two main issues: first, whether dementia is an appropriate term to capture the state that arises due to cognitive decline and, second, the delimiting of the degree or type of vascular disease that can be said to be causally linked to this state. There is a third, subsidiary issue, and that is whether the definition is being made for the purpose of the rigorous nature of research or the less exacting

requirements of clinical practice. At present, there are three main definitions: (1) the NINDS-AIREN criteria (Roman et al. 1993) for vascular dementia, usually applied in research; (2) the DSM-V criteria (American Psychiatric Association 2013) for vascular neurocognitive disorder, mainly used in the USA; and (3) the ICD-10 criteria for vascular dementia, mainly used in Europe (the WHO is due to release the ICD-11 coding taxonomy in 2018).

The NINDS-AIREN criteria (Roman et al. 1993) comprise three elements. First, there has to be dementia which is defined by decline in memory and *two* other domains of cognitive function to an extent that this interferes with activities of daily living which cannot be attributed to physical impairments (e.g., secondary to stroke). Second, cerebrovascular disease must be present, defined by specific deficits on neurological examination *and* evidence of related vascular insults (infarcts, white matter hyperintensities (WMHs)) on neuroimaging. Third, dementia and cerebrovascular disease must be causally related as inferred by cognitive decline within 3 months of a stroke, abrupt deterioration in cognitive functions, or a stepwise fluctuating course of cognitive decline. The diagnosis requires the exclusion of delirium, severe aphasia, psychosis, or other significant diseases of the brain. The diagnosis is supported by features of early gait disturbance (small steps, Parkinsonian gait), unsteadiness and falls, urinary frequency not associated with urological disorders, pseudobulbar palsy, and

changes in personality or mood (abulia, depression, emotional incontinence). A diagnosis of possible vascular dementia can be made when the clinical features are not supported by neuroimaging evidence, or where a clear temporal relationship with a cerebrovascular event is absent, or the course is of gradual onset and progression but cerebrovascular disease is present. A definite diagnosis can only be confirmed by histopathological examination of brain tissue. The criteria advise against making a diagnosis of mixed dementia when features of vascular dementia occur in the context of Alzheimer's disease (AD), but instead suggest labeling this as Alzheimer's disease with cerebrovascular disease.

The DSM-V criteria (American Psychiatric Association 2013) abandon the term dementia and instead use the term neurocognitive disorder. Neurocognitive disorders can be considered as major or mild. A diagnosis of a major neurocognitive disorder requires cognitive decline to a degree that it interferes with activities of daily living and is not due to delirium or some other brain disorder. In contrast to previous definitions, this can occur if only a single cognitive domain is affected, that is, the historic requirement of "global" cognitive decline required for a diagnosis of dementia is abandoned. By contrast, mild neurocognitive disorders are associated with moderate cognitive decline that does not affect activities of daily living. An example of this would be what was previously termed amnesic mild cognitive impairment. If formal psychometric testing is undertaken, major neurocognitive disorders are those where test scores fall below the third centile or two standard deviations below the population mean. Scores for mild neurocognitive disorders fall between the third and sixteenth centiles, that is, less than one standard deviation below the population mean, but not less than two standard deviations below the population means. However, adjustment may be needed for the effects of premorbid IQ (Rentz et al. 2004; Starr and Lonie 2008), and also the correlation between the degree of cognitive deficit and the impact on activities of daily living is not absolute (Burton et al. 2009).

Moreover, the domains DSM-V considers with regard to psychometric testing are complex attention, executive function, learning and memory, language, perceptual motor, and social cognition. The first five are captured as domains within the commonly used Addenbrooke's Cognitive Examination (and its revised versions) (Mathuranath et al. 2000; Mioshi et al. 2006; Hsieh et al. 2013). DSM-V also allows classification of neurocognitive disorders with or without behavioral disturbance and in terms of severity (mild where instrumental activities of daily living are preserved, moderate where basic activities of daily living are affected, severe where the person is fully dependent). For a diagnosis of vascular neurocognitive disorder, a vascular etiology must be inferred from a temporal relationship of onset to a cerebrovascular event or decline affects mainly complex attention or fronto-executive function. There must be evidence for cerebrovascular disease from history *or* clinical examination *or* neuroimaging that could explain the cognitive deficits. Probable vascular neurocognitive disorder may be diagnosed if one of the three conditions is present: (1) neuroimaging evidence of significant parenchymal injury, (2) temporal relationship of cognitive deficit to a cerebrovascular event, or (3) clinical and genetic evidence for cerebrovascular disease. Possible vascular neurocognitive disorder can be diagnosed with the above criteria in the absence of evidence from neuroimaging and/or temporal relationship. To diagnose vascular neurocognitive disorder with behavioral disturbance, there may be delusions or hallucinations or changes in other behavioral domains of (1) negative emotion (anxiety, depression, anger), (2) detachment (social withdrawal), (3) disinhibition (impulsivity, dangerous risk taking, agitation), and (4) antagonism (disrespectful, irresponsible, violent).

ICD-10 criteria (World Health Organization 1993) state that vascular dementia is the result of infarction of the brain due to vascular disease, including hypertensive cerebrovascular disease. The infarcts are usually small but cumulative in their effect. Onset is usually in later life. There are four possible diagnostic codes:

Vascular and Mixed Dementia, Table 1 Key differences between the main diagnostic criteria for vascular dementia and its equivalent

	NINDS-AIREN	DSM-V	ICD-10
Cognition	Memory plus two other domains	One domain, memory decline uncharacteristic	Memory plus one domain. Memory decline characteristic
Daily activities	Affected to any degree not due to physical impairments	May only affect instrumental activities. Impact of physical deficits not considered	Defined in terms of impact on social behavior
Behavioral and psychological symptoms	Abulia, emotional incontinence, depression supportive of diagnosis but not necessary	Separate classification if negative emotion, detachment, disinhibition, or antagonism present	Decline in emotional control or motivation or social behavior essential to diagnosis
Neuroimaging	Essential evidence of cerebrovascular disease	Evidence of cerebrovascular disease not essential for diagnosis	Infarcts or foci of destruction essential

- F01.0 Vascular dementia of acute onset usually develops rapidly after a succession of strokes from cerebrovascular thrombosis, embolism, or hemorrhage. In rare cases, a single large infarction may be the cause.
- F01.1 Multi-infarct dementia is largely cortical, gradual in onset, following a number of transient ischemic episodes which produce an accumulation of infarcts in the cerebral parenchyma.
- F01.2 Subcortical vascular dementia includes cases with a history of hypertension and foci of ischemic destruction in the deep white matter of the cerebral hemispheres. The cerebral cortex is usually preserved.
- F01.3 Mixed cortical and subcortical vascular dementia is a mixture of F01.2 with either F01.0 or F01.1.

Codes F01.8 and F01.9 are reserved for rarer or unspecified causes. For an ICD-10 diagnosis of dementia to be made, there must be evidence of decline over at least 6 months in both verbal and nonverbal memory together with deficit in at least one other cognitive domain. In addition there must be decline in emotional control or motivation, or a change in social behavior, manifest as at least one of the following: emotional lability, irritability, apathy, or coarsening of social behavior. ICD-10 dementia can be further coded as mild, moderate, or severe and additional features of delusions, hallucinations, and depression can be appended.

Table 1 summarizes key differences between these criteria. It can be appreciated that DSM-V diagnosis of a vascular neurocognitive disorder is the most encompassing, whereas NINDS-AIREN is strictest in terms of cognitive features and ICD-10 in terms of behavioral and psychological symptoms.

Mixed dementia, which is criticized in the NINDS-AIREN criteria, relates to a state where both Alzheimer’s disease (AD) and vascular dementia (VaD) clinical features and/or pathology is present. ICD-10 does not have a specific classification for mixed dementia, but does have code F03 for unspecified dementia where it is not possible to determine a single dementia etiology. Similarly, there is no specific category in DSM-V.

Implications arising from the definition

The major differences in how vascular dementia is defined raise serious challenges for clinicians and researchers. For example, the epidemiology varies depending on the diagnostic criteria applied. Similarly, the effects of interventions in the condition are difficult to generalize from samples diagnosed with one set of criteria to populations diagnosed by another set. Indeed, DSM-V is so recent that few studies have drawn on these criteria as yet, so knowing how many people are affected by a major vascular neurocognitive disorder is problematic let alone extrapolating findings from previous

studies of vascular dementia to decide on appropriate treatments. It is hardly surprising, then, that vascular dementia is relatively under-researched compared with Alzheimer's disease. If the situation is fraught for VaD, how much more so for so-called mixed dementia where a widely agreed set of diagnostic criteria is entirely lacking. Yet, as populations age, this may, in fact, emerge as the commonest form of dementia encountered in clinical practice.

Vascular Contributions to Alzheimer's Disease

Conventionally, Alzheimer's disease is considered to be a neurodegenerative disorder, typified by the presence of senile amyloid plaques and tau containing neurofibrillary tangles in the brain. Diagnostic criteria for AD usually exclude this diagnosis in the presence of significant vascular disease (e.g., a large infarct) on neuroimaging. Nevertheless, the same vascular risk factors that increase risk of VaD – hypertension, diabetes, etc. – also, in midlife, increase the risk of AD. The mechanisms for this remain unclear. Careful neuropathological examination, however, suggests one likely pathway. In the Religious Orders Study (Bennett et al. 2012) set in the USA, AD was more likely to be diagnosed in the presence of cerebral infarcts. Similar findings emerged from the UK-based MRC-CFAS study (Neuropathology Group 2001). Thus, in many cases where AD has been diagnosed clinically, there is, in fact, a mixture of AD and vascular pathology which might be termed a “mixed AD-VaD” dementia. The MRC-CFAS data indicate that white matter hyperintensities (WMHs) on MRI are more common in AD than normal controls, though it is unclear to what extent this indicates cerebral ischemia (Gouw et al. 2008).

The Blood–Brain Barrier and Vascular Dementia

One mechanism proposed by the MRC-CFAS investigators to explain increased WMH in AD

is increased blood–brain barrier (BBB) permeability accompanied by microglial activation. A subsequent study (Viggars et al. 2011) confirmed neuropathological changes to the BBB occurred early in AD and was associated with disease progression. BBB dysfunction is also associated with lacunar infarcts and WMHs where conventional vascular risk factors are less important than they are in large cortical infarction and is therefore proposed as underpinning a different end of the spectrum of VaD (Wardlaw et al. 2003). The key change in the BBB is the loss of tight junctions between endothelial cells. This allows increased passive permeability of water and various ions, but, probably more importantly, the tight junctions serve to ensure the polarity of transport of moieties across the cell. Transporter proteins and ion channels set in the cell's semipermeable membrane are free to move, but the tight junctions act as a barrier to this movement. Hence, a transporter such as the glucose transporter type 1 (GLUT1) will be oriented to transport glucose from outside the cell to inside the cell where the cell membrane is in contact with blood, but from the inside of the cell out to the interstitial fluid on the brain side. With the loss of tight junctions, the transporter is free to float and may end up in the opposite position so that glucose is being transported across the cell in the wrong direction. There is evidence that BBB dysfunction is associated with aging (Starr et al. 2009) and so may, in part, explain why VaD (and other dementia) is more common as people grow older.

Cognitive Decline Poststroke

Having postulated that there is a spectrum of different mechanisms ranging across cortical and subcortical stroke, it is informative to consider whether there are differences in neuropsychological deficits depending on whether infarcts are cortical or subcortical. This is especially germane given that DSM-V criteria would define all poststroke cognitive decline as a vascular neurocognitive disorder, whether mild or major. It should be noted that brief cognitive screening

instruments, such as the Mini-Mental State Examination, do not perform well in the acute phase of a stroke. Fortunately, indirect cognitive assessments such as the Informant Questionnaire on Cognitive Decline in the Elderly (IQCODE) (Jorm 1994), which contains items on both cognitive and activities of daily living performance, correlate well with more detailed directly administered psychometric tests (Starr et al. 2000). Around one-third of people who have a stroke will have persistent cognitive impairment whether the stroke is cortical or lacunar (Leys et al. 2005). Cognitive impairment is common after lacunar strokes, despite the lesions being small, suggesting that the impairment may be more pronounced due to small vessel disease (Makin et al. 2013). Subcortical lesions are typically associated with deficits in information processing speed and executive function. By contrast, cortical lesions may have a more discrete profile of deficits depending on the region affected (e.g., posterior cortical strokes have increased risk of visuospatial decline). However, such distinctions are not always easy since WMHs commonly coexist with cortical infarcts and cognitive decline not infrequently precedes and even predicts stroke. The clinical implications are that a tailored approach is required for communicating with people who have experienced poststroke cognitive decline and, by extension, vascular dementia. For example, people who have had cortical infarcts affecting the left middle cerebral artery territory may have particular difficulties with language, which will be fairly easy to pick up with cognitive assessments in everyday use, but those with right hemisphere infarcts may not have such pronounced language deficits, but may be more impaired in terms of visuospatial abilities (Annoni et al. 2003). It is likely that most patients will have a degree of information processing slowing affecting attentional abilities, hence the need to provide information more slowly and in smaller packages. It also follows that strategies that prevent the risk of stroke will also prevent a fair proportion of VaD, although interventions that ameliorate the deterioration of the BBB with age are as yet unclear.

Treatment of Vascular Dementia

Although primary prevention by the control of risk factors is the most effective strategy, in terms of the population, many people who develop vascular dementia do not have a high-risk profile in terms of high blood pressure, poorly controlled diabetes, etc. There is evidence that a life-course approach may be beneficial since childhood IQ predicts VaD in later life (McGurn et al. 2008). Treatments of established VaD can be divided into non-pharmacological and pharmacological. Non-pharmacological therapies are not really differentiated from those used in AD or other dementias aiming to support the person to live well: probably, given the nature of cognitive deficits in VaD, reminiscence therapies are less appropriate than in amnesic disorders such as AD. As the disease progresses, this differentiated therapeutic approach is more applicable; for example, therapeutic interventions to ameliorate severe distress whether from physical, mental, or existential causes. There are occasional studies that suggest acupuncture and some forms of Chinese medicine may be effective in improving VaD symptoms (Jianchun Yu et al. 2006), and transcranial magnetic stimulation also appears promising, but as yet no large studies have been performed (Rektorova et al. 2005; Wang et al. 2010).

Pharmacological approaches can, themselves, be divided into those that aim at secondary prevention (e.g., of further strokes) by vascular risk factor control and those that seek to improve cognitive function and activities of daily living. There is a further, hopefully less used, category of drugs used to ameliorate distress due to agitation. With these are antidepressants since depression is relatively common in VaD. Drugs commonly used in AD, cholinesterase inhibitors and memantine, are less effective in VaD and are generally not licensed for use in this condition. One small trial combined nimodipine and acupuncture claimed some therapeutic benefit (Peng et al. 2007; Zhong et al. 2009). All in all, however, given how common VaD is, especially when combined with AD, therapeutic options are lacking.

One difficulty with therapeutic advances for VaD is a suitable animal model. Models based on large infarcts, such as the stroke-prone spontaneously hypertensive rat, do not capture the subcortical pathology that underpins much of VaD. With regard to large infarcts, much is already transferable from human stroke studies. However, hypoperfusion models have recently become available based on partially occluding a carotid artery which induce WMHs (Holland et al. 2011) and which disrupt axon–glial integrity and induce deficits in spatial working and reference memory tasks. Such models are probably better suited to investigate alternative pathways to VaD in humans and to test potential interventions.

In contrast to treatments aimed at improving or alleviating mental symptoms of VaD, treatment of physical aspects is more developed. In particular, impaired mobility, balance, and urinary continence are often features fairly early on in the course of VaD reflecting white matter damage and thus disconnection within the central nervous system. A patient with VaD, therefore, should have a careful assessment to detect, and hopefully correct, any risk factors for falls beyond those directly due to brain disease. These will include visual impairment, peripheral sensory deficits, orthostatic hypotension, inappropriate footwear, environmental hazards (poor lighting as well as physical obstacles), sarcopenia, joint deformities, etc. A simple test of mobility, such as a Timed Up and Go test, can be a good predictor of falls risk (Gunter et al. 2000; Shumway-Cook et al. 2000). If falls risk is high, consequences of falls should be considered such as the ability to call for help (alarm systems, remote falls monitoring systems, etc.) and likelihood of fractures (consider osteoporosis treatment perhaps measuring vitamin D and a DEXA scan). Urinary incontinence is common in all types of dementia and, again, noncentral nervous system factors should be evaluated. There is commonly a mixed picture of urge and stress incontinence in older women, especially those that have had children, and in older men prostatic disorders are highly prevalent. People with diabetes are at higher risk of VaD and may have urinary incontinence due to poor

glycemic control and autonomic neuropathy leading to incomplete bladder emptying. A protocolled continence assessment may make a major difference to quality of life. In short, the assessment of VaD should usually include a more holistic assessment of common age-associated conditions. A holistic assessment can be undertaken through a comprehensive geriatric assessment (CGA) (Ellis et al. 2011).

Concluding Remarks

This entry discusses the complexity of vascular dementia including the terminology, the varying differences in the diagnostic criteria, and the impact of the degree or type of vascular disease on dementia.

In summary, the reason for defining vascular dementia differs in the context of whether it is for research or clinical practice, as well as in different locations worldwide. This has implications when translating different definitions between the three criteria and in different contexts. DSM-V is the most encompassing criteria; NINDS-AIREN is the strictest in terms of cognitive features; and ICD-10 focuses on behavioral and psychological symptoms.

There is a spectrum of vascular disease. Much is still to be known about how vascular disease impacts on the risk of subsequent vascular dementia. Certain characteristics such as vascular changes are more common in AD than normal controls which again makes understanding the vascular etiology in vascular dementia complex. Often is it difficult to determine a temporal relationship between vascular etiology and cognitive functional decline.

Depending on the diagnostic criteria used, vascular dementia may impact on one activity of daily living or a global impact on an individual's function. This is important when considering the person and the impact that vascular dementia may have on their day-to-day life as the level of cognitive functional deficit and impact on ADLs is not absolute. Indeed, there are a number of factors other than cognition affected in vascular dementia. Therefore, there is a need for a holistic

approach to care in the management of vascular dementia which can be best achieved through a comprehensive geriatric assessment.

Future Challenges

Dementia remains a major public health concern both now and for the future. To date there has been limited research undertaken in the field of dementia and particularly so within the domain of vascular dementia.

There is an urgent need to know more about worldwide dementia epidemiology to help with planning service provision and health policy and understand the disease trajectory. The difficulty in terms of classification poses a challenge for this. Currently, this is more pronounced due to the inability to compare worldwide changing rates if different classifications are used.

Therefore, the way in which vascular dementia is defined poses future challenges both in research and clinical practice. Cognitive functional decline is often a spectrum of disease and not always easily categorized. For instance, the term “mixed dementia” (mixed AD-VaD dementia) is very common clinically but currently limited by the classification within the three criteria used. This poses a further future challenge. As the worldwide population ages, this may be the future commonest form of dementia encountered in clinical practice. Future studies, if diagnostic criteria for this are tightened, will be difficult to relate to earlier work when this diagnosis was not concrete in any of the three criteria. Likewise, any effects from future interventions will be difficult to generalize from one population to another if different criteria are used.

These are the current and future challenges within this field of dementia.

Vision Loss

Bonnie Adele Sturrock, Marian Saeed and Gwyneth Rees

Department of Surgery, Centre for Eye Research Australia, Royal Victorian Eye and Ear Hospital, Ophthalmology, University of Melbourne, Melbourne, VIC, Australia

Synonyms

Age-related vision loss; Blindness; Eyesight impaired; Low vision; Sightlessness; Vision impairment

Definition

Vision loss is a deterioration of eyesight or decreased ability to see as distinct from premorbid or normed visual acuity.

Introduction

Vision loss is a leading cause of disability in older adults, and the prevalence of vision impairment

increases steadily with age. In fact, 285 million people worldwide are visually impaired with 65% of these people aged 50 or over (WHO 2010). While some forms of vision loss are caused by a biological predisposition to disease and may arise early in development, the most frequent causes of vision impairment are age-related eye diseases. Vision loss in older adults is the combination of normal age-related vision changes alongside diseases related to the eye and other systemic causes (Chou et al. 2009). Although 80% of vision impairment is preventable and/or curable, age-related eye disease can often go undetected due to the slow progression and asymptomatic nature of some conditions (Chou et al. 2009). Early detection and treatment for eye disease in older adults are crucial to avoid the detrimental impact of vision loss on quality of life (QoL).

Vision impairment can result in changes (over and above changes due to aging) to physical mobility (e.g., going to the shops), independence (e.g., driving), and accessing information (e.g., reading, watching TV), as well as a burdensome psychological impact made up of increased dependence and poorer QoL and mental health outcomes (Chou et al. 2009; Van Der Aa et al. 2015; Sturrock et al. 2015). Research shows the prevalence of depression to be double in aging persons with vision impairment when compared to matched samples of those without vision loss (Van Der Aa et al. 2015). Unfortunately, poor emotional well-being and mental health problems are often not recognized in this population (Dreer et al. 2008). This has led to recommendations that effective psychological screening measures are needed to bridge the gap and help identify mental health problems and lead the way to access to adequate support (National Institute for Clinical Excellence (NICE) 2009). However, research has identified various barriers to the provision of accessible psychological support for older people with vision impairment, and new models of care are urgently needed.

This entry will provide an overview of (1) age-related vision loss, its main causes, and prevalence; (2) the impact of vision impairment on physical and psychological functioning in older adults; (3) older adults' adaptation to vision

loss; (4) depression and anxiety in older people with vision impairment; and (5) current and novel approaches to the management of the psychosocial impact of vision impairment in older people.

Understanding Vision Impairment, Its Main Causes, and Prevalence

Visual acuity or the ability to see central fine detail is most commonly measured via the Snellen eye chart or LogMAR chart which examines the ability of the person to identify letters of differing sizes typically from a distance of 6 m or 20 ft (in the USA). Visual acuity is recorded in a fraction with the top number representing the testing distance and the bottom number representing the smallest line read on the chart by the person. For example, a person with 6/6 (20/20) or "normal" vision can see what a normal person can see at a distance of 6 m (or 20 ft). The *International Statistical Classification of Diseases and Related Health Problems – 10th Edition* (WHO 2003) – lists five categories of severity for vision impairment: (1) $<6/18$ to $\geq 6/60$, (2) $<6/60$ to $\geq 3/60$, (3) $<3/60$ to $\geq 1/60$, (4) $<1/60$ to light perception, and (5) no light perception. The former two categories are colloquial terms for moderate and severe vision impairment, respectively, and the latter three are labeled "blindness." "Low vision" is also a widely used term referring to visual acuity of $\leq 6/12$ and/or visual field loss of less than 10° from fixation that cannot be corrected with prescription lenses or ophthalmic treatment. A person's visual field is the area that they can see when the eyes are focused in one direction. Visual field loss can occur independently to visual acuity loss, meaning that a person may have good central vision but still have a reduced field of vision and therefore be deemed to have low vision or blindness because of this. Results from a visual field assessment help localize or define where in the visual pathway the vision impairment arises. For example, a lesion or pathology at the occipital cortex of the brain may result in whole right or left side blindness of the visual field (i.e., a hemianopia).

Globally, there are three main causes of vision impairment in older adults; age-related macular degeneration (AMD), glaucoma, and cataract. AMD is the chief cause of blindness in developed countries and the third leading cause of blindness worldwide. AMD results in central vision loss as it affects the macula area in the retina, which is the region responsible for fine detailed vision such as reading and recognizing faces. There are two types of AMD; dry and wet. Dry AMD is the most common form causing a gradual loss of central vision, while wet AMD causes more sudden and obvious central vision loss. Symptoms of AMD are distortion of central vision, blind spots, and loss of clarity and color vision. Approximately 5% of people between the ages 60 and 64 have early signs of the disease, and the prevalence of severe AMD doubles every 10 years after age 60.

Glaucoma is the second most common eye disease that causes vision impairment in older adults in both developed and developing countries. Glaucoma typically occurs when increased pressure in the eye causes damage to the optic nerve, although it can also present without increased eye pressure. The damage to the optic nerve results in visual field or side vision loss. The prevalence of glaucoma is approximately 2% in those aged 70–74, with the rate increasing to 6% of people aged 80 years and older. Due to the asymptomatic nature of glaucoma, a person may be unaware that they have it until they have lost peripheral vision, resulting in the prevalence of glaucoma being underreported.

Cataract is also a main cause of vision impairment in older adults and occurs due to clouding of the eye's clear lens. It is a progressive eye condition that hinders the eye's ability to focus images clearly. Vision with a cataract is often described as looking through a dirty window, and symptoms include blurred vision and light sensitivity. As cataracts are mainly related to the aging process, the prevalence increases from 9% of those aged 50–59 to over 70% of people aged above 80. Spectacle correction may be used in the early stages of cataract to improve vision; however, at the later stages, surgical intervention is required to improve vision. Due to the advances in surgical

techniques and accessibility of cataract surgical services, the rate of vision impairment due to cataracts in developed countries is significantly lower than the rate in developing countries. For example, according to the World Health Organization, 50% of blindness in Africa is a result of cataract as opposed to 5% in the USA and Australia.

Because the taxonomy uses best-corrected visual acuity (i.e., with prescription lenses), worldwide prevalence estimates of vision impairment are likely to be underestimated as they do not currently include those caused by uncorrected refractive error (i.e., without prescription lenses) (Dandona and Dandona 2006). In fact, uncorrected refractive errors, such as astigmatism and myopia, are the leading causes of vision impairment in the general population (Dandona and Dandona 2006), followed by unoperated cataract and glaucoma. Thus, epidemiological figures have been disputed based on out-of-date recommendations of visual acuity assessment and the variation of visual impairment classification currently listed in the nosology (Dandona and Dandona 2006). With increased life expectancy and increased population of older adults in many countries, it is expected that the risk of visual impairment due to these eye diseases will increase substantially in the coming decades. Currently, vision impairment is still a leading cause of disability in older adults and a global health problem. Worldwide estimates of low vision are currently at 246 million people (in addition to 39 million who are blind) with 82% of individuals with blindness being aged 50 years or over. The incidence of severe vision impairment has been found at 20% of those aged 65 and above, with the prevalence of severe vision impairment increasing to one in four people aged 75 years and older (Wahl 2013).

Physical and Psychological Functioning in Age-Related Vision Loss

Aging, like any transition to a different phase of life, can be accompanied by profound change and uncertainty that affects well-being. Importantly, most change in older adulthood is permanent in nature. Older individuals start to increasingly

suffer from physical symptoms and chronic and systemic disease and, therefore, become more dependent on others and also face increasing loss in other forms (e.g., the death of a spouse). In fact, many older adults report decreasing QoL as a result of the aging process. Age-related QoL has been reported to rely on four key determinants: (1) aged persons' demands for specific guarantees, (2) aspirations and expectations for future QoL, (3) fears and anxieties, and (4) external factors presenting a threat to QoL (Fry 2000). In contrast to any stereotypes of older people being vulnerable, one qualitative study showed that aged persons clearly demand autonomy and independence in making decisions, including the decision to terminate life (Fry 2000).

Functional change in older adults is significantly compounded when they experience vision loss. Vision loss can make it more difficult for older adults to take care of their physical health, such as getting to the doctors, identifying poor health (e.g., blood glucose levels), and reading labels on prescriptions. Over and above natural aging, older people with vision impairment can have reduced autonomy and be confronted with immediate or progressive loss of independence in performing certain household tasks, leisure activities, driving a car, employment, or seeing family and friends. Such loss can raise feelings of grief in addition to feelings of sadness, anger, frustration, fear, or guilt related to day-to-day activities. This can often result in further reduced QoL (i.e., on top of health-related aging QoL) and significant psychological distress. Many individuals with vision impairment experience distress specifically related to their vision loss (i.e., "vision-specific distress") including embarrassment, frustration, isolation, sadness, worry, and feeling like a burden because of vision loss.

Because of the varying impact of vision loss across a range of areas of life, there has been a strong focus on the development and use of tools to assess QoL specifically in people with vision loss or with particular eye diseases. QoL is a multidimensional concept, and measures have been developed that capture the impact of vision loss and eye disease on physical, functional, emotional, and social well-being. Vision-related QoL

(VRQoL) is the global effect of vision impairment on emotional well-being, interpersonal relationships, and independence in functional activities. The development of these tools has highlighted the range of areas of life that are affected by vision impairment, including everyday tasks, accessing information, mobility, independence, ocular symptoms, treatment concerns, uncomfortable feelings (e.g., anger, frustration), social relationships, and communication. The tools have also assisted to identify determinants to psychological functioning in vision loss.

Significant determinants of poorer VRQoL found in the literature have included sociodemographic factors (e.g., gender, educational level), clinical factors (e.g., poor health, severity of eye disease and vision loss), and psychosocial factors (e.g., quality of social support and coping strategies). Naturally, there is a complex interplay between distress, QoL, and depressive symptoms in vision loss, and for a proportion of people, vision loss does *not* result in persistent distress or lead to deteriorating mental health outcomes. The type and degree of functional and psychological impairment vary, even in those individuals with comparable diagnoses. Also, severity of vision impairment does not adequately explain the effects of ophthalmologic disease on emotional well-being and functioning (Sturrock et al. 2015).

Adaptation to Vision Loss

There is much variation in the way individuals adapt to vision loss (Sturrock et al. 2015; Dreer et al. 2008). Older adults may identify with the following psychological stages (Kuhner 2003):

1. *Lack of acceptance, uncertainty, and avoidance* – when a person has been informed of their diagnosis and is or is not attempting to determine the seriousness and extent of their physical impairment. Some people may initially deny their vision loss as a form of natural protection or defense. A person may hold the belief that problems associated with their vision loss are out of their control, are unsolvable, and are to be avoided at all costs.

2. *Acknowledgment of disruption and helplessness* – when the individual has come to a clear understanding that their vision loss is a serious limitation to day-to-day functioning. When this realization is made, some people may feel as if they are experiencing a crisis characterized by intense feelings of stress and dependence on others. They may also report feeling as if their condition controls their life and experience a great deal of pain, sorrow, sadness, and anger in relation to their vision impairment.
3. *Recovery of self-image and coming to terms with vision loss* – when the person acknowledges disruption caused by vision loss and makes various attempts to deal with the new situation, which can also be accompanied by strong emotions. Recovery can be in the form of beginning to adaptively cope with the controllable aspects of vision loss, for example, seeking social support, engaging in vision rehabilitation, or using problem-solving skills.
4. *Restoration of well-being and acceptance* – when the individual has acknowledged their vision loss, commenced using adaptive coping strategies, and begins to make room for painful emotions and thoughts that arise as a result of impairment.

With the aforementioned stages in mind, psychological functioning in vision loss can be impacted by the way the person views themselves in relation to their disability (Kuhner 2003). Because a person's self-worth or identity is partially related to specific roles and skills, such as being useful, being independent, and working toward achieving particular goals, it is likely that people who experience vision loss need to adjust to a new sense of the self. This sense of self is adjusted because the person begins to acknowledge that some of the things they could previously do are now not achievable and that they may need to rely on others to accomplish tasks. A challenge for people with vision loss is to derive self-worth and identity less on what they *do* and more on who they *are*; they are *not* their impairment. People with vision loss have their own personality, knowledge, skills, and goals and can still contribute, just as others without vision loss contribute in

various ways. While some life goals and future outlook may need to be adjusted, a person with vision loss can still rely on their values to guide them in living well.

Older adults with vision loss can still lead a meaningful life and experience satisfaction and happiness. Coming to terms with vision loss is a personal process, and sometimes people will oscillate between accepting their loss and fighting against it. Older adults who experience a gradual deterioration in vision, such as with AMD, may be more likely to experience ongoing loss. Nevertheless, because of their past experiences with loss, they may also become better equipped to deal with it as it occurs. It takes time to adjust to vision loss, and the duration is different for everyone.

The scientific literature has identified specific psychosocial factors that contribute to adaptation to vision impairment. For example, studies have found that adaptive coping strategies (such as using social support and assistive aids) predict better adjustment to vision impairment in adults (>age 18 years) (Senra et al. 2014), whereas avoidant coping has been associated with decline in VRQoL in older adults (mean age = 70 years) (Sturrock et al. 2015). The manner in which people think about their impairment is also important. For example, research has demonstrated that improved psychological adaptation to vision loss is associated with greater acceptance or tolerance of vision impairment, and poorer psychological outcomes in chronic health conditions are related to increased helplessness or perceived interference of symptoms in older individuals (mean age = 71 years) (Dreer et al. 2008). Another study exploring readiness for low-vision interventions, to assist adaptation to vision loss in older adults, demonstrated that the desire to maintain or regain independence, a positive attitude, and the presence of formal social supports served as facilitators, whereas barriers to readiness were limited knowledge of options and activity not being a priority (Mohler et al. 2015).

Depression and Anxiety in Vision Loss

Emotional disorders in older people with vision impairment are common. Subthreshold anxiety

and depressive symptoms (i.e., symptoms that do not meet the criteria for a psychological disorder) are estimated to be present in approximately 35% of older people with vision impairment (Van Der Aa et al. 2015), which is at least twice as high as the prevalence of the general population. Research has determined that the prevalence of major depressive disorder is approximately 5–7% and anxiety disorders 7%, with agoraphobia and social anxiety disorder being the most prevalent in people with vision impairment (Van Der Aa et al. 2015). These percentages are considerably higher than the prevalence of emotional disorders in the general older population (Beekman et al. 1999). Importantly, depression and/or anxiety in vision loss can be seen as a two- or threefold disability, such that these conditions impact on the person's ability to function (e.g., engage in employment) additional to existing impairments to functioning due to low vision (e.g., ability to read).

Psychological determinants of anxiety symptoms in vision loss research are scant. However, a multitude of dynamic biopsychosocial factors may predict anxiety in older persons with low vision, such as negative social experiences, fear of falling (on top of fear of falling related to general aging), or perceived or actual stigma. One study focused on vision-related biological predictors to mental health with self-reported cataract, motion and contrast sensitivity, and reduced low-contrast visual acuity determining anxiety symptoms (Eramudugolla et al. 2013); nevertheless, psychological contributors were not explored. Depression in vision loss, on the other hand, has had much research attention. Identified predictors for depression in older people (mean age = 71 years) with vision impairment include vision-specific distress (Rees et al. 2013a) and poor adaptation to vision loss (Senra et al. 2014). The research suggests that indicators of detrimental coping and lack of acceptance of vision loss, such as distracting oneself from problems related to vision loss, concealing one's vision diagnosis from others, or withdrawing socially, should be identified and addressed early to prevent the development of mood and anxiety disorders.

Management of Psychosocial Impact: Past Strategies and Current Novel Approaches

Because of the higher prevalence of emotional disorders in older people with vision impairment, psychological prevention and management strategies are crucial. Reviews of multidisciplinary low-vision rehabilitation services have found that these services primarily focus on functional ability and rarely target psychological outcomes. Low-vision rehabilitation focuses on clinical interventions such as training in visual aids and adaptive devices and skills training to enhance the use of remaining vision by occupational therapists and orientation and mobility specialists. While few “high-quality” outcome studies exist, a systematic review of standard low-vision services, which focused mostly on older adults (mean age of 70 years or over), demonstrated minimal impact on depressive symptoms with some improvements in VRQoL, self-esteem, and adaptation to vision loss (Rees et al. 2010).

Despite the need for support in psychological adjustment to vision loss in aging persons, significant gaps in access to support exist, and the integration of psychological services in vision rehabilitation is scarce. Research indicates that barriers to receiving psychological support in people with vision impairment include *older age*, denying depression, believing that talking therapies are not helpful, and feeling a lack of control over depressive symptoms (Sturrock et al. 2014). External barriers can be a lack of available services and limited numbers of skilled mental health professionals and reaching people residing in rural locations. Studies have indicated that many older people (mean age = 70 years) with low vision desire psychological support, particularly those with higher levels of depressive symptoms who reported poorer coping in relation to low vision (Sturrock et al. 2014). However, in a trial of depression screening plus referral to a GP for further assistance, fewer than half of the aged participants (mean age = 70 years) with low vision who screened positive for clinically significant depressive symptoms followed through with a GP referral (Holloway et al. 2014).

Those participants who did utilize the GP referral were more likely to have been prescribed psychotropic medication despite having expressed a preference for a talking therapy (Holloway et al. 2014). Accordingly, there are further barriers to accepting and accessing external referrals for adequate mental health support. Providing simpler methods for immediate expert care is important to overcome the various psychological, logistical, and external barriers that prevent older people with vision impairment from receiving the support they need.

The National Institute of Clinical Excellence (NICE) depression treatment guidelines recommend that effective screening and low-intensity treatments modeled on cognitive and behavioral treatment (CBT) principles be integrated into all chronic health rehabilitation programs (National Institute for Clinical Excellence (NICE) 2009). Recognizing this need, novel approaches designed to specifically target psychological well-being in older people attending vision rehabilitation settings, such as psycho-educational programs, behavioral activation, and problem-solving therapy (PST), have been trialed. PST has gained the greatest evidence to date, with reviews and meta-analyses suggesting that this approach holds promise for improving functional and emotional outcomes and reducing incidence of depression in people with low vision (Holloway et al. 2015).

PST is a CBT approach that focuses on guiding patients through a series of problem-solving steps to deal with observable problems under one's control, in combination with pleasant daily activities to improve mood. Individuals learn the process of problem identification, goal setting, and action planning in order to identify and cope with everyday problems. Problem solving assists with dealing with functional issues and their emotional consequences by providing patients with the skills to gain more control over their problems and reduce avoidance behavior.

While initial findings regarding CBT approaches are promising, further research is needed to confirm findings, examine the sustainability of such effects, determine for whom such interventions are most effective (e.g., older or

younger persons), and consider how best such approaches can be implemented into practice. Recent and ongoing studies have trained low-vision rehabilitation staff (e.g., occupational therapists) in these approaches and used various modes of delivery such as stepped care and guided self-help (Rees et al. 2013b; Van Der Aa et al. 2013; Rovner et al. 2014). These new models overcome issues of accessibility; however, it is unclear to date if such approaches will be able to deal with broader cognitive issues concerning thoughts of helplessness or acceptance of vision loss and the proportion of older individuals who may need more intense intervention by trained mental health professionals.

Given that how people think about and cope with their vision impairment is critical for mental health, another form of CBT, namely, acceptance and commitment therapy (ACT), may be efficacious in protecting against and reducing depressive symptoms among older individuals with low vision. There is evidence to support the effectiveness of ACT in many other chronic health areas (Wicksell et al. 2012), which are prevalent in older people (i.e., chronic pain). ACT helps people to create a "rich, full, and meaningful life while accepting the pain that life inevitably brings." By defusing helplessness-related cognitions, building acceptance, and designing value-driven goal-directed behavior acting to increase problem-focused coping, people can be gradually activated in a behavioral sense and begin to achieve personal goals. Evidence regarding ACT suggests that emotional suffering will decrease likely along with functional impairment and QoL will improve. Once individuals have been able to reappraise their low vision, they may be more likely to successfully implement other vision rehabilitation strategies (e.g., orientation and mobility, occupational therapy, etc.). It is important to note that aged people with low vision understand that acceptance is not an indicator of weakness or the end to a once satisfying life. Instead, acceptance is about acknowledging reality, learning to live with low vision, and ceasing efforts to control uncontrollable aspects of the condition so that more feasible and value-driven goals can be attained. ACT may be just one such

approach to decrease the detrimental psychological impact that research has shown is so prevalent in low-vision populations.

Conclusion

Age-related vision loss is a leading global health problem (WHO 2010). The physical, functional, and psychosocial consequences of age-related vision impairment are surmountable, yet left untreated, impact on emotional well-being and mental health (Chou et al. 2009; Van Der Aa et al. 2015; Sturrock et al. 2015). While some older people adapt well to vision loss, many others experience a great deal of distress that can lead to poorer mental health without appropriate intervention (Dreer et al. 2008; Sturrock et al. 2015). With the rates of emotional disorders doubled in this population and substantially higher than rates in the general aged population, current rehabilitation services do not adequately address the need for psychological care for aging individuals with vision loss (Rees et al. 2010). There is a need to overcome the barriers to psychological care and integrate psychological services within vision rehabilitation, either by training staff to provide low-intensity preventative strategies or by establishing collaborations with expert mental health practitioners trained to deliver effective treatments to this group of older people. Delivery of psychological strategies will need to focus on both prevention and treatment in an accessible manner. Current trials of psychological interventions and new modes of delivery that address barriers to uptake and target identified psychosocial determinants of deteriorating well-being in aging and vision loss are promising (Rees et al. 2013b; Van Der Aa et al. 2013, Rovner et al. 2014).

Vision; Active Touch

Definition

People perceive objects (their shape, size, & motion) in the environment through their senses of vision and active touch.

Introduction

Humans and other animals obtain knowledge about objects in their environment through a variety of distinct sensory modalities. Common modalities throughout the animal kingdom would include, but are not limited to, vision, audition, touch, and olfaction. An animal's survival obviously depends upon such sensory modalities, because without them it would be impossible to locate food objects, navigate safely, make and utilize tools, find potential mates, etc. This review will focus on the senses of vision and touch – one reason for this is that vision and touch are the only sensory modalities by which humans reliably perceive the 3-dimensional (3-D) shape of environmental objects. Other mammals, such as dolphins, can use their sense of echolocation (in addition to vision) to perceive the shape of 3-D objects. A tremendous amount of scientific research investigating the human senses of vision and touch has been conducted over the past 200 years. However, the study of whether and to what extent aging affects visual and tactile abilities is much more recent and has only been the focus of thorough investigation during the past few decades.

Visual Perception of 3-D Shape

Perceiving the solid (i.e., 3-D) shape of environmental objects is essential for humans and most animals in order to perform their everyday activities. If someone wants, for example, to take a drink, they must visually perceive the solid shape of a mug or cup sitting on their desk as well as its location relative to them in space. Only after visually perceiving the 3-D shape and location of the cup can the appropriate motor movements be programmed to reach for and successfully grasp the cup (humans and animals who

Visual and Haptic Perception, Fig. 1

Two of the 100 solid objects used as experimental stimuli by Norman et al. (2008). In this example, the object surfaces are covered with a texture that resembles granite

do not have effective vision often use their sense of touch, or haptics, to perceive 3-D object shape; haptic shape perception will be discussed in a later section). There are many optical sources of information that contribute to the visual perception of an object's 3-D shape. These would include motion, binocular disparity, shading, and specular highlights. When solid objects move relative to an observer (e.g., when they rotate in space), or an observer moves in its environment while viewing an object, the object's projected shape deforms in the visual image detected by the retinal neurons of the eye. This movement, or deformation, in retinal images facilitates the perception of an object's 3-D shape. The perception of 3-D shape from motion has often been referred to as the *kinetic depth effect* (it is also commonly called 3-D SFM, 3-dimensional structure from motion). Consider an experiment performed by Norman et al. (2008). On some trials, two different solid objects were successively presented (for example objects, see Fig. 1). On other trials, the same object was presented twice successively. The observer's task for any given trial was to simply indicate whether the objects they saw possessed the same shape or had different shapes. Of course, the observers' retinal images were different when two differently shaped 3-D objects were presented; the task was challenging, because the retinal images of the two stimulus objects were also different when the same 3-D object was presented twice. This occurred because even when the same 3-D object was presented twice, its orientation in depth was changed between the first and second

presentations (e.g., by a 45° rotation around a Cartesian vertical axis). In some experimental conditions, the two objects presented on any given trial continuously rotated (oscillated) in depth, giving rise to the kinetic depth effect. In other conditions, the two objects presented on any given trial were stationary (no kinetic depth effect). For objects that possessed texture, the younger observers' (mean age was 21.5 years) 3-D shape discrimination performance improved by 32% when the objects moved (i.e., rotated in space) relative to when they were stationary. This improvement in 3-D shape perception/discrimination that occurs in conjunction with object movement is characteristic of the kinetic depth effect. The older observers' (mean age was 72.2 years, range was 62–82 years of age) performance was also facilitated by object movement, but this improvement (21%) was significantly smaller than that exhibited by the younger observers. It is clear that while older adults can perceive 3-D shape from motion, their abilities are reduced relative to younger adults.

The previously discussed study (Norman et al. 2008) demonstrated that older adults' 3-D shape discrimination performance was less enhanced by motion than the performance of younger adults. A study by Andersen and Atchley (1995) found that older adults are also less able to detect the presence of 3-D surfaces defined by motion. On any given trial, Andersen and Atchley presented either a dotted surface shaped like a sine wave modulated in depth or a randomly arranged set of points occupying the same volume of space

Visual and Haptic Perception, Fig. 2 Drawings of the three differently shaped curved surfaces (from left to right, “bull’s-eye,” “snowflake,” and “egg-crate”) used in the shape discrimination task of Norman et al. (2013)

(as the sine wave). The observers’ task was to indicate for each stimulus display whether or not they saw a sinusoidally shaped 3-D surface. On average, the younger adults’ detection performance was 74% higher than that of the older adults.

If older adults do not detect or discriminate 3-D shape defined by motion as well as younger adults, when in the lifespan does this deterioration begin? A study by Norman et al. (2013) evaluated the shape discrimination abilities of middle-aged adults in addition to younger and older adults (observer ages were continuous between 19 and 84 years). In their experiments, observers were presented with one of three differently shaped surfaces on any given trial. Within these surfaces, the depth varied sinusoidally in various directions creating surface shapes that resembled bull’s-eyes, snowflakes, and egg-crates (see Fig. 2). The observers’ task on any given trial was to indicate which of the three surface shapes had been presented. The difficulty of the task was manipulated by limiting the “lifetime” (or temporal correspondence) of the moving points that defined the surface shapes. In the easiest condition, each of the 800 points defining a shape was visible in a particular surface location across 16 adjacent frames of the motion sequence (i.e., movie), while in the hardest condition, each surface point only “survived” for two adjacent frames. Once any given surface point “died,” it appeared in a new surface location, where it then survived for 2–16 additional frames. This type of stimulus display creates the perception of a continuously moving (rotating) 3-D surface whose constituent points appear and disappear over time. The results for a moderately difficult

(4-frame lifetime) condition (shape discrimination performance was neither near chance levels or perfect levels) were interesting and informative. Although there was considerable interobserver variability in performance within any particular age group (e.g., observers in their 20s, 30s, 40s, 50s, 60s, 70s, 80s, etc.), the observers’ overall shape discrimination performance remained essentially constant from the age of 19 years until about the age of 60 years. Beginning at an approximate age of 65 years, the observers exhibited a decline in performance that was linear with further increases in age. The results of this study demonstrate that the age-related deterioration in the ability to perceive 3-D shape from motion does not generally begin until after the age of 65 years.

Binocular disparity is an additional important source of optical information that helps a variety of animals, including humans, to perceive 3-D shape. The perception of solid shape from binocular disparity is usually referred to as *stereopsis* (i.e., “solid vision”). Because motion also leads to “solid vision” and an enhanced ability to perceive solid (3-D) object shape, the perception of 3-D shape from binocular disparity would be more appropriately described as *binocular stereopsis* (the perception of 3-D shape from motion could be similarly referred to as a form of *monocular stereopsis*, since 3-D SFM does not require the simultaneous use of two eyes). Binocular indicates the use of two eyes, and disparity is a synonym for difference. Binocular disparity, therefore, refers to the small differences that occur between our two eyes’ retinal images when we binocularly view solid environmental objects. The brains of many animals (but not all) contain neurons that

Visual and Haptic Perception, Fig. 3 A photograph of the 12 plastic replicas of bell peppers (*Capsicum annuum*) used as visual and haptic stimuli in the study by Norman et al. (2006)

are sensitive to, and selective for, binocular disparities. Since binocular disparity refers to the (small) differences that exist between the retinal images of two eyes that simultaneously view environmental objects, binocular stereopsis can only exist for animals that have two eyes located on the front of their head and therefore receive slightly different projective views of the same 3-D scene (animals with eyes on the sides of their heads cannot utilize binocular disparity, because each eye “sees” something totally different, not slightly different views of a single scene). In an experiment reported by Norman and Wiesemann (2007), younger and older observers judged the 3-D orientation of local regions on the surface of solid objects like those shown in Fig. 1; the observers made these judgments both binocularly (stimulus displays contained binocular disparity) and monocularly (stimuli did not contain binocular disparity). The results revealed a significant main effect of age: The errors (differences between actual local surface orientation and judged orientation) made by the older observers were 17.8% higher than those made by the younger observers. Observers in both age groups, however, benefited from the presence of binocular disparity in the

stimulus displays. In the stimulus condition where the object surfaces contained texture, the error magnitudes produced by the younger observers decreased by 36.0% when binocular disparity was available; the corresponding reduction in error magnitudes with binocular disparity for the older observers was 22.1%. While older adults definitely possess binocular stereopsis, they nevertheless do not gain as much information from binocular disparity as younger adults.

Despite the findings of Norman et al. (2008, 2013; Norman and Wiesemann 2007) and Andersen and Atchley (1995), it is important to note that older adults’ ability to visually perceive 3-D shape is not always reduced relative to that of younger adults. Norman et al. (2006) showed observers solid plastic replicas of bell peppers (*Capsicum annuum*, see Fig. 3) and asked them to discriminate shape: On any given trial, the observers were presented with two bell peppers (sequentially, for 3 s each) and were required to indicate whether the objects possessed the same shape or had different 3-D shapes. Since these stimuli were physical objects viewed in natural lighting, the viewing conditions were full cue; many optical sources of information were

available to support the observers' discrimination judgments (e.g., binocular disparity, motion, shading, specular highlights, occlusion boundary contours, etc.). Under these full-cue conditions, the younger and older observers' visual shape discrimination performance was identical (the younger and older observers' performance was 83.8% and 83.9% correct, respectively).

Haptic Perception of 3-D Shape

Human observers perceive 3-D object shape using multiple sensory modalities: vision and touch. The sense of active touch is called *haptics*. In the study most recently discussed (Norman et al. 2006), observers also made haptic solid shape discrimination judgments. On any given trial, the observers sequentially explored two bell peppers (Fig. 3) for 3 s each; the observers were allowed to feel the objects with both hands, but the bell peppers were not visible because they were presented behind an occluding curtain. Once again, the task was to judge whether the two objects had the same shape or possessed different shapes. The observers' haptic discrimination performance was comparable to the previously mentioned visual discrimination performance, and once again there was no significant difference in performance between younger and older adults (these observers' haptic performance was 84.7% and 81.9% correct, respectively).

It seems clear that haptic shape discrimination is well preserved with increases in age (Norman et al. 2006). A subsequent study evaluated whether the good ability of older adults to discriminate haptic shape extends to haptic shape estimation. Norman et al. (2011a) asked younger and older adults to estimate the shape of quadric surfaces (e.g., convex and concave hemispheres, convex and concave ellipsoids, convex and concave cylinders, as well as a variety of saddle-shaped surfaces) after haptically exploring each one for up to 30 s with one hand. Both the younger and older adults performed very well – when the estimated surface shapes were correlated with the actual surface shapes (for the higher surface curvature condition, 2.0/m), the resulting average

Pearson r correlation coefficients were 0.94 and 0.88 for the younger and older observers, respectively (Pearson r values range from zero, no correlation, to 1.0, perfect correlation). It is quite evident from this outcome that the relationship between actual surface shape and perceived surface shape was very strong for all observers, younger and older.

Visual Perception of Motion: Speed and Collision Detection

While mammalian and human visual systems are obviously sensitive to object shape, they also possess neuronal mechanisms that are sensitive to (and selective for) various aspects of object motion. A study by Norman et al. (2003) was the first to demonstrate that aging adversely affects the ability to visually discriminate the speed of moving objects. In their experiments, observers simultaneously viewed two spatially separated sets of moving objects (low contrast circles or high contrast points); the moving objects translated left or right (in a fronto-parallel plane) at varying speeds. The observers' task on any given trial was to indicate which set of moving points (the set located at the bottom or top of the stimulus display) moved faster. The dependent measure was the smallest difference in speed (between the two sets of moving objects) for which an observer could reliably determine which set was moving faster. Under the best conditions, the younger adults could reliably perform the task with a difference in speed of 5.1% (i.e., in order for a younger adult to reliably see/determine that one set of objects was moving faster than another, it would have to move at least 5.1% faster; younger adults would be unable to reliably perform the task for smaller differences in speed). In contrast, the older adults (on average) required an 8.7% difference in speed; in order to reliably discriminate the speed of moving objects, older adults needed a difference in speed that was 71% higher than that needed by younger adults.

A subsequent experiment by Snowden and Kavanagh (2006) evaluated aging and speed discrimination using very different stimuli and

methodology. In their experiment, younger and older observers viewed moving sinusoidal luminance gratings (visual patterns where light intensity varies sinusoidally across space). Two translating gratings were presented sequentially on any given trial, and the observers were required to judge which of the two (the first or second) moved faster. As in the study by Nonman et al. (2003), Snowden and Kavanagh found older adults to be substantially less sensitive to differences in speed than younger adults. The similarity in outcome of the two studies despite the differences in type of visual stimuli and methodology (simultaneous versus successive stimulus presentations) indicates that the deterioration in speed perception that accompanies aging is a significant and robust phenomenon.

A number of studies have asked younger and older adults to either detect whether approaching objects would collide with them or to discriminate which of two oncoming vehicles approach faster; such abilities are obviously critical for maintaining safety while driving. For example, in an experiment by Andersen and Enriquez (2006) observers were presented with a simulated roadway; on any given trial, an approaching object moved at a variety of speeds (30, 45, and 60 miles per hour, mph) and the object would either collide or pass by the observer in either 2, 3.5, or 5 s. The observers judged whether the object would collide with them or safely pass by to the side. The results were interesting and informative: There were effects of age, but their magnitude depended upon both the speed of the approaching objects as well as the simulated time to contact (TTC). The older adults' judgments were most impaired in the 60 mph, 5-s TTC condition: Under these circumstances, the younger adults' ability to detect the collision events was more than twice the ability of the older adults (d' , or perceptual sensitivity values, were 2.95 and 1.37 for the younger and older observers, respectively). In contrast, for the slowest approach speeds and shortest TTC (30 mph and 2-s TTC), there was no significant difference between the collision detection abilities of younger and older adults. In a later study, Ni et al. (2012) evaluated

collision detectability when observers' vision was obscured by varying degrees of fog. Ni et al. found that the older adults' detection performance deteriorated as the simulated fog density was increased; this deterioration did not occur for the younger adults.

In an experiment conducted by Poulter and Wann (2013), observers viewed simulations that included either two approaching cars or a car and a motorcycle; the observers' task was to decide which of the approaching vehicles was moving the fastest. For each observer and condition, the smallest difference in speed (e.g., between the car and motorcycle) for which correct judgments could reliably be made was determined. Adverse effects of age were found in both vehicle conditions. As an example, Poulter and Wann found that adults older than 75 years of age were unable to reliably distinguish between one car approaching at 20 mph and another that approached at 40 mph.

Visual Perception of Motion: Direction

The studies discussed in the previous section demonstrate that older adults have difficulty in detecting collisions and discriminating the speed of moving objects. Older adults also perform more poorly (than younger adults) when judging the direction of moving objects. Roudaia et al. (2010) used stimulus displays that depicted 2-frame apparent movement. Three hundred dots were initially presented for 100 ms; after a variable inter-stimulus-interval (ISI), a second pattern of 300 dots appeared that was displaced by some amount to the left or right. The observers judged whether the direction of movement was either to the left or right. Roudaia et al. found that age differences in direction discrimination performance occurred for many different combinations of ISI and displacement (e.g., for large displacements, 0.51–0.64° visual angle, across a wide variety of ISIs, and for medium ISIs, 0.06–0.16 s, across a wide variety of displacements). The authors concluded (p. 10) that their results “provide evidence of decreased functioning of low-level motion detectors.”

In a study by Billino et al. (2008), observers also discriminated the direction of movement in apparent motion displays. In their stimuli, however, only a subset of the total 100 dots moved coherently to either the left or right; the remainder of the dots moved in random directions. For each individual observer, the smallest number of coherently moving points needed to reliably judge the direction of left/right motion (i.e., the detection threshold) was identified. Older adults needed 67% more coherently moving points in order to successfully determine the direction of stimulus motion – the Pearson r correlation coefficient between the observers' chronological ages and their detection thresholds was 0.51.

Biological Motion Perception

Optical motion contains a wealth of important information that is available to animal and human observers. As we have seen, motion facilitates the ability to perceive the 3-D shape of environmental objects, and it allows us to know in advance about the possibility and timing of impending collisions. Retinal motion also enables us to perceive and recognize the behavioral activities of others. Imagine, for example, that 13 very small (and dim) lights are attached to another person's joints (Norman et al. 2004), such as their shoulders, elbows, wrists, hips, knees, and ankles. Now consider what this configuration of lighted points would look like if the environmental illumination (e.g., indoor room lights) was turned off – you would only see 13 small points of light floating in space, nothing else. When the person “wearing” the lights begins to move, however, an observer viewing this situation would immediately perceive the 13 moving lights in the dark to be a human being carrying out some meaningful activity (e.g., walking, dancing, exercising, etc.); this phenomenon is called *biological motion*. While biological motion has been appreciated and studied for more than 40 years, experiments evaluating whether and to what extent aging affects the perception of biological motion were not performed until 2004 (Norman et al. 2004). In this study, younger and older

observers viewed apparent motion sequences depicting actual biological motion: The joint motions of a human model performing various activities in the dark were recorded using a video camera. On any given trial, the observers were required to identify from the presented motion sequence whether the depicted action was walking, jogging, or skipping. The duration of the biological motion stimuli presented to the observers was very short – either 400 or 120 ms. For the longer durations of biological motion, the younger and older observers' discrimination performance was comparable: The younger observers' judgments were only 5.5% more accurate than those of the older observers (98.0 versus 92.9% correct). When the duration of the biological motion was reduced to 120 ms, the difference in recognition performance between the younger and older observers became much larger, such that the younger adults' judgments were 33.3% more accurate than those of the older adults (discrimination performance was 85.7% and 64.3% correct for the younger and older adults, respectively). Nevertheless, even for these very short stimulus durations (about a tenth of a second), the older adults were performing well, at much higher levels than chance (guessing would correspond to a performance of 33.3% correct).

Later investigations of aging and the perception of biological motion (Billino et al. 2008; Pilz et al. 2010) did not record and utilize actual human biological motion like Norman et al. (2004) but instead used a computer algorithm that simulated the movements produced during walking. On any given trial, Billino et al. (2008) presented two motion displays (for 400 ms) to their observers – the task was to judge which display (the one to the left or right of center) contained a “point-light walker” (only biological motion displays depicting walking were used). The two side-by-side displays were identical, except that in one, the positions of the dots forming the point-light walker were spatially “scrambled” so that the motions no longer simulated those of a walking human. The 11 dots whose motion defined the point-light walkers (signal dots) were embedded within varying numbers of “masking dots” (the “noise,” which moved

in random directions) in order to study the effects of a variety of signal-to-noise ratios. Billino et al. found modest effects of age: In general, the older observers needed somewhat higher signal-to-noise ratios (e.g., 20%) than younger observers (e.g., 13%) in order to successfully detect which displays contained the biological motion.

Pilz et al. (2010) used stimuli that were similar to those of Billino et al. (2008) (computer-generated point-light walkers, where the 11 points defining the walkers were embedded within 44 masking points). In this study, the observers judged the direction of biological motion – i.e., determined whether the point-light walker presented on any given trial (within a single stimulus display) moved towards the left or right. Following up and extending the experiments by Norman et al. (2004), Pilz et al. varied the duration of biological motion over a wide range from 80 ms to 3.2 s. The results of this newer study demonstrated that there was a large effect of age for all stimulus durations, short, medium, and long. As an example, for a duration of 400 ms, the younger adults' performance was approximately 93% correct (for upright point-light walkers) whereas the analogous performance for the older adults was approximately 63% correct. It is clear that the effect of age for this biological motion task was quite substantial. At shorter stimulus durations (80–200 ms), the older adults' performance (but not that of the younger adults) dropped even further, to near chance levels.

Visual Perception of Distance: Discrimination

In addition to perceiving solid objects and their motions within the environment, humans and other animals also use vision to perceive environmental distances. In 2011, Norman et al. (2011b) evaluated younger and older adults' ability to visually discriminate length/distance; they used the method of constant stimuli and the method of single stimuli. In the first method, observers saw two lengths (line segments) successively on any given trial and were required to judge which of the two (the first or second) was longer. One of the

two lines (the “standard” line) possessed a length of 9.0 cm, while the length of the other line (the “test” line) was longer or shorter (than 9.0 cm) by 1.6%, 4.8%, or 8.0%. Each participant made 300 length comparisons. The results indicated that older adults could visually discriminate length as well as younger adults – the younger and older adults needed differences in length of 6.3% and 5.4%, respectively, in order to reliably judge which of the two lengths presented on any given trial was longer (the smaller the difference one can detect, the more perceptually sensitive they are). In the other method (method of single stimuli), all aspects of the procedure were identical to those used for the method of constant stimuli, except that the standard line was never explicitly shown; its length had to be learned from feedback provided on prior trials. Although this method sounds odd (judging whether single test lines are shorter or longer than a standard length that is never explicitly presented), observers can effectively learn the magnitude of the “implicit” standard from prior feedback and use it to effectively evaluate test lengths. The results obtained using this method were similar to those obtained for the method of constant stimuli: no age differences in length discrimination ability occurred. Both the younger and older age groups needed differences in length of 4.6% (from the implicit standard) in order to reliably discriminate visual length.

Visual Perception of Distance: Estimation

As reviewed in the previous section, it was demonstrated in 2011 that older adults effectively discriminate visual length; they can, for example, compare the lengths of two stimuli just as precisely as younger adults. In 2013, Bian and Andersen (2013) found that older adults estimate egocentric distances much more accurately than younger adults. In their study, older and younger observers viewed and estimated distances outdoors (in a grassy field), from themselves to a single brick placed on the ground. The distances evaluated were 4, 6, 8, 10, and 12 m. The

Visual and Haptic Perception, Fig. 4 A photograph of the in-depth and fronto-parallel spatial intervals used as stimuli in the experiment by Norman et al. (2015). The endpoints of the spatial intervals were defined by the placement of 24 light-emitting diodes (LEDs). The LEDs

were located above a textured piece of fabric. The adjustable line segment used in the distance matching task is visible on the computer monitor located behind the array of LEDs

observers' estimates (perceived distances) were plotted as a function of the actual distances. Perfectly accurate performance would be indicated if the observers' estimates exhibited a linear relationship (with actual distance) with a slope of one. In Bian and Andersen's Experiment 1, the older adults' judgments were linear with actual distance, and the resulting regression line had a slope of 0.95; the analogous slope for younger adults was 0.56. These results conclusively indicate that older adults, on average, are almost perfectly accurate when making estimates of egocentric environmental distances. In contrast, the judgments of younger adults are far less accurate – the younger observers in Bian and Andersen's experiment, on average, only perceived about half of the distance in depth that was actually present (i.e., the younger observers perceived a 10 m physical egocentric distance as being only 5.6 m long).

Bian and Andersen (2013) evaluated how well observers could perceive large (4–12 m) egocentric distances outdoors. A subsequent experiment by Norman et al. (2015) sought to determine whether the results obtained by Bian and Andersen generalized to the perception of smaller exocentric distances (distances between objects or points in space without regards to one's self) that exist within indoor environments. In the Norman et al. study, observers viewed small distances

(approximately 10–20 cm) that were either aligned in depth (along an observer's line of sight) or possessed a frontal (fronto-parallel) orientation. The stimulus distances were defined by the spatial arrangement of 24 green light-emitting diodes (LEDs, see Fig. 4). On each trial, a single pair of LEDs was illuminated; these LEDs defined the endpoints of a particular environmental distance to be judged. There were 22 stimulus distances, which the observers judged five times each. The observers' task on any given trial was to adjust the length of a line segment displayed on a computer monitor until it appeared to match the physical distance between the two illuminated LEDs. Norman et al. found that the observers generally underestimated the stimulus distances and perceived them to be significantly shorter than they actually were. This was especially true for the younger observers – on average, they perceived the in-depth distances to be only 59.4% of their actual length. While the older observers' judgments were not entirely accurate, they were nevertheless more accurate in their perceptions of exocentric distance than the younger observers (on average, the older observers perceived the in-depth distances to be 79.8% of their actual length). The frontal distances (those not aligned in depth) were perceived more accurately than the in-depth distances: On average, the younger and older observers perceived their extents to be

77.9% and 85.7% of the actual distances, respectively. The judgments of the older adults were more accurate for both the in-depth and frontal distances.

Discrimination and Perception of Lifted Weight

When we pick up and haptically interact with objects using our sense of touch, we perceive their weight as well as their shape. An experiment was conducted in 2009 by Norman et al. (2009) to determine whether and to what extent aging affects the human ability to discriminate lifted weight. The method of constant stimuli was used in this study; the standard weight was 100 g. Six test weights were used by both the younger and older participants (younger participants: 90, 94, 98, 102, 106, and 110 g; older participants: 85, 91, 97, 103, 109, and 115 g). All objects possessed the same size and shape, but had differing weights. On any given trial, the participants were given two objects to lift in succession. One object had the standard weight while the other possessed a test weight; the participants' task was to judge which of the two objects, the first or the second, was heavier. In estimating the weight of any given object, the participants were only allowed to lift it once off the table and put it back down. Each participant performed a total of 216 judgments (each test weight was presented 36 times in a random order). The goal of the study was to determine each participant's difference threshold (the smallest difference in weight needed for them to make reliable judgments). At the end of the experiment, the difference thresholds for the younger and older adults were determined to be 6.6% and 10.4% of the standard, respectively. Thus the older observers needed either a 10.4% increase in weight or a 10.4% decrease in weight (relative to the standard) in order to reliably discriminate on any given trial which of the two presented weights, the first or the second, was heavier. These results indicate that older adults need much larger differences in object weight in order to perform well and make reliable judgments; the older participants' difference thresholds were 57.6% higher than those obtained for the younger adults.

The outcome of the previously described study (Norman et al. 2009) clearly demonstrates that aging is accompanied by a deterioration in the ability to discriminate small differences in object weight. However, this does not necessarily indicate that aging reduces the ability to compare the weights of two objects that differ substantially. The purpose of the experiment by Holmin and Norman (2012) was to evaluate how well younger and older adults can perceive and estimate weight ratios, how much heavier one object is relative to another (e.g., twice as heavy, five times as heavy, 50% heavier, etc.). Participants in this experiment lifted two objects (same size and same shape) successively on any given trial and gave a numerical estimate of the weight ratio. There were 16 actual weight ratios that ranged from 1:1 (the two objects had the same weight) to 10:1 (one object was 10 times heavier than the other). The participants were allowed to lift each object as many times as they wanted within 30 s; they grasped the stimuli with the thumb and first two fingers of their preferred hand and lifted with the forearm (while keeping the elbow on the table). Each participant estimated the weight ratios of 108 pairs of objects. In assessing the results of the experiment, the individual younger and older participants' perceived weight ratios were plotted as functions of the actual stimulus weight ratios – accurate performance would be indicated if the resulting best-fitting regression lines possessed a slope of one. The outcome of the experiment demonstrated that while the younger participants were able to estimate object weight ratios reasonably accurately (average slope of 1.32), the older participants' judgments were highly inaccurate (average slope of 4.64). This result demonstrates that the older participants, on average, perceived the weight ratios to be much higher than they actually were.

Discussion

As we have seen, there is no general across-the-board deterioration in perceptual functioning as human adults become older. It is true that large age-related deficits (Norman et al. 2003; Snowden and Kavanagh 2006; Andersen and Enriquez

2006; Ni et al. 2012; Poulter and Wann 2013; Pilz et al. 2010) do exist for many motion-related tasks (e.g., visual speed discrimination, detection of collision events, etc.). However, it is also true that under favorable circumstances older adults can effectively perceive 3-dimensional object shape from motion, binocular disparity, image shading, specular highlights, and object boundary contours (Norman et al. 2008, 2013; Norman and Wiesemann 2007). Under full-cue conditions where many optical sources of information are simultaneously available to support perception, older adults can visually discriminate 3-D object shape as well as younger adults (Norman et al. 2006). The situation for haptic perception of 3-D shape (Norman et al. 2006, 2011a) is even more encouraging: The haptic shape discrimination and estimation abilities of older adults have been demonstrated to be equivalent to those of younger adults.

With regard to other types of judgments, those not related to motion or the perception of shape, the situation is similar. Significant age-related impairments occur, for example, when human adults are required to discriminate or make judgments about the weight of lifted objects (Norman et al. 2009; Holmin and Norman 2012). However, when it comes to visually perceiving environmental distances (Norman et al. 2011b, 2015; Bian and Andersen 2013), the performance of older adults is as good as, or substantially better, than that of younger adults. Contrary to conventional wisdom, aging does not necessarily lead to declines in human perception. We can be confident that further research into the perceptual capabilities of older adults will continue to provide surprising and important insights into the human condition.

Synonyms

Altruism; Community service; Elderly; Happiness

Definition

Volunteering is the provision of unpaid services to organizations, community groups, or individuals.

Introduction

A recent and important trend in geropsychology that has emerged during the last 20 years termed positive aging addresses behavioral, psychological, and social factors that hold the potential to enhance the physical and mental well-being of older adults. This recent trend shifts the focus from aging-related decline to older adulthood as a stage that holds potential for contribution, adaptation, and success (Johnson and Mutchler 2013). Not surprisingly, maintaining a physically and mentally active lifestyle has repeatedly been noted to enhanced health and overall well-being during the later years. As this research domain has become more sophisticated, it has become clear that not all types of activity are equally beneficial; certain types of activity are more robustly related to enhance well-being among older adults than

others. Volunteering, the provision of unpaid services to organizations, community groups, or individuals, has been shown to be one of the most salubrious types of activity a postretirement older adult can engage in (Anderson et al. 2014). This entry will provide an overview of the current understanding of the relationship between older-adult volunteering and physical and mental well-being, theoretical explanations of why volunteering benefits older adults, how volunteering can be encouraged in the elderly with brief intervention, and concludes with a discussion of how the enthusiasm surrounding older-adult volunteering as a public health strategy should be tempered with caution, particularly among elderly from diverse backgrounds.

Volunteering and Mortality

Gerontology researchers have explored the possibility that engaging in voluntary activities in the later years is related to reduced mortality and have found encouraging results. One of the early, scientifically robust studies of the influence of volunteering on mortality conducted over an 8-year period in the USA found that engaging in substantial amounts of volunteer activities (volunteering concurrently for two or more organizations) reduced mortality in an older-adult sample by 44%, even while controlling for initial health status, health habits, and social support (Oman et al. 1999). The authors noted that in comparison to variables that have historically been associated with reduced mortality, the effect of volunteering was impressive. Volunteering's beneficial influence on mortality was greater than that for exercising four times per week and attendance at religious services; it was found to be roughly equivalent to the mortality benefits of not smoking.

Since this seminal study on the mortality benefits of volunteering, there have been numerous other well-designed, large-scale studies performed with older-adult participants. Okun et al. (2013) performed a meta-analysis of studies that have examined the influence of organizational volunteering on mortality among older

adults (55 years and older). They utilized findings from 14 prospective studies in which volunteering was measured prior to an ongoing surveillance period. Estimated unadjusted (no other variables were controlled for) and adjusted (other variables such as gender, health, economic status, etc. controlled for) effect sizes were calculated in this study. Regarding the unadjusted effect size, volunteering reduced mortality risk by 47%, and the adjusted effect size indicated a mortality risk reduction of approximately 24%. In other words, even when controlling for other important variables related to mortality (health, gender, etc.), engaging in volunteer activities in older adulthood reduced mortality by 24%. This meta-analysis suggests that across numerous studies, volunteering exerts an important and unique effect on mortality among older individuals. It has also come to light that the motivation behind engaging in volunteering may be an important mediator of mortality outcomes. Konras et al. (2012) indicated in their analysis of data from the Wisconsin Longitudinal Study that older-adult research participants who engaged in volunteer behaviors for self-oriented reasons had the same mortality risk as non-volunteers, but those who volunteered for other-oriented reasons evidenced substantial reductions in mortality. An altruistic, other-oriented motivation may thus be a key element in producing enhanced health functioning among older volunteers.

While research is still ongoing regarding exactly how engaging in helping behaviors can result in improved mortality, research has suggested that one pathway may be through improved cerebrovascular functioning. Heisler et al. (2012) found among a US nationally representative sample that older adults who reported providing helpful services to others (excluding immediate family) evidenced a reduced chance of having a cerebrovascular disease event in comparison to those who did not provide help to others.

Volunteering and Mental Health

In addition to examining volunteering's potential to reduce mortality and enhance physical health

functioning among older adults, research has also highlighted volunteering as an important contributor to late-life emotional well-being. Musick and Wilson (2003) found in their analysis of a large, US nationally representative sample of older adults that volunteering reduced depression among participants over a 5-year time period, while controlling for other factors also related to depression. This study also examined potential mediators of volunteering on depression, focusing on social and psychological variables. They found that the enhanced social resources that occurred in tandem with volunteering mediated the effect of volunteering on mood whereas enhanced self-esteem did not. As older individuals engage in volunteering organizations, they also attend meetings, make new acquaintances, and potentially replace previously lost social roles, which in turn bolsters mood. Numerous other longitudinal studies have demonstrated the beneficial effect of volunteering on depressive symptoms among older adults and have indicated that the effect is strongest for individuals in the postretirement compared with younger groups (Kim and Pai 2010; Morrow-Howell et al. 2003). While research into the influence of volunteering on mood functioning among individuals of different ages is at an early stage and more studies are needed, it appears likely that younger adult volunteering may actually be an added stressor to an already busy work and family life, whereas in the older-adult context, it may help to fill social roles that were lost upon retirement.

Research has also examined how older-adult volunteering can enhance levels of happiness among older adults (Midlarsky and Kahana 2007). Happiness has been highlighted as not just the absence of depression but the presence of enhanced energy, joy, and engagement with the moment (Fredrickson 2001). Results from numerous studies suggest that volunteering and providing helpful services to others specifically enhances levels of happiness. Dulin and Hill (2003) indicated in a study examining older-adult volunteers that hours spent providing services were related to positive but not negative affect. This study indicated that volunteering likely leads to increased joy and happiness, but

does not reduce distressful states such as irritability and anxiety. Morrow-Howell et al. (2003) suggested that results from their study, in combination with numerous other studies, provide a high degree of confidence that volunteering positively influences emotional well-being among the elderly. In fact, they call for a reduced focus on whether or not volunteering can reduce depression among older adults as so many studies are pointing to the same conclusion. They suggest that the more interesting and currently relevant question is under what conditions and for whom volunteering is beneficial.

Research into the beneficial effects of mood from engaging in volunteering among older adults has indicated a particular relevance of volunteering to individuals in the lower rungs of the socioeconomic ladder, which is intriguing because low socioeconomic status has been shown to be a robust predictor of physical and mental health impairment among the elderly (Marmot 2006). Results from a study of positive aging factors that utilized a representative sample of older adults in New Zealand found that volunteering had the strongest relationship with happiness among all variables included in the analysis and that economic living standards moderated the relationship between volunteering and happiness. Results from this study showed a strong relationship between volunteering and happiness among individuals in the lowest levels of economic living standards but not among individuals from the highest economic levels (Dulin et al. 2012). In this study, volunteering helped to equalize the distance in mental well-being between the haves and the have-nots. Borgonovi (2008) and Morrow-Howell et al. (2009) also found that volunteering was associated with enhanced happiness and perceived benefits among individuals with lower incomes and education and that differences between wealthy and poor older adults regarding mental well-being disappeared if older adults in the lower ranges of economic resources were engaged in volunteering. These findings are particularly important as many of the predictors of well-being among older adults are essentially fixed, whereas volunteering is a behavior that can be initiated by elderly adults that can help to bridge the well-being gap between wealthy and poor older individuals.

Ageing, Volunteering, and Health: Explanatory Models

As numerous studies have demonstrated, older adults are engaged in substantial amounts of volunteering and that seniors who choose to volunteer commit more time to their volunteer activities than all other age groups do (Anderson et al. 2014). Socioemotional selectivity theory (SST) is an older-adult-focused, empirically supported developmental theory that helps to explain why older adults volunteer, despite the presence of dwindling physical health and reduced energy levels that accompany the aging process. According to SST, as the end of life approaches and it becomes obvious that one's time is limited, goals become reprioritized with a greater importance placed on activities that are emotionally meaningful and a lower priority given to the pursuit of goals concerned with future achievements. SST suggests that this late-life shift is accompanied by greater importance being placed on developing and maintaining meaningful social relationships. Instead of focusing, as younger cohorts tend to, on personal ambition, older adults derive increasing satisfaction from helping others and the experience of present-focused emotional well-being (Carstensen and Lockenhoff 2003). Volunteering, according to SST, provides an important means for contributing to the lives of others that is consistent with an older adult focus on emotionally meaningful goals.

While SST provides a theoretical justification for why older adults volunteer, it does not address how older-adult volunteering results in the oft-cited benefits to physical and emotional health. As mentioned previously, a repeated finding in older-adult volunteering research is that volunteering enhances positive emotions. The broaden-and-build theory of positive emotions (Fredrickson 2001) suggests that positive emotions tend to broaden behavioral repertoires, which in turn builds health-enhancing resources and in a synergistic fashion, results in more positive emotions. Positive emotions, while important end points, have also been associated with increased longevity and potential health-protective effects such as improved immune responses. Pressman and Cohen (2005) highlighted the effects of positive

emotions on a number of physical health outcomes, including mortality, morbidity, and survival of serious illness. Similar to the broaden-and-build theory, they hypothesize that positive emotions lead to more adaptive health behaviors, decreased sympathetic nervous system arousal, better immune and cardiovascular system functioning, and improved quality and quantity of social relationships.

Brown and Okun (2014) have postulated what they term a “caregiver system” that when activated produces health benefits for older adults who volunteer. Their framework integrates animal models of parenting with nurturing-type responses within human neuroimaging studies to identify the neuroanatomical functioning and environmental conditions related to prosocial behavior. Their model suggests that perceptions of another’s need in combination with the ability to meet the need trigger a motivation to help. The help trigger then activates neural circuits related to parenting that produce hormones such as progesterone and oxytocin. The authors note that these hormones, while encouraging nurturing-type behavioral responses, also regulate stress and downregulate inflammation, both of which are related to improved health functioning. The caregiving system model thus indicates that volunteering is mediated by inherited neural mechanisms that activate natural dispositions toward caring for others. This model also indicates that certain preconditions determine if volunteering will produce health benefits. In addition to the volunteers believing that they have at least minimal resources to provide (i.e., skills, information, etc.), the authenticity of the need for assistance is also vital. In other words, the volunteering environment should be trustworthy and have a minimal possibility for exploitation.

Encouraging Volunteering Among Older Adults

Current research has also focused on intervention strategies aimed at encouraging older adults to volunteer. Warner et al. (2014) tested a social-cognitive intervention for increasing volunteering

in older adults in a randomized control trial. They found that a group-based, single session intervention with community-dwelling older adults that was focused on providing information about the benefits of volunteering in old age, enhanced self-efficacy for volunteering and modeled volunteering behavior resulted in substantially more engagement in volunteer activities over the course of 6 weeks than control groups. This study also demonstrated that the intervention group evidenced a higher degree of volunteering among current volunteers as well as higher rates of beginning volunteering among non-volunteers. They note that these effects may take some time to manifest; in their study there were no differences between groups at 2 weeks, but substantial volunteering differences at 6 weeks. This study is encouraging to community organizations interested in enhancing the well-being of elderly adults through volunteering in that it shows that simple and very brief group-level interventions can meaningfully increase volunteering among older adults.

Caveats to Older-Adult Volunteering

As research has underscored, volunteering has numerous benefits for older adults in terms of maintaining and even bolstering physical health and emotional well-being. Not surprisingly, enthusiasm regarding older-age volunteering as a public health intervention is high as evidenced by the increase in research and policy attention during the last 10 years. The economic benefits to societies of older-adult volunteering are another factor that motivates a drive to encourage older-adult volunteering. It is estimated that older-adult volunteering results in approximately \$19 billion in provided service annually in the USA alone (Anderson et al. 2014). This enthusiasm, however, needs to be tempered with some caution as older adults, even if happily engaged in volunteering, experience age-related reductions in energy levels, decreased ability to manage stressful schedules, and often have multiple caregiving duties within their own families.

Research has demonstrated that at high levels of volunteering, the benefits to health and well-being begin to decrease (Musick et al. 1999). For instance, Windsor et al. (2008) indicated that an inverted U shape emerges when emotional well-being is plotted against amount of volunteering among older individuals. Older adults who reported moderate amounts of volunteering had the highest levels of emotional well-being while those who reported no volunteering and high levels of volunteering evidenced similarly lower levels. This study utilized a sample of young-old adults (between 64 and 68 years of age) and found that more than about 15 hours of volunteering per week was associated with reduced well-being. While data are not available, it stands to reason that adults in the older and oldest-adult categories would need to moderate their volunteer hours even further to avoid volunteering becoming burdensome and stress inducing.

Most studies of volunteering have also been undertaken among older adults in the USA, Europe, and other developed Western countries. At this point in time, little is known about volunteering and older adults in other cultural contexts. Volunteering has been discussed as a term that has divergent meanings across cultures, particularly in the context of indigenous groups (Anheier and Salamon 1998). For example, the New Zealand Māori are thought to have a fundamentally different conception of what it means to volunteer. Robinson and Williams (2001) suggest that Māori tend to view family and community as intertwined, particularly in a small community context in which they have many familial connections. Within this context, providing unpaid help to others in their local community is considered to be a cultural norm in which older Māori often feel that their service activities are proscribed. Among Māori and other non-Western and indigenous groups (i.e., Alaska Natives), older adults may be highly active in their community, given their status as community leaders, and may have little time and energy for community volunteering. Caution should thus be exercised when considering recommending volunteering among older adults in non-European and indigenous cultural groups.

Conclusion

After decades of scientific study, it is now well understood that engaging in volunteer activities can lead to enhanced physical and mental well-being among individuals in their postretirement years. Volunteering as a means to encourage positive aging is particularly intriguing because it contains the possibility for a double benefit; individuals and communities receive benefit from older adults providing helpful, free services, and older-adult volunteers maintain or even enhance their overall health in the process. The same cannot be said for other positive aging factors such as a regular exercise routine or maintaining a healthy diet. While research has come far in highlighting the salubrious nature of volunteering among the elderly, there are still many unanswered questions regarding mediators of the effect and for whom volunteering is indicated. As this field of research progresses, more information will undoubtedly emerge regarding how much volunteering is indicated for different age groups, the type of volunteering that is most beneficial for older adults, and the cultural aspects of engaging in volunteer activities, particularly for members of non-Western, indigenous populations.

Definitions

Well-being is a key dimension of successful aging. Centenarians have high levels of life satisfaction and happiness, which are similar to middle-aged and younger-older individuals. Positive affect has been found to be lower in centenarians compared to octogenarians, but the differences are not strong; no differences were observed for negative affect. The majority of centenarians have low levels of depression, while findings on age differences are inconclusive to date. Factors associated with these well-being dimensions are, in line with suggestions of high psychological resilience in very old age, more often subjective evaluations than objective facts (e.g., subjective health being linked to well-being, but not number of illnesses). More objective factors predicting well-being included functional

health and some social factors. Psychological strengths such as optimistic outlook were found to have particularly strong associations with well-being. In sum, findings indicate that centenarians are quite able to deal with health issues and resource restrictions that seem to play only a limited role in their subjective well-being. Psychological strengths seem of key importance for well-being in very advanced age, but more research is needed to confirm and develop this picture.

Introduction

How advanced-age individuals feel about themselves and evaluate their lives is an important topic that is central to many discussions about quality of life in old age and successful aging. With the current increase in numbers of very old individuals and future projections indicating that every second child born after the year 2000 is likely to become a centenarian (Christensen et al. 2009), the question about whether life at age 100 is still worth living is gaining relevance for more and more individuals.

Questions about well-being (or morale) were asked at the outset of research on successful aging in the 1960s; “adding life to years, not just more years to life” was the motto of the first conference of the Gerontological Society of America. However, after all these years, the debate about what successful aging is – healthy aging, being cognitively intact, and socially active and

embedded – is still ongoing and has just recently gained more attention, also in the context of centenarian research. Interestingly, despite the fact that most laypeople tend to mention well-being when asked to define successful aging (e.g., Jopp et al. 2015), well-being has not been among the key factors in the most renowned models of successful aging. Yet, well-being has certainly been among the most investigated outcomes of empirical studies, particularly those which define successful aging in the tradition of resilience and adaptation.

Investigation of well-being aspects in centenarians is not only important because of its relevance for the many individuals who are likely to reach this age in the near future but because this research could help to better understand resilience and its underlying mechanisms under particularly difficult conditions. Although centenarians have long been discussed as models of successful aging given that they have outlived most of their cohort members, their physical, cognitive, and social functioning may be quite limited. For instance, studies from around the globe document that very few centenarians are in good health once they reach age 100. Centenarians are affected on average by about four to five diseases, particularly chronic diseases, which represent a considerable burden (e.g., Andersen-Ranberg et al. 2001; Jopp et al. 2016). Considering cognitive functioning, about half of centenarians have moderate to strong cognitive impairment or dementia (e.g., Kliegel et al. 2004). Regarding their social network, loss of loved ones is a central negative consequence of extreme longevity: many centenarians have outlived not only spouse, friends, and acquaintances but also some of their children (e.g., Boerner et al. *in press*; Martin et al. 1996). Thus, a key question is whether centenarians are able to cope with these challenges, and if so, which factors enable them to do so.

In the younger phases of old age, an astonishing discrepancy has been observed between, on the one hand, poor levels of functioning and lack of resources in central areas of life (e.g., health, cognitive capacity, and social function) and, on the other hand, rather high levels of well-being. That the poor resources do not translate into

equally poor levels of well-being has been termed the well-being paradox (e.g., Staudinger et al. 1995), and the investigation of underlying mechanisms is ongoing. Potential mechanisms are likely to be psychological in nature, such as life management or coping strategies which have been found to buffer poor resources in very old age (e.g., Jopp & Smith 2006). Thus, for centenarians, key research questions are whether they indeed experience decent levels of well-being at this advanced age despite very limited resources and which factors are associated with well-being at this age.

Given that the investigation of well-being was not a central theme in centenarian studies so far, the empirical basis is currently somewhat limited. Studies available offer findings on different facets of subjective well-being that are divergent in nature and could therefore lead to different findings. Furthermore, as research has shown that positive emotions and negative emotions are not different sides of a medal but rather independent, and both are likely to be affected by different factors, we included more positive as well as negative dimensions. Thus, the present entry considered different types of subjective well-being constructs: *cognitive well-being*, such as life satisfaction or morale, which represents the (somewhat more stable) outcome of a complex mental (cognitive) computation that is based on the evaluation of various aspects of life; *affective well-being*, including constructs such as happiness or affect, as expressions of (possibly fluctuating) positive or negative emotions; and *depressive symptoms*, representing a more negative aspect that has been used as a key outcome of many studies on adaptation and resilience.

High Level of Well-Being at Age 100 Is Possible

Against prejudice many people hold about very old age, several studies have documented that high well-being at age 100 seems possible. Considering life satisfaction first, a majority of centenarians are quite satisfied with their lives. A total of 80% of the participants of the Second

Heidelberg Centenarian Study reported to be moderately to strongly satisfied with their life, using the life satisfaction scale by Pavot and Diener (1993).

In an Italian study, Buono et al. (1998) compared life satisfaction levels of 38 centenarians with two younger age groups (young olds, aged 75–85, and old olds, aged 86–99). In this study, life satisfaction (assessed as part of the LEIPAD scale; De Leo et al. 1994) was positively related to increasing age, and this effect was significant even after controlling for education, suggesting greater life satisfaction with advancing age. The Second Heidelberg Centenarian Study did not find higher life satisfaction in centenarians: When comparing the centenarians with younger older adults, old-old (80–95 years old) individuals were found to have lower levels of life satisfaction compared to young-old individuals (65–79 years old), but there was no difference between centenarians and the two younger control groups (Jopp et al. 2013). Similarly, when comparing near-centenarians (aged 95–99) and centenarians (aged 100–108), no mean level differences in life satisfaction, assessed with Pavot's and Diener's (1993) scale, were found (Jopp et al. 2016).

An interesting question is whether more recently born centenarians show similar or maybe even higher levels of well-being. Cho et al. (2012) examined cohort differences in life satisfaction by comparing the later cohort (centenarians born between 1901 and 1907) and the earlier cohort (centenarians born between 1881 and 1895) from the Georgia Centenarian Study. They found a significant mean level difference in life satisfaction (as measured by the Life Satisfaction Index A (LSI-A), Neugarten et al. 1961). The later-born cohort of centenarians showed higher life satisfaction (.56 z-score) than the younger cohort, suggesting that more recent cohorts of centenarians are more satisfied with their life and may be better off in terms of quality of life than previous cohorts.

Considering happiness, a more emotional facet of well-being, studies indicate that centenarians tend to feel quite happy and even as happy as middle-aged adults. Jopp and Rott (2006) examined happiness in 56 German centenarians from

the First Heidelberg Centenarian Study, using single items from the Life Satisfaction Index A (LSI-A; Neugarten et al. 1961), as well as questions asking whether individuals laughed often and whether they felt mostly happy (yes/no). Descriptively, 71.4% of the centenarians indicated that they felt mostly happy, 54.0% reported that they were as happy as they were at younger ages, and 67.9% said that they would laugh easily. In order to determine potential age-related differences in happiness, comparison groups of middle-aged (43–46 years old) and older adults (aged 61–65) were drawn from the representative Interdisciplinary Longitudinal Study of Adult Development (ILSE). Group comparisons revealed no significant differences regarding being as happy as when they were younger: Centenarians reported feeling just as happy as at younger ages as did the middle-aged and older adults. Furthermore, centenarians and middle-aged adults indicated being significantly more often able to laugh easily than the group of older adults.

Comparisons between individuals in the fourth age (80+ years old) and centenarians are available from the USA: In the Georgia Centenarian Study, Cho et al. (2012) examined happiness in 234 centenarians and 72 octogenarians. The results revealed that 89.8% of the octogenarians and 89.7% of the centenarians were categorized as having a high level of happiness, showing no significant group difference.

The extent to which centenarians experience positive or negative affect was investigated within the Georgia Centenarian Study, which used the Bradburn Affect Balance Scale (Bradburn 1969), comparing centenarians and octogenarians. As reported in the analysis by Margrett and colleagues (2011), centenarians had significantly lower levels of positive affect than octogenarians, but there was no significant difference in negative affect. Longitudinally, Martin et al. (2012) assessed positive and negative affect for 19 centenarians during four time points over a 6-month period. Although there was individual variability, the mean scores for positive affect significantly declined over time, while no significant change was seen in negative affect.

Depressive Symptoms at Age 100 Are Not the Norm

Research on centenarians and near-centenarians shows that depressive symptoms are not typical in this advanced-age population. In contrast, mean scores on the commonly used Geriatric Depression Scale (GDS) generally fall in the nondepressed range (Yesavage et al. 1983). Similar levels of depressive symptomatology have been shown in American (Jang et al. 2004), Chinese (Wen et al. 2010), and Italian (Bauco et al. 1996) centenarian and near-centenarian samples. However, that is not to say that individuals with elevated depressive symptoms are nonexistent. Rates of depression have been shown to vary by country. For example, Infusino et al. (1996) found that the vast majority (80%) of Italian centenarians were not depressed, and the remaining 20% were moderately depressed, with no centenarians indicating severe depression, as assessed by the 30-item GDS. Even lower prevalence rates have been found among Australian centenarians, with only 13.5% showing any depressive symptomatology (Richmond et al. 2011). On the contrary, depression rates appear to be higher among Chinese centenarians, namely, about 25.5%, when considering a score of 10 or above on the Chinese version of the GDS (Wen et al. 2010).

Although research shows that the majority of centenarians are not depressed, studies that have examined differences in depressive symptomatology between centenarians and other older adult age groups have produced mixed findings. Buono et al. (1998) compared centenarians' levels of depressive symptoms to that of adults aged 75–85, as well as 86–99. They found no significant differences among the three age groups on two measures of depression (the LEIPAD depression and Anxiety subscales [De Leon et al. 1994] and the Brief Symptom Inventory depression subscale [Derogatis and Melisaratos 1983]). However, other research has shown that American centenarians have higher depressive symptomatology than octogenarians and sexagenarians (Jang et al. 2004). Data from the Fordham Centenarian Study (Jopp et al. 2016) further

indicates that although depression levels were low overall (72% had few or no depressive symptoms [GDS scores 0–4]; over 80% did not meet the criteria of clinical depression [GDS scores 8 and higher]), centenarians had higher levels of depressive symptoms than near-centenarians.

Predictors of Well-Being in Centenarians

Given that centenarians seem to experience rather high levels of well-being, the following question is which factors are associated with this phenomenon, in order to identify potential underlying mechanisms. Considering life satisfaction first, studies have considered different types of basic personal characteristics and psychological aspects. In the Fordham Centenarian Study, for instance, the predictive validity of various resources, including demographic variables (e.g., age, gender, marital status, education), health (number of illnesses, subjective health, activities of daily living), cognitive functioning, and social resources (number of living children, support by family, support by friends) for life satisfaction was tested in near-centenarians and centenarians (Jopp et al. 2016). Only three significant predictors emerged in the regression analysis: the strongest predictor was subjective health, followed by number of living children and basic activities of daily living.

In line with the finding that health perceptions are playing a role, Bishop et al. (2012) showed that a higher level of fatigue was significantly associated with lower levels of life satisfaction. Also, negative affect had a significant negative association with life satisfaction, while positive affect was not significantly associated with life satisfaction. When examining the mediating role of positive and negative affect between various predictors (i.e., perceived health status, functional health, cognition, fatigue, distal stress) on life satisfaction, perceived health, functional health, and fatigue each had significant indirect effects on life satisfaction via negative affect but not via positive affect. Thus, the findings suggest that negative affect plays a more pronounced role in linking health-related factors to centenarians' life

satisfaction. In Bishop et al.'s (2011) study with two measurement points over an 18-month period, a higher level of negative affect at baseline significantly predicted a lower level of life satisfaction 18 months later.

In the Second Heidelberg Centenarian Study, findings strengthen the impression that basic resources are less important than psychological aspects. Considering various demographic, health, social, and psychological variables, psychological strengths including self-efficacy, optimistic outlook, meaning in life, and will to live had the strongest links to life satisfaction. Concurrent examinations in the context of regression analysis revealed that optimistic outlook was the strongest significant predictor of individual differences in life satisfaction (Jopp et al. 2013).

Considering predictors of happiness, Jopp and Rott (2006) examined the predictive values of resources (i.e., job training, cognition, health, social network, extraverted personality) and self-referent beliefs and attitudes (i.e., self-efficacy, optimistic outlook) on happiness. Positive self-referent beliefs and attitudes, such as having high levels of self-efficacy and optimistic outlook, were positively linked to higher levels of happiness. Among basic resources, job training had a significant negative direct effect on happiness. Follow-up analyses suggested that female centenarians who managed to receive job-related education in Germany around 1915 were very autonomy oriented, which was a beneficial trait in younger years, but maybe was maladaptive when having to accept loss of autonomy in old age. Another basic resource, social network aspects, had a positive direct effect on happiness. At the same time, self-referent beliefs and attitudes were more powerful predictors of happiness than basic resources. These psychological factors and attitudes also had mediating roles between some of the basic resources and happiness. For instance, cognitive resource and extraversion had a significant impact on happiness mediated by self-efficacy. In another mediator model focusing on optimistic outlook as a mediating factor, extraversion showed a significant positive direct effect on happiness, and prior job training and social

resources had indirect effects on happiness through optimistic outlook.

In the Georgia Centenarian Study, Bishop et al. (2010) tested a structural equation model predicting happiness with the direct and indirect effects of congruence (satisfaction with life in the past), perceived economic status, social provisions, and perceived health. Specifically, congruence had a significant direct association with current happiness, while perceived economic status, social provisions, and perceived health were not significant predictors of happiness. Taken together, psychological factors, such as positive beliefs and attitudes, and positive appraisals of one's past, play important roles in centenarians' levels of happiness.

Considering positive and negative affect, Margrett et al. (2011) examined the effects of various demographics (i.e., age, sex, residential status, ethnicity) and functioning variables (i.e., perceived ease in completing desired activities despite health issues, ability to perform activities in daily life), cognition, social functioning (i.e., social provisions, social resources), and personality factors (i.e., extraversion, neuroticism) on positive and negative affect in the Georgia Centenarian Study. Predicting individual differences in negative affect with regression analysis, they showed that neuroticism was significantly associated with higher levels of negative affect and social functioning was associated with lower levels of negative affect in centenarians, while none of the demographic, functioning, or cognition factors emerged as significant predictors. Regressions predicting positive affect, centenarians with higher cognitive functioning and those with greater social provisions reported higher levels of positive affect.

Using the same sample, Cho et al. (2013) examined the effect of proximal (i.e., physical functioning, cognitive functioning, subjective health, health problems, social resources, perceived economic status) and distal influences (i.e., education, social productive activities, management of personal assets, learning experiences) on positive and negative affect. For positive affect, cognitive functioning emerged as a significant predictor, after controlling for gender,

ethnicity, marital status, age, and type of residence. For negative affect, the number of health problems was positively related. This is in line with the theoretical assumption that affect (as an indicator of the emotional well-being dimension) is more variable than other, more cognitive well-being constructs (such as life satisfaction which is the result of complex mental processing of specific evaluations), and may therefore be influenced more strongly by current experiences. Also in line with this assumption were the findings indicating that none of the distal variables had significant effects on positive or negative affect, supporting the idea that proximal experiences may play more important roles in centenarians' affect than distal experiences. When interaction effects between age and predictor variables were examined, lower physical functioning and lower cognitive functioning had negative effects on positive affect among centenarians, but not in octogenarians.

Bishop and colleagues (2011, 2012) examined the relationship among resources, positive and negative affect, and life satisfaction in the Georgia Centenarian Study. Bishop et al. (2012) tested the mediating role of positive and negative affect between various predictors (perceived health status, functional health, cognition, fatigue, distal stress) on life satisfaction. Based on a path analysis, perceived health and fatigue had direct significant effects on positive affect. For negative affect, perceived health, functional health, cognition, and fatigue had significant direct effects. Longitudinally, Bishop et al. (2011) examined 137 cognitively intact centenarians at baseline and at 18-month follow-up (68 survivors at Time 2). Poorer cognitive functioning at baseline was negatively linked to positive affect at the follow-up, but not to negative affect.

In a longitudinal study, Martin et al. (2012) examined predictors (i.e., walking activity, financial resources, self-rated health) on growth curve changes in positive and negative affect. For positive affect, walking activity and financial resources were significantly associated, while walking activity and self-rated health emerged as significant predictors for negative affect. Overall, this longitudinal finding complements previous

cross-sectional findings suggesting that centenarians with fewer resources, particularly proximal resources, tend to show decreasing levels of positive affect and increasing levels of negative affect.

Predictors of Depressive Symptoms

Experience of depressive symptomology may be less related to chronological age, but is likely to be the result of other age-associated interacting factors. One influential predictor of depression among the oldest old appears to be physical health and illness. Jang et al. (2004) found that disease and disability each independently predicted depressive symptomology among their sample of American older adults, including centenarians. However, this relationship is not straightforward, and factors such as illness type, gender, genetics, and personal beliefs appear to be influential. For example, Chang-Quan and colleagues (2008) also found that medical impairments were related to depression among Chinese older adults. However, this relationship was found only for certain types of illnesses and impairments. Specifically, out of 13 medical illnesses, only chronic lung disease, hypertension, arthritis, and hearing loss were associated with increased risk for depression. Gender also moderated this association; increased risk for depression was only observed among older Chinese women with these conditions. Depression was not related to any medical illness among older Chinese men. However, Chinese nonagenarians and centenarians with hypertension were not found to have an increased risk of depression compared to those without hypertension (Wen et al. 2010), prompting a need for further research in relation to certain medical illnesses and depression.

In the Fordham Centenarian Study, subjective health was the strongest predictor of individual differences in depressive symptoms: a more positive health evaluation was associated with fewer depressive symptoms (Jopp et al. 2016). Competence regarding instrumental activities of daily living had an independent negative and somewhat weaker effect. Social support through family and

relatives emerged as the third independent predictor, also being negatively associated. Other health aspects such as number of illnesses or personal activities of daily living were not associated with depressive symptoms.

There is further evidence that personal health beliefs are an important mechanism that may be responsible for buffering the effect of objective health issues, such as number of diseases, as they seem to contribute to the relationship between illness and depression among centenarians. Jang et al. (2004) found subjective health to mediate this relationship among American older adults, with the largest effects seen among centenarians. This finding might help explain the low rates of severe depression among this age group. For instance, only about 10% of participants perceived their health as poor among a sample of Italian centenarians whose mean GDS score was in the nondepressed range (Bauco et al. 1996). Thus, centenarians' health perceptions could protect against the effects of physical impairment on mental health.

Other factors such as personality and living environment have been shown to contribute to depression among centenarians as well. For instance, the personality trait neuroticism was found to relate to elevated depressive symptomology among American centenarians (Margrett et al. 2010). Furthermore, Margrett et al. (2010) reported that institutionalization status among American centenarians and near-centenarians (≥ 98 years) predicted greater depressive symptomology. However, living in an institution was not associated with depressive symptoms in the Fordham Centenarian Study (Jopp et al. 2016). Also, only 10% of Australian centenarians who resided in nursing homes or hostels met the criteria for depression in Richmond et al.'s (2011) study. Thus, in conclusion, evidence regarding predictors of depression in centenarians seems somewhat mixed.

Conclusion and Future Outlook

In sum, centenarians express high levels of well-being, and they show quite low levels of

depressive symptoms, both suggesting that psychological resilience is quite substantial at age 100. Notably, centenarians have high cognitive well-being, such as life satisfaction, and they feel as satisfied as younger-older adults and even middle-aged individuals. This indicates that the computation of overall life satisfaction, which is likely to take into account past and present aspects of different domains of living (e.g., life accomplishments, health, social and family relations, and other domains) is still working rather well in the sense that those domains with poorer evaluations get compensated by domains with more positive evaluations, allowing centenarians to maintain a rather positive evaluation. Findings are similar for happiness, representing a somewhat more emotional (and less computational cognitive) dimension of well-being. Regarding more emotion-centered fluctuating well-being dimensions, centenarians have lower levels of positive affect than octogenarians, although the differences are not large. Also, a reduction of positive affect has been documented over time, which suggests that difficulties encountered in life at age 100 result in the experience of less frequent positive emotions, maybe because instances that tended to be associated with moments of joy and enjoyment become fewer; yet, such differences or changes have not been observed with respect to negative affect which is experienced at a similar rate compared to younger-older adults and is stable over time. Together, these latter findings can also be interpreted as an indication that the mechanisms which buffer the influences of day-to-day experience still function quite well, so that challenging experiences do not result in an augmentation of negative feelings. As for depression, there seems to be no comprehensive evidence base today regarding higher or lower levels of depressive symptoms in centenarians; however, findings clearly indicate that only a minority of centenarians show elevated levels of depressive symptoms, underscoring that depression is not a normal part of reaching very advanced age.

These findings on high average levels of well-being are encouraging, yet there are of course individual differences. As for the factors that contribute to well-being, findings suggest that

objective factors, such as multimorbidity indicated by number of illnesses, play less of a role for positive well-being dimensions. Health variables that are related to cognitive well-being were functional aspects, which reflect the amount of autonomy a centenarian is still able to maintain despite health problems, as well as the evaluation of one's health, which depends only in part on objective health conditions but reflects the centenarian's capacity to cope with them, for example, by changing evaluative standards and expectations (i.e., judging one's health at age 100 as good, as all peers have already passed away). Social aspects, such as the number of living children, also were significant in some studies. Notably, for affect, more direct effects of proximal resources (instead of more distal) were found, including baseline walking capacity for changes in both affects, and financial means was further important for change in positive affect, but not for negative affect, underscoring differential effects for both affects. Yet, findings confirm that psychological strengths such as optimistic outlook have a strong direct influence and also mediate the effect of other, more objective resources on well-being, suggesting that these factors may be of particular importance. Thus, the well-being paradox apparently not only holds at age 100, but the psychological mechanisms that may be responsible for it are still in place and functioning quite well. Whether the same strengths are responsible and whether their effects are similar to those of younger ages warrant further examination.

Depressive symptoms, instead, seem to be more strongly associated with objective health issues such as number of illnesses. However, in some studies, only specific medical conditions were significant, and some effects were only found in women. Similar to the well-being dimensions, subjective health was also an important predictor for depressive symptoms across different studies. Single studies also report on the effects of neuroticism, social aspects, and living conditions, but more research is needed to clarify their potential influences. Thus, currently available studies seem to indicate similarities but also differences in the predictive patterns, yet this may

be, at least in part, a function of the predictors included in the study or analysis.

Limitations of the presented findings include that they stem from a small number of studies to date; thus, study characteristics such as sample representativeness need to be kept in mind. More research efforts are needed that investigate well-being dimensions at age 100 to strengthen the evidence available. Furthermore, the evaluation of some of the findings is difficult as these studies used different predictors and measures. More systematic efforts are required, for example, to determine the predictive validity of similar predictor sets for cognitive and emotional well-being dimensions and depressive symptoms within the same sample, to gain a better understanding of differential effects, and, across different samples, to ensure generalizability. In addition, comparing well-being levels and predictors across centenarian samples from different countries would help to examine which factors are relevant across and within specific cultural settings, given that not only person factors but also societal or cultural frameworks may be of influence. Currently, several efforts are undertaken to pool existing data to investigate, for example, depressive symptoms and their predictors in the context of a centenarian consortium. In addition, data from some centenarian studies are now also available which used similar recruitment and measurement and included various psychological constructs (Jopp et al. *in press*), which will not only result in findings on cultural specificity but will also enable testing more complex models predicting well-being, given they will be able to draw on larger samples. Moreover, studies are needed that address well-being predictors not only in centenarians but also in younger age groups in parallel, in order to determine which variables may contribute to well-being at different ages and which have unique contributions at age 100. And, of course, longitudinal studies in very old age would be important to address in more detail the dynamics of the mechanisms, such as, for instance, how changes in predictors (e.g., loss of meaning in life) may be related to change in well-being dimensions (such as depression). This could add to urgently needed groundwork regarding

development of preventions and interventions, as psychosocial interventions may be much cheaper to help older individuals in crisis, compared to paying for resulting costly medical interventions. Finally, long-term prospective studies will be instrumental in clarifying the extent to which well-being and psychological strengths facilitate reaching very advanced age and whether centenarians have a specific psychological makeup that has helped contribute to their exceptional survival.

Together, these research efforts will hopefully increase the understanding of centenarians' well-being and contributing factors and lead to a strong knowledge base that can be used for prevention and intervention efforts. In the end, maybe, the findings will confirm that successful aging in centenarians should be conceptualized as the amazing capacity of these extremely old individuals to cope with the challenges of their exceptional longevity, as a true victory of the human mind over age-related adversity.

Synonyms

Bereavement; Death; Loss; Spousal bereavement; Widow; Widower

Definition

The death of a spouse is considered one of life's most stressful experiences yet it is, for many, a central experience of growing older. The terms "spousal bereavement" and "widowhood" are often used interchangeably in the literature. Both are marked by the death of a spouse but while spousal bereavement is generally understood to be a short-term state, *widowhood* refers to the ongoing, longer-term experience which requires an individual to reestablish their life in their new status as a widow, a woman whose husband has died, or a widower, a man whose wife has died. The death of a spouse has immediate and

longer-term consequences for many aspects of the surviving spouse's life, including their health and well-being, their personal relationships, how they spend their time, and their sense of self. The experience following the death of a spouse is personal and is influenced by a wide range of factors including prebereavement health, access to support, features of the married relationship, and characteristics of the surviving spouse. It is important to distinguish between these two distinct though related terms, bereavement and widowhood, since the effects of one may differ from the effects of the other. For example, shorter-term disruptions in sleeping and eating patterns are common following spousal loss, but these do not typically continue, longer term (Stroebe et al. 2001). The typical cut timescale of bereavement effects is around 2 years, after which effects are usually attributed to nonbereavement events.

Theoretical Perspectives

The experience of the death of a husband or wife, or spousal bereavement, is a high probability event in later life, particularly for women. In developed countries, people are living longer and the proportion of older adults is increasing. In the UK, recent statistics suggest that around 30% of women aged between 65 and 74 are widowed, compared to around 10% of men of the same age. Among those aged 85 and over, while 44% of men are still married, nearly 80% of women are widowed (Office for National Statistics 2005). These patterns may be explained by higher life expectancy for women, women tending to marry older men and women remarrying after bereavement less frequently than men. Thus, men do not expect to be widowers as much as women expect to be widows. In line with demographic trends, much of the literature on widowhood focuses on women.

As early as 1917, Sigmund Freud (1953/1974) considered the impact of the death of a loved one on mood and the complex process involved in overcoming grief. Bereavement research traditionally categorized the experience of loss as prescriptive stages. In order to "recover" from their

bereavement, a person should confront their grief by moving through a series of ordered emotional states within a particular timeframe. Both the absence of grief, or prolonged distress, would be viewed as dysfunctional. However, these approaches tend to medicalize the experience of bereavement and fail to address the complex personal adaptation process. Colin Murray Parkes (1996) examined the effects of bereavement, with a focus on people widowed at a younger age, identifying the features of grief and the ways in which the bereaved could be better supported. The majority of research on spousal loss examines the effects up to 2 years after bereavement.

Helena Znaniecka Lopata was the first scholar to study, in detail, the experience of widowhood for older American women. In her book, *Widowhood in an American City* (Lopata 1973), Lopata made significant contributions to the understanding of the emotional and the social consequences of losing a husband. Stroebe and Schut drew on the large literature on coping with stress to develop the Dual Process Model of bereavement. The Dual Process Model (Stroebe and Schut 1999) attempts to explain the ways in which people adapt to bereavement. It outlines two types of coping: loss oriented and restoration oriented. Loss-oriented coping is characterized by grief work, which involves working through feelings, memories, and thoughts associated with both the spouse and their death itself. Clearing the deceased spouse's possessions or moving to a new home would be examples of loss-oriented coping. Restoration oriented, by contrast, comprises activity which facilitates change, such as taking up new hobbies, forming new relationships. It also involves avoiding things that serve as reminders of grief. For example, trying to keep busy so that there is little time to think. In this conceptual model of bereavement, coping moves, or oscillates, between loss- and restoration-oriented coping tasks, Stroebe and Schut argue that loss-orientated behaviors are more common in the period following bereavement, with more restoration-oriented behaviors as time progresses.

Contemporary research continues to extend the understanding of the experience of bereavement

and widowhood. While many studies of bereavement are limited by their cross-sectional design, a team of researchers at the University of Michigan designed the Changing Lives of Older Couples (CLOC) study (Carr et al. 2006) – a large-scale prospective longitudinal study which tracked the experiences of older widows and widowers over a 4-year period following the death of their spouse. The CLOC data has revealed the complex associations between variables including marital quality, level of forewarning, economic resources, and a wide range of health and social outcomes, such as depression, health behaviors and relationships, following spousal death. The knowledge offered by this, and other research on the experience of spousal bereavement and widowhood is summarized below.

Challenges in Late Life Widowhood

Health challenges Widowhood represents a decline in health, both psychologically and physically. Marriage has a protective effect on health. Research demonstrates that, at least in the shorter term, the death of a spouse causes lowered levels of psychological well-being (Soulsby and Bennett 2012). Widowed older adults report higher levels of mood and anxiety disorders, lower levels of life satisfaction, and elevated levels of loneliness. A much smaller proportion experience clinical levels of depression, contradicting the view of bereavement as an “illness.” Marriage can provide a sense of meaning and has been found to influence feelings of mastery and self-esteem. Evidence shows that spousal death has the potential to cause feelings of worthlessness and reduced morale for older adults, which persist even after several years (Soulsby and Bennett 2012). Further, psychological stress has a physical impact. Thus, it is perhaps not surprising that, since widowhood is regarded as one of the most stressful life experiences, older widowed adults, who may already be experiencing failing health, report a higher number of health problems and more disturbed patterns of sleeping, and are more likely to engage in health poor behaviors (e.g., poor diet, lower levels of exercise and substance use)

compared to their married counterparts. The relationship with medical support is less clear: for some, use of medical support increases, while for others, widowhood represents a decline in the maintenance of health behaviors. People often talk about spouses dying from “broken hearts” after the death of their spouse and research shows that widowed adults, and men in particular, have a higher mortality risk compared with married people, especially in the immediate period following bereavement (Stroebe et al. 2007). However, while physical health impacts may persist alongside an age-related decline in health, the psychological impact of the death of a spouse is typically acute with significant psychological disruption in the immediate period following bereavement, which usually resolves over time.

Social challenges One mechanism explaining psychological and physical health changes in widowhood is the loss of support associated with spousal death. Relationships are important to health, independent of a person’s marital status, and it is well established that greater access to support allows for better levels of health by providing a sense of self-worth, for example, or helping us to cope during times of stress. The way people organize their personal relationships, including how and how often they interact with family and friends, vary by marital status. For example, there is evidence that widowed women develop a preference for friendships with other widows (Morgan et al. 1997). Marriage is often regarded as a fundamental basis for support and integrates people into wider social networks. Not only is widowhood marked by the death of a primary source of support, the spouse, it also causes significant changes in the wider social network. Thus, social changes in widowhood have implications for health. The structure of the social network changes with increasing age, and older adults typically report a smaller network, comprised of more fulfilling relationships. Widowhood has been called a “social crisis”: the bereaved must learn to socialize as a single person, renegotiate relationships with friends and kin, weakening some ties while strengthening others, and may face the loss of relationships with married couples and shared friends. Often,

changes in social relationships occur not only after spousal bereavement but also before the loss where there is a period of illness (Carr et al. 2006). In the immediate period after spousal bereavement, family members are the central support providers and an important center of social activity, especially as the widowed manage the tasks and ceremonies associated with death. The widowed have reduced involvement in leisure activities, which may result from reduced desire to socialize, loss of a leisure partner, or the practical barriers, such as money or transport. This, in turn, can have a negative impact on well-being. Over time, the social network then evolves and the duration of widowhood is positively related to the likelihood of contact with friends, forming new friendships and, for some, development of new romantic relationships.

Renegotiating identity A person's sense of self is challenged following the death of a spouse. The married relationship is a central source of identity, both privately and publically, and it is common for the death of a spouse to be compared to the loss of a limb. Widowhood prompts a process of identity reconstruction through the loss of the coupled identity, the performance of day-to-day activities as a spouse, and the social meaning of being married. The surviving spouse must adjust to the new status as a widow or widower. This involves the loss of an often long established identity as a wife or husband, accommodating new roles and responsibilities and adjusting to changed relationships with family and friends. The experience of widowhood is assimilated into a person's understanding of themselves. For older widowers, becoming a widower is usually in addition to the negative identity consequences of the transition out of work through retirement. There is evidence that the loss of the married relationship threatens men's masculinity and that, often, men find ways to maintain a masculine identity, including remarriage (Hoonard 2010). Yet, the status of "widow" or "widower" allows the surviving spouse to maintain a bond with their spouse and is an acknowledgement of their married relationship, as someone who was married and experienced spousal death. Indeed, research demonstrates that those who continue to

communicate with their deceased spouse appear to cope better than those who do not. In one British study, older widows spoke about the way their identities had changed as a consequence of their widowhood. The women reported an augmented identity. That is, they described not having a sole identity as a widow, but having an identity as a widow whilst retaining their identity as a wife (Bennett 2010a). As this suggests, coping is associated with the widowed trying to establish a new autonomous identity. Researchers have argued that widowhood provides an opportunity for the widowed to learn new skills and the experience of personal growth is not uncommon. For example, older widowed adults might experience a sense of achievement, or describe themselves as a stronger, more independent or a better person having experienced this loss. Older women tend to describe these changes more frequently than do older men. Continuity of relationships with family and friends, as well as having opportunities to develop independence and a sense of personal autonomy may all facilitate better adjustment in widowhood.

Practical challenges As well as changes in the social resources described above, older widowed adults face a loss of economic and practical resources, and significant changes to their daily routine. There is usually reduced financial security; they may need to relocate physically; and must learn to live alone, reconstructing their daily lives to account for the changing responsibilities. Widowhood affects the performance of day-to-day household tasks, particularly for older men (Carr et al. 2006). Gender-based household responsibilities are typical in this cohort of older adults and, while friends and family may assist with instrumental tasks in the early stages following bereavement, the widowed must learn to adapt to new domestic responsibilities that were previously performed by their spouse. Widows describe learning how to manage their finances and home maintenance, while the amount of housework performed by men typically increases. The quality of the married relationship influences the ease with which people manage these practical adjustments in widowhood. For example, higher levels of anxiety have been found among those who were highly dependent on their spouse for

household tasks (Carr et al. 2000). Adult children are usually a central source of instrumental support for older widowed. While research suggests that widows are more likely to give and receive higher levels of support from adult children than widowers, there is evidence that men are perceived to receive more support than women after the death of a spouse. As time passes, the provision of support typically declines, as the widowed adapt and no longer need as much support. However, declining health remains a physical barrier to instrumental independence among the older widowed.

Factors Influencing Adjustment in Late Life Widowhood

The experience of widowhood is complex and may vary considerably from person to person, depending on situational factors surrounding the death, access to the resources needed to support adjustment and individual-level factors, such as gender and age.

Circumstances of the death Situational variables, including forewarning, can influence adaptation following bereavement. The experience of spousal death varies between those who had some forewarning and those whose spouse died suddenly (Carr et al. 2006). Care work is emotionally and physically challenging, and older adults providing care for a spouse may also experience isolation. Yet, longer terminal illnesses may allow the surviving spouse to discuss and prepare for the death with their spouse and anticipatory grieving may take place. In sudden death situations, on the other hand, there is usually no opportunity to discuss impending death with the spouse, which may cause poorer health. Research demonstrates that unexpected deaths, violent deaths and suicide are more often associated with psychological distress compared to other types of deaths, especially those which occurred in natural circumstances. Other circumstances of death, such as the relationship between the deceased and the surviving spouse, influence the adjustment to widowhood. A higher level of dependence on a spouse during marriage is associated with a higher level of yearning and anxiety in widowhood. In contrast, marriages which were high in conflict

predict better outcomes following the death of a spouse (Carr et al. 2006). For those who were heavily dependent on their spouse, adjustment in widowhood may be more challenging.

Gender While spousal bereavement is less common among men, the central experiences of widowhood do not differ by gender. Both men and women miss their spouses and find life without their spouses challenging. Yet, the majority cope well enough. Research suggests that there are gender differences in the shorter-term psychological impact of spousal death. In general, older women are more likely to report higher levels of depression than men. However, in widowhood, these gender effects are generally reversed. Both men and women have lower levels of psychological health compared to their married counterparts but, compared to widows, widowers are more vulnerable to depression and are more likely to die (Stroebe et al. 2007). Gender also influences access to support in widowhood. Older widows are more likely to be involved in kin and friend networks, whereas older widowers report less access to support and may be disadvantaged by the absence of a peer group (Stroebe et al. 2001). One common assumption is that men are more likely to remarry to address this lack of support. The rate of remarriage or consideration of remarriage is higher amongst widowers than widows, and widowers are quicker to do so than widows (Bennett et al. 2013). However, actually only a small proportion of widowers remarry. In the UK, 6.1/1000 widowers aged 55 years and over remarry, compared to 1.1/1000 of widows (Office for National Statistics 2005). Interestingly, men and women talk about the events that led up to the death of their husband or wife in different ways (Hoonaard and Bennett 2013). Women's death narratives focus on goodbyes, on the emotional impact of the death and on the (un)expectedness, and place, of death, while men talk about the deaths in a way that enables them to show themselves as men. They are more factual about the events and use masculine speech, describing how they protected their wives.

Age Widowhood is a more expected event in later life. Compared to spousal death in midlife, older widowed adults may be more prepared

emotionally and practically and are more likely to have a widowed peer group (Soulsby and Bennett 2012). In a study comparing the experiences of widows over three age groups, young widows were found to be more symptomatic and, moreover, the symptom severity was more pronounced for those widows who had lost their husband at an earlier age (Ball 1977). There appears to be a curvilinear relationship between age and mortality/morbidity. Evidence suggests that those widowed in midlife are at greater risk compared to both younger and older widows. However, there are specific challenges faced by those widowed at an older age (Stroebe et al. 2001). Vulnerability to the short-term strains of widowhood increases with age. Most likely, this is in part attributable to the fact that it aggravates existing health problems, which are more prevalent in older adults. Older widowed adults may be faced with other losses, including reduced finances and the death of older family and friends. Older adults may feel that they should suppress their emotions. There are also differences in access to support: younger (aged 50–75 years) widows and widowers have a more stable social network compared to older (aged over 75 years), who typically experience a reduced sense of closeness to members of their social network (Lund et al. 1990). Thus, those widowed in later life may be at greater risk of experiencing social isolation or loneliness (Carr et al. 2006).

Coping in Late Life Widowhood

Research demonstrates that, while widowhood is no doubt one of life's most stressful events, the negative impacts of spousal bereavement recover over time and most people are able to adapt to their changed circumstances. What facilitates adaptation? Traditional approaches to bereavement held that the bereaved must engage in grief work: working through thoughts and feelings in response to the death as a means of moving forward. More contemporary views argue that grief work is not a necessary part of adaptation in widowhood. Many older widowed adults cope reasonably well with the death of their spouse

without professional help. They instead draw on their own resources.

The Dual Process Model of bereavement (Stroebe and Schut 1999), described earlier in this entry, offers an insight into the types of coping processes that are associated with successful adjustment: accessing support when needed, making meaning, developing new relationships and reconstructing a new identity help to foster adaptation. As has been discussed earlier in this entry, access to support following the death of a spouse is a predictor of health outcomes and those who are embedded in supportive networks generally fare better. Friendships are particularly important for emotional and social well-being in widowhood and research has demonstrated that opportunities for reciprocal emotional and instrumental support are associated with lower levels of depression, greater satisfaction with life, and better coping.

Research using data from the CLOC study has revealed different adjustment trajectories in widowhood: time-limited disruptions, or “common grief”; chronic disruptions, lasting several years or longer; improved well-being; and the relative absence of depression (Bonanno et al. 2004). Among those who exhibit chronically elevated levels of depression, researchers have highlighted the importance of prebereavement functioning, distinguishing between those experiencing *chronic grief*, characterized by marked, longer-term increases in depression in response to the challenges of the death of a spouse, and those experiencing *chronic depression*, who report elevated levels of depression prebereavement, which then persist in widowhood. Another group, labeled the “depressed-improved” group, show a pattern of high levels of depression prebereavement, which is significantly reduced after spousal death. The pattern of adjustment in this group suggests that spousal bereavement represented the experience of the end of a chronic stressor such as an unsatisfying marriage and/or care work prior to the death. Finally, research shows that between approximately 30–50% of widowed men and women are resilient and do not show significant increases in depression, or other grief responses including searching for

meaning, thinking and talking about the loss, and distraction, following bereavement.

Resilience may be broadly understood as an ability to “bounce back.” A person could be classified as resilient if they viewed their current life positively, they were currently actively participating in life, and felt that their life had meaning and satisfaction (Moore and Stratton 2003). Thus, although most older adults are able to adjust in widowhood, not all who adjust appear to be resilient. Resilience may develop gradually, such as through the exercise of practical skills and the maintenance of emotional ties, or following a turning point, such as the receipt of support (Bennett 2010b). Contrary to the clinical view that the absence of grief symptoms is indicative of unresolved grief or denial, there is no evidence that resilient individuals are maladjusted or have a lesser emotional bond with their spouse.

Summary

Research demonstrates that the death of a spouse in later life has a profound psychological, physical, and social impact. Spousal bereavement poses challenges for health, personal relationships, financial stability, and identity and widowed older adults must adjust to a new life as a widow or widower. Despite this, most older widowed adults demonstrate a capacity to adapt to the challenges associated with the death of a spouse, and many are resilient. Yet, there is still much to learn about the experiences which follow the death of a spouse. For example, we have not discussed the cross-cultural variations which may exist in the meaning and impact of spousal bereavement and subsequent widowhood. There may be generational differences in coping strategies, and this will influence the experience of widowhood for future cohorts of older adults. Limited research has considered the loss of a partner in same-sex unions and this needs more attention. It is hoped that future research will shed more light on the short- and longer-term experiences of both heterosexual and LGBT spousal loss.

Aging; Gender; Retirement; Work transitions

Definition

A woman's retirement is a subjective experience that includes personal (lifestyle) as well as objective indicators (ceasing work). A women's retirement age is defined as the age when a woman

describes herself as permanently not working or looking for work.

Introduction

Acknowledgment of the gender differences for working women has intensified awareness of the issues surrounding women in retirement. Prior to the 1980s, retirement research included women specifically only as a proviso to examine married women's perceptions of their husband's retirement or to analyze the effect retirement had on marital behavior. This trend reflected societal norms which tended to perceive women as dependent wives of male earners, who had minimal income independence or financial security in their own right. However, women's participation in the labor force has significantly increased over the last four decades, predominantly due to improved access to postsecondary education, legislative changes regarding pay parity for female workers, and a greater demand for workers in the service industry. With the increase in women participating in the workforce and as they continue to live longer than men, women will continue to make up a larger proportion of the retired population. The focus of this discussion is to illustrate that women's retirement experiences, like their working experiences, are different from men's experiences and therefore require specific attention in research and theory development.

Women's Retirement: Research Approaches

Calasanti (1996) has argued that a historically "androgynous" view of retirement fails to acknowledge the ways in which women's experiences are distinct and/or unique from men's. While similarities between men and women's experiences in work life, such as seeking feelings of competence or aiming to make a productive and necessary contribution (Perkins 1992), may have provided support for this approach, substantial differences exist between the working lives of

men and women. Women tend to be employed at lower organizational levels and are more likely to be employed in clerical, sales, and service roles. Conversely, jobs involving supervisory or managerial capacities are more likely to be held by men. In addition, women's employment pathways tend to be more circuitous and intervallic than men's, largely due to commitments to care for family members. Such pathways have a significant impact on a woman's opportunity to develop a continuous set of skills or to improve their occupational status (Quick and Moen 1998). They also tend to have had job assignments with lower remuneration, limited benefits, and fewer opportunities for career progression or promotion (Jefferson and Preston 2005). Compared to men, women are also more likely to occupy jobs that do not offer highly remunerative superannuation schemes.

Differences in men's and women's work life play an important role in differentiating the retirement experience of women from men, beginning fundamentally with the way in which retirement is defined. Common conceptions of retirement involve the transition from work as a distinct point in the life cycle when a working adult (usually an older male) leaves the workforce and never reenters it. For the growing number of retired women who continue to carry on with the domestic tasks and the activities they had always done while working, the notion of a "crisp" or one-time break from working life does not closely align with their experiences. Moreover, given demographic changes in the workforce and a concurrent move away from traditional gender roles and conventional family structures, it is neither appropriate nor accurate to assume that a woman's transition to retirement or her post-employment experience will follow the same pattern of previous generations of women or of men. New models for research on women and retirement are needed that consider the changing nature of the work environment and the unique experiences of women in and beyond the workforce. Two research approaches that work toward these ends include gender comparison studies and within

gender studies that more specifically focus on the female experience.

Gender Comparison Research

Gender comparison research has been influential in identifying the ways in which the differences in men's and women's working lives influence their retirement experience. Four areas of research in this field include examination of the differences between men and women in remuneration and benefits, retirement planning and decisions, retirement goals, and levels of satisfaction upon retirement.

Gender Differences in Remuneration and Benefits

Pay differential between working men and women is one variable that gender comparison research has explored for its effects upon retirement adjustment and well-being. According to aggregate statistics from 15 Organisation for Economic Co-operation and Development (OECD) countries in 2005, women on average have 29.2 years in employment, whereas men have 36.1 years (OECD 2009). Moreover, in the United States, women's full-time earnings were on average 81% of their male counterparts' earnings in 2005 (US Department of Labor 2006). The pay differential in the United Kingdom currently stands at 86% (Women and Equality Unit 2005) and ranges from 53% to 79% in European countries (OECD 2002).

These figures show that in general the extent of inequality has narrowed slightly since 1950 when a woman, on average, earned 60 cents for every dollar earned by a man (Blau and Kahn 2000). Nevertheless, for many families, the woman's income is a secondary source of earnings and is typically used for current consumption, presumably because this income has been considered temporary due to her discontinuous work history (Butrica and Iams 2000). If however the marriage fails, the inequality of this financial situation comes to the forefront, and

the financial disadvantage falls heavily on the woman (Orel et al. 2004). She consequently has more limited earning power or job opportunities, is without sufficient pension, and has not accumulated an asset base for her future security (Butrica and Iams 2000).

Differences in employment tenure and disparities of income during employment continue to impede women's abilities to qualify for pension schemes or accumulate savings; thus, the average income of women during retirement is disparate from that of men (Jefferson 2009). Women, on average, earn 79% of a man's retirement income (Social Security 2014), and in some high-income nations, more than 75% of the elderly poor aged 65 and older are women (Smeeding and Sandström 2005). With life expectancies surpassing that of men in industrialized nations, women are more likely to spend additional time in retirement, relying on accumulated lifetime savings for extended periods of time and thus contributing to their quality of life in retirement.

Retirement Planning and Decisions

In general, women spend less time planning and preparing themselves for retirement compared with men (Jacobs-Lawson et al. 2004), a finding that has been attributed both to financial (lower disposable income leading to less planning) and socialization factors. In many cultures, women are socialized to believe that retirement is an exclusive life event for men, even if both husband and wife have been working throughout their adult lives. For example, Barnes-Farrell's (2003) research has shown that in dual career couples, the husband's anticipated retirement is quite often the most important factor in a woman's own retirement decision. In an earlier study, Whiting et al. (1998) found that retirement preparation was either exclusively focused on the husband's planned lifestyle, or what the couple would do together, leaving many women in the study unprepared for retirement in terms of financial preparation or recreational planning. Further, older women have often exercised less economic influence within the family and therefore have had

little experience in financial planning. In many cases, women have been insulated from understanding or knowing about their husband's financial situation, which can leave them vulnerable if widowhood occurs (Society for Research on Women in New Zealand 1999).

Retirement Goals and Roles

When women do actively engage in planning for retirement, research suggests that their goals and aspirations tend to be more ambiguous than those reported by men. For example, Jacobs-Lawson, Hershey and Neukam (2004) found that women had more abstract goals, whereas men had more concrete goals. Women's goals were typically "other" focused compared to men (e.g., spending time with family, going out with friends). This corresponds with conventional beliefs that females are more apt at establishing and maintaining interpersonal bonds. The men in the sample rated leisure goals much more highly than women (e.g., golf, walking). Both men and women had a comparative number of goals regarding financial stability, exploration (e.g., holidays), contribution to others (e.g., volunteering), and spiritual (e.g., church, ministry work). However, men tended to generate task-specific goals, whereas women generated abstract goals, and were typically more concerned with general states of well-being than the realization of retirement goals (ibid.).

Particularly for older men and women, gender roles may also have an influence upon retirement decisions. One area in which the influence of gender roles manifest was the number of dependents in a working women's household; the greater the number of dependents, the greater the likelihood of women being retired (Talaga and Beehr 1995). Women in Talaga and Beehr's (1995) study were more likely to be retired if their husband was in poor health, enabling them to stay home to provide care. In addition to highlighting the extent to which external or uncontrollable factors in the women's environment were significant predictors of women's decisions to retire, Talaga and Beehr's (1995) research

further showed that many women continue to fulfill traditional roles as homemakers and caregivers in retirement, potentially affecting their retirement experiences and levels of retirement satisfaction.

In addition to retirement decisions, gender roles may also influence how retirement affects one's identity in retirement. Research by Hanson and Wapner (1994) suggests that many women experience retirement as a continuation of life rather than a defining change of role. Because women in Hanson and Wapner's (1994) study were more likely to derive their identity from informal roles and relationships, as opposed to structured roles in occupational settings, many found the transition to retirement less taxing than men. These findings led the researchers to suggest that women's working lives, often full of discontinuity, contributed to their ability to find role continuity as they transitioned into retirement (Hanson and Wapner 1994).

Retirement Satisfaction

Studies that compare retirement adjustment through the lens of gender have produced some interesting, although at times contradictory, findings. For example, Quick and Moen (1998) reported that men are more likely than women to report satisfaction in their retirement compared to the last 5 years of employment. A more recent study explored the level of satisfaction of married retirees with their own retirement experience compared with their spouses, finding that husbands of retired wives are more satisfied than the wives of retired husbands (Smith and Moen 2004). Richardson and Kilty (1991) point to extended periods of unemployment in a female's work history and their propensity to spend more time in part-time employment as adversely affecting their retirement quality. However, Quick and Moen's (1998) research suggests that employment disruptions do not necessarily directly trigger retirement dissatisfaction. Their research found that women were more likely to report satisfaction with their retirement if they had experienced several yearlong gaps in their employment history. According to the researchers, the

transition to retirement perhaps is not as stressful for these women because they have experienced reasonable amounts of time away from the workforce, compared to those women who have been working continuously. Yearlong breaks may also be part of a planned employment strategy, which may not affect job reentry and occupational stability, or dramatically alter pension plans or lifetime savings. In addition, the ability to take multiple yearlong breaks probably also signals a socioeconomic and social support/marital status that enables this choice. The continuing availability of these greater resources may be a factor that contributes to the greater retirement satisfaction reported by women who appeared to have a planned strategy in their broken employment history.

Other studies have identified no significant differences between men and women with regard to retirement satisfaction (Kim and Feldman 2000). For example, Seccombe and Lee (1986) found that the antecedents of retirement satisfaction were similar for both genders; retirees in better health and those with higher incomes were more likely to report greater retirement satisfaction, regardless of gender. However, it should be noted that while moderating effects were not apparent in Seccombe and Lee's (1986) study, a number of individual differences associated with retirement satisfaction differed across gender, including length of time in the workforce, employment opportunities, and lifetime income. As such, the status of women on these variables can mean that at retirement, they are positioned in less favorable circumstances. Thus, individual differences in life circumstances may have more of an effect upon retirement satisfaction than gender per se. For Dailey (1998), key factors contributing toward a comfortable retirement for women include being married, having a high education, having an uninterrupted work history (or planned breaks maintaining occupational status), and owning a home. Circumstances such as divorce, downsizing, and disability reduce women's prospects during retirement and increase the risk of poverty in old age, a pattern that does not hold for both genders (Dailey 1998).

Within Gender Research

Both male-oriented theoretical models and gender comparison research have contributed to a greater understanding of women's unique experiences in retirement. However, today's female retirees' experiences differ in important ways from both their foremothers and from their male counterparts, making women's retirement an important area for research and theory development. A discussion about women's experiences with retirement must consider the unique circumstances such as employment history and the nature of work commitments and family responsibilities that have shaped their lives within and outside of the context of their work. Three key areas are discussed below which consider the ways in which women's experiences are distinct from men's: women's roles and role identities, caregiver responsibilities, employment pathways, and remuneration opportunities.

Women's Identity in Retirement

For many people, regardless of gender, one's position in the workforce is a principal source of personal identity. Research by Barnes and Parry (2003) found that women with strong work identities viewed retirement as a negative life event in ways that differed from men; women described retirement as a loss of a source of sociability while men described retirement as a time of potential loss of status. Price (2000) found that women retired from a professional career were more inclined to miss the challenge that work provided, as well as opportunities to tackle issues of problem solving, or to face novel experiences or other complex dilemmas on a daily basis. Many of the interviewees in Price's (2000) study had to confront stereotypes regarding retired women, particularly the perception that retired women are incompetent. As a result, many felt that they experienced discrimination because of their retired status. Despite the loss of the sense of achievement that came from their daily work, the majority of women retirees Price (2000) interviewed maintained that their sense of identity had not been severely threatened following their retirement.

Adjustment to retirement has also been shown to be affected by the type of jobs women held in their working life. For example, Price (2002) interviewed 29 retired women about their working and retirement experiences, half of whom had held professional jobs (e.g., medical doctor), while the remaining half had held nonprofessional jobs (e.g., clerical worker). In terms of the women's attachment to work, professional women in the study viewed retirement as an ending to a significant chapter in their lives. These women indicated that they felt a loss of social status after retirement, and over half of these women reported missing the social interaction that their work had provided. For professional women in particular, the incorporation of structure into their daily lives facilitated the adjustment process. In contrast, nonprofessional women expressed little difficulty in leaving their work roles, indicating that they felt relieved from the workforce. Nonprofessional retirees also indicated that they did not miss the interaction with former coworkers and reported being more involved with community and social activities. Nonprofessional women were inclined to view their family as their primary job, even during their working years. Finally, due to their more transitory employment histories, nonprofessional women were more likely to have greater familiarity with the adjustment process necessary to successfully adapt to moving out of the workforce (Price 2002).

In some aspects supporting and in some contrasting these findings, Richardson and Kilty (1991) found that women who had worked in jobs with low occupational status and experienced a large drop in income were most vulnerable to retirement adjustment problems. The authors suggested that retirees who had worked in professional or prestigious jobs are more likely to retain professional contacts, be involved in professional groups, and take on part-time professional employment, therefore maintaining their connections to, and status and integrity within, the community. Moreover, because of the nature of their occupations, many professional women are able to continue to practice their skills and abilities in

new roles that provided them with a sense of accomplishment and self-esteem. In contrast, retirees who had worked in low-status occupations were less likely to be able to utilize their skills in a way that generated postretirement income or facilitated social contact during retirement (Richardson and Kilty 1991).

Family Responsibilities and Women's Retirement

For many working women with comparable levels of education and income to men, family commitments and responsibilities have had an effect on their ability to actively participate in the labor force. Thus, a large majority of today's female retirees have faced child-rearing responsibilities and are also likely to have had an, at least somewhat, intermittent employment record. This generation of retirees is also the first cohort of women whose participation in paid work has extended most of their adult lives. In contemporary research on women and retirement, women's work history and pathways are considered important factors in how and when retirement is experienced by women.

At varying stages of their lives, many working women find they must negotiate the demands of family and work obligations simultaneously. For example, childcare responsibilities often compete with work demands during a parent's early life, and eldercare needs may create significant strains during a woman's midlife. For many women, family care responsibilities take precedence over participation in the paid workforce. This results in a substantial proportion of women taking time out of paid employment in order to meet family needs, with particular impact on women whose country's pension scheme is based on participation in paid work (Jefferson 2009) or work for companies with employee-sponsored plans (Even and McPherson 2004; Thompson 2006). For many women, meeting these family responsibilities can dramatically affect the economic security and timing of their retirement. Through these effects, family responsibilities have the potential to significantly influence the psychological well-being of women during their elder years (Jefferson 2009).

During their working lives, a high proportion of women take on either full-time or part-time childcare responsibilities. Over the time, these occupational interruptions can have negative consequences for career continuity, upward mobility, and income potential. A causal link has been made by some researchers between access to affordable childcare and women's capacity to engage in employment and thus accumulate adequate pension entitlements (Frericks et al. 2006). Women who leave the employment setting for childcare responsibilities face losing potential seniority and job training opportunities and may experience skill depreciation or skill obsolescence (Dailey 1998). Further, because many retirement pensions and benefits are directly related to lifetime earnings, many women will receive significantly less than men in retirement income. Effectively, the operation of these factors can introduce a "wage penalty" for women who bear children (Hewlett 2002, p. 124). Although the entitlements for parental leave differ across countries, the effect of reduced overall earnings is not only economically disadvantaging for women during their working years, but also during their retirement. As noted previously, however, those women who experience several yearlong gaps in their employment history are more likely to report greater satisfaction with their retirement (Quick and Moen 1998). Such research indicates that planned career breaks need not be detrimental to a women's retirement well-being.

In addition to childcare responsibilities, women continue to cope with family obligations later in life when they face caring for their spouse or aged parents. The price of eldercare can be extensive in terms of time away from work and in the resources required to care for the family member. For instance, elderly parents must be taken to and from medical appointments, meals must be prepared and provided, housework must be completed, and personal hygiene must be attended to. Thus, in addition to the financial demands, eldercare almost inevitably requires an expenditure of time away from the employment setting (Hatch and Thompson 1992). The extent of these time requirements sometimes initiates the early retirement of women.

In addition to the need to care for elderly parents, ill health or disability in one's spouse has consistently emerged as an important predictor of the retirement decisions of married woman (Talaga and Beehr 1995; Hatch and Thompson 1992). In Talaga and Beehr's (1995) research, women who believed that their husband was in poor health were more likely to retire from the workforce to care for their spouse than were men with an unwell spouse or family member. In contrast, the men were more likely to continue to participate in paid employment to provide financially for their dependent family member. Further supporting this pattern, research by Matthews and Brown (1988) showed that female retirees, more so than male retirees, were more likely to retire for reasons that had to do with others, typically the health of their spouse or other family members.

Retirement from paid employment often implies a period of newly found freedom, a time when recreational pursuits can be engaged in with increased vigor, intensity, and commitment. However, for women who prematurely leave paid employment to assume a caregiving role, retirement is not generally viewed as an opportunity to pursue leisure activities but is considered another form of work in itself. Thus, the extent to which retirees have a sense of control over when they leave the workforce and deciding how to spend their time once leaving work seems to significantly affect retirement satisfaction and adjustment (Costa 1998).

Conclusion

One of the most consistent research findings in the retirement literature is that the cessation of paid employment is financially challenging for women, and a number of factors have been identified as contributing to this situation. Two of the most significant factors are gender-associated income differences during employment and the fact that women tend to experience greater temporal discontinuity in employment due to family responsibilities (US Congress Joint Economic Committee 2011).

Gender serves to shape the nature of one's occupation as well as the timing of retirement

and welfare during old age. The conflicting nature of a women's role in the home and in the workplace continues to result in economic disadvantages for a great number of women, inevitably creating a dependency on a wage-earning partner. Many women do not have access to their own pension schemes through their workplace and are unable to independently accumulate sufficient personal savings to retire in comfort.

Women are making significant inroads toward occupational advancement and in the past few decades have experienced work patterns typically found in male-oriented roles. As such, women currently forming expectations about their retirement will not generally replicate the retirement experiences of their mothers or grandmothers nor will their retirement experiences look like men's retirement. Overall, compared to their mother's generation, women will have spent more time in the workforce, will have enjoyed higher incomes, and will have accumulated more pension privileges (US Congress Joint Economic Committee 2011). However, even though women who are currently in the workforce place a greater emphasis on their own opportunities in considering retirement, they, like previous generations of women, still have a high dependence on their husband's retirement income (Jefferson 2009). The reality remains true that a woman's marital status, her discontinuous participation in the workforce, her occupational and wage discrimination, and her extended life expectancy all significantly impact upon her retirement well-being.

It is therefore important that future cohorts of female retirees have sufficient knowledge about retirement which is based on their life experiences, not that of males (Price 2000). Because the number of retired employees will double in most industrialized countries over the next three decades, the need to determine the diverse experiences of women in retirement is necessary and timely (Everingham et al. 2007). Retirement models and macro-level policies need to recognize that retirement involves the intersection of social and economic factors as well as important life events such as childbearing and changes in marital status (Wong and Earl 2009; Dailey 1998).

Synonyms

Aging workforce; Big Five; Organizational behavior; Personality change; Personality plasticity; Social investment; Socialization; Work outcomes

Definition

Personality refers to how a person typically thinks, feels, and behaves. *Personality development* refers to how personality changes over time and with increasing age.

The Work Context and Personality Development Across Adulthood

Personality refers to individual differences in characteristic patterns of thinking, feeling, and behaving. Contrary to the hypothesis that personality is more or less stable after young adulthood, studies have robustly demonstrated that the Big Five personality traits continue to develop across the life span (Big Five Personality Structure and Aging). Due to the centrality of the (paid) work context for adult life, developmental researchers have been interested in how aspects of working life may be related to personality development, while organizational researchers have long been interested in how personality traits are related to work outcomes such as job performance and job attitudes. Given demographic changes including longer working lives and a higher share of older workers in the workforce taking place at the time of writing, there has been increasing interest over the last decade in understanding not only how personality and work outcomes are cross-sectionally related but also how normative patterns of personality *development* may affect the work context and work outcomes. In addition, the retirement transition as one of the major developmental tasks in later adulthood has been related to personality development at the end of (paid) worklife.

In the following we review the current state of scholarly literature on the relationship between the work context and adult personality development across the adult life span as described by the “Big Five” personality traits. With varying labels, the Big Five model refers to five personality dimensions: openness to experience (O; the breadth, depth, originality, and complexity of an individual's mental and experiential life), conscientiousness (C; socially prescribed impulse control that facilitates task- and goal-directed behavior, such as thinking before acting, following norms and rules), agreeableness (A; prosocial and communal orientation toward others, altruism, trust, modesty), neuroticism (N; negative emotionality, sensitivity to negative stimuli, tendency to feel anxious, nervous; the reverse of emotional stability), and extraversion

(E; energetic approach to the social and material world; sociability, activity, assertiveness, positive emotionality) (e.g., McCrae and Costa 2008). The Big Five model is the most widely studied model of personality within the work and personality literature and hence the focus of the current entry. There are, however, other personality characteristics and processes that are not subsumed by the Big Five model but which are relevant for discussion of personality development and the work context. Two examples are emotion and motivational processes. The relationships between work and developmental changes in emotional functioning (► [Affect and Emotion Regulation in Aging Workers](#)) and motivational orientation (► [Work Motivation and Aging](#)) are treated elsewhere in this volume.

Implications of the Paid Work Context for Adult Personality Development

Contemporary theories of personality development, most notably the neo-socioanalytical model of personality trait development (e.g., Roberts and Wood 2006), have challenged traditional assumptions that normative patterns of personality development are predominantly driven by biologically induced “intrinsic maturation” processes (e.g., McCrae and Costa 2008). Instead, normative changes in adult personality are thought to be driven at least in part by investment in more or less universal, age-graded social roles or “developmental tasks” such as working and establishing a partnership and/or family. Fulfilling social roles and developmental tasks requires certain behaviors. For instance, the work role requires that a person shows up on time, completes tasks satisfactorily, and gets along with colleagues. Meeting the demands of the work role is rewarded (e.g., through positive feedback, status, income), while failure to meet demands is punished (e.g., through negative feedback, lower status, lower income). People are therefore encouraged to develop in ways that lead to successful fulfillment of the demands of the particular social role (Roberts and Wood 2006). Over time the behaviors and characteristics that a person adopts in order to

meet the demands of a social role become automatic and can subsequently “spill over” into other life domains. The extent to which fulfilling the social role affects personality development depends on the extent to which a person psychologically invests in the social role (for the work context, e.g., Hudson et al. 2012).

In addition to a socialization effect, people also tend to select themselves into social (work) roles that correspond with their personalities. For example, people with a higher level of O to start with tend to seek out and stay in work contexts in which they are continuously exposed to new situations and leave work contexts that are characterized by monotonous routines. In turn, the very characteristics that attract a person to a certain work context are the same characteristics likely to be reinforced by the demands and rewards of the work role over time (*corresponsive principle*, e.g., Roberts et al. 2003).

Empirical evidence of the influence of the work role and specific workplace characteristics on personality development in line with the neo-socioanalytical model of personality trait development has accumulated (for an overview, see Woods et al. 2013). First longitudinal studies in the field of personality development and work demonstrated that increases in work satisfaction were associated with increases in measures of emotional stability in young adulthood (e.g., Roberts et al. 2003; Scollon and Diener 2006). Job satisfaction, social status, and financial rewards as well as the degree to which individuals in New Zealand reported investing in their jobs moderated the degree to which typical developmental patterns took place between ages 18 and 26. For example, young adults in jobs that provided higher status, more satisfaction, and more financial security decreased faster in N and increased faster in communal positive emotionality (related to A) relative to their peers in less rewarding jobs (Roberts et al. 2003). In a more recent study, workplace characteristics such as income, autonomy, and benefits at work were predictive of increases in positive emotionality (related to E) and decreases in negative emotionality (i.e., N) among a sample of US adults followed between adolescence and young adulthood (Le et al. 2014).

Furthermore, and in line with the corresponsive principle, participants tended to have jobs in young adulthood that (a) were associated with their personality traits in adolescence (selection) and which (b) led to further accentuation of the same traits associated with the selection processes. For instance, assertive and ambitious adolescents were more likely to later work in positions with higher security and stability. In turn, higher security and stability were associated with increases in ambition and assertiveness. Recent evidence based on representative data from Germany also supports the corresponsive principle. Young adults were found to select job contexts that matched their personality traits (e.g., participants high in E tended to select jobs that had high E demands). Moreover, their personality traits changed in the direction of their current job demands if they stayed in the same job over the course of the 4-year study period (Denissen et al. 2014).

Interestingly, the timing of entry into the workforce is associated with changes in personality. Based on representative German data, people who started their first job increased more in C than those who had not (yet) begun their first job (Specht et al. 2011). Furthermore, cross-country differences in the timing of transition to the work role were found to explain variation in age patterns of personality across 62 countries. Namely, accelerated increases in A and C and decreases in N were observed in countries with earlier normative timing of job-role transitions (Bleidorn et al. 2013).

Taken together, the body of evidence reviewed above suggests that social investment in the work role appears to be a major driver of normative developmental increases in functional or social maturity, that is, the qualities that serve to facilitate functioning in society (Roberts and Wood 2006). Namely, social investment in the work role is associated with increases in the Big Five traits A and C along with decreases in N, particularly when people invest in their work role and when their work role is rewarding. Results have been consistent across samples from multiple countries (e.g., the USA, Germany, New Zealand). In contrast, *not* investing in the work

role or having particularly unrewarding work experiences seems to be related to atypical patterns of personality development, such as increases in N and decreases in A and C. For instance, young adults who invested less in their work role tended to *increase* in N and maintain initial levels of constraint (related to C) (Roberts et al. 2006). Unemployment has further been linked to decreases in C, A, and O and increases in N (German data; Boyce et al. 2015), while being fired (versus being promoted) has been associated with larger increases in N and decreases in C across 9 years (US data; Costa et al. 2000).

In contrast to the more or less consistent evidence with regard to the relationship between social investment in work and the Big Five traits associated with social maturity (N, A, C), social investment in work does not seem to be consistently related to development in the Big Five traits O or E. Potentially, the absence of a relationship between social investment in work and either O or E may be because employees in most occupational settings are rarely faced with “openness demands” (e.g., the need to master novel and challenging experiences) or with “extraversion demands” (e.g., the need to be socially outgoing), at least after an initial acclimation period. There is, however, evidence that people who work in specific occupations with high role demands for E (e.g., performer) and high O (e.g., poet) likewise increase in E and O (Denissen et al. 2014). In addition, the seminal work of Schooler and colleagues found that self-directed, complex work was related to more positive trajectories of intellectual flexibility and cognition, both related to O (Schooler et al. 2004).

Most of the evidence regarding the relationship between social investment in work and personality development stems from young adult samples. Social investment in the work role is thought to be a driver of normative personality development particularly as people enter worklife (typically in young adulthood) and also to support the stabilization of personality characteristics as long as the social role is maintained (cf. Denissen et al. 2014). There is less empirical evidence regarding the role of social investment in work and specific work

experiences and personality development later in life. Individual differences in job characteristics contributed little to personality development in a middle-aged US sample followed across 10 years (Sutin and Costa 2010). In another study based on US data, however, the strength of the correlation between change in psychological investment in the work role and change in personality development across average of two and a half years was similar for young and middle-aged adults (40+), suggesting that the influence of investment in work roles on personality trait change is a phenomenon that is not restricted to young adulthood (Hudson et al. 2012). Evidence based on representative German data suggests that middle-aged and older individuals have a higher level of “heterotypic stability” with regard to the demands of their work role relative to younger individuals. That is, older adults tend to find themselves in work contexts with similar personality trait demands, even when they change jobs (Denissen et al. 2014). Taken together, while there is some evidence that the *potential* for social investment driven personality change continues beyond young adulthood (Hudson et al. 2012), middle-aged adults may nevertheless maintain personality stability by exposing themselves to work environments that support personality continuity. More studies are needed before conclusions on the potential moderating effect of age on the relationship between social investment and personality development can be drawn.

Implications of Adult Personality Development for Work Outcomes

While developmental researchers have been interested in how social investment in work and specific work experiences affect personality development, organizational researchers have long been interested in the relationship between personality and work outcomes such as performance, career success, and job attitudes, particularly as a means for optimizing employee selection processes. Historically, researchers have overwhelmingly tended to analyze the

relationship(s) between personality and work outcomes at a single point in time. The results of decades of cross-sectional studies have by now firmly established that personality is robustly related to a number of work outcomes. For example, the results of meta-analyses have demonstrated that E (+) and N (–) are related to job satisfaction while C is positively related to task performance across a wide range of jobs (see Judge et al. 2008 for an overview of the cross-sectional relationships between the Big Five traits and work outcomes).

Changes in the structure of the workforce taking place at the time of writing, including extensions of the years spent working and increasing proportions of older adults in the workforce, alongside increasing evidence of normative personality development, have stimulated a number of organizational scholars to question how adult personality development may be related to work outcomes at a single point in time and/or trajectories of work outcomes. Woods and colleagues (Woods et al. 2013) have suggested that *trait activation theory* (TAT; Tett and Burnett 2003) provides a theoretical framework for understanding why adult personality development might affect (trajectories of) work outcomes. According to TAT, organizational behavior results from an interaction between the person and the work situation. The demands and resources of the work context are in a state of flux, as, for example, learning demands and relationships with colleagues change or people gain autonomy with increased tenure. Hence, fulfilling the demands of the work role at different time points during one’s career might render different personality traits important (e.g., high A may be more important for an entry-level employee than for a tenured employee or supervisor).

Indeed, longitudinal studies have demonstrated that personality traits are differentially related to work outcomes at different time points. Using Australian data, Minbashian and colleagues (Minbashian et al. 2013) examined performance trajectories of 129 newly employed professionals across 4 years. On average, supervisor-rated performance peaked after about 3 years and then

started to decline. Participants high in O at baseline did not initially perform better than their peers. However, high O participants had more positive performance trajectories: in comparison with low O participants, they plateaued later and decreased less. In another study based on US data, the Big Five traits were used to predict sales performance of a sample of employees at two different career phases across a year (Thoresen et al. 2004). The results demonstrated that different personality traits predicted performance and performance growth among employees in a “maintenance” versus “transitional” (i.e., employees faced with new tasks) career phase. Among employees in the maintenance career phase, C and E were both associated with mean performance, and C predicted performance growth over time. In comparison, among employees in a transitional phase, O and A were associated with higher mean performance and with performance growth. As in the study by Minbashian et al. (Minbashian et al. 2013), employees in a transitional career phase who were high in O were less likely to experience performance plateaus. In light of the results of the two studies, it appears that especially C predicts performance and performance growth when employees need to sustain performance on the same tasks, whereas O seems to predict adaptation and may hence be especially important in transitional contexts in which employees must respond to changing job demands (Woods et al. 2013).

As of 2015, there were few empirical investigations of how personality *change* may affect how work outcomes change over time. The normative increases in C and A observed between young adulthood and late midlife are thought to have positive implications for different aspects of job performance (Ng and Feldman 2013). In particular, normative increases in C and A are thought to explain why older age is associated with more *organizational citizenship behaviors*, that is, in behaviors that are not part of the job description but that nevertheless benefit the organization (e.g., helping colleagues). Change in C was positively correlated with changes in work investment and

organizational citizenship behaviors and negatively correlated with changes in counterproductive work behaviors in a sample of US adults (Hudson et al. 2012), lending some empirical support to the hypothesis that normative increases in C might lead to more prosocial behavior at the workplace. In another study, changes in E and N were correlated with changes in work role satisfaction: decreases in N and increases in E were associated with increases in work satisfaction (Scollon and Diener 2006). Thus, there is some limited evidence that normative decreases in N across the adult life span may underlie normative age-related increases in positive work attitudes. Noting the importance of C for job performance during the maintenance career stage (see above), normative increases in C across the working life span are also thought to be one factor that help aging workers to maintain task performance over long periods of time (Ng and Feldman 2013), though this hypothesis has yet to be tested empirically.

Not only do people seem to change as a result of their work contexts, there is also some evidence that people’s personality is related to how the nature of their work changes over time. Baseline personality characteristics significantly predicted changes in job characteristics across 10 years in a sample of US adults (Sutin and Costa 2010). Participants high in N at baseline decreased in decision-making latitude, whereas participants high in E, O, and C reported more decision-making latitude 10 years later. A at baseline was unrelated to change in decision latitude. Baseline E predicted a decrease in hazardous work, and baseline A predicted a decrease in physical demands. Because job characteristics were based on self-reports, it is difficult to decipher the extent to which work contexts *objectively* changed versus the extent to which *perceptions* of the work context changed over time. It remains to be investigated whether normative and individual patterns of personality development lead to transformation of the work context over time as the proportion of older workers increases (e.g., whether normative increases in A result in more agreeable workplaces).

Personality Development, Retirement, and Post-retirement Volunteering

Given evidence that particularly entering the work context is one driver of personality change, it logically follows that *exit* from the work force may also be reciprocally related to personality development. Like workforce entry, exit from the work force also has a substantial impact on people's lives, changing, for example, the structuring of time, social networks, sources of self-esteem, and financial means. Curiously, however, the notion that retirement might be reciprocally related to personality development has yet to find much resonance in the literature, perhaps because the very notion of personality changes in late middle adulthood/young old age is a relatively new idea. At the time of writing, two studies had investigated the relationship between retirement and personality development. Compared with participants who remained employed, in one study based on longitudinal US data, retirees increased in A and decreased in activity, a facet of E - (Löckenhoff et al. 2009). Personality changes in response to retirement did not differ depending on the voluntariness of retirement or post-retirement involvement in part-time work. In another study based on a representative German sample, retirement was associated with a decrease in C (Specht et al. 2011), suggesting that retirement may be one factor underlying the mean-level decrease in C observed in young old age (Big Five Personality Structure and Aging).

Despite the potential usefulness of identifying predictors of retirement timing and adjustment, to date there have likewise been few empirical studies on the relationship between personality and the timing of the retirement transition. In the longitudinal study based on US data cited above, personality at baseline was not related to future retirement (Löckenhoff et al. 2009). The lack of a significant relationship between personality and future retirement may indicate that the timing of retirement is highly context dependent, being related to, for instance, an individual's work, financial, and greater life context. In another longitudinal study based on Norwegian register data, the Big Five traits predicted disability retirement

but not non-disability retirement (Blekesaune and Skirbekk 2012). Different patterns were found for women and men. For women, higher N predicted disability retirement and the effect appeared to be mediated by worse health. For men, O was positively and A and E were negatively related to disability retirement. The study did not, however, provide clues regarding the mechanisms underlying the relationships between personality characteristics and disability retirement among men. Cross-sectionally, lower N and higher E have been related to higher retirement satisfaction in a sample of US adults (Löckenhoff et al. 2009). We are unaware of any studies that have analyzed the longitudinal relationship between the Big Five personality traits and adaptation to retirement (e.g., recovery, maintenance, and/or higher levels of well-being post-retirement when compared to pre-retirement levels), which leaves a gap to be filled by future research.

After retirement, volunteering has become an important activity for many adults in later life (► [Volunteering in Older Adults in Retirement](#)). Like paid work, volunteering contexts are also characterized by different resources and demands that may potentially stimulate particular patterns of personality development. Furthermore, in light of interest in encouraging post-retirement volunteering in many industrialized countries, it would be helpful to identify personality predictors of volunteering in late life. Empirical research on personality (development) and volunteering is also scarce, though the few existing studies point to interesting relationships. Based on cross-sectional and longitudinal analyses of data from the Health and Retirement Study in the USA, conscientious, retired individuals were more likely to volunteer than conscientious, working individuals (Mike et al. 2014). The authors suggested that retired high C individuals may volunteer as an outlet for their goal-striving tendencies. A and E were also related to a greater likelihood of volunteering, independent of working status. In addition there is some alluring evidence that volunteering in late life can under certain circumstances stimulate personality change. In a quasi-experimental study in Germany, older volunteers (60+) that received

competence training increased in O relative to a waiting-list control group of active volunteers that did not receive training. This was, however, only the case for trained volunteers that also had high internal control beliefs (Mühlig-Versen et al. 2012). The results of this study suggest that volunteering, in combination with certain internal (internal control) and external (training) resources, can reverse the typical adulthood pattern of decreasing O in late life.

Conclusions and Future Research Directions

Evidence has accumulated that personality continues to develop across adulthood and into old age. A number of studies have identified work experiences and features of the work context as drivers of adult personality development. In particular, entry into the workforce appears to lie behind normative increases in A and C and normative decreases in N in young adulthood. First empirical studies also suggest that personality is related to work outcomes not only at a single moment in time but also to *trajectories* of work outcomes over time. Finally, the results of a handful of studies have suggested that retirement and post-retirement volunteer work are related to personality (development) in young old age.

Theoretical and empirical examinations of the relationship between work and personality development have contributed greatly to the fields of adult developmental and organizational science. Studies that have identified work experiences as drivers of personality change have provided direct evidence for both the contextualism and lifelong plasticity of adult development (Baltes et al. 1980). Increasing evidence of adult personality development in light of the links between personality and work outcomes has encouraged a number of organizational researchers to take more dynamic theoretical and empirical approaches that acknowledge that both people and work contexts – and their interaction – may change over time. Scholarly achievements in the study of work and personality development across the life span have therefore helped to further

knowledge about the contextual and individual conditions under which the potential for positive personality development and satisfying, productive work lives across the life span may be reached.

The current review of the literature on the relationship between work and personality development points to a number of directions for future research. While the relationship between work and personality is assumed to be reciprocal, most empirical work to date has focused *either* on how personality (development) influences work (development) *or* how work influences personality. More studies that investigate bidirectional effects of level and change in personality and work outcomes/characteristics are needed. There is a particular need for longitudinal studies with multiple measurement points that investigate how personality change affects changes in work outcomes. More studies including samples of middle-aged and older adults would be helpful in order to better understand how the relationship between the work context and personality development may depend (or not) on age, life phase, and career phase. Intervention studies that pinpoint modifiable aspects of the work context that can foster and support positive personality development across adulthood would be most helpful for organizations interested in maximizing employee productivity and well-being over the full working life span. Importantly, there is enormous variation between individuals with regard to their personalities and with regard to how they change with age. In addition, work contexts are characterized by different demands and resources/rewards depending on, for instance, occupation, company policy, supervisor, and colleagues. Investigations that are sensitive to differences between individuals and to differences between work contexts are likely to be the most helpful for identifying specific kinds of work context that best support positive trajectories of personality development and work outcomes for specific groups of individuals. Finally, at the time of writing there were few empirical studies on the (reciprocal) relationship between personality and the timing and/or experience of the retirement transition. Future research on the retirement transition, post-retirement

activity (e.g., volunteering), and personality development would be useful for identifying individuals who may need additional support in managing the retirement transition, factors that may help more people optimize the potential for positive personality development across the life span, and for helping organizations and policy makers to create contexts that support longer working lives and volunteering post-retirement.

Job design and aging; Job redesign and aging; Work redesign and aging

Definition

There are two approaches to work design research relevant to older workers. First, some work design research focuses on physical aspects of the workplace and ways to accommodate workers as they

age. This research line takes a more ergonomic approach. In contrast, psychological work design addresses ways to address psychological changes (e.g., cognitive ability, personality) that take place over the work lifespan.

Introduction

The workforce is expected to age in the coming decades in most industrialized countries (Eurostat 2013; Toossi 2012); this is a result of decreased birthrates, later retirements due to financial need, and raising of the retirement age in many countries because of longer lifespans (Vaupel 2010). As a result of these changes, people are working later in life, often well into their 60s and even 70s.

In this entry, the extant literature on job design for workers over the work lifespan is described. Specifically, two types of job design research are differentiated: research on physical aspects of the workplace to accommodate people as they age (a more ergonomic approach) versus job redesign that addresses psychological changes (e.g., cognitive ability, personality) that take place over the work lifespan. The focus in this entry is primarily on psychological job design, integrating lifespan development theories, age-related models of work motivation, and models of job design to describe how characteristics of the workplace can interact with worker age to affect job attitudes and behaviors. The few empirical studies that have examined psychological job design and age are cited. This entry concludes with a discussion of the several additional moderators that may further affect the interplay of age and job characteristics and concludes with a discussion of the practical challenges involved in implementing job redesign for workers of different ages in actual work settings.

Physical Job Design and the Older Worker

It is well documented that a number of physical declines and disabilities are associated with age and that these may affect a person's ability to carry

out his or her work tasks. For example, age is associated with declines in aerobic capacity, muscle strength and flexibility, and basic sensory capacities such as hearing and vision (Maertens et al. 2012). There are also changes in ability to adapt to workplace changes in sleep patterns as required by shift work (Blok and de Looze 2011). However, although there is evidence for a decline in the health of older people, meta-analytic evidence shows little relationship between age and self-reported health issues (Ng and Feldman 2013). Further, despite physical declines, older workers also appear to have fewer actual workplace injuries (Ng and Feldman 2008), although older workers may take longer to recover from injuries (Sterns et al. 1985).

It is worth noting that the relationship between age and job performance is generally weak, with slightly positive associations between age and certain types of performance measures (e.g., organizational citizenship behaviors) (Ng and Feldman 2008). This null relation between age and work performance may be the result of a decline in physically demanding jobs in many industrialized workforces (Johnson et al. 2011). In other words, as physical aspects of jobs in industrialized countries appear to be on the decline, age-related physical declines may have less of a relationship with job performance.

Psychological (Cognitive and Personality) Changes That May Affect Older Workers

In addition, a number of psychological changes can take place through adulthood, and these changes are relevant to the psychological design of jobs. First, cognitive changes include a gradual decrease in fluid intelligence (e.g., processing speed) starting at age 20. However, there are increases in crystallized intelligence (e.g., accumulated knowledge) up through a person's 50s and 60s (Schaie 1994). Second, some personality dimensions change throughout adulthood, with increases in conscientiousness and agreeableness and decreases in neuroticism (Roberts et al. 2006; Salthouse 2012). However, it is also important to

note that there is considerable variability in how people age (e.g., (Hansson et al. 1997), with some people aging more quickly than others and in different ways. This variability between people increases in the later decades of life, such that the job design needs of older workers may vary. In addition, some people appear to be more "successful" at aging (Hansson et al. 1997), that is, they may have less disease or illness, greater longevity, lack of disability, and increased life satisfaction (Bowling 2007). An important factor is an individual's ability to adapt to age-related changes within themselves, an issue that is central to lifespan development theories, described below.

Lifespan Development Theories and Psychological Job Design Models

In this section, lifespan development theories that take into account these physical and psychological changes are described. This is followed by a discussion of the most influential job design models and how theories of lifespan development might be used to explain how worker age and job characteristics interact to affect attitudes, performance, and well-being.

Lifespan development theories and motivation. Lifespan perspectives, such as selective optimization with compensation theory (SOCT; Baltes and Baltes 1990) and socioemotional selectivity theory (SST; Carstensen 1991), describe aging as an essentially adaptive process and are useful for examining the interplay between age and work characteristics. These theories include a focus on the physical and psychological changes (e.g., cognitive skills, personality) that take place as people age and how people adapt to these changes. SOCT (Baltes and Baltes 1990) proposes that people use three strategies to successfully adapt to the aging process. *Selection strategies* refer to selecting specific goals that match personal resources which will likely change as people age due to physical and psychological changes. *Optimization strategies* refer to allocating time, efforts, and existing resources to achieve the desired results. *Compensation*

strategies refer to coping with losses to maintain positive functioning, that is, offsetting declines in certain areas by choosing to focus resources on other things. In the work context, older workers might use these strategies to fit their personal resources and job demands. For example, to compensate for declines (e.g., physical disabilities), an older worker might select to focus on job characteristics that give them the opportunity to use their accumulated experience (crystallized intelligence), allowing them to optimize their resources to achieve the desired results.

SST (Carstensen 1991) suggests that older adults perceive that time is limited, and they thus tend to prioritize present-oriented goals to pursue emotionally and socially gratifying experiences. At work, these might translate into focusing on satisfying work and relationships. In contrast, young adults are more likely to perceive time as open-ended and thus tend to prioritize future-oriented goals; in the workplace, this might include a focus on knowledge-acquisition goals that could advance their careers. According to socioemotional selectivity theory, older and younger workers are likely to be interested in different psychological job design features. While younger adults should benefit from a job that increases work-related knowledge important for future career development, older workers should benefit from a job that gives them the opportunity to maximize socially gratifying working experiences in the present (Truxillo et al. 2012b). SST has been used to explain the generally positive job attitudes observed among older workers (e.g., Ng and Feldman 2010). Note that many of the predictions from SOCT and SST do not necessarily differ.

Consistent with SOCT, SST, and psychological and personality changes that take place in individuals, Kanfer and Ackerman's (Kanfer and Ackerman 2004) age-focused model of work motivation describes how work motivation may change across the lifespan. This might include a shift from extrinsic to intrinsic motivation (a process generally supported meta-analytically (Kooij et al. 2014)) and the development of generativity motives (focused on supporting future generations) in middle age.

Job design models. A number of major job design models in the organizational psychology literature focus on psychological aspects of the job. Historically one of the first is Hackman and Oldham's Job Characteristics Model (Hackman and Oldham 1976) focused on five intrinsic job characteristics: autonomy, skill variety, task identity, task significance, and feedback from the job. *Autonomy* is the extent to which the job provides discretion and freedom to plan, schedule, and perform the work; *skill variety* is the extent to which the job involves the use of a wide range of skills and capabilities; *task identity* is the extent to which the job allows people to complete a whole piece of work from start to finish; *task significance* is the extent to which the job provides opportunities to have a meaningful impact on other people; and *feedback* is the extent to which the job provides employees with information about their performance. These five characteristics lead to critical psychological states (meaningfulness, responsibility, and knowledge of results), which in turn lead to positive work outcomes such as motivation, satisfaction, and performance. A number of studies have been conducted on the Job Characteristics Model over the last 40 years, and meta-analyses provide support for most of the hypothesized relations (Humphrey et al. 2007).

Karasek's job demands-control model (Karasek 1979) hypothesized that the combination of high job demands (e.g., work overload and time pressure) and low job control leads to high job strain. The author proposed that enhancing job control could buffer the detrimental effects of job demands on employee health. Subsequently, Karasek and Theorell (Karasek and Theorell 1990) included social support, expanding the model into the job demands-control-support model. The authors theorized that social support together with control helps to mitigate the effects of high demand on strain. Research has generally supported the effects of these models, as high job demands and low control and social support are associated with greater job strain (Häusser et al. 2010).

More recently, another related model is Demerouti, Bakker, Nachreiner, and Schaufeli's

job demands-resources model or JDR (Demerouti et al. 2001) model. This model suggests that while every occupation may have its own specific risk factors related to stress, these factors can be categorized into two general groups: job demands and job resources. Job demands consider physical, psychological, social, or organizational aspects of the job that require effort and are associated with certain individual costs. Job resources are defined as aspects that facilitate goal achievement, personal growth, and demand reduction and may be found at an organizational level (e.g., career opportunities), social and interpersonal level (e.g., supervisor and coworker support), and task level (e.g., skill variety, task identity, task significance, autonomy, performance feedback). Job demands are suggested to contribute to the emotional exhaustion aspect of burnout; in contrast, job resources are suggested to reduce disengagement. Empirical studies have provided evidence for the hypotheses of the job demands-resources model, showing the effects on important organizational outcomes (Schaufeli and Bakker 2004).

A recent perspective on job design, Morgeson and Humphrey's work design model, and related Work Design Questionnaire (Morgeson and Humphrey 2006), was developed to be a comprehensive model of job design, including a wider range of job characteristics compared to the previous models. The Work Design Questionnaire (WDQ) is the most comprehensive measure of job design available and utilizes 21 work characteristics, integrating the categories of motivational characteristics (i.e., task and knowledge characteristics), along with social and work context characteristics. Motivational work characteristics include both task characteristics (i.e., autonomy, task variety, task significance, task identity, and feedback from job) and knowledge characteristics (i.e., job complexity, information processing, problem solving, skill variety, and specialization). Social characteristics include elements such as social support, interdependence, interaction outside the organization, and feedback from others. And contextual characteristics include features such as ergonomics, physical demands, work conditions, and equipment use. Morgeson, Humphrey, and colleagues (Humphrey et al. 2007; Morgeson

and Humphrey 2006) found in their original study and later meta-analysis that the different features of job characteristics were differentially related to different work outcomes, such as work attitudes and behaviors, and that these relations can be mediated and/or moderated by psychological states.

Integration of lifespan development and job design: conceptual development. Recent theoretical contributions integrating age into job design suggest that different psychological job characteristics can differentially benefit workers of different ages, in terms of well-being, performance, satisfaction, and engagement (Truxillo et al. 2012a, b). However, although many researchers point to a need for research examining the role of individual differences such as age in job design (Grant et al. 2010; Morgeson and Humphrey 2006), only a few studies have examined how people of different ages may respond to different job characteristics (Shultz et al. 2010; Zacher and Frese 2009; Zaniboni et al. 2013, 2014).

Truxillo and colleagues (Truxillo et al. 2012a, b) used the lifespan development theories of SOCT and SEST (Baltes and Baltes 1990; Carstensen 1991) and the work design model of Morgeson and Humphrey (Morgeson and Humphrey 2006) as bases to propose that some job characteristics may be more beneficial for workers of different ages. For example, among task characteristics, the authors suggest that *autonomy* and *task significance* will lead to more positive working outcomes for older compared to younger workers. Older workers may prefer work autonomy, allowing them to craft their jobs (Grant et al. 2010) and choose roles that fit their strengths. Considering that generativity motives begin to develop in late career (Kanfer and Ackerman 2004), older workers may prefer to be more focused on meaning in their job (i.e., task significance). Among the knowledge characteristics, Truxillo and colleagues (Truxillo et al. 2012b) suggested that *job complexity*, *information processing*, and *problem solving*, to the extent that they require fluid intellectual abilities, can lead to more negative working outcomes for older workers compared to younger workers.

However, when older workers are able to successfully apply their accumulated knowledge and ability (e.g., selection, optimization, and compensation strategies), complex jobs can lead to positive work outcomes. For the same reason, older workers benefit from *skill variety* because it allows them to use their accumulated skills. The *specialization* requires in-depth knowledge and skills in a particular area, and older workers may prefer this characteristic since it can allow them to focus on a single specialty in which they have gained expertise. Among the social characteristics, giving *social support* and *interdependence* should lead to more positive working outcomes to older workers fulfilling the desire to be emotionally and socially integrated with other people.

Integration of lifespan development with job design: empirical support. Although to date there have been relatively few empirical studies that have actually demonstrated the importance of fitting job characteristics to the age of the worker, there has been some initial support. For example, research suggests that, in contrast to younger workers, older workers have more positive outcomes when they perceive increased autonomy (Hertel et al. 2013) and skill variety (Zaniboni et al. 2013) and decreased task variety (Zaniboni et al. 2014). Further, when older workers are able to successfully apply their accumulated knowledge and ability (e.g., selection, optimization, and compensation strategies), complex jobs can lead to positive work outcomes (Zacher and Frese 2009, 2011; Zacher et al. 2010). For the same reason, older workers appear to benefit from skill variety because it allows them to use their accumulated skills (Zaniboni et al. 2013). Despite this initial support for the importance of psychological job design to workers of different ages, the fit between a worker's age and job characteristics is probably a complex with additional moderators at play.

Additional Moderators

Throughout this entry an assumption is that factors associated with a person's age will interact with their work environment to affect attitudinal

and performance outcomes. However, the situation is far from a simple age X job characteristics interaction, and a number of additional moderators need additional research attention. These moderators may qualify the ability to draw conclusions about the way that an individual worker of a given age may react to a job's characteristics. In other words, it is not as simple as considering matching a job's characteristics to a person's age, but rather, a number of additional factors should be considered as well (Truxillo et al. 2012b). In other words, there may be a great deal of variability in between individual workers of the same age, especially in later years.

Truxillo et al. (2012b) break down these additional moderators into three categories. *Individual difference* moderators include differences in work experience, health, and personality. They also include factors such as differential trajectories between individuals in terms of cognitive and personality changes. For example, similarly aged workers, one in good health and one in poor health, would likely seek and need different job characteristics to thrive. *Contextual factors* that may affect the way that similarly aged people react to job characteristics include the characteristics of the organization, team, profession, or national culture and norms. For example, there may be different norms for what is considered "old" within different professions, causing similarly aged workers in different professions to seek different types of job characteristics. Other contextual factors would be the job itself, with some jobs including tasks that are difficult for older workers to perform, whereas others might capitalize on an older worker's strengths. As an example, jobs with heavy physical demands may be difficult for older workers to carry out, whereas other jobs may incorporate the mental challenge that is needed to engage some older workers. Another contextual factor that may complicate the relationship between job characteristics and age includes generational status, in that similarly aged workers from different generations may have differential expectations for their jobs; in other words, the requirements of older workers today may be different from those of older workers 40 years from now. *Multiple job characteristic interactions*

denote the fact that the relationship between a particular job characteristic and age may be affected by an additional job characteristic. In particular, the job characteristic of autonomy may allow workers to craft their jobs to where it provides the greatest benefit for them.

Challenges for Organizational Implementation

Despite increased research and interest on matching job characteristics to the worker, a number of challenges remain. Perhaps the most significant challenge is that almost no research has examined how interventions focused on objective changes in job characteristics affect older workers. Rather, the majority of the research has examined how workers' perceptions of their job characteristics affect their job attitudes and behaviors (Truxillo et al. [in press](#)). Relatedly, relatively little empirical work has been done on how actual changes to organizational human resource (HR) systems (e.g., training, performance management, teams) can affect older worker attitudes and behavior (Truxillo et al. [2014](#)). However, the extant literature on how older workers' perceptions of their job characteristics and outcomes should provide a path forward for empirical research on this issue (e.g., Hertel et al. [2013](#); Zaniboni et al. [2013, 2014](#)).

A second challenge for implementing age-sensitive job design is the significant differences among similarly aged people. As noted earlier, the differences among employees in the same age group may be greater than the differences between age groups, and within-age group variability appears to increase in later decades. For that reason, job design should incorporate not only differences between employees of different ages but also take into account how an individual employee is aging throughout their career. This approach would consider age-related job design from the standpoint of what is needed at different time points in an individual employee's career.

Another challenge is the issue of developing age-differentiated HR systems and jobs (e.g.,

Kooij et al. [2014](#)) while at the same time balancing issues of fairness and staying within legal constraints (Truxillo et al. [in press](#)). For example, SOCT strategies might suggest that older workers be allowed to off-load certain tasks that they are no longer able to carry out effectively. At the same time, this might affect their team members, such that younger employees would need to "take up the slack." This issue further illustrates that by definition work redesign cannot be done for any one individual employee without having cascading effects for the organization and for other workers.

Finally, it has been suggested that age-related interventions such as job design should use approaches that support workers of all ages and depending on their particular needs (Truxillo et al. [in press](#)). Such an approach is similar to the three-tiered intervention framework that is used in the health promotion/prevention literature. Using this approach, primary interventions would focus on the prevention of disease among workers starting from early in their careers, such as preventing exposure to stressful job designs. Secondary interventions would be focused on controlling negative outcomes for workers as they age, such as providing greater autonomy so workers could balance work and nonwork demands and be better able to continue working. Tertiary interventions would be focused on compensating for physical and psychological losses due to age and would generally focus on workers in late career.

Summary

A number of physical and psychological changes occur over the work lifespan, with both positive and negative consequences for older workers. The issue of designing jobs for older workers takes on particular importance as the workforce in most industrialized countries continues to age. Lifespan development theories (Baltes and Baltes [1990](#); Carstensen [1991](#)) and research on work motivation for workers of different ages (Kanfer and Ackerman [2004](#); Kooij et al. [2011](#)) integrate this basic research on age-related changes to provide guidance for the design of jobs to fit the aging

workforce. Job design models (e.g., Morgeson and Humphrey 2006) from the organizational behavior literature identify key job characteristics that might be important for understanding how jobs are designed by taking worker age into account. Thus, the issue of age-differentiated job design is a complex one involving a number of variables, with a number of challenges its implementation in organizational settings. Additional research on the actual implementation of age-related job redesign in organizations is needed to help guide organizational practices.

Definition

This entry summarizes the present understanding of the relationships between work motivation and worker age. The central propositions are that work motivation does not linearly decline with age and that a look at the interplay of global and specific levels of motivation is required to understand the particular situation of workers over 50 years old. The entry concludes with an outlook to emerging research.

Work motivation translates a worker's knowledge, skills, and abilities into actual work behavior and job performance. The former enable workers to carry out their jobs as required, while the level of motivation determines the amount of effort workers actually put into their jobs, i.e., it regulates the intensity, duration, and persistence of work behaviors (Pinder 1998).

In light of the impact of demographic change on the contemporary workplace, understanding the motivation of older workers – who are usually considered as “older” from the age of 50 – is of particular importance. In almost all industrialized countries, the average age of workers will be increasing markedly over the next two decades, as the numbers of young entries into the labor force will be decreasing. In response to this trend, retirement ages have been raised in several countries. Work lives will therefore become longer, making retention a key issue for many employers. Maintaining high levels of work motivation is an indispensable ingredient of successful retention.

Established theories of work motivation, however, are quite silent about the influence of age on motivation. While research into work motivation has had a long tradition since the 1950s, the interest in age-related changes in work motivation is a relatively recent phenomenon. Only in the past 10 years or so have the relationships between worker age and motivation begun to receive substantial research attention.

This entry summarizes the present understanding of the relationships between work motivation and worker age. To foreshadow, the most important research finding is that work motivation does

not inevitably and linearly decline as a function of biological aging. Like for younger workers, motivation is influenced by interactions of workers' goals and job demands. To understand what makes these interactions age-specific, current models incorporate constructs from lifespan psychology to describe the principles of motivational regulation. This regulation may be seen as multidirectional; it will be in the focus of the first section. Furthermore, contemporary models look at the interplay of global and specific levels of motivation to understand the particular situation of workers over 50 years old. That multilevel perspective will be the core of the second section. The entry concludes with an outlook to emerging research in the final section.

The Multidirectional Perspective

The early view on age-related changes in work motivation was characterized by a notion of decline and seemed to justify the common stereotype (see Posthuma and Campion, 2009) that work motivation decreases as workers age. Warr (2001) listed a number of reasons why work motivation was likely to go down with age. First, the longer one has received certain bonuses and incentives, the higher a threshold these incentives must exceed to have equal value. As incentives cannot increase indefinitely, however, that *hedonic treadmill effect* will decrease motivation. Habits are a second source of motivation decline, because deviations from long-practiced work behaviors (e.g., when new technologies are introduced) might be perceived as aversive. A third source is workers' need for comparison of their performance to their colleagues' attainments. Across work life, the reference group may change as older workers compare their performance not only to that of their peers but also of their younger colleagues. Age-related norms and stereotypes could be a fourth source of age differences. For instance, older workers might show little interest in work-related training simply because others (supervisors, colleagues, friends, etc.) do not expect them to do so. Finally, older workers might have lower perceptions of the probability

of attaining positive work outcomes, which would also adversely affect work motivation.

Although that early view draws attention to the fact that rather heterogeneous factors might influence work motivation, motivation itself was depicted as a relatively passive and mostly negative “response” to personal (e.g., capability declines) and environmental (e.g., altered work demands) changes. However, job satisfaction research shows that job satisfaction is usually higher in older than in middle-aged workers. Furthermore, age has in several meta-analyses been demonstrated to be unrelated to core job performance. For some dimensions of job performance, even positive age effects have been shown such that the number of safety behaviors and avoidable absences rises and falls, respectively, with age.

This suggests that there may be more to older workers’ motivation than mere decline. Borrowing from lifespan psychology, more recent models of age effects on work motivation have adopted the notion that such age effects may be *multidirectional*, i.e., there may be decline in some aspects of work motivation, but stability, or even an increase in other facets. As a first version of the contemporary view, Kanfer and Ackerman (2004) proposed a theoretical framework centering on the notions that (a) the level of work motivation results from a worker’s beliefs about how likely he or she would be to attain certain work-related outcomes and how attractive these outcomes are to that worker and that (b) age moderates these beliefs in a systematic way. For instance, workers hold beliefs about how much effort they will have to invest to attain a particular performance level. As capabilities for the fast processing of complex information decline from middle to late adulthood, workers will expect they have to invest particularly high effort, which might lower their performance expectancies – and thus motivation – whenever such fast and complex processing is required. Performance expectancies might remain unaffected or even increase with age, however, if workers can use expertise, routines, or job experience, because such experience-based capabilities remain stable or even increase well into late adulthood (Baltes et al. 2006). At least in principle, this would leave older workers

with the option of focusing on roles and tasks in which they can use their expertise and routine in order to experience feelings of mastery and accomplishment.

Current conceptions capitalize exactly on that latter notion of *motivational selectivity* that features in general models of developmental regulation in lifespan psychology. In other words, contemporary models of age-related changes in work motivation are premised on the notion that people use a variety of strategies to match their resources to external demands. As a general strategy, people select subjectively important goals, optimize the ways they try to attain their goals, and thereby compensate for age-related losses (SOC strategy; see Baltes and Baltes 1990). More specifically, socio-emotional selectivity theory (SST; Carstensen 2006) predicts that the nature of subjectively important goals will change across the lifespan as people’s general sense of time shifts from “time since birth” to “time until death” around mid-life. As a consequence, goals which concern the acquisition of knowledge and goals concerning the regulation of positive emotional states shift importance. When time is perceived as open ended, prioritized goals rather relate to “investments,” focusing on gathering information, on experiencing novelty, and on expanding skills and knowledge. When time is perceived as constrained, goals related to “harvesting” become more salient that can be realized in the short term, such as emphasizing feeling states and regulating emotional states to optimize psychic well-being.

Consistent with these assumptions, the empirical evidence converges in the finding that work-related motives systematically differ in their relationship with age. Motives refer to a worker’s preference for particular job characteristics and classes of outcomes (e.g., high performance, good pay, friendly coworkers). Most broadly, growth-related, security-related, and social motives may be distinguished. The former include activities aimed at reaching higher levels of functioning, such as, for instance, participation in organizational training and development programs or taking on leadership roles. Social motives represent a preference for job

characteristics and work outcomes that pertain to affiliation and collaboration with others, whereas security motives involve a preference for job features and work outcomes that secure one's general welfare. From a socio-emotional selectivity viewpoint, security and social motives would be expected to be higher for older workers, as these convey positive emotional states. The strength of growth motives, on the other hand, would be expected to decline. Supporting the latter hypothesis, across studies, negative correlations of age with motives such as seeking advancement or promotion, as well as development and challenge, emerge. At the same time, older workers report stronger motive strength for job characteristics and outcomes related to accomplishment, job enjoyment, and utilizing their existing skills. In terms of security motives, older workers indicate a stronger preference for job security, while the correlation of age with the importance of compensation and benefits is generally negative. In a similar fashion, relative to their younger colleagues, older workers indicate a stronger preference for helping people or contributing to society through their jobs, but pay less attention to the recognition they gain from their job and to working with people. There are moderators of the age-motive relationship; for instance, the relationship between age and growth motives was positive among blue-collar workers, but negative among white-collar workers. In sum, therefore, research shows that work preferences from the same class (growth, security, social) may show differential relationships with age. This finding is consistent with the assumption that work motivation may change with age in a multidirectional way. Also, the finding that growth motives are positively related to age in some groups of workers, but not in others, supports the assumption that there is no normative, biological motivation decline with age.

In sum, the evidence available to date suggests that work motivation does not uniformly decline with age, but may increase for certain aspects of jobs and decrease for other aspects. Like for their younger colleagues, older workers' motivation is shaped by the interaction of person characteristics and job demands. Older workers are likely to have

a different perspective on their occupational future than their younger colleagues in that they perceive fewer remaining developmental opportunities in their work lives, but this future time perspective, rather than depend on age per se, is largely influenced by the complexity of one's job and the degree of control workers have over their jobs.

The Multilevel Perspective

The research summarized above is primarily intended to account for the determinants and consequences of *motivation at work*, i.e., as workers perform their work roles on a daily basis. Motivation at work is largely determined by momentary and situational drivers and can be defined as the kind of motivation that one experiences at a specific time and toward a specific activity.

A profound understanding of age-related changes in work motivation requires, however, that other levels of motivation on top of motivation at work be taken into account. The central proposition of a recent model is that workers' motivation is determined by three levels of work-related goals and motives (Kanfer et al. 2013). One of those levels concerns the at-work goals discussed in the previous section. Together with those, to-work goals and to-retire goals need to be considered. *Motivation to work* is similar to earlier constructs such as *work centrality* or the *meaning of work* and refers to the general value and importance one attaches to one's work. More technically speaking, motivation to work denotes the motivation to enter into a formal or informal public work arrangement in which workers allocate personal resources (e.g., time, attendance, mental or physical effort) in exchange for a portfolio of expected material (e.g., pay, healthcare benefits) and immaterial (e.g., sense of competence, recognition) rewards. The motivation to retire simply refers to the intention and preparedness to exit from one's current work.

There are two main reasons why it is important to integrate into models of age differences in work motivation both the motivation to work and the motivation to retire. First, it is around the age of

50 that the latter types of motivation begin to change and to play a more influential role than in earlier phases of one's work life. For instance, around that age, most workers' careers have reached or are near their "peak" in terms of the highest possible position and salary level. Also, as most people's financial situation might relax (e.g., because mortgages have been paid off), benefits and compensation begin to be of lesser importance. At the same time, retirement might be on the horizon for the first time. Therefore, the constellation of motivational drivers might be quite different to that of younger and middle-aged workers, for whom the motivation to work might be a more uniform motivational driving force and for whom the motivation to retire might not play a significant role at all. These marked differences between younger and middle-aged workers on the one hand and older workers on the other hand need to be considered in research on work motivation and aging.

The second reason for the multilevel view on older workers' motivation is that a uniform, "hierarchical" relationship between the motivation to work and the motivation to retire on the one hand and motivation at work on the other hand is less than likely. Even if motivation to work decreased and motivation to retire increased beyond the age of 50, this would not necessarily imply that motivation at work also went down. As mentioned above, motives of accomplishment, job enjoyment, and utilizing one's existing skills are positively related to age; they convey a sense of mastery and competence and thus are beneficial to one's job-related well-being and presumably even to one's general well-being. Therefore, workers are likely to maintain relatively high levels of motivation at work even in light of decreasing motivation to work. In line with these assumptions, recent research on the transition from work to retirement in the age group of 55–70 years shows that sizeable percentages of workers who leave their jobs before the official retirement age – indexing relatively low motivation to work – engage in voluntary work after retirement. This trend is most pronounced in workers who report having enjoyed their last position before retirement. This fits with Kanfer et al.'s

(2013) proposition that the association between the motivations to work and at work is relatively weak, given that motivation to work is influenced by sociocultural and economic conditions, while at-work goals are most strongly influenced by local work conditions.

Summary and Outlook

As the percentage of older workers continues to rise, age-related changes in work motivation receive growing research attention. Understanding the system underlying such changes is vital for developing work design and managerial practices that enable motivated work throughout one's work life. After a decade of research on age differences in work motivation, one of the most important insights is that those age differences may best be described as being of a qualitative, rather than a quantitative, nature. In terms of motivation at work, i.e., motivated work on a daily basis, older workers are not generally motivated more or less than their younger colleagues, but they might be motivated for different aspects of their jobs. These differences are not so much a result of biological aging, but of changes in goal priorities. Motivation to work might be lower in older workers relative to their younger counterparts, but this will not invariably incur decline in motivation at work.

As far as the "big picture" is concerned, research on work motivation and aging appears to be in good shape. Current models integrate the global level of motivation to work and the specific level of motivation at work; by looking at the interactions of these levels, such models take a more fine-grained look than many of the established "age-free" theories of motivation. Also, adopting the motivational selectivity principles from lifespan psychology builds a bridge toward a stronger incorporation of work-related affect into theories of work motivation. These have been criticized of overemphasizing cognitive processes at the price of neglecting affect. Research on work motivation and aging has begun to show, however, how affective processes might be central determinants of motivation and

that certain aspects of motivation cannot be reasonably studied isolated from affect. In the face of longer work lives, understanding the links between affect and motivation will be of growing importance to enable the designing of physically and psychically sustainable work.

That said, one of the goals for the next decade of research could be to work toward coherent, integrated models. For a couple of years now, there have been calls for metatheories of motivation. At present, in the field of general work motivation, there are several established theories that are used “in parallel,” but how they relate to one another remains largely unexplored. On top of this, research on work motivation and aging imports additional concepts (e.g., socio-emotional selectivity) into the field and proceeds in a theoretically eclectic fashion. This might further complicate the situation unless some of the future work is dedicated to “tidying up” the conceptual landscape.

On the methodological side, more longitudinal work will of course be needed to model age-related changes in work motivation. In addition to established multiple-wave survey designs, research might benefit from experience-sampling designs. For instance, to reveal age differences in at-work goals, which are most strongly influenced by local work conditions and which change in a multidirectional fashion, week-level studies could look at workers’ perception of their work conditions (e.g., supervisor support, job complexity, and intensity) in a given week and their levels of motivation in that same week. Also, job-related well-being could easily be included as an outcome measure. Conducted over a number of weeks and with workers from several age groups, such studies would show work motivation and its drivers and underlying age differences “in motion.”

Attitudes toward retirement; Intentions to retire; Transition to retirement

Definition

This entry aims at proposing theoretical and practical aspects related to the transition from work to retirement. The major psychosocial theoretical models that try to explain this transition are presented. Individual and contextual (organizational) factors that influence the nature and quality of the transition to retirement are then discussed. Finally, bridge employments are presented as a pragmatic way adopted by workers and organizations to have a progressive transition from full employment to full retirement.

Introduction

In most of the Economic Co-operation and Development (OECD) countries, a strong demographic transition is ongoing, characterized by increasing life expectancy and a reduction of birth rate. This transition is accompanied by the retirement of the baby boom generation and budget restrictions of the national pension systems exacerbated by the financial crisis (Jeungkun 2009). Due to all these combined reasons, retirement has become a major concern for (a) governments that have to ensure the future sustainability of the social security system and equity between generations, (b) work organizations that have to develop age management policies to ensure a productive participation of older workers in the workplace, and (c) individuals who may feel more insecure about their future as retirees and have to plan a longer late career at work.

Today, in comparison to the past, retirement has become a new social object that is rethought by decision-makers and the overall society. For that reason, some researchers have started to use the terms “modern retirement” (Beehr 2014). While 70 years ago only a restricted number of people benefited from retirement, for a limited number of years (remember that in the 1950–1955, the general life expectancy in EU countries was around 65 years), nowadays, a larger number of people reach the eligible age for retirement pension and for a longer period of

life (the life expectancy at 65 years is currently in EU around 17 years for men and 20 years for women, OECD 2012). At the same time, most of people enter in the retirement age in a better health condition, in comparison to the past, and they are still able to be active in the social life. Also, the combination between different life stages is more mixed, with increased flexibility and gradual transition from work to retirement.

In other words, new retirement may be quite different from the traditional conception that retirement occurs among older workers who quit a long full-time paid work when they have reached the specified retirement age and subsequently receive private and/or public pension benefit that only retired people receive (Beehr 2014). Many countries no longer have compulsory retirement ages, and many are extending the age at which access to public pension schemes may be possible (Hesketh et al. 2011). In this framework, the subjective choice to postpone retirement age and to continue to work longer is an issue at the individual and organizational levels. As an example, employees in OECD countries tend to retire considerably earlier than the age of 65 years (i.e., before the country’s official retirement age or the age at which the individual is usually entitled to a full old-age pension, Jeungkun 2009), but at the same time, due to employment policies in different countries, in Europe (EU-28), the rate of people aged between 55 and 64 years old who are still active in the labor market has improved for the last 10 years from 39.9% (in 2003) to 50.1% (in 2013). Echoing the increased activity rate of older workers, bridge employment has received an increased consideration in retirement literature as the transition between workers retire from their main career but before their complete withdrawal from the workforce (Alcover et al. 2014; Wang et al. 2008).

This entry aims at proposing a selective but representative review on literature at the following levels. The first section puts some guidelines about the major theoretical perspectives that have framed studies in retirement and that are likely to substantively contribute to future research. The second section focuses on the individual and contextual (especially related to the organizational

situation) factors that contribute to the decision to retire. In a final section, the different ways to move from work to full retirement are analyzed with a particular attention to the so-called bridge employment, a transitional solution that is aimed to reduce engagement in the main career but continuing working with a lower level of obligations.

Theoretical Perspectives on Retirement

In their comprehensive review, Wang and Shultz (2010) analyzed how different theories are applied to understanding the retirement process (for a deepened insight in theories, see Wang 2013). Building on an extended literature, they proposed an integrative theoretical framework that conceptualizes retirement as decision-making, retirement as an adjustment process, retirement as a career development stage, and retirement as a part of human resource management. From this, two key approaches emerge when analyzing retirement as a process that occurs over time: retirement as a decision-making process and retirement in the life span. Each of them highlights specific aspects of retirement as well as different theoretical approaches.

In the retirement as decision-making perspective, as the final exit from a process of older workers' gradual disengagement from work, retirement is conceptualized as an informed (rational) choice behavior. In other words, when workers decide to retire, they choose to decrease their psychological commitment to work and to behaviorally withdraw from work (Beehr 2014; Wang and Shultz 2010). Most theories about retirement decision-making process refer to a cost-benefit framework, assuming that older workers decide to retire once the benefits of retirement exceed those of working on the basis of information individuals have regarding their own characteristics and their work and nonwork environment. The particular factors (e.g., economic or noneconomic, individual, organizational, etc.) that are analyzed in this perspective depend on the discipline and the theoretical framework (Van Solinge and Henkens 2014). Feldman and Beehr (2011) proposed a three-phase model of

retirement decision-making where workers start to envision the possibility of their future life as retirees, then they assess the past experience at work to inform when to retire, and finally they put concrete plans for acting their retirement into action. The authors do not suggest that these three phases of retirement decision-making are completely distinct, but they assume that the salience of various retirement-related issues varies across the time period during which the retirement decision is made.

This model helps to clarify which theories will be the most relevant in explaining processes that contribute to each phase of the decision to retire. However, one major limitation of this perspective, as Wang and Schultz (2010) noticed, is that not all retirement decisions are voluntary as supposed in the informed-choice. Sometimes, retirement can be enforced on a person by the organization, for example, through downsizing, or by other constraints like mandatory retirement. Therefore, the voluntariness of the retirement decision could be viewed as a boundary condition for applying the informed decision-making approach in analyzing predictors of the retirement decision.

In the life span approach of retirement, the decision to retire is viewed as less important than the characteristics of retirement process embedded in the decision-making (Wang and Shultz 2010). In other words, because patterns of transition are variable regarding the timing of the decision, the previous preparation for the decision, the resources, and other aspects associated with the decision, the life span approach is more interested in apprehending the diversity of retirement patterns, that is, "how" people retire rather than strictly "when" they do decide to retire. The life span approach conceptualizes retirement as an adjustment process (Kim and Moen 2002) and in the perspective of adults' development (Löckenhoff 2012). In the adjustment perspective, retirement is seen as a process through which retirees achieve a new equilibrium into their new lives. In this respect, Kim and Moen (2002) considered the economic, personal, and social mechanisms that might facilitate the psychological well-being into retirement. Basically, people are seen as willing to maintain earlier lifestyle

patterns as well as fulfilling roles and identities even as they exit their primary career jobs in order to prevent psychological distress. This conceptualization of retirement as adjustment leads research on both the retirement transition (i.e., from employment to retirement) and postretirement trajectory (i.e., individual development in postretirement life) (Kim and Moen 2002; Wang and Shultz 2010).

Retirement as a career stage (Wang and Shultz 2010) offers some consideration about retirement in a developmental perspective. Bridge employment is especially into the focus as the way to fulfill older individuals' career needs. In a more extensive way, Löckenhoff (2012) proposed that life span developmental theories could contribute to conceptualize change over time in retirement studies, depending on how people maintain a sense of control, balance gains and losses, and perceive time horizons in retiring. In particular, socioemotional selectivity theory [SST] (Carstensen et al. 1999) might be of prime interest in lengthier transition contexts. SST proposes that as people age, their perspective of remaining lifetime changes from being expansive to limited. Awareness of remaining time influences people's choice of goals: the more time is perceived as limited, the more people will value emotional goals as well as meaningful social interactions and the less they will value knowledge-relevant goals. Applied to the career, analyzing the role of changing time orientation perspective has been recognized has a major issue for retirement studies. In particular, some findings indicate that older workers who had a greater subjective life expectancy were less inclined to retire early (see examples of studies in Hesketh et al. 2011; Löckenhoff 2012). Other researches reveal that the work environment can shape the developmental processes and their consequences on older workers' attitudes (see the review and conceptual paper by Truxillo et al. 2012). As a whole, recent research leads to conclude that life span developmental perspective would be especially well suited to analyze the role of contextual resources and their role in older workers' intention to retire.

Why Do Older Workers Retire?

Recent years have seen increasing research on retirement (for an extensive review, see Wang 2013). Echoing the decision-making perspective on retirement, a vast portion of research is devoted to understand why people retire. In studies, retirement has been measured as individuals' behavior, that is, if people actually retire or not (Van Solinge and Henkens 2014) and how (e.g., with a retirement pension or disability retirement (Blekesaune and Solem 2005) or if they retire fully or partially (Zaniboni et al. 2010)). Based on the rational assumption that people do what they intend (Beehr 2014), other studies analyzed planned or preferred age to retire (Zappala et al. 2008) and (early) retirement intentions (Lagacé et al. 2010). Turnover intention has also been considered as retirement in studies including younger workers (Henry et al. 2015). Antecedents of retirement are usually analyzed at the macro-level (contextual and normative factors), the micro-level (i.e., individual factors), and the meso-level of the organization- and work-related factors (Schalk and Desmette 2015; Wang and Shultz 2010). From this, public policies, specific individual characteristics, a complex pattern of work characteristics, and age climate emerge as at particular interest.

Public Policies as Contextual and Normative Frame

Older workers are assumed to retire when they are eligible for pension funds and when they can afford to do so financially. However, the decision to retire depends on other aspects than economics. In particular, public policies frame what routes for retiring are actually possible. Several national governments decided to remove mandatory age retirement (the USA, the UK, Finland) giving workers more flexibility in transitioning to retirement as well as the opportunity to decide how long to stay at work. The advantages of such policies could be related to a reduction of age discrimination (for instance, giving the same opportunities to women and men) and to recognizing the right for older people to use their

competences and to maintain a productive position in the society if they want (Baruch et al. 2014). Beyond the age limitations from mandatory or out of mandatory retirement, the type of social security system is of importance. Early retirement tends to be higher in countries with public policies that support early exit routes like in Belgium and France rather than employment like in Sweden and Japan. Similarly, a high unemployment rate is likely to force older workers who want to keep working to withdraw from the labor force (Jeungkun 2009). Moreover, public and private pension schemes contribute to define social norms as well as expectations that organizations share about the “right time” to retire. Also, in the frame of SST, such public policies and their organizational effects might contribute to older workers’ time orientation in the career.

The Sociodemographics and Health Conditions

Age, wealth, and health emerge among the most decisive individual characteristics (see the reviews by Schalk and Desmette 2015; Wang 2012): Workers who start considering retirement are likely to be older, they perceive a better adequacy of their actual or future income, and/or they have a poorer mental and physical health. Health conditions are the ones of the strongest predictors of perceived work sustainability in older workers as well as of older individuals’ adjustment in retiring.

Other sociodemographics lead to a more mixed pattern. In general, less educated workers tend to retire earlier, among others through disability retirement due to more aversive working conditions (Blekesaune and Solem 2005). Regarding gender, findings are somewhat inconsistent. In fact, they highlight that retirement decision is not an individual but often a marital and/or family matter. In general, having a family and especially a spouse may contribute to the decision to retire. As Beehr (2014) noticed in his review, dual-career couples often tend to retire at about the same time. Moreover, early retirement has been shown more frequent among workers with a partner than in

older workers without a partner (Van Solinge and Henkens 2014) as well as when older workers perceive lower family-to-work conflict (Kubicek et al. 2010). Studies found effects of gender in combination with marital status: Married women retired earlier more often than married men (Blekesaune and Solem 2005) and women were more likely than men to willing partial retirement (Desmette and Vendramin 2014). The lower loss of status associated with retirement for wives than for husbands as well as their greater family-care roles would explain early retirement of women compared to men (Blekesaune and Solem 2005).

The Job Characteristics

In their meta-analytic review, Topa et al. (2009) found that as a whole, negative working conditions would have somewhat limited effects on retirement intentions. In fact, findings regarding the organizational situation conclude to a heterogeneous pattern except for hard physical work conditions that are at risk for the health (e.g., jobs exposing to musculoskeletal disorders, biochemical and ambient risk, night and shift working hours, etc.). These hard physical jobs have consistently been shown make retirement more likely, through either early retirement scheme or disability retirement (Blekesaune and Solem 2005; Kubicek et al. 2010). In general, but with more mixed results, older workers will be more in favor to retirement when they perceive work-time pressure (i.e., high-speed work), when their task is repetitive, and/or when they have a job with low autonomy and control in the task (Blekesaune and Solem 2005; Schreurs et al. 2011). Similarly, older workers who feel they are plateauing in their career and/or that their job does not still offer higher levels of challenge will tend to consider early retirement (Zaniboni et al. 2010). Based on a Belgian older workers’ sample from the European Working Conditions Survey (EWCS2010), all these working conditions have been confirmed as adverse factors that make the job unsustainable until the retirement age (Desmette and Vendramin 2014).

As regards research on social relationships, findings tend to conclude that retirement is

postponed when older workers benefit from positive social relationships in their workplace, like social support from colleagues and/or supervisor (Schreurs et al. 2011; Van Solinge and Henkens 2014), maybe because workers could feel the risk of poorer social integration when retiring. As an example, Zaniboni et al. (2010) found that older workers who anticipated a loss of social integration in retirement were more willing to have part-time retirement rather than full retirement. However, in some cases, social cohesion can increase early retirement. Results of a study by Oakman and Wells (2013) indicated that older workers who perceived the most that they had opportunities for networking at work (i.e., the measure of social cohesion) were significantly more likely to retire within the next 5 years. In this study, older workers might have adjusted their retirement age on the average retirement age in their workgroup because of normative and affective processes. In other words, social relationships might play both a pro and con role in retirement depending on either they activate the norm of retirement or they fulfill meaningful social needs.

Studies have recently proposed conceptualizations of work characteristics in the frame of job demands and job resources in order to explain the role of health impairment and disengagement processes in retirement (Kubicek et al. 2010; Schreurs et al. 2011; Van Solinge and Henkens 2014). For example, a study by Schreurs et al. (2011) showed that job resources had an indirect effect on early retirement intentions through work enjoyment. The more older workers perceived control and social support from their colleagues and supervisor, the less they intended to retire early because they felt more pleasure in doing their work. Congruently to this perspective, studies on older workers' attitudes at work have given some support (however with some contradictory findings) to the hypothesis that voluntary retirement closes a process of disengagement process. In particular, lower involvement in the job and lower satisfaction at work contribute to increase early retirement (see the meta-analytic review by Topa et al. 2009) despite reviews concluding a weak relation between retirement and satisfaction (Beehr 2014).

The Organizational Age Climate

As a whole, findings on work characteristics lead to conclude that organizations should apply human resource management strategies that could foster the postponement of retirement of older workers (age management). Echoing pressure to increase older workers' activity rate and longer retirement transitions, this field of research is currently growing. There are many retention strategies to support work for people in late career (see, e.g., the review by Paullin and Whetzel 2012):

(a) Tailoring human resource practices

Human resource (HR) practices that aim at specifically fulfilling the needs of older workers for reduced job demands should consider hard physical working conditions, flexibility in the work schedule, and age-related opportunities for skills development because these working conditions have been shown crucial in impairing older workers' health or in increasing their work disengagement. Studies tend to give some support to this assumption but with caution.

Positive effects of age tailoring have been shown extensively. For example, building on several previous studies that supported the usefulness of tailored HR practices in postponing retirement, Armstrong-Stassen and Schlosser (2010) found in a nurses' sample that flexible work options (flexible work schedules, reduced work week (part-time), job sharing, and unpaid leave options) reduced the likeliness of retirement because these older nurses perceived stronger procedural justice in their organization and higher support from their supervisor. Similarly, early retirement tended to be less likely when older workers benefited from organizational practices that were specifically tailored for improving the development of older workers' career aspects, like displaying special attention to maintaining the employability of elderly employees (Zappala et al. 2008), as well as from practices that sustained their development needs like providing job opportunities for learning new things (Zaniboni

et al. 2010). In terms of job enrichment, Zaniboni et al. (2013) showed that increased skills variety rather than task variety contributed to decreasing older workers' turnover intentions. Moreover, (career) development needs should not be the only aspect taken into account. Henry et al. (2015) highlighted that age-related social needs are of importance in older workers. They showed that when older workers perceived that their organization provided practices that nurtured their generativity needs (i.e., older adults' motives to care and guide younger generations), they were significantly less inclined to quit. Higher quality of contact with younger colleagues explained this indirect effect between higher opportunities of fulfilling generativity needs and lower retirement likelihood in older workers.

However, studies can fail to find a significant association between age-related HR practices (including among others work schedule, job design, training) and retirement consideration (Hennekam and Herrbach 2013; Van Solinge and Henkens 2014). Moreover, tailored HR could have detrimental effects. In particular, as preferential treatment toward a social category, age accommodations can contribute to increased stereotypes and discrimination toward older workers. Iweins et al. (2012) revealed that when younger workers perceived that their organization implemented age-tailored HR practices like specific work-time reductions for older workers, they were more prejudiced against older workers as a whole. In other words, age-related practices may be a double-edged sword because they can – or not – contribute to reduce retirement but also because they may contribute to the unintended effect of increasing ageism.

(b) Organizational ageism

The organizational culture regarding retirement signals older employees in multiple ways when they should move out of the workplace. For example, examining an organization's customs and practices regarding retirement timing, Van Solinge and Henkens

(2014) found that when older workers perceived that early exit was commonplace in the organization, that is, all their colleagues were retiring early, participants were much more inclined to retire early themselves as well. One explanation could be that mean age for retiring in the environment contributes to frame older workers' occupational time horizon. Another explanation might be that ageism pushed older workers outside the workforce. In countries where older workers' activity rate is relatively low like Belgium and Italy, older workers are perceived as willing to retire early and they are also more likely to be more discriminated because of their age (Desmette and Vendramin 2014). Some researchers assume that early retirement is a coping strategy that individuals may adopt to avoid the negative social identity associated with their membership to the stigmatized older workers group. For instance, it has been shown that the more individuals self-categorized as older workers (Gaillard and Desmette 2008) and the more they had negative feelings about this social identity (Zaniboni et al. 2010), the higher their intentions to retire early. Other studies emphasize the role of the context as the cause of retirement viewed as the avoidance from identity threat. Intentions to retire have been shown to be higher in older workers who perceived that their organization discriminated them because of their age (von Hippel et al. 2013) and when the context had made salient negative stereotypes rather than positive stereotypes about their age group (Gaillard and Desmette 2010). Finally, a study by Lagacé et al. (2010) depicted the process of early retirement as the final step of an identity disengagement from the work domain. In a study with older nurses, they found that an organizational ageist culture (including discriminating practices and denigrating language) induced a feeling of strong frustration in older workers that lead them to question the value of their professional environment and consequently to subjectively disengage from the occupational role. Retirement was the final issue of

this process. Of course, age-related discrimination is not limited to older workers but also affects younger workers but being old seems to be an aggravating factor of the effects of perceived discrimination (von Hippel et al. 2013).

Bridge Employment

As already mentioned in the “Introduction,” in the recent years, the transition from work to retirement has been less linear and less characterized as a unique event. The passage from a full-time job to a full-time retired condition is more progressive, with variable durations, and different career paths can be followed to become “retiree” (Beehr 2014). In summary, the international labor market for people aged from 55 to 65–70 years has deeply changed in the last two decades (1995–2015). An increase has been registered in employment rates among people aged over 55 because public policies, particularly in Europe, have raised the pensionable age in order to balance the ratio between active and retired people. Work experiences have also substantially increased after retirement. Mainly because of economic necessity, some individuals at the retirement age try to continue working, even if in part-time or fixed-term jobs, although they are entitled to a pension. Even at an elderly age, workers are requested to manage their careers, to search for jobs well suited to their work abilities, and to begin new pathways and reactivate processes of skills acquisition and development.

As a result of these processes, many career pathways between the full work position and full retirement are today prevalent in the older workers experience (Alcover et al. 2014): “Phased retirement” refers to the alternative of working shorter hours for the same employer, “partial retirement” concerns a job change from a career job to a new full-time or part-time position, “bridge employment” involves a change in employer and sometimes a switch to self-employment, and “reentry” is a come back into the labor force after retiring.

Especially well-studied form of this progressive transitional experience from work to

retirement is “bridge employment” (Alcover et al. 2014). Bridge employment may be defined as jobs that follow full-time employment and precede complete labor force withdrawal or retirement from work. Different types of bridge employment can be identified. One of the main distinctions is between career-consistent bridge employment and noncareer bridge employment (Wang et al. 2008). The former type may occur in the same occupation, when older workers continue to work in previous job in the same organization or in a new one. The latter type (noncareer bridge employment) is related to the experience of people who choose to work in a different field, usually also with a lower status and a reshape salary. In many cases people are engaged in bridge job as self-employees such that they benefit from more autonomy and more flexibility in managing work hours and workload (Alcover et al. 2014).

A key issue in research on bridge employment is explaining retirement versus intentions to continue working. Indeed, intention to continue working would not be just the opposite of a low desire to retire (Schalk and Desmette 2015). On this respect, various antecedents of bridge employment have been examined by researchers. Alcover et al. (2014) and Wang et al. (2008) offer a quite complete list of these elements that could explain the access to this step of the work career. Some variables are related to individual psychological attributes such as career commitment and the entrepreneurial attitude. Some other variables are related to the lifestyle like living in a family with dependents and financial demands. Finally, some antecedents are connected to organizational conditions that could facilitate bridge employment experience. Retention strategies for preserving older workers’ skills and competences seem especially important in this respect. Examining which antecedents predict either full retirement or bridge employment, Wang et al. (2008) found that being younger, more educated, and healthier and having experienced less work stress in the previous job are favorable antecedents to bridge employment (either in the career or in another field) rather than full retirement.

Another key issue is concerned with outcomes of bridge employment for older people. The

positive outcomes of the bridge employment experience have been shown by a number of studies. Findings have been systemized in Alcover et al. (2014). In short, there are evidences for some psychosocial benefits for the individual workers in terms of work and life satisfaction, reduction of work stress and workload, engagement and motivation, and financial stability after retirement. From the organizational point of view, bridge employment could have the effect of reducing the negative stereotypes against older people in the workplace.

Conclusion

In the context of new retirement where frontiers between work and retirement have been somewhat blurred for older individuals because of longer transitions, routes for future researches are numerous and challenging. Three perspectives may be into the focus to conclude.

First, from a theoretical point of view, life span developmental approaches offer quite promising frameworks to go further in analyzing retirement motives over time. In particular, the increasing diversity of retirement routes (Alcover et al. 2014) calls for better understanding the role of time perceptions in retirement decision, its antecedents and consequences, into and outside the workplace. Social and organizational norms in the context of new retirement as well as their role in individuals' perceptions and attitudes at work should be better understood. Also, research should improve the understanding of the consequences of retirement patterns and lengthier transitions not just for the older workers but also the family and the society as a whole.

Second, organizations should develop HR practices devoted to care older workers' health and to support motivation in the job. Above all, working conditions have to be sustainable in the aim to preserve the health of the older workers until full retirement. In this objective, tailored HR practices for reducing aversive job demands, especially those at risk for the health, are needed. Moreover, organizations should provide resources

in order to support older workers' work enjoyment and motivation. Bridge employment might be a relevant route to keep them at work for longer. However, bridge employment has been shown to be more desirable when the quality of previous job was higher. Therefore, active aging (i.e., working longer) requires that organizations take care of their employees all along the career.

Finally, social relationships might be better into the scope of researchers and organizations. Indeed, congruently with SST assumptions, studies lead to conclude that social relationships can play a significant role in retirement decision. In this respect, intergenerational relationships seem a crucial issue. Conditions for qualitative contact between younger and older workers, because they contribute to postpone retirement, should be implemented. In particular, organizations should pay attention to fulfill older workers' needs but avoiding feelings of intergenerational inequity and ageism that can be related to age-tailored HR practices. In other words, age diversity management is a part of a sustainable work environment for older workers.

Working Memory in Older Age

Vanessa M. Loaiza¹ and Klaus Oberauer²

²University of Zurich, Zurich, Switzerland

Synonyms

Working memory capacity; Short-term memory; Working memory updating; Updating and monitoring

Definition

Working memory (WM) refers to the immediate and limited memory system that is responsible for maintaining, processing, and updating information flexibly and for brief periods of time. WM is sometimes used interchangeably with short-term memory in the literature, although WM is often considered more active and dynamic than the more passive short-term memory. The construct has been fundamental to researchers' understanding of age-related changes in a broader range of other cognitive abilities, such as fluid intelligence

(i.e., abstract reasoning) and long-term episodic memory (i.e., retrieval of information that is no longer held in working memory). This chapter reviews several important life-span models of WM from the literature and their supporting evidence, while also considering other aspects of WM, such as methodologies for testing WM capacity in older adults, the neural signatures of WM in the aging brain, and whether it is possible to train WM in order to yield improvements to other areas of cognition across the life-span.

Introduction

In daily life, we are regularly required to briefly hold some information in an accessible state for an ongoing task. While planning a trip, for example, it is often the case that we must consider the prices of several hotels to make comparisons between them, perhaps while also considering their relative distances to a desirable location in the city. The immediate memory system thought to underlie such tasks is called *working memory (WM)*, a concept that has been fundamental to many theories regarding age-related changes in cognition due to its hallmark responsibility of maintaining information available for processing.

Working memory capacity refers to the maximum amount of information that a person can maintain efficiently in WM. It is well known that WM capacity is limited: The system can become quickly overloaded (e.g., considering the prices of a large number of hotels), resulting in considerably impaired performance. Moreover, WM capacity only becomes more constrained with increased age: Older adults show worse performance on WM tests compared to younger adults (Bopp and Verhaeghen 2005; McCabe et al. 2010; Park et al. 1996). This fact is particularly important because the functioning of WM has a large impact on many other forms of complex cognition. Individual differences in WM capacity correlate highly with success on other cognitive tasks, such as tests of long-term episodic memory and of reasoning ability. Moreover, individual variation in WM capacity accounts for a large proportion of age-related variance in cognitive

abilities such as episodic memory (McCabe et al. 2010; Park et al. 1996). In other words, how much individuals of different ages vary in their episodic memory performance can largely be ascribed to their variation in performance on the WM measure. For that reason, WM has been a core construct at the center of research on age-related decline in higher-order cognition.

The explanation that many researchers offer for such findings is that the mechanisms underlying WM are similarly required during tasks measuring other forms of higher-order cognition. However, researchers have disagreed about what causes the limitations in WM and why WM capacity predicts other cognitive functions. In the aforementioned example of maintaining hotel prices and locations for a trip, it could be that younger adults excel at this task relative to older adults because: (1) they are just generally faster and therefore more efficient at the task (*processing-speed hypothesis*); (2) they are better able to disregard irrelevant information (e.g., checking emails, distracting music) during the task (*inhibitory-deficit hypothesis*); (3) they are better able to flexibly coordinate between the different subtasks involved (*coordination and task-switching hypotheses*); or (4) they are more effective at integrating the hotel price and location information into a cohesive unit (*binding-deficit hypothesis*). Accordingly, age differences in one of these predicted underlying functions in WM are thought to be similar in other tasks of higher-order cognition (e.g., episodic memory) that likewise rely on the same function.

The goal of this section is to review several frameworks and concepts that have been important to explaining age-related differences in WM and elucidating its role in higher-order cognition. Important findings from the neuroscientific literature concerning age-related changes in the brain that correspond to changes in WM performance are also reviewed. Furthermore, findings from the relatively recent field of WM training are also considered. Prior to these overviews, a summary of the typically used empirical methods in the field of cognitive aging and WM is presented.

Empirical Methodologies and Working Memory Measures

There is a wide range of commonly used empirical methods in the study of WM across the lifespan. The use of any one of these particular methods depends on the research question of the researcher, and unfortunately, sometimes the convenience and cost of the study. Furthermore, the WM literature in general is rife with discussion on the best tasks to use to properly assess WM capacity. Much of the research attempts to balance the practical importance of utilizing well-established and reliable tasks with the aim to use theoretically informative tasks that could adjudicate between purported mechanisms of WM. A thorough consideration of these empirical and task-specific methodologies is essential for any study on WM in older adults.

Empirical Methods. As is the case in many areas concerning development, studies of WM generally fall under the umbrellas of either cross-sectional or longitudinal designs. Both types of designs either recruit participants for a continuous age sample (e.g., adults aged 18–80 with the ages more or less equivalently represented) or recruit participants to represent prearranged and discrete or extreme age groups (e.g., younger adults aged 18–30 vs. older adults aged 65–80). Cross-sectional studies compare adults of various ages or age groups at the same singular time point. Thus, cross-sectional studies assess interindividual variability, or how WM differs between these disparate age groups. Conversely, longitudinal studies examine adults representing one or several age groups across at least two time points. Thus, longitudinal studies are primarily concerned with intraindividual variability, or how WM differs within a person across different points in time. Whereas cross-sectional designs tend to show a steep linear decline from age 20 on in a host of cognitive functions including WM (McCabe et al. 2010; Park et al. 1996), longitudinal designs usually show much more modest rates of decline in WM (Hertzog et al. 2003). Within either cross-sectional or longitudinal designs, researchers typically implement

experimental or individual differences methods, or a combination of the two, depending on their research question. Experimental research questions concern the effect of manipulating one or several factors on subsequent performance. In cross-sectional designs, for example, researchers may examine whether increasing the amount of information (i.e., load) in WM yields different patterns of brain activity in the prefrontal cortex in younger and older adults (Daselaar and Cabeza 2014). Experimental studies very commonly test for age \times variable interactions, such that effect of manipulating a variable (such as WM load) is more pronounced for one age group than another.

As will be discussed more thoroughly in the overview of theories of WM age differences, such interactions can be informative for differentiating key aspects underlying age-related changes in WM. However, many age \times variable interactions are ordinal, and as such, are uninformative because they depend on the scale of measurement. Several methods have been developed to address this issue. First, a Brinley plot is a scatterplot wherein older adults' mean performance is plotted as a function of that of younger adults' for the same task condition. The regression line represents the relation between young and old adults' performance scores across a number of tasks and experimental conditions. A meaningful interaction between age and the variable of interest can be inferred if two separate regression lines are necessary to explain the young-old relation in two conditions (e.g., a baseline condition and a critical experimental condition). Two lines would suggest that there is a specific age-related deficit associated to the experimental condition over and above the age deficit observed in the baseline condition. Conversely, if only one regression line is necessary to explain the relationship between younger and older adults' performance on the different task conditions, then it can be inferred that the age-related deficit can be reduced to a single underlying variable that accounts for the age effects in all task conditions.

In a similar vein, state-trace plots also examine interactions between age and a variable of interest by plotting performance on one task (e.g., the

baseline condition) against performance on another task (e.g., the experimental condition) in order to ascertain if the relationship between these tasks differs between younger and older adults. Similar to Brinley plots, an age \times variable interaction can be inferred if two regression lines (one for either age group) are necessary to explain the performance relations between the tasks. However, if only one regression line is necessary, then it can be concluded that the relationship between the tasks can be reduced to a single variable that changes across the lifespan. Thus, Brinley plots and state-trace plots can be very informative to indicate whether an underlying process or mechanism is uniquely deficient in older age or not.

Individual-differences research asks to what extent differences between individuals on a particular task or set of tasks covary with differences on other measures. Because no single task is a pure measure of a construct, it is increasingly common to administer a number of tests that purportedly measure the same underlying construct, such as WM capacity. The construct is represented by the latent factor that reflects the common variance of all the WM tests. Researchers then use structural-equation modeling (SEM) to examine how these latent constructs correlate with other constructs, such as fluid intelligence. These methods are important for assessing the contribution of WM in explaining age-related variability in other complex cognition. For example, in a longitudinal design, one could examine how changes in WM performance from age 64 to 70 accounts for the changes shown in other variables like episodic memory (Hertzog et al. 2003). Analogous analyses in cross-sectional designs using path models examine how WM accounts for age-related variability in other measures (McCabe et al. 2010; Park et al. 1996). Individual differences methods like hierarchical linear regression and SEM can be useful for comparing alternative models to each other, but such methods applied to cross-sectional designs are inadequate to infer that age-related changes in one construct (such as WM) are causally responsible for age-related changes in other constructs (Lindenberger and Pötter 1998).

Working Memory Measures. Most researchers agree that WM is a system that briefly maintains, manipulates, and updates information. Given this characterization of WM as a construct, researchers have created a plethora of tasks that aim to assess these functions.

Complex span tasks have dominated the literature: They require participants to briefly maintain information (e.g., in verbal complex span tasks, digits, letters, or words) while concurrently engage in other processing activities (e.g., in operation span, arithmetic problems, such as “ $4 \times 6 = 24?$ ”). Typically, after 2–7 memoranda have been presented, participants are asked to recall them in their original order of presentation. Other WM tasks emphasize the updating function of WM, such that initially presented information (e.g., the digits 4 2 9 presented across three frames) is updated using new incoming information (e.g., successively presented operands such as +2, +1, and –3, to be applied to the first, second, and third digit, respectively). Other studies, especially neuroscientific studies using fMRI, commonly use *n*-back tasks. In the *n*-back paradigm, participants observe a long series of items and decide for each presented item (e.g., letters) whether it matches the item presented *n* steps back (e.g., in a 2-back with letters, the sequence L-R-L-Q would require “yes” to the second presentation of L but “no” to Q). Neuroscientific and behavioral studies have also commonly employed immediate short-term recognition or probed-recognition paradigms: A set of stimuli is presented, followed by a brief delay. WM is then tested by presenting a probe stimulus and requiring participants to decide whether it was included in the memory set, or whether it matches one particular stimulus in the memory set.

There are several methods of determining whether various measures of WM capacity are good indicators of the construct as well as informative about the nature of WM itself (Oberauer 2005b). These methods are not necessarily specific to WM research but have been immensely informative for the literature in general and for considering age-related changes in WM performance. As discussed previously, researchers often use factor analysis to the benefit of

understanding how these WM measures share common variability at the latent level. That is, if different kinds of measures of WM capacity load on the same factor, then it can be concluded that only one factor of common variability is necessary to explain performance on the tasks (i.e., construct validity). Furthermore, the different WM measures should correlate to the same extent with other criterion measures commonly associated to WM, such as fluid intelligence (i.e., convergent validity). Conversely, the measures should not predict performance on other tasks that are theoretically assumed to be unrelated with the construct, such as visual search (i.e., discriminant validity). Finally, the measures should be similarly affected by experimental manipulations and by age at both the behavioral and neural level, especially as predicted by the theoretical understanding of the construct. While it is greatly important to establish the reliability and validity of these different measures, the selection of any one of them thereafter depends on the research questions of the study. Specifically, the selection of one task over another is motivated by the task characteristics that allow one to test the underlying mechanisms of interest.

Theoretical Accounts for Age-Related Decline in Working Memory

Given the many proposed models of WM (Miyake and Shah 1999), it is not surprising that there are a variety of corresponding theoretical accounts for age-related differences in WM. Some of these theoretical accounts have focused on interpreting age-related deficits in WM as deficits in more basic functions (i.e., processing speed, binding), whereas others have emphasized the importance of cognitive control in WM (i.e., inhibition of irrelevant information, coordinative ability).

Processing Speed. Among the earliest and arguably the most profoundly influential explanations for age-related decline in WM, and fluid cognition in general, was the *processing-speed hypothesis* (Salthouse 1996). It is regularly observed that older adults process and respond to information much more slowly than

younger adults. For example, on a typical processing speed measure (e.g., letter comparison), the speed with which one decides whether a string of consonants matches another string of consonants (e.g., LHQFPY – LHRFPY) tends to increase with increasing age. The processing speed hypothesis states that information in WM declines over time. Therefore, adults' slower speed of processing means that fewer cognitive operations on information in WM can be completed before that information is lost. Moreover, less information is simultaneously accessible in WM because encoding and rehearsal of information is also slowed, compared to younger adults. Thus, processing speed is argued to cause the age-related decline in performance in WM tasks. Evidence for the processing-speed hypothesis comes from the well-established finding that the negative correlation between age and measures of WM capacity is substantially attenuated when measures of processing speed are statistically controlled for, particularly in cross-sectional studies.

Despite consistent evidence that processing speed shares a large proportion of age-related variance with performance on tasks of higher order cognition, age differences in WM capacity cannot be reduced to mere speed of processing. A number of studies varying different dimensions of task complexity have shown that age differences in speed of processing depend on the demands of the task: As task complexity increases, the ratio of average response times between old and young adults increases from about 2:1 to about 4:1 (Oberauer 2005a). This suggests that the age difference in speed is not a cause but a consequence of the age difference in WM capacity: With reduced WM capacity all task-relevant representations – including task sets that implement the goals and instructions – are represented less robustly, resulting in slower processing, and that effect is exacerbated the more WM is loaded. Further evidence has indicated that older adults' comparatively slower processing speeds are largely due to different speed-accuracy trade-offs between younger and older adults: Older adults are more likely to prioritize accurate responses at the cost of response times, whereas younger adults tend to balance

speed and accuracy to achieve the most correct responses per unit of time (Starns and Ratcliff 2010). Therefore, much of the age-related slowing observed in response times does not reflect slowing of information processing.

From an individual differences perspective, WM and processing speed at the latent level are often strongly related but still distinguishable constructs. Moreover, structural-equation models including both WM and processing speed as separate predictors of higher-order cognition (e.g., episodic memory) have provided better fits of the data than models that only used speed as a predictor variable and WM as a measure of general memory ability (McCabe et al. 2010; Park et al. 1996). Thus, although processing speed is an important factor in age-related decline in cognitive abilities, research from experimental and individual differences perspectives alike show the unique predictive utility of a WM factor that cannot be entirely reduced to processing speed.

Inhibition. The *inhibitory-deficit hypothesis* attributes age-related changes in WM to a decreased ability to keep irrelevant information out of WM, and thereby prevent it from interfering with the task at hand (Hasher et al. 2007). According to this view, age differences in WM arise not because older adults are less capable than young adults of maintaining information in WM; rather, there is *too much* irrelevant information cluttering their WM that disrupts the maintenance and processing of relevant information and consequently yields worse performance.

The evidence for inhibition as a crucial factor in WM stems from a number of different paradigms that infer successful inhibition from the contrast of two experimental conditions. Inhibition can be inferred from slower response times to information assumed to be suppressed previously, less priming of suppressed information, or fewer intrusions of information that was deemed irrelevant to the task, compared to a baseline condition in which suppression is unnecessary (Hasher et al. 2007). Compared to younger adults, older adults have shown diminished inhibitory ability in each of these regards. The paradigms developed to test inhibitory functioning have included negative priming, directed forgetting, and resistance to

prepotent responses (e.g., antisaccade, Stroop), among many others. In many of these paradigms, the crucial measure is the relative difference in response times during the critical task that requires inhibition of irrelevant information compared to a baseline condition. For example, the negative priming task simultaneously presents two stimuli and requires a response to the predetermined relevant stimulus (e.g., name the red letters) while also ignoring the irrelevant distracter (e.g., a superimposed green letter). Negative priming effects are shown when response times are differentially slower when the irrelevant distracters are repeated as relevant stimuli on the following trial, compared to a baseline condition wherein none of the distracters are repeated. Thus, *smaller* negative-priming effects indicate failures to inhibit the irrelevant stimulus, whereas in other paradigms, which measure the influence of distraction or prepotent responses (e.g., antisaccade, Stroop), *larger* effects indicate failures to inhibit distracting or irrelevant stimuli compared to the neutral baseline. Accordingly, proponents of the inhibitory-deficit hypothesis have shown that older adults show less evidence of inhibiting the distracting or irrelevant stimuli in these paradigms compared to younger adults (Hasher et al. 2007).

A recent meta-analysis has cast doubt on inhibitory functioning as the main culprit of age differences in WM (Verhaeghen 2011). This is largely demonstrated by using Brinley plots that plot older adults' response times as a function of younger adults' response times for the aforementioned baseline and critical conditions. If increased age is associated with impaired inhibitory function, then the function relating older adults' response times to those of younger adults in the critical condition should have a higher intercept, or a steeper slope (or both), than the function for the baseline condition. However, as the meta-analysis showed, older adults' relatively slower response times in the baseline conditions were not further exacerbated in the critical conditions requiring inhibition. This result contradicts the assertion that older adults suffer from a specific deficit in inhibitory function. Furthermore, critics have questioned whether inhibition is really necessary to explain the results of the studies that purportedly support

deficient inhibition in older adults (Oberauer 2005a). As will be discussed in a later section, it is possible that intrusion errors or slower response times to irrelevant information may not reflect inhibitory failures per se, but rather poor discrimination of the proper source context of the information due to failures of binding (Oberauer 2005a).

Coordination and Task Switching. Another explanation of age differences in WM is the relatively diminished ability to coordinate or switch between different subcomponents of a task. Research on coordination between tasks in WM has utilized dual-task paradigms, wherein performance on a single-task condition (e.g., responding to visually presented stimuli) is compared to performance when that task is performed concurrently with an additional task (e.g., also responding to auditorily presented stimuli). A meta-analysis has indicated that the relative cost of performing the dual-task relative to the single-task is reliably larger in older adults than younger adults, although the effect is relatively small (i.e., an age difference of 36 ms) (Verhaeghen 2011).

Somewhat relatedly, the ability to switch between tasks has also been a considered source of age-related differences in WM. This ability can be tested with the task-switch paradigm, in which participants must perform one of two tasks on successively presented stimuli, with a task cue informing participants on each trial about the task to be carried out. As in the dual-task paradigm, these tasks are first performed alone (pure blocks; e.g., reporting the parity of a digit vs. reporting its magnitude relative to 5) and then together (mixed block; e.g., report the parity of the digit if the digit is red, report the magnitude if the digit is blue). Two measures of interest are assessed: the *local task-switching cost* associated with switching tasks within the mixed block (i.e., switch vs. nonswitch trials) and the *global task-switching cost* associated with the general requirement of switching (i.e., pure vs. mixed blocks). Global task-switching costs are larger for older than younger adults, whereas local task-switching costs are similar in both age groups (Verhaeghen 2011). Thus, age differences appear to be largest when participants must maintain two distinct task sets, as is required during dual-task and global task-switching paradigms.

Whereas this research demonstrates age-related differences in cognitive control as manifested by task coordination and global task-switching, correlations between measures of WM capacity and task-switching are typically low (Oberauer 2005a). If age differences in WM arise from differences in the ability to coordinate and switch between tasks, then these variables should be highly correlated, and account for similar variance in other measures of higher-order cognition. However, the aforementioned meta-analysis showed that a latent construct representing task-switching and coordination did not explain additional variance in complex cognition (representing reasoning, episodic memory, and spatial ability) over and beyond the influence of WM and processing speed (Verhaeghen 2011). Thus, age differences in these abilities likely do not reflect the differences shown in WM capacity.

Binding. Another potential source of age-related decline in WM concerns whether older adults are specifically impaired in their ability to establish temporary bindings between information and their contexts within a common cognitive coordinate system (Oberauer 2005a). Much of this research is guided by the premise that WM tasks require robust bindings between contents (e.g., information to remember, such as words) and their contexts (e.g., the relative positions of the words in the trial), as do other complex cognitive tasks with which WM is correlated (Oberauer 2005a). This conception of age differences in WM also corresponds to evidence from the episodic memory literature: Older adults exhibit a specific deficit in the retrieval of information on the basis of associations (Old and Naveh-Benjamin 2008) or recollection of specific details (Jacoby and Rhodes 2006), both of which presumably require some binding of that information during encoding.

Research testing the *binding-deficit hypothesis* has focused on the importance of constructing, maintaining, and dissolving temporary bindings among representations in WM and their temporal-spatial source contexts (Oberauer 2005a). The contribution of bindings in WM can be measured through short-term recognition paradigms that separate two contributions to the recognition

decision: (1) recollection, reflecting memory for which content was presented in which context, based on temporary bindings, and (2) familiarity, reflecting memory for which content was presented without memory for its context, which merely requires the activation of content representations but no bindings. The two contributions can be measured separately by recognition paradigms in which participants must decide whether the test probe has been presented in a particular context. For instance, in the local-recognition paradigm a set of words is presented across a row of boxes, and a recognition probe appears in one box, requiring a decision whether the probe matches the memory word in that box. In this paradigm there are two kinds of to-be-rejected probes: new probes, not included in the memory set, and intrusion probes, which were in the memory set but in a different box (i.e., a different context). Whereas new probes can be rejected based on their lack of familiarity alone, rejection of intrusion probes requires bindings between the words and their boxes. Older adults exhibit disproportionately larger costs for intrusion probes compared to new probes, as predicted by the assumption that their recollection is impaired by a binding deficit. In contrast, older adults were much less impaired in rejecting new probes, suggesting that their ability to use familiarity for recognition decisions is largely intact (Fandakova et al. 2014; Oberauer 2005a).

The disproportionate intrusion costs for older adults cannot be explained by an inhibitory deficit (Oberauer 2005a). Rather, the intrusion costs reflect an age-related deficit in binding information in WM. In addition to the aforementioned meta-analysis concluding that older adults do not exhibit deficient inhibitory control, these studies have further supported the notion that the source of intrusion costs commonly attributed to inhibitory failures may in fact be due to relatively deficient binding in WM. Furthermore, age-related deficiencies in building or maintaining bindings in WM connects the age differences exhibited in WM to the specific age-related impairment of retrieving associative information from episodic memory (Jacoby and Rhodes 2006; Old and Naveh-Benjamin 2008).

Working Memory in the Aging Brain

The advent of neuroscientific techniques has also been considerably important to scientists' understanding of the underlying brain mechanisms that correspond to age-related change in WM performance. Neuroimaging techniques include positron emission tomography (PET), functional magnetic resonance imaging (fMRI), electroencephalography (EEG), and transcranial magnetic stimulation (TMS). Researchers have also been interested in the role of neurotransmitters, especially dopamine, associated with age-related changes in WM.

Much of the neuroscientific research has centered on the frontal lobe, especially the prefrontal cortex, and its interactions with other brain regions in supporting WM functioning. Among other regions, the frontal lobes are known to decline in structural integrity with increased age. Thus, researchers have been interested in whether these structural changes correspond to functional decline in WM capacity with older age (Daselaar and Cabeza 2014; Nagel and Lindenberger 2014; Nyberg et al. 2012; Reuter-Lorenz and Cappell 2008). Much of this research has been guided by examinations of how neural activity differs between younger and older adults on WM tasks, especially as the tasks increase in attentional demand or WM load. There are a number of studies indicating underactivation of task-relevant neural regions in the prefrontal cortex in older adults, whereas other studies have suggested overactivation relative to younger adults (Daselaar and Cabeza 2014; Nagel and Lindenberger 2014; Nyberg et al. 2012; Reuter-Lorenz and Cappell 2008). Underactivation occurs when older adults activate a brain region to a lesser extent than younger adults, whereas overactivation often manifests as bilateral activation of the prefrontal cortex, or activation of the mirror area in the opposite hemisphere in older adults that is unilaterally active in younger adults (i.e., Hemispheric Asymmetry Reduction in Older Adults, or HAROLD (Daselaar and Cabeza 2014)). Both patterns can occur in the same task, especially when WM load is varied: Whereas younger adults show increasing activity with increasing load, older adults show overactivation under low WM loads and underactivation at higher loads relative to younger

adults. Underactivation is typically interpreted as an age-related functional deficiency in the processes that rely on the particular neural substrate. The interpretation of overactivation in the HAROLD pattern, however, is less clear than underactivation, primarily due to conflicting results regarding the performance associated with this activity.

Some studies have shown that overactivity is correlated with higher performance in older adults, indicating that the recruitment of additional brain regions may serve a compensatory role in WM and other cognitive functions (Daselaar and Cabeza 2014; Reuter-Lorenz and Cappell 2008). These studies are commensurate with the compensation-related utilization of neural circuits (CRUNCH) hypothesis (Reuter-Lorenz and Cappell 2008). Specifically, in order to meet task demands, older adults recruit more neural circuits than younger adults to compensate for declining neural efficiency. However, older adults appear to reach their maximal capacity of compensatory function at low WM loads, and therefore show underactivation during high loads relative to younger adults. The pattern of overactivation has been linked to successful aging in that older adults who more strongly show overactivation are more likely to exhibit greater WM performance relative to those who do not (Daselaar and Cabeza 2014; Reuter-Lorenz and Cappell 2008). However, others have interpreted the HAROLD pattern as dysfunctional; that is, older adults with preserved WM should be more similar to younger adults in terms of patterns of brain activity (Nagel and Lindenberger 2014; Nyberg et al. 2012). Overactivation may rather be more indicative of increased effort, and those who are successfully aging would not need to recruit additional neural regions if their performance was comparable to that of younger adults. Accordingly, some studies have shown that the older adults with the highest WM capacities had more similar patterns of activation in the prefrontal cortex to younger adults than low performers (Nagel and Lindenberger 2014; Nyberg et al. 2012). Moreover, increasing prefrontal activity was related to increasing WM recall accuracy in younger and older adults when an index of responsivity was considered

(i.e., subtracting the signal change in the lowest from that of the highest load). Thus, the causative role of overactivity in regions of the prefrontal cortex in older adults' behavioral WM performance is presently to be determined.

Other research has indicated that WM age differences are not solely localized to the prefrontal cortex. In addition to its interaction with the parietal cortex, the circuitry between the prefrontal cortex and the medial temporal lobe has more recently received much attention. Activity in the medial temporal lobe is more traditionally linked to episodic memory. However, more recent research has suggested that the medial temporal lobe is additionally important during visual-spatial WM tasks, particularly when the tasks involve binding between spatial/pictorial elements of the memoranda (Daselaar and Cabeza 2014). These studies indicated greater age-related underactivation of the hippocampus when the WM tasks explicitly required binding (e.g., an object in its location) relative to maintenance of item-specific information (e.g., just the object or just its location) (Daselaar and Cabeza 2014). Such studies converge with the previously described behavioral studies showing that the age differences in WM may be attributable to older adults' relative inability to bind information in WM (Fandakova et al. 2014; Oberauer 2005a).

Finally, a number of studies have also investigated the functional role of dopamine (DA) activity in the age-related decline in WM. There is much evidence that both presynaptic (i.e., the DA transporter) and postsynaptic markers (i.e., D1 and D2 receptors) deteriorate with increasing age (Nyberg et al. 2012). Among other cognitive functions, age-related decline in D1 receptor binding potential in the caudate nucleus and the prefrontal cortex have been associated with underactivation of fronto-parietal regions and corresponding reduced performance in older adults during WM tasks (Nyberg et al. 2012). Specifically, statistically controlling for D1 binding in the caudate and prefrontal cortex fully mediated the age-related underactivation in the left prefrontal cortex and partially mediated the age-related underactivation in the right prefrontal and left parietal regions (Nyberg et al. 2012). Moreover,

simulating older adults' DA activity in young adults by allocating a D1 antagonist induced increased frontal bilateral connectivity in younger adults that significantly predicted WM performance (Nyberg et al. 2012), supporting a compensatory view of the previously described HAROLD pattern exhibited by older adults (Daselaar and Cabeza 2014; Reuter-Lorenz and Cappell 2008).

Training Working Memory

An increasingly important topic in the cognitive aging literature is whether the effects of age-related cognitive decline can be circumvented by training older adults on these cognitive functions, especially WM. Given its aforementioned importance for a wide range of higher-order cognition, many researchers have focused on WM as an access point to generalizing the benefits of increased WM capacity. If WM accounts for substantial age-related variability in other factors (e.g., fluid intelligence), then perhaps training WM could improve older adults' performance in these other cognitive functions (i.e., *far transfer effects*). However, it may also be that the effects of training are only specific to the trained task (i.e., *trained task effects*) or, at best, other measures of WM capacity (i.e., *near transfer effects*). Finding that WM training does not improve broader cognitive functions would undermine the practical utility of training WM in older adults.

Although rising in popularity, the question of whether older adults' WM capacity can be improved and can show generalizable benefits to other forms of cognition is still not settled. Theoretically speaking, it is not clear which aspects of WM that training actually improves, and further still, how improvements to those aspects bring about improvements in other far transfer tasks. Further complicating matters, assessments of the effectiveness of WM training vary substantially across studies, with some showing massive near and far transfer effects after only several sessions whereas others only indicate improvements to the trained task, but no transfer, even after extensive training. This complication is compounded when one considers the bias toward publishing

statistically significant rather than null results, thereby increasing the visibility of training-related gains in the literature that may in actuality overestimate the true effectiveness of training.

A recent meta-analysis of 61 training experiments with older adults who received WM training (Karbach and Verhaeghen 2014) showed significant improvements to performance (i.e., pre- vs. post-test) on the trained tasks (effect size = 0.91), near transfer tasks (effect size = 0.47, corrected for publication bias), and far transfer tasks (effect size = 0.38). Moreover, these improvements were similar to those shown in younger adults and reliably larger than the improvements shown in the active and passive control groups, who generally showed statistically indistinguishable effects. Thus, although the improvements of training WM were largest for the trained tasks, there was still a modest improvement even in tasks representing other cognitive functions (e.g., fluid intelligence, episodic memory).

Conclusions

Although the book is far from closed as to what underlies the age differences exhibited in WM capacity and the construct's importance for other age-related cognition, the field has made important strides toward this goal. A bird's-eye view of the literature taken through meta-analyses helps to identify sources of age-related variability that are correlated with WM capacity, most notably processing speed, and others that are uncorrelated with WM capacity (e.g., task switching). Moreover, age-related declines in inhibitory functions do not go beyond declines in general speed. Together, these findings rule out the task-switching/coordination hypothesis and the inhibition-deficit hypothesis of age-related declines of WM capacity. The speed hypothesis provides at best an incomplete explanation because age-related slowing accounts at best for a part of the age-related decline in WM capacity. A deficit in maintaining temporary bindings is likely to be one factor responsible for that decline. Neuroscience research has shown that older adults recruit WM-related neural networks less effectively

when WM is challenged by a high load; at the same time, older adults recruit a larger network at lower levels of load, perhaps to compensate for reduced neural efficiency. Reduced sensitivity to dopamine appears to be one factor responsible for the deterioration of neural efficiency in the WM system. Training studies have yielded promising results showing that performance in WM tests can be improved in old adults as much as in young adults, but it remains an open question how far these training gains transfer to performance in other tasks. These findings collectively demonstrate the importance of understanding age-related changes in WM capacity, especially as they relate to those of other areas in complex cognition.

Adaptation; Change; Invention; Originality

Definition

Creativity is the generation of ideas that are both novel and appropriate. Innovation is the subsequent intentional implementation of those ideas.

While work performance is a complex and multifaceted construct (Viswevaran 2001), one of the most coveted and elusive dimensions of work performance is creative and innovative performance. Organizations look for ways to stimulate (or at least not hinder) their employees' creative and innovative performance, because this will – it is believed – contribute to individual, team, and organizational success (Gilson 2008). Since the workforce is aging and will continue to do so over the next decades, organizations need to know what ramifications – if any – this demographic change will have for their

innovative potential. The goal of this entry, therefore, is to examine relationships between employee age and workplace creativity and innovation.

Overview of This Entry

This entry consists of four main parts. First, the concepts of creativity and innovation are defined. Second, the entry briefly discusses the common belief that older employees are less creative and innovative, followed by a summary of the actual empirical state of affairs regarding direct, zero-order relationships between age and creativity and innovation. Third, our entry takes a closer look at two broad themes within the literature on creativity and innovation (motivation and group creativity) and describes some ways in which aging and age-related processes might fit within these perspectives. Finally, an important direction for future research is pointed out.

Defining Creativity and Innovation

Creativity is commonly defined as the generation of ideas that are both novel (i.e., original or surprising) and appropriate (i.e., useful or feasible within a particular context) (Amabile 1996). Thus, employees show creative performance to the extent that they generate and contribute (e.g., to their team or organization) original and useful ideas. Then again, ideas by themselves are not enough; what organizations aim for, in the end, is *innovation*, which has been defined as “the intentional introduction and application within a job, work team or organization of ideas, processes, products or procedures which are new to that job, work team or organization and which are designed to benefit the job, the work team or the organization” (West and Farr 1990). In sum, creativity is about the generation and contribution of new and useful ideas, whereas innovation entails the actual implementation of those ideas. Creativity, then, is a necessary but insufficient condition for innovation to occur (West 2002).

Are Older Employees Less Creative and Innovative?

There is a pervasive belief that older employees are less creative and innovative than their younger colleagues. Older employees are also often believed to be less flexible, less open to change, and less motivated (e.g., Ng and Feldman 2012; Sherrington 1992). The general picture that emerges does not bode well for older employees. Indeed, it cannot be disputed that aging does bring about changes in cognitive, affective, and physical functioning and motivation (e.g., Salthouse 2012) and that some of these changes might plausibly be related to lower creativity. For example, measures of fluid cognitive abilities, such as novel problem-solving, show a clear and substantial linear age-related decline (Salthouse 2012). Given that the ability to solve new problems is crucial for creativity, it may seem plausible that this would translate into lower creativity and innovation among older employees. Moreover, it could be argued that negative age-related stereotypes have a detrimental effect on older employees' creative and innovative performance because they undermine relevant self-efficacy beliefs. Interestingly, however, a generally negative relation between age and creative or innovative performance is not what emerges from the empirical literature.

Although empirical work on age and work has increased enormously in the past decade (e.g., Hertel and Zacher 2016), to date there have been relatively few studies that actually focus on age and creativity and innovative performance in work settings, despite calls for such studies (Sherrington 1992). Nevertheless, several studies have measured age as a predictor or, in most cases, as a covariate, and other studies on age in the work context have measured creativity or innovation as relevant aspects of work performance, which made meta-analytical work possible. A first meta-analysis on studies addressing the relationship of age to several dimensions of job performance, including creativity, found that age had zero relationships with self- and supervisor ratings of creativity (Ng and Feldman 2008). A second meta-analysis by the same authors examined bivariate relationships between age

and innovation-related behavior, such as idea generation (i.e., creativity), idea dissemination (the “selling” of ideas to stakeholders), and idea implementation (Ng and Feldman 2013). Results again showed that age was largely unrelated to innovation-related behaviors (neither linear nor nonlinear associations emerged).

These meta-analytical findings, which are mainly based on cross-sectional data, should not lead to the conclusion that employee age and aging are completely irrelevant to creativity and innovation. Although very few primary studies have actually *focused* on age and creativity, those that have suggest that the relationship between age and creativity/innovation is not a simple, zero-order relationship, but is moderated by other individual and contextual factors, such as individual differences in personality, job-related resources, and contextual characteristics. For instance, a study found that the relationship between employee age and creativity was positive when job autonomy was high (Binnewies et al. 2008).

Empirical studies such as those reviewed above are still relatively scarce, but it seems clear that an understanding of the relation between aging and creativity/innovation will require a more sophisticated approach than merely studying direct or zero-order relationships. One particularly fruitful strategy for aging research would be to focus on specific topics or domains within the creativity and innovation literatures, because these might suggest concrete moderating and mediating variables of the age-creativity/innovation relationships. The following section addresses two themes that seem particularly promising: motivation and group creativity.

Motivation and Need Fulfillment

One of the most important and fruitful lines of (basic) research on creativity and innovation concerns the role of motivation. Broadly speaking, the consensus is that *intrinsic motivation*, or the motivation to engage in an activity for its own sake, because one enjoys it, is important and beneficial for creative performance (Amabile 1996).

In contrast, the role of *extrinsic motivation*, or the motivation to engage in an activity to attain or avoid a particular outcome (such as a reward or a punishment), is more complex: it can both stimulate and stifle creativity (Byron and Khazanchi 2012). Overall, the literature shows that contextual factors (such as rewards) that make employees feel *controlled* (i.e., less autonomous) are likely to stifle creativity through a decrease in intrinsic motivation.

In this line of research, work environments are thought to be conducive to intrinsic motivation (and hence creativity) to the extent that they contribute to (vs. thwart) the fulfillment of employees’ psychological needs (such as the need for autonomy or the need for competence). External motivators such as rewards can easily detract from intrinsic motivation, because they can cause employees to attribute their efforts primarily to the reward, rather than to their own task interest, and hence threaten need fulfillment regarding autonomy (Amabile 1996). Rewards are not necessarily controlling, however; when rewards are made contingent upon creative performance, they can actually stimulate creativity (Byron and Khazanchi 2012).

Such motivational issues probably are particularly important for older employees, because research suggests that older employees are not necessarily motivated by the same things as younger employees, due to, for instance, age-related changes in time horizons and experiences. For example, older employees tend to attach less weight to financial rewards and more to the sense of satisfaction they can derive from the work itself and to job characteristics such as autonomy (Kooij et al. 2011). In other words, the classic finding that creativity is stimulated by intrinsic motivation and likely to be hindered by controlling circumstances would appear to hold particularly strongly for older employees. Thus, organizations that wish to stimulate creativity among their older employees should pay even closer attention to job characteristics such as autonomy. Initial empirical support for this notion comes from a study reported in Binnewies et al. (2008), which found that the relationship between age and creativity at work was positive only when job autonomy was high.

Moreover, to the extent that extrinsic motivators such as financial incentives can motivate employees to perform creatively (Byron and Khazanchi 2012), this will probably be less effective for those employees who find such rewards relatively unimportant, such as older employees. Further, Kooij et al. (2011) found that age was negatively related to self-reported extrinsic motives (e.g., benefits and promotions) and work-related growth motives (e.g., training or learning opportunities). In contrast, age was positively related to work-related intrinsic motives (e.g., a sense of accomplishment and autonomy). All in all, it seems that older employees simply are not motivated or demotivated by the same factors as their younger colleagues. Thus, motivational effects on creativity and innovation are highly likely to depend on employee age – and, by extension, the same is likely to be true for the effects of contextual factors that influence employee motivation.

Team Creativity and Age Diversity

Another line of research has looked into the benefits and risks of team or group collaboration in creative efforts and the factors determining the success or failure of such collective endeavors (see Paulus and Nijstad 2003 for a collection of overviews). One reason why group collaboration is thought to enhance creativity and innovation is because of the potential for cognitive stimulation: group or team members have different knowledge, experiences, and opinions, and this could – in theory – stimulate divergent processing and creative decision-making.

In fact, research on group creativity and group decision-making shows that groups tend to perform below their potential and often fail to make effective use of the divergent expertise and perspectives that are available (Paulus and Nijstad 2003). Demographic or surface diversity in particular seems to be problematic for groups; it has been found to relate to subgroup formation, within-group conflict, superficial information processing/exchange, and lower creative performance (Paulus and Nijstad 2003).

Other researchers, however, point to the possible advantages that come along with having a team comprised of members from diverse age groups. For example, when team members differ from each other in age and age-related characteristics, they are likely to also have different networks of communication outside the team (Joshi and Jackson 2003), which in turn could stimulate team innovation. Further, in addition to their unique expertise and experience, older team members may have more time to help and mentor their younger colleagues (Wegge et al. 2008). Moreover, when a workgroup consists of employees of the same age, these may in effect be competing for the same resources (such as promotion opportunities). The presence of older team members who are not (or no longer) competing for these scarce resources may contribute to a more positive atmosphere and enhanced creativity within the team (Choi 2007).

Thus, like other forms of team diversity, age diversity is a double-edged sword, presenting both opportunities and threats for team creativity and innovation. Further, it seems that, overall, these opportunities and threats may cancel each other out: in a meta-analysis of research on demographic diversity and team performance, Bell et al. (2011) found no relation between age diversity and team performance (although no specific results were reported on the relation between age diversity and creativity or innovation). Thus, the question once again does not seem to be whether age diversity is a good thing or not, but rather *under which circumstances* it contributes to team creativity and innovation or not. In other words, what might be relevant moderators of the relations between age diversity and team creativity/innovation? A particularly important moderator seems to lie in the way age/aging and age diversity themselves are viewed within the team, something we already alluded to above. In the following, this issue is addressed in some more detail.

Age Stereotypes and Diversity Beliefs

Research on age stereotypes suggests that employees have specific expectations of their older colleagues. As discussed above, older

employees are commonly seen as less creative and innovative. Such stereotypes are potentially problematic, because they can become self-fulfilling prophecies and threats to the self-concept that impact on employees' actual performance. This could take place through mechanisms on the individual level and the team level.

Individual Level: Stereotype Threat. At the individual level, older employees may experience so-called *stereotype threats* which could undermine their creative and innovative behavior in the workplace (Walton et al. 2015). Stereotype threat has been defined as the concern of confirming or being reduced to a negative stereotype about one's social group (Steele and Aronson 1995). It is particularly likely to occur on difficult and nonroutine tasks and has been found to cause people to underperform on a variety of tasks and tests, including organization-relevant behaviors such as learning, feedback seeking, interpersonal behavior, and task performance (Walton et al. 2015).

Several subtle or not-so-subtle cues in the work environment could give rise to stereotype threat, for example, when ideas expressed by older employees are responded to differently, when older employees are underrepresented in organizations or in project teams working on innovation projects, or when the organization implicitly equates "innovative" with "young" or "a new generation." Sometimes such cues are not easy to remedy immediately; for example, if an organization has neglected to hire an age-diverse workforce, older employees will for some time be confronted with the cue that age diversity is not valued, even if the organization aims to remedy this by changing its hiring policies (Walton et al. 2015). In such situations, what might be important is for the organization or team to emphasize the value it places on age diversity, in other words, by stressing certain *diversity beliefs*.

Team Level: Diversity Beliefs. At the group or team level, negative age stereotypes are incompatible with the positive diversity beliefs that are necessary to make effective use of diversity (e.g., Homan et al. 2010). Thus, workgroups and teams where people hold the stereotypical belief that older employees have little to offer in the way of

creativity and innovation will be less likely to consider age diversity an asset and hence will be less likely to reap any potential associated benefits. For example, such groups might be less likely to seriously consider ideas put forward by older employees or even to discourage these employees from participating in the creative process. Given that the potential for cognitive stimulation stemming from a diverse knowledge base is one of the reasons for using teams and workgroups in the first place, it should be clear that this is something to avoid. As discussed above, one of the main stumbling blocks in group's effective use of diversity lies in social categorization and the formation of subgroups (Paulus and Nijstad 2003; Homan et al. 2010). Groups that hold positive diversity beliefs, however, appear to view diversity not so much in terms of subgroups, but rather in terms of individual differences – implying that the group is composed of unique individuals who may each have something worthwhile to offer (Homan et al. 2010), which in turn is likely to enhance group creativity.

Future Research

As noted above, as well as by other researchers, more research on age and creativity/innovation is needed. The two sections above illustrate how a more fine-grained approach, focusing on specific creativity/innovation-relevant phenomena or processes, may yield more informative empirical results (or more fine-grained hypotheses) and may help link the budding field of age and creativity/innovation to existing theories from social and organizational psychology. One topic that has already been alluded to above, and that has been neglected for a long time, is the relation between creativity, or the generation of ideas, and innovation, or the implementation of these ideas.

Idea Implementation. Although creativity is, of course, a necessary condition for innovation, research shows that it is by no means sufficient and that reaping the benefits of creative ideas is a unique challenge in itself (West and Farr 1990; Anderson et al. 2014). Little empirical research thus far has addressed the factors that contribute to

successful idea implementation, although individual characteristics, such as networking abilities, and team process characteristics, such as team climate, have been found to play a role. One question that is sometimes raised is whether the more extensive experience and domain knowledge of older employees might not put them in a better position when it comes to successfully “selling” and implementing their ideas. Again, there is very little data on this, but an important exception can be found in *historiometric* creativity research, which has led Simonton (1997) to formulate the *equal odds rule*.

Basically, according to this rule, the relation between the total number of works produced in a given period (e.g., a career) and the number of “hits” (i.e., highly successful products, which would include successful innovation attempts) tends to be linear and stable. One implication of this (empirically derived) rule is that individuals do not seem to necessarily get better at realizing implementation or adoption of their creative ideas; instead, what seems to matter (over time) is total productivity. Although historiometric research suggests that productivity shows an inverted U-shaped pattern across careers or life spans, the meta-analytical results described above suggest that it is far from clear that such a pattern will always hold (although most of the research included in those meta-analyses is cross-sectional and/or limited in age range). All in all, only very little is known about the relation between creativity and innovation, let alone the possible moderating role of age.

Conclusion

In this entry, the relationship between employee age and creative and innovative performance at work was discussed. While meta-analytical work suggests that, overall, younger and older employees do not differ with regard to creativity and innovation, primary empirical studies suggest that the relationships are more complex and influenced by various individual and contextual moderators. It was argued that individual motivation (i.e., intrinsic needs) and team-level

characteristics (e.g., climate for aging at work) may play a particularly important role in shaping the creative and innovative performance of older employees or teams with older employees. This does not mean that there are no other relevant factors or processes, rather the opposite. This review has inevitably been limited and selective. What is clear, however, is that the role of age in creativity and innovation at work has, thus far, received far too little attention. This is also witnessed by the fact that primary studies do not routinely report even zero-order correlations between age and creative or innovative behavior (which makes meta-analytical work unnecessarily difficult and limited). Given the existence of negative age stereotypes, the strong evidence that such stereotypes may have devastating effects on employee well-being and (creative) performance, and the fact that meta-analytical and primary empirical work fails to yield strong support for these stereotypes (if not the opposite), it is high time to remedy this.

support at work

Definition

Workplace mentoring occurs when a member of an organization with advanced experience and knowledge (the mentor), either as part of a formal mentoring program or informally, supports the psychosocial and career development of a less experienced member (the protégé).

Background

As the number of older workers is rising in industrialized countries and a great proportion of experienced workers is approaching retirement, two issues become increasingly important for organizational success: (1) to recognize and utilize older workers' potentials and (2) to retain older workers while keeping them engaged (Calo 2005). One effective organizational practice that can capitalize on older workers' knowledge and keep them motivated is workplace mentoring. Workplace mentoring occurs when a member of an organization with advanced experience and knowledge (the mentor), either as part of a formal mentoring program or informally, supports the psychosocial and career development of a less experienced member (the protégé; Kram 1985). Usually, this means that an older employee serves the role of a mentor for a younger employee (Finkelstein et al. 2003), but the reverse age constellation is also possible in cases where a younger employee is more experienced in a certain work domain than an older employee (Murphy 2012).

In general, mentors provide two types of support, namely, career and psychosocial support (Kram 1985). Career support focuses on the protégé's career advancement and involves behaviors such as enhancing the protégé's visibility, sponsorship, and providing assignments that are challenging for the protégé. Psychosocial support focuses on the personal development of the protégé including a higher sense of competence and self-esteem and involves behaviors such as counseling or role modeling. Another important distinction in mentoring is between informal and formal mentoring relationships. While informal mentoring relationships evolve naturally in organizations, formal relationships are initiated by the organization such that the organization matches mentor and protégé.

Benefits of Mentoring

Mentoring, and informal mentoring in particular, has been associated with numerous benefits for mentors, protégés, and organizations (Tong and

Kram 2013). The somewhat smaller benefits derived from formal relative to informal mentoring have been attributed to the stronger focus on career-related support than psychosocial support in formal mentoring programs and the potential lack of mutual identification as these relationships do not develop naturally (Ragins et al. 2000). Despite the difference in the magnitude of gains depending on type of mentoring, a considerable amount of research has documented benefits of both forms of mentoring.

Regarding *protégé benefits*, cross-sectional research has found positive relationships between receiving mentoring and protégé's job performance, salary, and promotion for both formal and informal mentoring (for a review, see Allen et al. 2004). Moreover, receiving mentoring has been associated with higher levels of job and career satisfaction (for a review, see Tong and Kram 2013). There is also some longitudinal evidence for the gains of mentoring for protégés. Specifically, receiving career-related support has been positively associated with affective well-being and organizational commitment at the end of a 7-month formal mentoring program, controlling for initial levels in both variables (Chun et al. 2012).

Regarding *mentor benefits*, a meta-analysis of cross-sectional studies on formal and informal mentoring indicates that providing mentoring can be beneficial for mentors' perceived career success, their organizational commitment, and job performance (Ghosh and Reio 2013). Moreover, cross-sectional research has found that proximal benefits of mentoring such as a sense of fulfillment for mentors predict more global work-related outcomes such as job satisfaction, organizational commitment, and the willingness to serve as a mentor in the future. Interestingly, proximal instrumental benefits for mentors such as increased recognition appear to be particularly important for mentor's job satisfaction, whereas relational benefits such as personal gratification might be more influential for intentions to become a mentor again (Eby et al. 2006). Noteworthy, proximal benefits for mentors appear to be unrelated to some more objective post-mentoring career outcomes such as salary and promotion

(for a review, see Tong and Kram 2013). A likely reason is that these career outcomes are influenced by many factors beyond mentoring, such as general job performance or position.

Regarding *organizational benefits*, cross-sectional research has shown that mentoring is associated with decreased turnover rates, increased performance, and organizational learning, though quantitative studies are scarce (Tong and Kram 2013). So far, there are no empirical studies that investigate the long-term benefits for organizations. However, since studies have generally shown that job satisfaction, affective well-being, and organizational commitment positively predict job performance, it is likely that organizations profit as well from the long-term benefits of mentoring.

Negative Consequences of Mentoring

Despite the well-documented benefits of mentoring, mentoring relationships do not guarantee success and may even have harmful consequences (Tong and Kram 2013). Although the prevalence of negative mentoring experiences has been assumed to be rather low, they nevertheless occur according to researchers and practitioners and often have adverse effects (Eby and McManus 2004). A growing body of literature has therefore made an effort to identify common reasons why mentoring relationships may become dysfunctional. More specifically, studies have revealed that negative mentoring experiences are frequently due to the mentor's deficits in the required mentoring skills, the protégé's egocentrism or exploitative behavior, and, more generally, dysfunctional relationship dynamics between mentor and protégé (Tong and Kram 2013).

The consequences of these negative mentoring experiences compared to positive experiences for protégés include decreased job satisfaction and higher turnover intentions. While less is known about the negative effects for mentors, the available research has found that mentors who had dysfunctional relationships with their protégés had decreased intentions to become a mentor in the future (for a review, see Tong and Kram 2013).

Given the potential of mentoring to have negative effects on protégés and mentors, it is crucial to determine factors that predict who is suited to become an effective mentor. Moreover, it is important to identify characteristics of the protégé and the dyad that contribute to mentoring success, such as the protégé's personality or the fit between mentor and protégé regarding their personality. One important individual difference variable that is likely to affect mentoring effectiveness is *age*, as a characteristic of the mentor, the protégé, or in terms of the age composition of the dyad.

The Role of Age in Mentoring

To date, research systematically examining the role of age in mentoring is limited and studies have yielded mixed results. In the following, dyads composed of an older mentor and a younger protégé and dyads composed of a younger mentor and an older protégé will be compared. Subsequently, zooming in on age of each party of the dyad, literature on the role of mentors' and protégés' absolute age for mentoring will be discussed.

Age Composition of the Mentoring Dyad

Traditionally, mentoring involves an older employee supporting a younger employee. However, this relationship can also reverse such that a younger employee with more experience in a certain work domain provides mentoring to an older employee with less experience in that domain (*reverse mentoring*; Finkelstein et al. 2003). Both traditional mentoring and reverse mentoring involve career support, encompassing, for example, knowledge sharing or networking, and psychosocial support, encompassing friendship or stimulating personal development. Noteworthy, it has been assumed that reverse mentoring is best initiated through formal mentoring programs, since informal mentoring relationships rarely develop between younger mentors and older protégés (Murphy 2012).

Traditional and reverse mentoring relationships are thought to be associated with unique benefits. Specifically, traditional mentoring has

the potential to fulfill *generativity motives* that become more salient with age (Parise and Forret 2008). The concept of generativity was first introduced by the developmental psychologist Erik Erikson (1963) and refers to establishing and guiding the next generation. Generativity motivation has predominantly been associated with middle age, falling into the second half of the working lifespan (i.e., 40–65 years; Erikson 1963). Organizational psychology research has demonstrated that age is associated with an increase in generative work motives across the working lifespan (for a meta-analysis, see Kooij et al. 2011). Scholars have suggested that mentoring represents an excellent way to express generativity at work (Parise and Forret 2008). Specifically, by mentoring co-workers, the mentor can meaningfully contribute to the protégé's development and thereby provide guidance to someone from the next generation.

Giving older workers mentoring opportunities, which allow fulfilling their generativity motives through mentoring, could also be an effective retention strategy as it addresses age-related changes in motivation. Specifically, work motivation tends to become more intrinsic with age and older workers' work motivation appears to be more strongly affected by a sense of meaningfulness and fulfillment gained from work than that of young workers (Kooij et al. 2011). Being a mentor may add meaning to older workers' work by addressing age-related increases in generativity motivation and thereby fostering older workers' motivation to continue working.

Reverse mentoring also likely has unique benefits although empirical research on reverse mentoring is absent to date. While reverse mentoring has initially been introduced to transfer technological knowledge from the younger generation to older workers (Murphy 2012), the benefits are thought to go beyond novel skill acquisition. Specifically, reverse mentoring may eliminate negative stereotypes that generations hold about each other (Murphy 2012) and enhance sensitivity for workplace diversity (Chaudhuri and Ghosh 2012). Furthermore, theoretical work suggests that younger mentors perceive the special opportunity to mentor senior

colleagues as a sign of recognition and organizational support, increasing their organizational commitment (Chaudhuri and Ghosh 2012). Older protégés, in turn, perceive the opportunity for learning and development, which they often lack, as a sign of organizational support, increasing their work engagement.

At the same time, reverse mentoring may also have unique threats. Specifically, reverse mentoring is in stark contrast to age norms in mentoring, in which an older worker offers mentoring to a younger co-worker (Chaudhuri and Ghosh 2012). Violating these norms might be perceived as threatening, impeding the mentoring process. However, it is yet unclear where the age cutoff lies, thus, when the age distance between a younger mentor and older protégé violates norms and has adverse consequence for mentoring effectiveness.

Absolute Age of the Mentor

Regardless of whether traditional or reversed mentoring relationships are concerned, mentor's age likely affects mentoring outcomes. Among the mentor characteristics that have been associated with effective mentoring relationships are emotional abilities, which are subject to age-related increases. *Emotional abilities* refer to the capacity to handle one's own as well as others' emotions effectively. Specifically, research has identified three core emotional abilities: emotion regulation, emotion understanding, and emotion perception (Joseph and Newman 2010). *Emotion perception* pertains to the ability to correctly identify one's own and other people's emotions, while *emotion understanding* refers to insight into the development of emotions, the ability to differentiate between them and to identify appropriate emotions for a specific context. *Emotion regulation* encompasses cognitive or behavioral strategies used to influence the way emotions are experienced and expressed.

Together, these abilities are particularly important for mentors, as they help establish a trustful relationship with protégés (Chun et al. 2010) and represent important job skills that mentors can pass on to their protégés through role modeling (Cherniss 2007). Emotion perception might be

crucial for the mentor to identify the protégé's difficulties and react appropriately. Emotion understanding should be a critical skill for mentors to help the protégé gain insight and select effective coping strategies. Emotion regulation should help the mentor to establish a trustful relationship through authenticity, consistency, and reliability in emotional displays. Moreover, mentors may teach their protégés how to regulate their emotions effectively in critical work situations.

Interestingly, mounting evidence suggests age-related improvements in two of the three emotional abilities and maintenance in the other (for a review, see Walter and Scheibe 2013). These improvements are attributed to accumulating knowledge in dealing with affective events throughout life. Regarding emotion perception, evidence has been mixed but recently has pointed to minimal age differences. Older adults have further been found to have an enhanced emotional understanding relative to younger adults (Kafetsios 2004). They use adaptive emotion regulation strategies (e.g., reappraisal, deep acting) more often and maladaptive strategies (e.g., suppression, surface acting) less often and are also better at implementing many emotion regulation strategies (Scheibe and Carstensen 2010). These overall improvements in core emotional abilities may make older adults well suited for mentoring roles.

Another mentor characteristic, which is thought to be associated with effective mentoring relationships in traditional mentoring dyads (older mentor, younger protégé) and increases with age, is mentors' generativity motivation, as discussed above. Generativity motivation should facilitate mentoring effectiveness by leading mentors to invest their time and energy in mentoring relationships and at the same time increase protégé trust in the mentor. Though studies on generativity and mentoring are scarce, the available research has found that generativity is beneficial for mentoring such that generativity is positively associated with mentors' number of protégés and mentors' perceived effectiveness of mentoring training in a formal mentoring program (Parise and Forret 2008).

Absolute Age of the Protégé

Cutting across both traditional and reverse mentoring relationships, some empirical research has examined relations of protégé's age to characteristics of the mentoring relationship and associated outcomes. For example, protégé age has been found to be negatively related to the duration of the mentoring relationship and positively to mentors' hierarchical level in the organization (Finkelstein et al. 2003). This suggests that older protégés in both formal and informal mentoring relationships have more short-lived mentoring relationships and are closer to the mentor's hierarchical level. Moreover, age of protégé is positively related with informal mentoring relationships, such that older protégés were more often part of informal mentoring relationships, whereas younger protégés were more often part of formal mentoring relationships (Finkelstein et al. 2003). Furthermore, while some studies have found that protégé age is unrelated to the type of mentoring support received, there is some evidence that older protégés, compared to younger protégés, receive less career-related mentoring, but experience higher levels of mutual learning and relationship quality in formal and informal mentoring relationships (Finkelstein et al. 2003).

One important characteristic of protégés are their emotional abilities, which tend to increase with age, as discussed above. Specifically, protégés' emotional abilities are predictive of trust in the mentor, which is an essential ingredient of a good mentoring relationship (Chun et al. 2010). Moreover, protégés' high emotional abilities can compensate for possible low emotional abilities of the mentor. As older adults overall tend to have higher emotional abilities compared to younger, this might be particularly relevant in the context of reverse mentoring. That is, older protégés' emotional abilities may buffer against low emotional abilities of the younger mentor.

Future Directions

Evidence on the influence of age on mentoring processes and outcomes is only recently beginning to emerge. Future research should examine

additional age-related variables that may play a role in the mentoring process. In addition, the available research has some methodological limitations. In the following, a number of promising avenues for future research will be suggested.

Considering Age-Related Variables

To date, previous research has only investigated linkages between age and mentoring, largely ignoring potential mediators. As discussed, emotional abilities and generativity might be two potentially important mediators to consider. A large body of research has demonstrated age-related improvements in emotional abilities (Walter and Scheibe 2013), and the relevance of these abilities of mentors for mentoring has been acknowledged (Chun et al. 2010). However, it remains to be tested whether emotional abilities mediate relationships between mentor's age and mentoring outcomes. Moreover, future studies should explore the dyadic composition of age, emotional abilities, and mentoring outcomes such as relationship quality, in more depth. Taken together, studies should combine research on age and emotional abilities with mentoring to gain a better understanding of the role of emotional abilities in the age-mentoring effectiveness link for both mentor and protégé. This might also shed light on the general mechanisms underlying effective mentoring processes.

Similarly, although scholars have highlighted that mentoring is an expression of generativity (Calo 2005), the generativity motivation of mentors as predictor of mentoring benefits has not yet received attention in the literature. Generativity may not only make older workers well suited for providing effective mentoring by leading them to invest their time and energy in mentoring relationships, it may also enhance their work motivation. More specifically, by fulfilling older workers' generativity motives through mentoring, they might become more motivated to continue working. In light of the demographic shift, the retention of older workers has become crucial for organizations to retain their accumulated knowledge and to prevent shortage of qualified workers.

Furthermore, a relatively small amount of research has investigated mentoring outcomes

for mentors, although it has been widely acknowledged that mentoring is beneficial for both mentors and protégés (Tong and Kram 2013). Future research should consider outcomes for mentors that gain importance with age, including fulfilling one's generativity motive, motivation to continue working, and affective well-being, which may subsequently positively affect desired organizational outcomes, including low absenteeism rates, commitment, and productivity. In addition, establishing mentoring programs with older workers serving the role of a mentor for a younger worker might contribute to an age-friendly organizational climate.

Investigate Effects of Reverse Mentoring

Although reverse mentoring has been assumed to confer extensive benefits for all parties involved, there is no empirical evidence supporting this statement (Murphy 2012). Therefore, future research needs to carefully test the proposed benefits of reverse mentoring and the mentor, protégé, and dyad characteristics that support or hinder effective reverse mentoring. Another important task for future research would be to investigate the potential threats to mentoring success that may accompany reverse mentoring as it contradicts age norms in mentoring.

Relatedly, researchers could examine potential moderators that help to specify under which circumstances reverse mentoring is likely to be successful. For example, it would be important to test whether reverse mentoring is more successful when it is initiated formally as compared to informally (Murphy 2012). Moreover, it might well be that the effectiveness of reverse mentoring depends on organizational age norms such that reverse mentoring in organizations with strong age norms might be less effective than reverse mentoring in organizations with weak age norms (Chaudhuri and Ghosh 2012).

Extending Methodology

With regard to methodology, research on age and mentoring has so far mainly relied on cross-sectional self-report data (Tong and Kram 2013). Therefore, longitudinal, multi-source studies are needed to uncover the mechanisms underlying the

relationship between age and mentoring and to evaluate long-term benefits of mentoring for younger and older workers. In addition, intervention studies might test whether high generativity in combination with emotional abilities training leads to better mentoring outcomes, or examine older workers' motivation to continue working when they receive the opportunity to mentor versus no opportunity to mentor, which might shed more light on the potential of mentoring as a valuable retention strategy. Finally, experience-sampling studies may focus on mentors' and protégés' changes in affect, cognitions, and behaviors during periods with versus without mentoring.

Synonyms

Anxiety; Generalized anxiety; Older adults; Prospection

Definition

Worry features chains of negatively valenced thoughts about potential future events and can be conceptualized as a future-oriented cognitive process aimed at minimizing the likelihood or impact of disadvantageous future outcomes in the face of uncertainty (Borkovec et al. 1983; Dugas et al. 1998; Miloyan et al. 2015a; Szabó and Lovibond 2002).

Introduction

In its normal state, worry facilitates the detection and management of potential future threats and can also serve as a cognitive coping mechanism for the suppression of negative anxious affect (Borkovec et al. 1998; Eysenck 1992). In its extreme state, it represents the central feature of generalized anxiety disorder (GAD) and is a source of considerable distress and disability (Andrews et al. 2010; Ruscio et al. 2005). There are age-related differences in the manifestation of worry that may have an important bearing on efforts aimed at conceptualizing late-life anxiety and promoting the mental health of older adults.

General Worry Processes

Worry features sequences of thoughts concerning potential negative future events (Borkovec et al. 1998). These thoughts are frequently associated with physiological arousal, thereby capturing present attention and alerting the individual to threats or potential problems with uncertain outcomes (Dugas et al. 1997; Hallion et al. 2014; Ruscio and Borkovec 2004; Tallis and Eysenck 1994; York et al. 1987). Those who engage in excessive worry orient to potential problems more readily than those with more moderate worry (Davey 1994; Dugas et al. 1995; Ladouceur et al. 1998). As a result, extreme worry is usually associated with a greater propensity to produce false alarms in the process of threat detection (Bateson et al. 2011; Nesse 2001, 2005).

Worry persists, most frequently in a verbal representational format, as the individual attempts to solve or resolve a perceived threat (Borkovec and Roemer 1995; Freeston et al. 1994; Hirsch and Mathews 2012; Leigh and Hirsch 2011; Williams et al. 2014). However, problem-solving ability does not differ significantly as a function of worry frequency (Davey 1994; Dugas et al. 1995; Ladouceur et al. 1998). Worry may also serve as a cognitive avoidance strategy for dealing with aversive anxiety about perceived threats, in part because verbal representations of imagined events may suppress emotional experience (D'Argembeau and Van Der Linden 2006) and because future-oriented thoughts can facilitate planning and preparation, leading to lower levels of arousal and stress based on subjective and physiological markers (Borkovec and Roemer 1995; Borkovec et al. 2004; Engert et al. 2014; Freeston et al. 1994; Laguna et al. 2004; Miloyan et al. 2015a; Ruby et al. 2013). Worry can also assist people to come to terms with inescapable problems. For example, individuals who worry prior to encountering a fearful stimulus have lower arousal when confronted with that stimulus relative to non-worriers (Borkovec and Hu 1990).

Worries tend to be generalized and abstract, likely due to the fact that the future is inherently

uncertain and harbors the potential for myriad threats (Stöber and Borkovec 2002; Miloyan et al. 2015a). In fact, uncertainty itself is a strong causal and maintaining factor of worry (Dugas et al. 1998). Worry-prone individuals often demonstrate a pessimism bias, characterized by heightened expectations of negative future outcomes (Mathews et al. 1997; Miloyan et al. 2014c). Repetitive thinking about future threats, a characteristic feature of worry (Watkins 2008), may lead to increased likelihood estimates for negative future outcomes (Szpunar and Schacter 2013). Importantly, even in its pathological form, worry is not associated with a reduction of positive future expectancies (MacLeod and Byrne 1996; Miloyan et al. 2014c; Miranda et al. 2008; Miranda and Mennin 2007). Alongside appraising a possible future threat, the worrying individual can also come to appraise the state of his/her own cognition about that threat, in a so-called “metacognitive” worry process (Wells 1995). This may manifest as beliefs about one’s own cognition, such as “my worries are uncontrollable” or “worrying helps me avoid negative outcomes,” and may result in individuals “worrying about their worrying” in a vicious cycle that may represent a key feature of pathological worrying (i.e., GAD) (e.g., Wells 1995).

Age-Related Differences

We now turn our attention to age-related differences in the manifestation of worry, in terms of its *phenomenology* and constituent *processes*.

Phenomenology. There is a progressive age-related downward trend in worry frequency such that older adults report fewer worries than younger adults. Such a trend has been observed in cross-sectional studies, with nationally representative samples from the USA, the UK, and Australia, as well as in community studies conducted in Canada and the USA (Basevitz et al. 2008; Gonçalves and Byrne 2013; Gould and Edelstein 2010; Hunt et al. 2003; Lindsay et al. 2006; Miloyan and Pachana 2015; Powers et al. 1992). Similar downward trends have been observed for

anxiety symptoms more generally (Deer and Calamari 1998; Böttche et al. 2012; Frueh et al. 2004; Gretarsdottir et al. 2004; Miloyan et al. 2014a). However, older adults with higher levels of anxiety and depression worry comparatively more relative to age-matched controls, suggesting that there are important differences within the population of older adults (Conaghan and Davidson 2002; Gonçalves and Byrne 2013; Wetherell et al. 2003; Diefenbach et al. 2001).

Furthermore, there are age-related differences in worry content. For instance, older adults tend to worry about their own health as well as the health and welfare of loved ones, in contrast to younger adults who tend to worry about work, finances, and interpersonal relations (Gonçalves and Byrne 2013; Powers et al. 1992). Older adults also tend to worry *more* about particular topics than younger adults, including “family concerns” and world issues such as environmental degradation and economic downturn (Hunt et al. 2003). These “world issue” worries typically center outwardly on problems that could be faced by future generations, which may be of particular relevance during this developmental life stage (Hunt et al. 2003). In fact, late-life developmental transitions have been associated with other context-specific worries, such as about becoming a burden after transitioning out of a primary caregiver role and into retirement (Skarborn and Nicki, 2000; Wetherell 2006). Caregiving, too, can be a significant source of worry, anxiety, and distress in later life (Anthony-Bergstone et al. 1988; Lim et al. 2014; Razani et al. 2014). Additionally, older adults who endorse financial worries tend to be concerned about receiving care and about their own capacity to make decisions (Litwin and Meir 2013). However, despite the observation that older adults with GAD tend to endorse a greater variety of worries than matched non-GAD controls, there are fewer differences in worry phenomenology between older adults with and without GAD than there are between younger adults with and without GAD (Diefenbach et al. 2001; Miloyan et al. 2014b). In sum, the expression of worry may vary significantly as a function of the developmental stage of the

individual, with older adults endorsing worries commensurate with their changing life circumstances (Wolitzky-Taylor et al. 2010).

Processes. Memory systems play a critical role in anxiety-related future-oriented cognitive processes such as worry (for review, see Miloyan et al. 2014c). With a capacity for semantic memory, one can draw on conceptual information with which to construct mental representations of future scenarios; and with a capacity for episodic memory, one can integrate autobiographical information into conceptual schemas in a future-directed manner (Irish and Piguet 2013; Suddendorf and Corballis 2007; Szpunar et al. 2014). As individuals age, they report fewer semantic and episodic details when recalling past and generating future scenarios, and this reduction in details correlates with age-related neurological differences (for review, see Schacter et al. 2013). In other words, older adults tend to engage in highly generalized future thinking, such that these thoughts contain relatively few concrete details. Thus, general age-related reductions in worry frequency may be partly attributable to such neurocognitive changes, which lead to the construction of fewer and more generalized future-oriented thoughts, regardless of their emotional content.

However, observations of age-related reductions in worry frequency must also be assimilated with concomitant improvements in emotional well-being and the tendency of older adults to focus less on negative than positive stimuli (Bauer et al. 2013; Carstensen et al. 2011; Mather and Carstensen 2005). In fact, age-related reductions in worry frequency are also partly attributable to changes in emotional processes, considering that older adults experience more positive and fewer negative emotional states (Carstensen et al. 2011; Sutin et al. 2013). Additionally, negative emotional states are more transient for older versus younger adults, due in part to an improved capacity for emotion regulation (Carstensen 2006; Hay and Diehl 2011; Urry and Gross 2010). Thus, older adults come to experience fewer negative states and consequently worry less about the occurrence of negative future events, because one's current emotional state can have a profound impact on the content of future-oriented thoughts (Miloyan et al. 2014c).

Finally, age-related differences in meta-cognitive beliefs and attitudes about worry may also be invoked to explain age-related reductions in worry frequency. Compared to younger adults, older adults believe less in the functional value of worry and report being more tolerant of uncertainty (Basevitz et al. 2008). As a result, older adults may be less likely to worry in order to detect potential future threats and would also be less prone to worrying about the potential occurrence of negative future events that lie outside of their control. Despite these general age-related trends, there are important differences within the population of older adults, such that those who report comparatively higher levels of worry tend to harbor negative attitudes and beliefs about the future, as well as an external locus of control (i.e., that the future holds negative outcomes in store and that these potentialities lie largely outside of the individual's control) (Montorio et al. 2006; Powers et al. 1992). In sum, the manifestation of worry in later life is dependent upon cognitive, affective, and motivational processes. The way in which these processes change with age has practical implications for clinical approaches to worry in older adults – to which we now turn.

Clinical Implications

Despite worry potentially providing short-term avoidance of unpleasant anxiety (Borkovec 1994), its role as a coping mechanism may be maladaptive in the long term (Borkovec et al. 2004). In its pathological state, worry is the central feature of generalized anxiety disorder (GAD) and is frequently associated with severe distress and functional disability (Lee et al. 2010). Uncontrollable worry, a key feature of GAD, is particularly associated with distress, disability, and poor clinical outcomes (Hallion and Ruscio 2013). Older adults with GAD report higher levels of disability, lower levels of well-being, poorer health-related quality of life, and increased use of healthcare relative to asymptomatic older adults and younger adults with GAD (Brenes et al. 2008; de Beurs et al. 1999; Porensky et al. 2009; Wetherell et al. 2004). Older adults

with GAD also have poorer cognitive functioning, which can improve with treatment, and even healthy older adults with mild worry symptoms show greater declines in learning and memory at two-year follow-up relative to asymptomatic controls (Butters et al. 2011; Pietrzak et al. 2012).

Worry may be associated with poorer cardiovascular health, as well as other somatic complaints and conditions (Brosschot et al. 2006, 2007; Brosschot and van der Doef 2006; Pieper et al. 2007). In older adults, GAD has a higher prevalence among individuals with cardiovascular health problems, and higher levels of worry may be associated with a higher risk for incident coronary heart disease (Grenier et al. 2011a; Kubzansky et al. 1997). Late-life GAD may also be associated with a higher risk of incident gastrointestinal disease (El-Gabalawy et al. 2014).

Worry, in its normal or pathological form, may also be preceded by some medical conditions; for instance, arthritis is associated with increased risk for incident GAD among older adults (El-Gabalawy et al. 2014). There are less pronounced differences in worry frequency and health characteristics between older – as compared to younger – adults reporting high and moderate worry, indicating that the relationship between worry, health, and functional outcomes also varies with age (de Beurs et al. 1999; Grenier et al. 2011b; Miloyan et al. 2014b, 2015b). Finally, GAD is highly prevalent among older adults in the context of primary care (Ansseau et al. 2008; Kroenke et al. 2007).

The impact of age on the presentation of worry occurs in a number of different ways, with implications for diagnosis and treatment of GAD. First, due in large part to age-related cognitive and emotional changes, older adults report fewer and less concrete worries (Basevitz et al. 2008; Hunt et al. 2003; Gonçalves and Byrne 2013; Gould and Edelstein 2010; Miloyan and Pachana 2015). Second, older adults with cognitive impairment may have particular difficulty reporting or identifying their worries in concrete terms (Beaudreau and O'Hara 2008; Wolitzky-Taylor et al. 2010). For example, in the context of neurocognitive impairment, it is possible for stressors to evoke bouts of negative affect without leaving strong

mnemonic traces as to their origins (Feinstein et al. 2010; Guzman-Vélez et al. 2014). This could be particularly problematic given that informant report is ineffective for identifying unobservable symptoms such as worry among cognitively impaired older adults (McDade-Montez et al. 2008). Finally, among older adults, physical symptoms exacerbate the emotional and functional impact of worry (Miloyan and Pachana 2015). The need for age-appropriate assessment strategies is being increasingly recognized on the basis of such findings (Wolitzky-Taylor et al. 2010). Existing CBT and psychosocial interventions for late-life GAD are at best moderately efficacious, suggesting the need for improved interventions for excessive worry in older adults (Gonçalves and Byrne 2012; Thorp et al. 2009). However, it is also important to note that some degree of worry could be advantageous. For instance, lower levels of anxiety may be associated with excess mortality; and specifically, those who endorse greater worries about particular health problems may be more likely to seek medical care and take preventative or corrective action (Chapman and Coups 2006; Edward Ransford 1986; Hay et al. 2006; Lee et al. 2006; Mykletun et al. 2009; but see Consedine et al. 2004; Dijkstra and Brosschot 2003).

Conclusion

Worry consists of sequences of thoughts about negative future events and is aimed at minimizing the likelihood and impact of negative outcomes. Worry fundamentally relies on an individual's present emotional state, characterized by negatively valenced affect, and a capacity for future-oriented cognition. Thus, relative to asymptomatic individuals, worriers fixate more on threat-related stimuli, mentally generate a greater number of negative future events, and harbor increased expectations for the occurrence of future threat-related events. Older adults worry less than younger adults, due to reductions in the frequency of imagined future events, the experience of more positively valenced and fewer negatively valenced emotional states, and differences

in attitudes and beliefs about worry. There are also important differences in the content of worry across the lifespan, with developmental transitions in later life presenting new challenges about which older adults may be particularly prone to worry.

In its pathological state, worry is associated with increased distress and disability. Among older adults, relatively fewer worry symptoms are associated with distress and disability, partly due to the increased prevalence of physical symptoms. Pathological worry has also been linked to a number of negative health effects, particularly with regard to self-rated health, cardiovascular health, and quality of life. However, despite the key role worry plays in psychopathology, it also acts as a functional mechanism that could serve to reduce the likelihood or impact of future harm and may thereby be strategically (though not necessarily volitionally) employed. Nonetheless, chronic and uncontrollable worry frequently leads to poor psychosocial outcomes over extended time frames, making it an important target for intervention in later life.

Introduction

Young-onset dementia (YOD) refers to the onset of dementia before the age of 65. However, agreeing upon the nomenclature and definition of dementia with an onset before the age of 65 years is a matter of debate in the literature (Kelley et al. 2008;

Koopmans and Rosness 2014). In a recent editorial of *International Psychogeriatrics*, Koopmans and Rosness elaborated on this discussion (Koopmans and Rosness 2014). Two main points are indispensable concerning younger persons with dementia. First, it is difficult to distinguish between forms of dementia solely by age of onset since older adults with dementia differ in more aspects from younger people than simply in age. The second point is how to answer the question: when in fact should a person with dementia be considered young? A 64-year-old person with dementia is not viewed as young compared to a 44-year-old with dementia, even though they both have been diagnosed with the same label of YOD. Two terms are commonly used in literature: *early-onset dementia (EOD)* and *young-onset dementia (YOD)*. However, some still use presenile dementia (Vieira et al. 2013). In Australia, they prefer using *younger-onset dementia*, to express that these individuals are younger than those in general with dementia. Maybe people with YOD should be divided in a group of those with the first symptoms before the age of 45 and those with the first symptoms before 65 and after 45 years of age. Those with symptom onset before the age of 45 probably have more distinct etiologies than people with a later onset of dementia. In a study of 235 cases of dementia before age 45 years, the causes varied, with neurodegenerative etiologies accounting for 31.1% of the cohort. Alzheimer disease was uncommon, and autoimmune or inflammatory causes accounted for 21.3% (Kelley et al. 2008).

Figures on the prevalence of YOD are scarce. In 2003 Harvey and colleagues published an often-cited study on the prevalence of dementia in people under the age of 65 of a large catchment area in the UK covering 567,500 people (Harvey et al. 2003). The prevalence in those aged 30–64 was 54.0 per 100,000; for those aged 45–64 years, it was 98.1–118.00 per 100,000. From the age of 35 onwards, the prevalence of dementia approximately doubled with each 5-year increase of age. A Japanese study investigated the prevalence of YOD by sending a questionnaire to a variety of medical institutions (Ikejima et al. 2009). In a second step, they asked some additional information about the type of dementia. They found an estimated prevalence of 42.3 cases per 100,000. The most frequently diagnosed type of dementia was vascular dementia (42.5%) followed by Alzheimer dementia (25.6%), dementia caused by head trauma (7.1%), dementia with Lewy bodies/Parkinson dementia (6.2%), frontotemporal dementia (FTD, 2.6%), and other causes (16%). However, a recent study from Australia found that the primary clinical subtypes were alcohol-related dementia (18.4%), Alzheimer disease (17.7%), vascular dementia (12.8%), and frontotemporal dementia (11.3%) (Withall et al. 2014). The overall prevalence was 68.2 per 100,000 population at risk for the 30–64-year age group (95% confidence interval (CI), 54.9–83.4), 11.6 per 100,000 for the 30–44-year age group (95% CI, 5.3–21.7), and 132.9 per 100,000 for the 45–64 age group (95% CI, 105.8–164.2).

Diagnosis

A timely diagnosis of dementia is a prerequisite for adapting to the changes that occur, access to support and care, planning for the future, and coping with the prognosis (Salloway and Correia 2009). Especially in YOD a timely diagnosis is a challenge because of its lower prevalence and larger variety of etiologies (Mendez 2006). YOD often presents differently from late-onset dementia (LOD), with more marked neuropsychiatric symptoms (NPSs) than cognitive symptoms

(Kelley et al. 2009). The Dutch Needs in Young-onset Dementia (NeedYD) study investigated the time between the first symptoms of dementia and diagnosis using a large sample of both YOD and LOD patients (van Vliet et al. 2013). The results showed that the duration of the pre-diagnostic period in the YOD group took an average time of 4.4 years, which is 1.6 years longer than in the LOD group. Especially in FTD the time to diagnosis was long with 6.4 years. This can be explained by the typical clinical characteristics of FTD including neuropsychiatric symptoms (NPS), personality changes, and lack of insight that can delay help seeking (van Vliet et al. 2011).

A recent Australian study, the INSPIRED study, found similar results (Draper et al. 2016). They included 88 people with YOD (PwYOD) due to Alzheimer dementia (AD), FTD, and other causes. They divided the period before the first symptoms and a final diagnosis of dementia in three phases: time between symptom onset and the first consultation (2.3 years), dementia diagnosis (3.2 years), and final diagnosis to the type of dementia (4.7 years) (Draper and Rigoni 2016). Patients with younger age at onset, minimal cognitive impairment, depression, and dementia other than AD or FTD had longer time to dementia diagnosis. The overall time to diagnosis of 4.7 years was comparable with the findings of the NeedYD study. However, in the NeedYD study, those with FTD had the largest delay in establishing a diagnosis, while in the INSPIRED study, people with other causes had the longest period. These differences are difficult to explain and may be caused by different methods used and the fact that the INSPIRED study took place in a specific Australian area (New South Wales), while the NeedYD study was a national study with many memory clinics involved.

In a qualitative part of the NeedYD study, insight was gained in the experiences of the caregiver in this pre-diagnostic period (van Vliet et al. 2011). Caregivers reacted differently to the first changes that they noticed ranging from feelings of uneasiness to a clear suspicion that something was wrong. Apart from cognitive changes, caregivers frequently reported behavioral changes, mostly apathy and lack of reciprocity.

These changes were difficult to understand and to deal with without a clear understanding of the cause. It disrupted the daily routines in family life and caused conflicts and tension in relationships. Some caregivers were even on the verge of leaving their spouse. In retrospect, once the diagnosis of dementia was established, they felt guilty about their negative feelings, and they were better able to understand the changes in cognition, behavior, and/or daily functioning.

Besides relational problems caregivers reported also problems at work and financial consequences. They were often not aware of work-related conflicts or mistakes until the person with dementia got fired before the diagnosis was established. An important factor that delayed help seeking was denial of the person with dementia and refusal to seek medical advice. Mostly caregivers rather than the person with dementia were the one to seek help. This was facilitated when friends or family members confirmed their suspicion. If a doctor was consulted, they were not always referred, or they received an erroneous diagnosis, such as depression or burnout, prior to the dementia diagnosis.

These problems seem specifically related to diagnosing dementia at a young age. The difficulties that were experienced in the period pre-diagnosis underline the importance for younger people to receive a timely diagnosis. Understanding the cause of the changes in the person with dementia offers caregivers and patients the opportunity to cope with their situation; it may prevent loss of their jobs, divorce, or disrupted relationships with children.

It is highly important to raise clinicians' alertness to the possibility of dementia at a young age, to increase responsiveness to caregiver reports, and to do regular follow-ups of people presenting with cognitive and/or behavioral changes. But even then establishing a dementia diagnosis at a young age will remain a challenge for clinicians until unique differentiating markers are found.

Course

Next to the diagnostic difficulties, the person with YOD and other family members experience

problems that are specifically related to their phase of life. Therefore, it is important that they receive tailored support and counseling. For instance, at the time first symptoms occur, people are still working, raising children, and managing the household and often engaged in an active social life. For YOD caregivers this often results in a double burden because they have to combine the care for the person with dementia with these other roles and responsibilities (Bakker et al. 2013a; van Vliet et al. 2010). In addition, because of the dementia occurs at a relatively young age, both the person with YOD and their caregivers have to adjust their future plans. YOD families also often face financial difficulties, due to the loss of work and the fact that sometimes they are not eligible for receiving benefits (Sperlinger and Furst 1994).

The clinical characteristics in YOD also differ from LOD. Younger people with AD have a different cognitive profile with a higher prevalence of atypical symptoms (Smits et al. 2012). Whether they decline more rapidly than people with late-onset AD remains inconclusive. Some studies show that it may be more rapid, while others say they progress at the same rate (Stanley and Walker 2014; Grønning et al. 2012). It is important to note that the characteristics of young-onset AD are not generally applicable to all young-onset dementias. Not much is known about the rate of cognitive decline in YOD in other forms such as vascular dementia or FTD, and future research is needed. However, we do know that younger persons are less likely to suffer from coexisting diseases and are more physically fit (Gerritsen et al. 2016).

People with YOD experience cognitive and functional impairments and changes in personality, hindering them in their ability to work and engage in (social) relationships, hobbies, and other aspects of daily life, resulting in a loss of autonomy and identity. This adversely affects their well-being (Harris and Keady 2009). Specifically in younger people with dementia, behavioral changes are more pronounced, due to the high prevalence of FTD (Mendez 2006). The caregiver and other family members have to learn to cope with these changes, which can be difficult to deal with on top of the other challenges

they are facing. Unfortunately, they often have to deal with these difficulties with little support (Bakker et al. 2012). Furthermore, YOD caregivers often postpone institutionalization until the person with YOD shows advanced dementia and high levels of care dependency (Bakker et al. 2013b). Within this context the high levels of depressive symptoms and burden in YOD caregivers might be explained (van Vliet et al. 2010). YOD also affects relationships within the family structure in general (Millenaar et al. 2013; Svanberg et al. 2011; Werner et al. 2009). The reciprocity between spouses diminishes, and the caregivers gradually lose the relationship that existed prior to the dementia diagnosis and become a caregiver instead (Ducharme et al. 2013). Children often take on caregiving responsibilities as well, as they feel responsible for the well-being of their parent (Millenaar et al. 2013; Allen et al. 2009).

Mainstream dementia services are often specifically designed for the elderly and might have difficulties in addressing the needs of younger individuals (Chemali et al. 2011; Bakker et al. 2010). When people with YOD were asked about their needs, they reported that social company, intimate relationship mobility, and information about the dementia and care options were important (Bakker et al. 2013c). They would like to remain useful and have a sense of purpose in daily life (Roach et al. 2008). Furthermore, persons with YOD are more likely to be physically fitter than elder individuals and therefore require different care approaches (Delany and Rosenvinge 1995).

Interventions

In several countries in the world, there have been initiatives to develop specific services for YOD families. These services include memory clinics with specific expertise on diagnosis and support in YOD (caregiver), support groups, community care, day care centers, and respite services as well as long-term care facilities offering care attuned to the needs of these younger individuals. However, there are large differences between

countries in the extent to which these services are offered and whether or not people have access to these specialized services.

Research on interventions specifically targeted at the needs of people with YOD is still in its infancy. A recent literature search on, for instance, the management of NPS in PwYOD in long-term care setting or living in the community, revealed only 1 and 26 hits, respectively. However, a closer look at the papers revealed no papers with a multicomponent and multidisciplinary approach to NPS.

A recent European study on the needs of people with YOD and their experiences with service provision as well as access to services revealed that PwYOD and their caregivers encounter a wide range of difficulties during the disease process and that there still is a lot to be gained in their care (www.rhapsody-project.eu/home). This has resulted in a specific web-based support program for YOD caregivers, offering interactive modules to learn more about relevant topics in YOD such as basic knowledge on causes, diagnosis and treatment, frequent problems and possible solutions, dealing with problem behavior, changes in family structures, and practical advice. Currently this intervention is being piloted in France, Germany, and the UK.

Furthermore, an empowerment plan was developed for people with YOD and their caregivers in the Netherlands, with a specific aim to put people with YOD in the lead. It aims at improving sense of competence, participation in society, and social contacts. Its content is based on focus groups with people with YOD and their caregivers and regards daytime activities with social contacts, having fun, being physically active, and being useful. Its (cost-)effectiveness is currently being studied in a cluster-randomized controlled trial.

As challenging behavior provides a major challenge for both informal and professional caregivers in YOD, also interventions aimed at the improvement of the management of these behaviors are being developed. For instance, in the Behavior and Evolution in Young-onset Dementia (BEYOND-II) study, a care program is developed for long-term care facilities that have specific

special care units (SCUs) for people with YO-D. The care program is a multicomponent intervention aimed at educating the SCU staff about the context and management of challenging behavior in YOD as well as improving the actual management of these behaviors in daily practice. The latter is achieved by providing SCU teams with a web-based care program in which tools are integrated for the detection of challenging behavior, the detection of unmet care needs in the resident, the analysis of challenging behavior, the construction of a care and treatment plan, and the systematic evaluation of the effect of the plan. Also a tool for the self-evaluation of the appropriateness of psychotropic drug prescription is integrated in the intervention, to facilitate the SCU's physician. Although this intervention is currently being piloted in Dutch nursing homes, this intervention looks promising as the effect of the care program has already been positively evaluated in a previous study in LOD (Zwijssen et al. 2014).

Conclusion

PwYOD have specific healthcare needs that differ from those of people with LOD. However, research on these needs and interventions to effectively address these needs are still in his infancy. Also, there is no international consensus on the nomenclature and operational definition of YOD. More research and agreement on the definition are urgently needed in order to formulate recommendations for service provision specifically tailored to the needs of this specific group of people with dementia.
