(e.g., nausea, drowsiness, sedation), with these effects varying across specific drugs. Sedative-hypnotic medications (e.g., the benzodiazepines) have been used to treat acute cases of agitation, but they increase the risk of impaired cognitive functioning and falls. Mood stabilizers (e.g., carbamazepine, valproate, gabapentin) have been used to manage challenging behaviors, but only carbamazepine has research support. However, carbamazepine has significant adverse effects (e.g., sedation, hyponatremia). The deliberations and recommendations of a panel of experts regarding the use of psychotropic medications to manage neuropsychiatric symptoms of dementia (NPS) were summarized by several researchers (Kales et al. 2014). They concluded that “Given the limitations in the evidence-base, the panel consensus was that psychotropic drugs should be used only after significant efforts have been made to mitigate NPS using behavioral and environmental modifications and medical interventions if needed, with three exceptions” (p. 767) (Kales et al. 2014). These included situations in which there was “significant and imminent risk” to the individual or others.

Behavioral Interventions

Behavioral interventions for the management of challenging behaviors are variously termed behavior modification, behavior therapy, behavioral problem-solving, and functional analysis-based interventions. These can involve direct interventions by staff and alteration of the environment to reduce the frequency or duration of challenging behaviors or to increase more adaptive behaviors. Interventions emphasize the function of the challenging behavior and typically involve the identification of the variables controlling the target behavior. This includes identification of the antecedent stimuli (A) that set the occasion for (trigger) the challenging behavior (B), which is strengthened or maintained by specific consequences (C). The analysis and intervention is usually individualized, as the controlling variables can differ between individuals. In recent years some researchers have conceptualized challenging behaviors as arising from unmet needs, with the intervention aimed at meeting those

needs. As with earlier behavioral conceptualizations, the focus remains on the function of the challenging behaviors, but the interventions are individualized and conducted across large sample sizes.

One of the difficulties of reviewing this literature was that some researchers employed multiple interventions that focused both on the individual and the environmental determinants of the challenging behaviors. A variety of different caregivers (e.g., nurses, nurses' aides) have been employed as well. Finally, the outcome measures have varied considerably across studies. Some studies focused on the frequency or duration of specific behaviors (e.g., wandering, hitting, biting), some on classes of behaviors (e.g., aggression, agitation), and others on scores obtained on rating scales that incorporated several different behaviors and yielded a total score that included all behaviors.

Several reviews have found mixed results for the effectiveness of behavioral interventions. Results of studies in which an intervention was applied to groups of participants have yielded mixed results even with studies employing similar interventions and outcome measures. In addition, it is difficult to offer an overall judgment regarding the effectiveness of these approaches in light of the variety and combinations used in the literature. The interventions employing what is variously termed a behavior analytic (Spira and Edelstein 2006) or functional analytic approach (Moniz-Cook et al. 2012) appear to have some of the clearest supporting evidence. Studies employing single-case designs with individuals have demonstrated support for the use of stimulus control interventions for wandering behavior. These interventions involved manipulating environmental stimuli (e.g., disguising doors, installing visual barriers, covering doorknobs, placing grids on floors) that contributed to wandering behavior. Several single-case studies have been published demonstrating the effectiveness of individual interventions (e.g., reinforcement of appropriate behaviors, differential reinforcement of other behaviors) for a wide range of challenging behaviors. However, all of these studies need to be replicated to establish the generalizability of

the findings. Overall, there is promising support for the effectiveness of many behavioral approaches to reducing the frequency of challenging behaviors associated with dementias (Moniz-Cook et al. 2012).

Systematic Individualized Intervention

This approach appears to have been developed from a behavioral perspective and is based on the notion that one can reduce agitated behaviors associated with dementia by addressing unmet needs of the individual that are thought to be the basis for the behaviors (e.g., pain, feelings of loneliness or isolation, boredom, sensory deprivation). As previously noted, this approach is similar to other behavioral approaches that focus on the function of the challenging behavior and identify the antecedents and consequences of challenging behaviors. However, the studies of this approach have combined characteristics of group (nomothetic) and individualized (idiographic) approaches with large numbers of participants. This large-scale approach has been used exclusively with agitation. In two placebo-controlled studies, agitation was directly observed. Agitated behaviors included physically agitated (e.g., repetitive movements) and verbally agitated (e.g., screaming) behaviors. Interventions were individualized and included, for example, individualized music, family videotapes and pictures, stress balls, electronic massagers, and pain treatment. The results revealed significant reductions in agitation when compared to the control groups. Although these studies were not included in recent reviews, this approach has sufficient evidence, including one randomized, placebo-controlled study, to support its effectiveness. Please note there is some overlap between some of the stimuli used in these studies and those used in simulated presence therapy, described in a subsequent section.

Cognitive/Emotion-Oriented Interventions

Cognitive/emotion-oriented interventions, such as reminiscence therapy, simulated presence therapy, and validation therapy, have been examined as treatment for a range of challenging behaviors, including agitation/aggression and comorbid

disorders, such as depression and anxiety (O'Neil et al. 2011). Although the effectiveness of these cognitive/emotion-oriented interventions in reducing challenging behaviors is mixed, each intervention will be briefly reviewed (O'Neil et al. 2011).

Reminiscence Therapy

Reminiscence therapy for older adults grew out of the work of Robert Butler on "life review." Life review is conceived as a naturally occurring process of recalling past experiences, including unresolved conflicts. Reminiscence therapy involves a progressive awareness of one's past experiences, which affords older adults the opportunity to examine these experiences, resolve conflicts, and place their lives in perspective. Various forms of this approach with dementia patients appear in the literature. Common features include, for example, discussions of past experiences accompanied by familiar objects (e.g., old photographs) that are used to stimulate discussions. There is considerable support in the literature for the reduction of depression (Woods et al. 2009) but little evidence to support the reduction of challenging behaviors associated with dementia.

Simulated Presence Therapy

Similar to reminiscence therapy, simulated presence therapy involves the recalling of a patient's positive life experiences and memories (Zetteler 2008). However, in simulated presence therapy, the recalling of positive life experiences is accomplished through the use of audiotaped or videotaped recordings of conversations with a patient's family members (Zetteler 2008). The purpose of these recordings is to bring comfort to the patient by serving as a reminder of the patient's family (Zetteler 2008). There is mixed evidence regarding the effectiveness of simulated presence therapy. Additionally, there is evidence that simulated presence therapy can produce increases in agitation or disruptive behaviors (Zetteler 2008). Overall, these results suggest that simulated presence therapy may be effective in reducing challenging behaviors. However, current findings need to be replicated and extended.

Validation Therapy

Naomi Feil developed validation therapy for older adults with cognitive impairment, particularly those with dementia. Feil classifies cognitively impaired individuals according to four stages: mal orientation, time confusion, repetitive motion, and vegetation. The emphasis of the intervention is on acknowledging and dignifying the feelings and experiences of a person. A variety of techniques comprise the approach (e.g., paraphrasing, touching, linking behavior with unmet needs). Feil identified several principles that she believes underlie her approach (e.g., all people are unique and should be treated as such, there is reason behind the behavior of disoriented behavior of older adults, and older adults should be accepted nonjudgmentally).

Outcomes measured employed in studies of validation therapy have included cognition, behavior, emotional state, and activities of daily living. As previously noted (Neal et al. 2005), and unchanged today, there are few experimental studies of validation therapy, and their results are mixed, with insufficient evidence to support this approach.

Sensory Stimulation Interventions

Sensory stimulation interventions and complementary and alternative medicine (CAM) include interventions such as massage therapy, acupuncture, aromatherapy, light therapy, music therapy, Snoezelen or multisensory stimulation therapy, and transcutaneous electrical nerve stimulation (O'Neil et al. 2011). Sensory stimulation interventions and CAM therapies have both been investigated as interventions to reduce problem or challenging behaviors, including agitation/aggression, wandering, and inappropriate sexual behavior.

Massage Therapy

In general, massage or touch therapies involve applying pressure to the body. This application of pressure may include a variety of styles of touch, such as slow strokes, expressive touch, rubbing, kneading, and effleurage (Hansen et al. 2008; Moyle et al. 2012). Massage may also be applied to different body areas, including

the back, shoulders, neck, hands, lower legs, or feet (Moyle et al. 2012). Typically, massages are conducted by nursing staff or massage therapists (Hansen et al. 2008; Moyle et al. 2012). The limited number of studies precludes the ability to evaluate the effectiveness of massage therapy (Hansen et al. 2008; Moyle et al. 2012). However, the preliminary evidence suggests that massage therapy may reduce agitated behavior among older adults with dementia, at least in a short term.

Multisensory Stimulation Therapy

The goal of multisensory stimulation (MSS) or Snoezelen therapy is to promote balance of the sensory system through stimulation of the five senses by using a range of stimuli (e.g., music, aromatherapy) (O'Neil et al. 2011). In some cases, guidelines identify specific stimuli that should be included in treatment. Alternatively, patient preferences may be used to identify specific stimuli (Chung et al. 2009). The current evidence for the effectiveness of MSS is mixed. There is preliminary evidence that disruptive behavior decreases during MSS treatment. However, these effects are not maintained when treatment is discontinued (Livingston et al. 2005). Other research concluded that there is no evidence for the effectiveness of MSS on agitation/aggression among individuals with dementia (Chung et al. 2009). Further, the evidence for the effectiveness of MSS on wandering is inconclusive (O'Neil et al. 2011). In sum, the limited evidence available suggests that MSS may be effective in reducing some challenging behaviors (i.e., disruptive behavior).

Music Therapy

Music therapy typically involves listening to music or playing musical instruments, but may also involve having patients compose music or dance (O'Neil et al. 2011; Livingston et al. 2005). In active music therapy, patients and providers participate in the intervention (e.g., composing, singing, dancing, and playing instruments). Receptive music therapy involves having patients listen to music and therefore involves less interaction (McDermott et al. 2013). Similar to other sensory stimulation interventions, music therapy may be implemented as a stand-alone

intervention or integrated in other activities (O'Neil et al. 2011). Music therapy may be individualized by employing the patient's favorite music. In contrast, standardized music therapy protocols typically employ relaxing, quiet, classical, and big-band music (Livingston et al. 2005; McDermott et al. 2013).

Music therapy is effective in producing short-term (during and immediately following the intervention) decreases in disruptive behavior (i.e., agitation and aggression) (O'Neil et al. 2011; Livingston et al. 2005; McDermott et al. 2013). However, there is no evidence that the decreases in agitation and aggression are maintained (McDermott et al. 2013). Evidence regarding the effectiveness of music therapy in reducing other challenging behaviors is mixed (O'Neil et al. 2011). Despite the promising findings of several reviews, poor methodological quality and reporting of studies prevented the ability to draw conclusions about the effectiveness of music therapy (Vink et al. 2011).

Light Therapy

Light therapy increases exposure to bright and naturalistic light and is therefore hypothesized to help regulate circadian rhythms and reduce fragmented or disrupted sleep, which in turn is hypothesized to reduce challenging behaviors (i.e., agitation, cognitive dysfunction, functional impairment, and depression) (Forbes et al. 2014). Light therapy involves use of varying levels of brightness (e.g., between 2500 and 10,000 lx). Recent research suggests that light therapy should involve exposure to light in the short wavelength range (i.e., 450 to 500 nm, the blue to green range) as this is the light range at which melanopsin cells are stimulated to shift circadian rhythms (Forbes et al. 2014). Exposure to light can be produced by using a light box, wearing a light visor, light fixtures, or dawn-dusk simulation (Forbes et al. 2014). One advantage of light therapy is that few adverse effects have been reported (Forbes et al. 2014). Overall, there is a lack of sufficient evidence to support light therapy as an effective treatment for reducing challenging behaviors (O'Neil et al. 2011; Forbes et al. 2014).

Transcutaneous Electrical Nerve Stimulation

Transcutaneous electrical nerve stimulation (TENS) has also been explored as a potential treatment for challenging behaviors, such as aggressiveness, among individuals with dementia. TENS involves the application of biphasic pulsed waveform, pulsed electrical currents, to the skin and can produce muscle contraction depending on the intensity of the current (O'Neil et al. 2011; Cameron et al. 2009). When TENS is used to treat individuals with dementia, electrodes are applied to the head or earlobes, which produce cranial electrical stimulation (Cameron et al. 2009). TENS is associated with minor side effects, such as dull pain in the head, and therefore may be advantageous as compared to other interventions (Cameron et al. 2009). Literature examining the effects of TENS on challenging behaviors is limited. One Cochrane review noted a lack of sufficient data limited the ability to draw conclusions about the effects of light therapy on challenging behaviors, specifically aggressiveness (Cameron et al. 2009).

Reality Orientation Therapy (Cognitive Stimulation)

Reality orientation therapy was originally developed for the rehabilitation of war veterans and later used to address the disorientation of older adults in hospitals. This approach is typically directed at individuals with dementia and involves the presentation of information regarding time, place, and person with the goal of reorienting the individual. Clocks and calendars are often employed to assist with this endeavor. One review examined all randomized controlled trials (RCTs) of cognitive stimulation for dementia that focused on cognitive change outcomes (Woods et al. 2012). These included studies in which the following terms were used to describe the intervention: cognitive stimulation, reality orientation, memory therapy, memory groups, memory support, memory stimulation, global stimulation, and cognitive psychostimulation. Cognitive stimulation, the overarching term, was defined as "engagement in a range of activities and discussions (usually in a group) aimed at general enhancement of cognitive and social

functioning" (Woods et al. 2012, p. 2). Outcome assessments of challenging behaviors were based on care provider ratings of participant behavior. More specifically, ratings of general behavior and behavior scales were used as outcome measures. No differences in challenging behaviors were found between intervention and control groups. Consequently, reality orientation therapy cannot be recommended as an intervention for challenging behaviors.

Psychosocial Interventions

Psychosocial interventions, such as animal-assisted therapy and exercise, promote social interaction and communication and have been examined as interventions to reduce challenging behaviors.

Animal-Assisted Interventions

Animal-assisted interventions are a broad category, which includes three main types of interventions, animal-assisted activities, animal-assisted therapy, and service animal programs (Bernabei et al. 2013). Animal-assisted interventions can involve the use of living animals such as, dogs, cats, or even fish. Alternatively, these interventions may employ nonliving animals, such as robot animals or toy animals (e.g., plush dog or cat). Animal-assisted activity involves the use of a companion animal. Animal-assisted therapy employs therapy animals, is typically provided by health or human service professionals, and addresses specific treatment goals (Kamioka et al. 2014). Service animal programs employ service animals (Kamioka et al. 2014). Research suggests that exposure to animals has beneficial effects on health, may reduce depressive symptoms, and may improve socialization and interaction (Bernabei et al. 2013). Moreover, animal-assisted interventions reduced challenging behaviors, such as aggressiveness and irritability, although it is unclear whether these effects were maintained (Bernabei et al. 2013).

Physical Exercise Interventions

In general, there are several types of physical exercise/activity programs, including mobility training (e.g., walking), isotonic exercises,

strength training, or mixed modalities (e.g., chair exercises, aerobic dance class) (Heyn et al. 2004). These exercise programs may be delivered as an independent activity or may be incorporated into recreational activities/programs. The primary goal of these types of programs is to increase older adults' ability to perform tasks of everyday living (Forbes et al. 2013). An additional goal of some exercise interventions is to increase socialization. Similar to other psychosocial interventions reviewed, the effects of exercise on challenging behavior are mixed (Forbes et al. 2013; Eggermont and Scherder 2006). Currently, there is insufficient evidence to determine if exercise reduces aggressive/agitated or wandering behavior among individuals with dementia (Forbes et al. 2013).

Summary and Conclusions

The primary focus of this entry is psychosocial interventions for challenging behaviors associated with dementia in residential care. Additionally, pharmacological interventions are briefly addressed. Reliance on pharmacological interventions continues in spite of limited support and potential adverse effects. Psychosocial interventions offer safer alternatives, but conclusions regarding several of the psychosocial interventions are limited for a variety of reasons, including methodological problems and inconsistencies in findings across studies. Most reviews of this literature have relied primarily upon large-scale studies that meet standards that are challenging for research with dementia-related problems. These include, for example, large sample size, equivalent control group, blindness of participants, and assessor to intervention (Cohen-Mansfield et al. 2012). Single-case design studies, which often clearly demonstrate the effects of interventions, have insufficient sample sizes and inadequate design characteristics to be included in most reviews. Cohen-Mansfield et al. (2012) have argued against restricting reviews to studies employing stringent inclusion criteria, such as those for RCTs. They argue that the resulting reviews fail to contain considerable useful

information that is often more externally valid than that obtained from studies with very strict inclusion criteria. The conclusions of this entry are driven largely on the basis of major reviews of the relevant literature. Further, research that does not meet the standards for RCTs (e.g., reviews of behavior analytic interventions) was also reviewed when possible. The conclusions tend to be mixed, which is consistent with the findings of most of the reviews cited in this entry. The most promising approaches to managing challenging behavior appear to be the ones that are individualized in general and those that attempt to address the antecedents and function of the challenging behaviors in particular. Future research should offer a balance of methodologies; address the lack of a consistent operationalization of challenging behavior and use of inconsistent outcome measures; and explore whether the reductions in challenging behaviors are maintained once treatment is terminated. In addition, reviewers should consider the implications of eliminating empirically sound and externally valid studies which may not meet all of the criteria previously required for inclusion.

CHARLS

Definition

This entry provides an overview of the China health and retirement longitudinal study, focusing on its value in geropsychology research in China. The entry starts with an introduction on CHARLS Sampling and Implementation including the background, the sampling procedure and design, tracking protocol, data release, and demographics of the respondents. It then describes the contents of the questionnaire, followed by psychologic measurements. This entry is concluded with future plans.

Introduction

China has the largest aging population in the world and also one of the highest aging rates in the world today. It is projected that the proportion of those aged 60 or over will increase from 13% of the population in 2010 (National Bureau of statistics of China 2011) to 33% in 2050 (United Nations 2013), whereas the elderly support ratio (the number of prime-age adults aged 20–59 divided by the number of adults aged 60 or

above) will drop from about 4.9:1 in 2010 to 1.4:1 in 2050 (United Nations 2013).

With the rapid aging of Chinese population, the problem of providing for the aged population is becoming increasingly important. One feature of rapid economic growth is that lifetime incomes for younger people tend to be considerably higher than they were for their elderly parents, making the elderly one of the largest disadvantaged groups in China. At the same time, China's birth control policy means that China's elderly today have fewer children to support them than in the past. How to deal with problems of support for the well-being of the elderly is one of the greatest challenges to the fast-booming Chinese society in the decades to come.

In face of challenges posed by population aging, the health status of the elderly population is of great importance. A healthy older population can not only reduce the financial and personal care needs but can also contribute to the family and society in the form of working or helping to take care of the young children.

Of all dimensions of health, psychological health is at least as important as physical health to the functionality of older persons. Depression is already listed as a major cause of death and disability in China (Yang et al. 2013; Phillips et al. 2002). In the United States, dementia or cognitive impairment has been shown to cause major caring burdens to the family (Hurd et al. 2013).

At present, scientific studies of China's aging psychological health problems are still at an early stage, the greatest obstacle being a lack of sufficient micro-longitudinal data. The existing data tend to be small scale in parts of China, not collecting the breadth of data necessary for good social scientific analysis of psychological health of the older population. China Health and Retirement Longitudinal Study (CHARLS) is the first nationally representative survey of the older population that enables the study of psychological health of the older population in China patterned after the Health and Retirement Study (HRS) in the United States, English Longitudinal Study of

Ageing (ELSA), and the Study of Health, Ageing, and Retirement in Europe (SHARE).

This entry will give a comprehensive introduction of the CHARLS data set, its sampling method, longitudinal tracking protocol, the content of the questionnaire especially existing psychological measures, and plans for future data collection.

CHARLS Sampling and Implementation

Baseline Sampling

CHARLS is a biennial survey that aims to be representative of the residents of China aged 45 and older, with no upper age limit. The CHARLS national baseline survey was conducted in 2011–2012 and wave 2 in 2013. CHARLS is a nationally representative survey that includes one person per household aged 45 years of age or older and their spouse, totaling 17,708 individuals in wave 1, living in 10,257 households in 450 villages/urban communities (Zhao et al. 2013, 2014). At the first stage, all county-level units were sorted (stratified) by region, within region by urban district or rural county, and by GDP per capita (Tibet was the only province not included). Region was a categorical variable based on the NBS division of province area. After this sorting (stratification), 150 counties or urban districts were chosen with probability proportional to population size (Zhao et al. 2013). For each county-level unit, three PSUs (villages and urban neighborhoods) are randomly chosen with probability proportional to population

(Zhao et al. 2013). Hence, CHARLS is nationally represented for both rural and urban areas within China. Counties and districts in 28 provinces are included in the CHARLS sample (Zhao et al. 2013).

In light of the outdated household listings at the village/community level due to population migration, CHARLS designed a mapping/listing software (Charls-GIS) that makes use of Google Earth map images to list all dwelling units in all residential buildings to create sampling frames.

The response rate for the baseline survey was 80.5%, 94% in rural areas and 69% in urban areas, lower in urban areas as is common in most surveys undertaken in developing countries (Table 1) (Zhao et al. 2013). A description of the sample for waves 1 and 2 is provided in Table 1. After applying sampling weights created using the sampling procedure, the CHARLS sample demographics mimics very closely that of population census in 2010 (Zhao et al. 2013).

In each sampled household, a short screening form was used to identify whether the household had a member meeting the age eligibility requirements. If a household had persons older than 39 and meeting the residence criterion, one of them will be randomly selected. If the chosen person is 45 or older, then he/she became a main respondent and his or her spouse was interviewed. If the chosen person was between ages 39 and 44, he/she was reserved for refresher samples for future waves. In wave 2, respondents who were aged 43–44 in wave 1 (plus their spouses) were

China Health and Retirement Longitudinal Study (CHARLS), Table 2 Number and age/sex structure of individuals: 2011 Baseline and Wave 2, 2013

	Baseline, 2011			Wave 2, 2013		
	Total	Male	Female	Total	Male	Female
–50	4,277	1,806	2,471	4,178	1,754	2,424

66–70	1,802	913	889	2,037	1,032	1,005
71–75	1,214	652	562	1,442	732	710
76–80	790	386	404	787	410	377
80+	548	231	317	830	374	456
OBS	17,708	8,476	9,232	18,648	8,882	9,766

Note: There are 11 individuals in 2011 and 15 individuals in 2013 lacking age information

added from the refresher sample. The same for wave 3 (4) will be done in 2015 (2017), out of those aged 41–42 (39–40) in wave 1. Starting in wave 5 (2019), a new mapping/sampling exercise will be conducted to replenish the sample with appropriate aged cohorts.

Tracking Protocol

Respondents and spouses will be tracked if they exit the original household. While the original CHARLS sample is of the noninstitutionalized elderly population, if a respondent becomes institutionalized, such as entering a nursing home or hospital for a long stay, CHARLS follows them. This potentially matters for obtaining prevalence rates for dementia since it might be that some of the population with dementia is institutionalized. However, in China, the institutionalized population is very small, so in practice for CHARLS, this is unlikely to be an important issue.

Main respondents and spouses in the baseline survey are followed throughout the life of CHARLS or until they die. If a main respondent or spouse remarries, the new spouse is interviewed so long as they are still married to the baseline respondent at the time of the specific wave. In wave 2, only 25 couples split up because of divorce.

For respondents in the baseline, after deaths, 91% of them were recontacted (Table 1). Four hundred twenty-seven exit interviews were conducted on respondents who died between the

baseline and wave 2 (464 deaths), including verbal autopsies using the 2012 version from the World Health Organization. In addition, the households which were not found in the baseline were revisited. One thousand one hundred twenty-nine of these (51.6% of those households who had age-eligible members living in nonempty dwellings) were contacted. The households that split because of divorce or moving were also followed. The total household size in wave 2 is 10,832 households with a total of 18,648 individuals (main respondents plus spouses). The age distribution of respondents in baseline and wave 2 is shown in Table 2.

Data Release

The national baseline data and documentation were released publicly, on the CHARLS website (www.charls.ccer.edu.cn/en), in early February 2013, less than 1 year after the fieldwork was completed. The second wave of the national CHARLS sample was fielded in the summer and through the fall of 2013. It was released publicly at the end of this January.

Demographics of the CHARLS Sample

Table 2 describes the age/sex composition of the CHARLS sample. There are 17,708 individuals in the national baseline sample, of which 52.1% are female. While most of the samples are the younger old, 40% are aged 60 years and older. Of the sample, 91.3% were directly interviewed and

8.7% were interviewed by proxy respondent (Table 2).

Content of the Household Survey

Household Survey Instruments

The core survey consists of the following sections: (1) demographics; (2) family structure/transfer; (3) health including biomarkers; (4) health insurance and healthcare utilization; (5) work, retirement, and pension; (6) relative income; (7) family income, wealth, and expenditures; (8) personal income, assets; and (9) housing characteristics. All interviews are conducted using the computer-assisted personal interview (CAPI) technology. The health modules will be described in detail.

Health Status: Self-Reports and Assessments

The self-reports start with the respondent rating health on a scale of excellent, very good, good, fair, and poor or instead very good, good, fair, poor, and very poor. As in HRS, respondent's self-assessment is asked twice, using each scale, once at the start of the module and once at the end of the sub-module asked randomly determined within CAPI. This is followed by questions asking about diagnoses by doctors of a set of chronic diseases, including stroke and separately psychology diseases, and the timing of diagnoses of specific conditions. Where relevant, current medications and treatments for each specific condition are also collected. Questions about eyesight, hearing, and dental health are asked next and then questions on hedonic well-being. The CHARLS team follows this subsection with a section to obtain information on activities of daily living (ADLs), instrumental activities of daily living (IADLs), and physical functioning. For those who have been identified as having difficulties in ADL or IADL, the care givers are collected. Up to three names are chosen from all of list of family members. Time of care and financial arrangement are asked. Sections on depressive symptoms and cognition follow.

In addition to self-reported health outcome variables, information is collected on several

health behaviors. This includes detailed information on smoking, drinking, and physical activities.

Health Status: Biomarkers

Following ELSA and HRS, detailed biomarkers, blood and non-blood, were collected. Non-blood biomarkers such as anthropometrics and blood pressure were collected in waves 1 and 2 and will again be in wave 3. Then the blood biomarkers was collected in wave 1 and will be collected in every other wave, to harmonize with HRS and other aging surveys. In CHARLS the data are collected on height, lower leg and upper arm lengths (useful to get measures related to height not contaminated by shrinkage), waist circumference, blood pressure (measured 3 times), grip strength (measured by a dynamometer two times for each hand), lung capacity measured by a peak flow meter, and doing a timed sit to stand (5 times starting from a full sit position on a common, plastic stool). The balance tests are also conducted, just the same as those used in HRS, and a timed walk at normal speed for 2.5 m again follows HRS.

Healthcare Utilization and Insurance

Indicators of curative and preventive healthcare utilization and health insurance coverage are collected in this module. A separate section on health insurance is asked to collect details of current and past coverage and whether coverage was lost. Healthcare utilization of outpatient care for the last 1 month is asked, with details about last visit. Inpatient utilization over the past 1 year is asked, with details about last visit. The questions include from whom and at what location medical care was received, how much was total cost, what was out of pocket cost, whether insurance was used, if others help pay for the care, whom, and how far respondents traveled.

Life Histories

A special wave to collect life histories was fielded in 2014. Life histories can greatly add to aging surveys because they help to fill in very important details regarding earlier periods in the respondent's life, which are germane to understanding outcomes when older. Ways to minimize recall

China Health and Retirement Longitudinal Study (CHARLS), Table 3 CES-D questions

English	Mandarin
DC009 I was bothered by things that don't usually bother me	我因一些小事而烦恼。
DC010 . I had trouble keeping my mind on what I was doing	我在做事时很集中精力。
DC011 . I felt depressed	我感到情绪低。
DC012 . I felt everything I did was an effort	我得做任何事都很劲。
DC013 . I felt hopeful about the future	我对未来充满希望。
DC014 . I felt fearful	我感到害怕。
DC015 . My sleep was restless	我的睡眠不好。
DC016 . I was happy	我很愉快。
DC017 . I felt lonely	我感到孤独。
DC018 . I could not get "going"	我得我无法继续我的生活

error have been greatly improved primarily through the use of calendars that are anchored to key lifetime or calendar events (both national events, like the Cultural Revolution and local, like a major flood) that are salient to respondents' memory. Such calendars have been developed.

The CHARLS life histories are developed using as a base the ELSA and SHARE life histories, the most complete life histories of the HRS-type aging surveys. The CHARLS life history includes retrospectives on domains that cover family background when the respondent was a child, child health and health care, work and retirement, marriage, childbirths, migration, some retrospective information on income, wealth and poverty status when young, and schooling is collected. Some special history issues germane to China are also included, such as experiences during the Cultural Revolution and the Great Famine and during local events such as a major local flood. These life histories will be especially useful for linkage with the CHARLS ADAMS 2 data.

Community Survey Instrument

One special feature of CHARLS that is new to the HRS-type surveys is to collect detailed panel data from community-level informants (e.g., formal and informal community leaders). Basic community information is collected on, for example, land and its allocation, population, and the most populous surnames and their numbers. More standard information is also collected, such as details about local infrastructure and public facilities such as roads, electrification, water and sanitation infrastructure, and the availability of schools; health

insurance and health facilities; and pensions and prices. In addition, the Policy Questionnaire collects details of social welfare programs such as pensions and health insurance. In addition, at the county level.

Psychological Health Measures

Depression

CHARLS uses the ten-question version of the Center for Epidemiologic Study depression (CES-D) battery (The CES-D ten questions are reported in Appendix Table 3, and CHARLS uses the Chinese translation provided at the Center for Epidemiologic Studies website). The answers for CES-D are on an f-scale metric, from rarely, to some days (1–2 days), to occasionally (3–4 days) to most of the time (5–7 days).

Lei et al. (2014a) provides a descriptive analysis of the depressive symptoms as revealed in CHARLS. They scored these answers using the metric suggested by Radloff (1977). Numbers from 0 for rarely to 3 for most of the time are used for negative questions such as "do you feel sad." For positive questions such as "do you feel happy," the scoring is reversed from 0 for most of the time to 3 for rarely. A validation exercise of answers to these questions indicates a reasonable level of internal consistency. Lei et al. (2014b) report that in 2011/12 a high fraction of Chinese people 45 and older, both men and women, are suffering from high levels of depressive symptoms, with some 30% of men and 43% of women having CES-D scores 10 and over (out

of 30 as a maximum). Rural residents have substantially higher levels of depressive symptoms than urban residents.

Cognition

In the first two waves, CHARLS used a reduced form of the Telephone Interview for Cognitive Status, TICS (Brandt et al. 1988). This includes recognition of date: month, day, year, season (lunar calendar is allowed in addition to Gregorian calendar), day of the week, how the respondent rates their own memory on an excellent, very good, good, fair, poor scale, and serial subtraction of 7s from 100 (up to five times). The respondent is asked to redraw a picture of overlapping pentagons. In addition, immediate and delayed word recall is used, using ten nouns randomly chosen from a list of four groups of words, with approximately 5 min between the immediate and delayed answers. The words will not be read out a second time before the delayed recall (the word lists are reported in Appendix Table 4).

CHARLS shows a steep decline of cognitive functions with age (Lei et al. 2014b). There exist large sex-related differences in cognition to the disadvantage of women, with the large sex-related gap in education being the primary reason for this. These sex-related disparities are eliminated in younger cohorts.

Future Plans

Starting in wave 3 (2015), CHARLS will be introducing a number series test of fluid intelligence,

patterned on the HRS number series test (Fisher et al. 2013; Prindle and McArdle 2013).

In CHARLS wave 4, it is scheduled to diagnose dementia and impaired of cognition among the CHARLS respondents aged 65 and older. This will be done in two steps. First, a formal validation sample will be collected from which both interviewer assessment and doctor diagnosis will be conducted. From these data, a statistical model will be built to use interview tests to predict dementia and CIND. This information will be used to inform the final choice of tests and the estimation of weights and cutoff points specific to China with which to classify CHARLS respondents as having dementia and CIND. Among the tests currently planned are the mini-mental state exam (MMSE); immediate and delayed word recall; a measure of verbal fluency, animal naming; the symbol digit modalities test; and backwards digit span.

Acknowledgments This work was supported by the Behavioral and Social Research division of the National Institute on Aging (grant numbers 1-R21-AG031372-01, 1-R01-AG037031-01, and 3-R01AG037031-03S1); the Natural Science Foundation of China (grant numbers 70910107022, 71130002 and 71273237); the World Bank (contract numbers 7145915 and 7159234); China Medical Board, and Peking University.

Definition

This entry aims to introduce the centenarian subsample of the Chinese Longitudinal Healthy Longevity Survey (CLHLS) and present some key findings on psychological traits of centenarians.

Background: Centenarian Studies in the World

Tireless efforts are made to explore the secret of human longevity throughout history. However, it is not until very recent that science-based studies on the mechanism of longevity appeared with sufficient sample sizes and multidisciplinary perspectives have been launched (Poon and Cheung 2012). One shortcoming of most existing longevity research projects is that little research has been done for those who survive to age 100 and

Disclaimer: Views expressed in the study are only those of the authors and do not reflect those of the United Nations, National University of Singapore, Duke University, or Peking University

beyond, namely centenarians (Poon and Cheung 2012; Zeng 2012).

The urgent call to study centenarians is largely due to the increasing importance of this special subpopulation. Because of the steady decline of mortality at very old ages (Vaupel et al. 1998; Wilmoth et al. 2000), the number of centenarians is booming in the world (Robine et al. 2010; Wilcox et al. 2008, 2010) and is projected to exceed three million by 2050 and possibly 20 million by 2100 in a conservative estimation of the United Nations Population Division (2015). More importantly, with the world population aging, centenarians come to be considered as a model of successful aging or healthy aging (Andersen-Ranberg et al. 2001; Poon et al. 2010). But why could some people live up to age 100 and beyond, while others die at much younger ages? Why could some people live so long but still remain healthy? Although there has been a consensus among researchers that socioeconomic, behavioral, environmental, and biological factors jointly determine one's longevity and health, to what extent and how exactly these factors contribute to centenarians' exceptional long and healthy life is mostly unknown.

There have been a number of centenarian studies around the world to attempt to address such research questions. For example, the longest ongoing centenarian study in the contemporary world is the Okinawa Centenarian Study (OCS), which was launched in 1975. The OCS has heretofore collected over 900 centenarians and several thousands of their siblings of septuagenarians, octogenarians, and nonagenarians in Okinawa, Japan. The Georgia Centenarian Study (GCS) is the longest centenarian study in the USA, which started in 1988. In the Phase I (1988–1992), the GCS collected 76 centenarians with 92 octogenarians and 89 sexagenarian as comparisons; 250 centenarians were further included with 80 octogenarians as comparison in the Phase III (2001–2009). The largest centenarian study in the USA is the New England Centenarian Study (NECS), which was launched in 1995. The NECS has collected data from about 1,600 centenarians in the USA with 500 children (in their 70s and 80s) and 300 younger controls since

1995. Several European countries have also launched centenarian studies since the early 1990s such as the Italian Multi-center Study on Centenarians (IMUSCE) (around 2,000 centenarians) and the Longitudinal Danish Centenarian Study (about 300 centenarians) (Koenig 2001; Poon and Cheung 2012). These centenarians and all other relevant studies have resulted in a boom in centenarian studies and improved understanding about their secret of longevity.

However, nearly all centenarian studies are from developed countries. There was almost no scientific research project with a sufficient sample size of centenarians in developing countries before the late 1990s (Zeng et al. 2001). Because the contributions of sociodemographics, psychological factors, and behavioral factors to longevity vary in different cultures and societies with different development stages (Poon et al. 2010; Kolovou et al. 2014; Willcox et al. 2006), it would be interesting to study centenarians from developing countries where the socioeconomic resources, healthcare service, and technology are limited. Furthermore, while there were about 50 centenarians per million in Western Europe (Jeune and Vaupel 1995; United Nations Population Division 2015), there were less than three centenarians per million in China in the 1990s (United Nations Population Division 2015). The genomes of long-lived individuals from China may be more enriched for disease-preventive genes than their counterparts in the West, because they survived the brutal mortality regimes of the past when famine, civil wars, and starvation affected their birth cohorts of many millions. In addition, the genetic composition of the Han Chinese ethnic group is relatively homogeneous. Unlike Western countries that received many immigrants from other parts of the world and thus provide relatively heterogeneous genetic compositions even within the same ethnic group, China received very few international immigrants. Consequently, the Han Chinese are relatively genetically homogenous, compared to the Western counterparts. For example, it was estimated that “the average of genetic differences between Han Chinese population samples ($F_{ST} = 0.002$) was much lower than that among

European populations ($F_{ST} = 0.009$)” (Xu and Jin 2008). This is a comparative advantage to increase statistical power for studying effects of genetic and GxE interactions on healthy aging.

Another major limitation of existing literature on centenarian studies has been the lack of surveys with large sample sizes. To address above research questions, including investigating genetic variations in longevity and examining gene-environment interaction effects on longevity and health, large samples are required. Small sample sizes of surveys often produce results with insufficient statistical power or poor robustness; and in some cases, small-sized surveys on centenarians often lack representativeness when the size of underlying centenarian population is relatively large, such as in China. Yet, with few exceptions, the sample sizes of most centenarian studies around the world are less than 1,000 centenarians (Koenig 2001; Poon and Cheung 2012). To promote centenarians studies, there is thus a need for studies with large representative samples in developing societies, such as in China which homes about 1.3 billion population or about 19% of the world total population.

Research Objectives of the CLHLS

Launch of the CLHLS

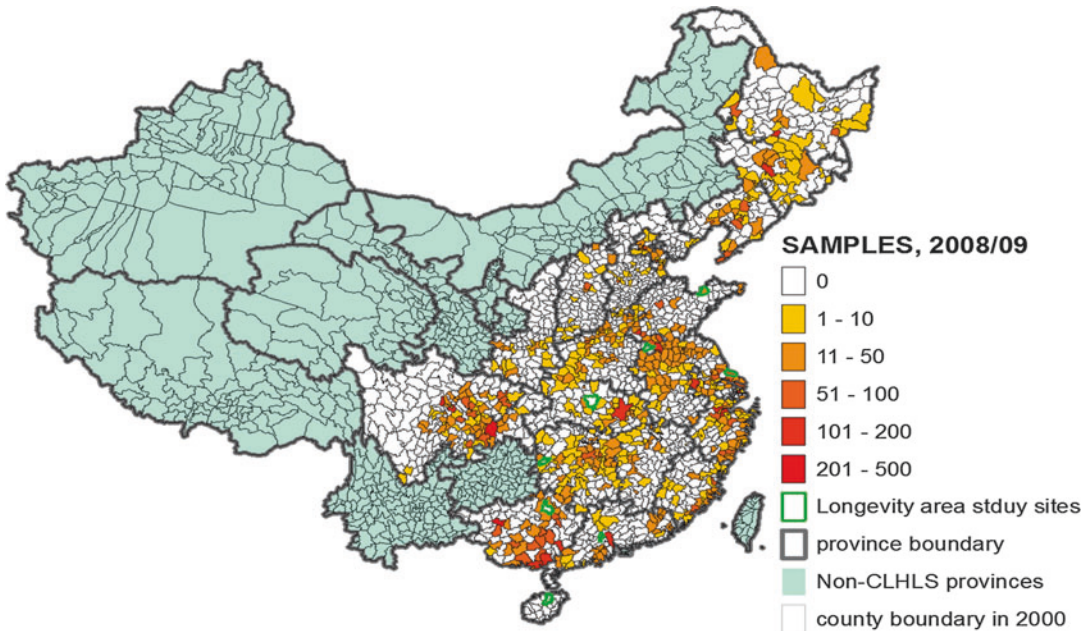

While it is very useful and important to uncover the secrets of human longevity to study centenarians, it is also equally important or even more prominent to study the oldest-old population aged 80 or older. This is because the remarkable increase in the number of oldest-old population in the recent years and near future presents a serious public health challenge to promote the quality of life. Because their large consumptions of social and medical care services and benefits of research on them are far out of proportion to their size, the oldest-old population in aging and longevity studies has received increasing attention over the past decades. In this context, Drs. Yi Zeng and James W. Vaupel launched a nationwide project in China on determinants of healthy longevity in 1998, titled as the Chinese Longitudinal Healthy Longevity Survey (CLHLS). This project received

financial supports from the National Institute on Aging, the National Natural Science and Social Sciences Foundations of China, UNFPA, and other resources.

The CLHLS aims to collect extensive data on a large sample of the oldest-old aged 80 years and older with a comparison group of younger elders aged 65–79. The project also collected information on the offspring of the elderly in 2002 and 2005 to better investigate the role of intergenerational transfers and its association with human longevity. Starting in 2009, adult children of centenarians and controls of nonrelatives of centenarians in seven longevity areas (later becoming eight longevity areas in 2012 and 2014) were included in the CLHLS (see section “Centenarian Sub-Sample in the CLHLS” below). More specifically, the objectives of the CLHLS research project are threefold: (1) to shed light on the determinants of healthy longevity and to discover social, behavioral, environmental, and biological factors that may have an influence on the healthy longevity of human beings, as well as to answer questions such as why some people survive to very old age without much suffering while others suffer considerably; (2) to fill in the data gap and gain a better understanding of demographic and socioeconomic conditions, as well as of the health status and care-giving needs of the oldest-old population; and (3) to provide a scientific base for sound policy making and implementation, so as to improve the system of care-giving services and, ultimately, the quality of life of the elderly.

Sampling Strategy of the CLHLS

The CLHLS is conducted in a randomly selected half of the counties and cities in 22 of China’s 31 provinces. The 22 provinces are Liaoning, Jilin, Heilongjiang, Hebei, Beijing, Tianjing, Shanxi, Shaanxi, Shanghai, Jiangsu, Zhejiang, Anhui, Fujian, Jiangxi, Shandong, Henan, Hubei, Hunan, Guangdong, Guangxi, Sichuan, and Chongqing (see Fig. 1). The exclusion of nine provinces in the North-West parts of China, where ethnic minorities represent a high proportion of total population, was based on concerns about the inaccuracy of age-reporting among

Chinese Longitudinal Healthy Longevity Study, Fig. 1 Spatial distribution of the sampled counties/cities in the CLHLS, the 2008 wave. Note: This map was made by the authors based on a county boundary map from the National Bureau of the Statistics of China. The designations employed and the presentation of material on this

map do not imply the expression of any opinion whatsoever on the part of the Secretariat of the United Nations concerning the legal status of any country, territory, or area or of its authorities or concerning the delimitation of its frontiers or boundaries

local elders. Previous studies have evidenced major inaccuracy (mainly exaggeration) in age reporting at old ages in these nine provinces (Coale and Li 1991; Huang 1993). In contrast, in the 22 provinces as chosen, local people, mostly Han, tend to use the Chinese lunar calendar and/or Western solar calendar to specify their birthdays, which largely reduces the inaccuracy of age reporting. The accuracy and reliability of age reporting for Han Chinese is related to the fact of their cultural tradition that the exact date of birth is significant for them in making decisions on important life events such as matchmaking for marriage, date of marriage, and the date to start building a house, among other events (Coale and Li 1991; Zeng 2012). The total population of the survey areas constituted about 85% of the total population in China in 2000 and 82% in 2010. So far, seven waves in 1998, 2000, 2002, 2005, 2008/09, 2011/12, and 2014 have been conducted.

In the sampling areas, the CLHLS aims to interview all centenarians who voluntarily agreed

to participate in the study. For each centenarian interviewee in each wave, the CLHLS interviewed one nearby octogenarian (aged 80–89 years) and one nearby nonagenarian (aged 90–99 years) with predefined age and sex. “Nearby” is loosely defined – it could be in the same village or in the same street, if available, or in the same town or in the same sampled county or city district. The predefined age and sex are randomly determined, based on the randomly assigned code numbers of the centenarians, to have comparable numbers of males and females at each age group. In the first two waves (1998 and 2000), the CLHLS did not collect data from elders aged 65–79 years. Since the 2002 wave, the CLHLS extended its sample to include elders aged 65–79 under same sampling strategy with approximately three nearby elders aged 65–79 of predefined age and sex in conjunction with every two centenarians. Respondents who were younger than age 100 at an interview but subsequently died before a subsequent wave or resettled or refused to

be interviewed at a subsequent wave were replaced by new interviewees of the same sex and age (or within the same 5-year age group). However, such a strategy was not applied to the sixth and seventh waves where only follow-ups were performed due to shortage of budget, except the eight longevity areas where new participants were recruited to replace the deceased or the refusals.

To avoid the problem of small subsample sizes at the more advanced ages, the CLHLS oversampled respondents at more advanced ages, especially among male elders, in addition to recruiting all centenarians with a consent agreement. Consequently, appropriate weights were generated based on the age-sex-rural/urban-specific population distribution in the census. The method for computing the age-sex-rural/urban-specific weights and the associated discussions are presented in Zeng et al. (2008) and available at the CLHLS web page.

The questionnaire design was based on international standards and was adapted to the Chinese cultural/social context and carefully tested by pilot studies. The CLHLS collects various information covering demographics, socioeconomic conditions, psychological traits, health practice, and various health condition. All data were collected via in-home visits. The basic physical capacity tests were performed by a local doctor, a nurse, or a medical student.

Centenarian Subsample in the CLHLS

Subsample of the Centenarian Interviewees

In the research design of the CLHLS, the group of centenarians is one of the major components. As shown in Table 1, the CLHLS from 1998 to 2014 interviewed 10,804 centenarians in total with 2,130 male centenarians and 8,674 female centenarians. The total number of interviews of these centenarians is 16,582, of which 3,876 centenarians have two interviews and 1,360 centenarians have three interviews; only 372, 117, 39, and 14 have 4, 5, 6, and 7 interviews, respectively.

Data Quality of the Centenarians

Accurate age reporting is crucial in centenarian studies. The CLHLS has employed different methods to verify centenarians' ages, including birth and marriage certificates if available; household registration information; ages of their siblings, children, and relatives; genealogical record; any relevant document from local communities if available; and reported ages in Chinese zodiac. (The Chinese zodiac is a repeating cycle of 12 years, with each year being represented by an animal according to the Chinese lunar calendar. These zodiac animals are used to record one's date of birth). Based on the solid comparisons of various demographic indices, it was concluded that although the age reporting quality of centenarians of Han Chinese was not as good as in Sweden, Japan, England, and Wales, it is almost as good as in Australia and Canada, slightly better than in the USA (white, black, and other races combined), and much better than in Chile (see Zeng et al. 2008).

The systematic assessment of data quality of the CLHLS indicates that there was no substantial underreporting of deaths, and most variables or items in the questionnaire were in high quality. However, the causes of death of centenarians reported by next-of-kin might not be reliable, because nearly 60% of reported deaths had no information on causes of death (Zeng et al. 2008). This might be due to that significant portion of the centenarians did not go to the hospital to diagnose/treat the disease prior to death or they in fact died without specific disease.

In-Depth Study of Longevity Areas Including Adult Children of Centenarians

The CLHLS launched a subproject for an in-depth study in seven longevity areas where the density of centenarians is exceptionally high in 2009 as part of the 5th wave of the CLHLS, and in eight longevity areas (the previous seven plus a new one) in 2012 and 2014 as part of the 6th and 7th waves of the CLHLS, to investigate why some areas have a much higher proportion of healthy and long-lived individuals than other areas. The seven areas in 2009 were Chenmai County (Hainan Province), Yongfu County (Guangxi

Note: The number of centenarians at a follow-up wave includes those whose ages were in 90s or 80s in a previous wave of the CLHLS who are not presented in the table. For the number of sample distribution for other ages, please refer to Zeng (2012:138)

Province), Mayang County (Hunan Province), Zhongxiang City (Hubei province), Xiayi County (Henan Province), Sanshui City (Guangdong Province), and Laizhou City (Shandong Province). Rudong County (Jiangsu Province) was added since 2012. The criteria of section for longevity areas come from the Committee of the China's Longevity Areas associated with the Chinese Society of Gerontology, including high density of centenarians and nonagenarians, high life expectancy, and a series of within-area consistency checks including good health status and good environment quality, etc. One biological child of each centenarian interviewee in the

longevity areas was recruited since the 6th wave. The purpose of such design is to collect data on factors associated with longevity by comparing longevity transmission between families with and without centenarians. In addition to the regular home-interviews, the in-depth study on these longevity areas includes more sophisticated health exams and blood and urine sample collections for biomarker analysis.

In 2002, with support from the Taiwan Academy Sinica and Mainland China Social Sciences Academy, the CLHLS collected a sample of 4,478 adult children aged 35–65 of the elderly interviewees in eight provinces out of the 22 CLHLS

Note: The number of centenarians at death during two adjacent waves includes those whose ages were in 90s in a previous wave

sampled provinces: Guangdong, Jiangsu, Fujian, Zhejiang, Shandong, Shanghai, Beijing, and Guangxi (mostly eastern coastal provinces). Of 4,478 dyadic pairs of data, there are 440 pairs for centenarians and their adult children in these eight provinces. Unlike the dyadic pairs of dataset in the longevity areas which deals with familial transmission of longevity, this dyadic dataset focused on the family dynamics of adult children and their intergenerational transferring. One follow-up survey for these 4,478 adult children was conducted in the 2005 wave. Such a study design is rare and valuable, as these dyadic datasets are particularly useful for studying familial factors that are associated with healthy aging.

Deceased Centenarian Interviewees Between Surveys

One unique feature of the CLHLS is the relatively comprehensive information collection on the extent of disability and suffering before dying of each centenarian (also of each respondent of other age groups) who died between two adjacent waves. The information was retrospectively collected from the next-of-kin or the primary caregiver of those deceased centenarians as well as other died respondent. The information includes dates and causes of death, and health and healthcare conditions from the last interview to the time of death, such as chronic diseases, activities of daily living (ADLs), number of hospitalizations, whether the centenarian had been bedridden, and whether the subject had been able to obtain adequate medical treatment when

he/she was sick. Data on how many days before death the elder did not go outside and how many days before death the elder spent more time in bed than out of bed were collected as well. Information on socioeconomic and demographic characteristics, such as marital status, family structure, caregivers, financial situation, and living arrangement before death, as well as the caregiving costs within 1 month before the death were also collected.

Table 2 presents the number of the deceased centenarians between two adjacent waves from 1998 to 2014 in the CLHLS, which was 9,853 centenarians with 2,159 males and 7,694 females, for whom the data in the 2 years prior to death have been collected.

DNA Samples and Home-Based Health Examinations

The CLHLS collected DNA samples from 4,849 centenarians in addition to 5,190 nonagenarians, 5,274 octogenarians, 4,770 aged 65–79, and 4,609 aged 40–64. Health exams for a total of 2,035, 2,862, and 2,651 participants in the longevity areas were performed in 2008/09, 2011/12, and 2014, respectively, by local certified doctors and nurses who are affiliated with the China Center for Disease Control and Prevention (CDC) as contracted for this project. The medical personnel used standard instruments to check heart, lungs, breast, waist, lymph, limbs, and thyroid of the participants. They also wrote down impressions and symptoms of disorder if any, and furthermore enquired about the participants' family disease history and current medications.

In sum, the large population-based sample size, the focus on healthy longevity (rather than on a specific disease or disorder), the simultaneous consideration of various risk factors, and the use of analytical strategies based on demographic concepts make the CLHLS as an innovative project of demographic data collection and research (Zeng 2012).

Psychological Traits of Chinese Centenarians

Variables of Psychological Traits

In addition to the internationally standardized mini-mental status examination (MMSE) of cognitive function tests, the CLHLS contains seven variables relevant to psychological traits: (1) Do you look on the bright side of things? (being optimistic) (2) Do you keep things neat and clean? (3) Can you make your own decisions concerning your personal affairs? (self-determination) (4) Do you feel as happy as when you were young? (5) Do you feel fearful or anxious? (6) Do you feel lonely and isolated? (7) Do you feel useless? Each question above has six response options: always, often, sometimes, seldom, never, and unable to answer; proxy responses were not allowed. The first four questions reflect positive affect of psychological traits, while the latter three questions refer to the negative affect.

These questions are mainly derived from the Positive Affect and Negative Affect schedule (PANAS) scale and could also be considered a short version of a recently developed Scale of Positive and Negative Experience (SPANE). Both PANAS and SPANE scales mainly focus on the general adult population (see Diener and Biswas-Diener 2009). Different from the SPANE and PANAS scales, psychological traits questions in the CLHLS contain an option “unable to answer” for each question, which aims to accounting for the possibility that some oldest-olds may not be able to answer the question due to, for example, various health problems or difficulties in making up their minds. Based on the CLHLS data from the 1998 wave to the 2011/12

wave, this has been well justified by the fact that about 75% of the oldest-old respondents who were unable to answer these questions were due to health problems (this proportion was about 95% among centenarians who were unable to answer).

In order to better quantify the contribution of these psychological traits to exceptional longevity, these seven variables were dichotomized (coding 1 for answering “always” and 0 otherwise for positive affect called as “always positive affect”, whereas coding 1 for answering “never” and 0 otherwise for negative affect called as “never negative affect”) and then generated an index of always positive and never negative affect (abbreviated as APNNA) by summing these seven dummies, which ranges from 0 to 7. Because the wording of psychological traits questions in the 1998 wave is slightly different from that of the other waves and because the 2014 wave is not publicly available yet, in this section the focus of analyses of psychological trait of Chinese centenarians was on the waves from 2000 to 2011/12.

Positive and Negative Affect in Centenarians

Figure 2 shows that there was a clear decreasing trend with age in the score of the APNNA index. The overall mean scores of the index in centenarians were significantly lower than those in other age groups (Fig. 2). However, when demographics (age, urban–rural residence), socioeconomic status (education, primary lifetime occupation, economic independence), family and social support (marital status, coresidence with children), health practice (smoking, alcoholic intake, exercising), and health condition (ADLs, instrumental ADLs, cognitive function) were controlled, the pattern was reversed (results not shown). That is, centenarians had the highest mean scores of the APNNA, followed by nonagenarians and octogenarians, whereas the elders aged 65–79 had the lowest mean score. The difference between centenarians and older adults aged 65–79 was significant ($p < 0.01$) for males but not for females.

Table 3 reveals that with few exceptions (e.g., self-determination (column 3) and loneliness

Chinese Longitudinal Healthy Longevity Study, Fig. 3 Mean scores of the APNNA index by birth cohort, sex, and whether the respondents interviewed in 2000 who survived to age 100 (as indicated by yes for survival to age 100 and no for those who deceased before age 100) from

2000 to 2011/12. Note: (1) The score of the APNNA index ranges from 0 to 7, which includes four always positive affect variables and three never negative affect variables. (2) n, sample size. (3) Only the results from birth cohorts 1901–1904 were significant

Chinese Longitudinal Healthy Longevity Study, Table 4 Relative mortality hazards of the APNNA index of centenarians in comparison with other age groups, CLHLS 2000–2011/12

	Model I	Model II	Model III	Model IV
Ages 100+	0.95***	0.95***	0.96***	0.98**
Ages 90–99	0.92***	0.92***	0.93***	0.97***
Ages 80–89	0.89***	0.89***	0.90***	0.95***
Ages 65–79	0.84***	0.84***	0.85***	0.90***

Note: (1) Please refer to section “[Variables of Psychological Traits](#)” for definition of the APNNA index. (2) The results are almost identical for men and women across age groups and models and thus only results for both sexes are presented. (3) Model I controlled for demographic factors (single-year of age, sex, urban/rural residence, ethnicity, marital status, and coresidence with children). Model II further controlled for socioeconomic factors (education, primary lifetime occupation, and economic independence). Model III additionally controlled for health practice (smoking, alcoholic taking, and doing regular exercise). Model IV added baseline health condition (function in activities of daily living (ADL), cognitive function, and chronic disease conditions) in Model III. All variables in the models were considered as time-varying covariates whenever possible. (4) The sample sizes are 8,036 for centenarians, 10,872 for nonagenarians, 11,593 for octogenarians, and 10,490 for septuagenarians and sexagenarians. Those who were lost to follow-up were excluded from the analyses (with 5,281 females and 3,746 males). (5) * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$

(column 6)), the difference in percentage was not large for both male and female centenarians in comparison with their younger counterparts. Furthermore, Fig. 3 reveals that centenarians were likely more psychologically robust in terms of APNNA than their same cohort peers who died between ages 90 and 99. These results suggest that presence of positive affect and absence of negative affect among centenarians may have contributed to their exceptional longevity.

Psychological Traits and Healthy Longevity

Table 4 shows that each additional increase in the APNNA index (or each additional positive possession out of the seven psychological traits) among centenarians reduced mortality risk by 4–5% (Model I to Model III). Even after controlling for baseline health (function in activities of daily living, cognitive function, and chronic conditions), such a protective effect of psychological traits was still significant, although the effective

(1) Please refer to section “Variables of Psychological Traits” for the definition of the APNNA index. (2) Model I controlled for demographic factors (single-year of age, sex, urban/rural residence, ethnicity, marital status, and coresidence with children). Model II further controlled for socioeconomic factors (education, primary lifetime occupation, and economic independence). Model III additionally controlled for health practice (smoking, alcoholic taking, and doing regular exercise). All variables in the models were considered as time-varying whenever possible. (3) For onset of disability in activities of daily living (ADL) models, only those who were ADL not disabled were at a given wave were included. The sizes of the female sample are 1,327 for centenarians, 2,714 for nonagenarians, 4,387 for octogenarians, and 4,872 for septuagenarians and sexagenarians model, whereas the sizes of the male sample are 352 for centenarians, 2,065 for nonagenarians, 4,351 for octogenarians, and 5,144 for septuagenarians and sexagenarians. For onset of cognitive impairment models, only those who were cognitively unimpaired were included in a given wave. The size of the female sample are 951 for centenarians, 1,986 for nonagenarians, 3,464 for octogenarians, and 3,411 for septuagenarians and sexagenarians model, whereas the sizes of the male sample are 301 for centenarians, 1,587 for nonagenarians, 3,431 for octogenarians, and 3,552 for septuagenarians and sexagenarians. The cognitive impairment is measured by mini-mental status examination with the cut-off point at a score of 18. In all models of the both panels, those who were lost to follow-up were excluded from the analyses. (4) *p < 0.05, **p < 0.01, ***p < 0.001

size was reduced to 2% (Model IV). The protective effect of psychological traits on mortality was larger in other ages: the younger the age group, the greater the protective effect of psychological traits. The results further reveal (not shown) that the protective effect of psychological traits on mortality were the same for both males and females and for both centenarians and other age groups.

The left panel in Table 5 further reveals that each additional increase in the APNNA index among female centenarians reduced the odds of onset of ADL disability by 6%. Such a reduction was similar to those in female nonagenarians and octogenarians and persists even after controlling for a rich set of covariates.

However, such a reduction was not significant in male centenarians, possibly due to the smaller sample size. The reduction in other, younger age groups of males was significant and mostly larger than in the corresponding age groups of females. The right panel of Table 5 shows that the reduction in onset of cognitive impairment due to one additional point of the APNNA index was about 11% in female centenarians and did not change in presence of covariates. Females in other age groups had a similar pattern. In contrast, for male centenarians, such a reduction was slightly larger than in female centenarians and other age groups of males, although the significance was weakened when covariates were added.

Concluding Remarks

Using data from more than 10,000 centenarians of mainland China, the largest centenarian sample in the contemporary world, this entry presents a summarized introduction of the CLHLS and a brief description on psychological traits of centenarians in comparison with other older adults. We find that centenarians were more psychologically robust than noncentenarian peers of the same birth cohorts when they were all in ages of 90s and further report a significant association between possession of positive psychological traits and mortality and health worsening in centenarians. These findings suggest that centenarians are better able to handle stress, depression, or other unfavorable condition than their cohort peers, which is in line with many other centenarian studies and that maintaining a good psychological well-being is an important pathway to reach age 100 (e.g., Gondo et al. 2006; Jopp and Rott 2006; Perls 2006; Poon et al. 2010).

The findings of the present study are also similar to one recent study by Zeng and Shen (2010) that applied a concept of psychological resilience to Chinese centenarians based on questions (1), (3), (5), (6), and (7) in section “[Variables of Psychological Traits](#)” and two other variables in the CLHLS (to whom the respondent usually talks most frequently in daily life? and who does the respondent ask first for help when having problems/difficulties?). That study reports that centenarians are more psychologically resilient than elders of young ages and that psychological resilience positively contributes to exceptional longevity. Indeed, when further accounting for the response option “unable to answer” for these questions, one recent study found that there are still about 6–9% of centenarians whose psychological well-being is as good as those elders aged 65–79 years (Gu and Feng 2016).

Recently, there is a call among scholars in studies of exceptional longevity, emphasizing the importance of both quantitative and qualitative methodologies, replication of mechanisms, interdisciplinary and systems perspectives, and generalizability of results (Poon and Cheung 2012). Among these new directions of the future studies in centenarians, scholars particularly concern about

instable results from small sample sizes (Willcox et al. 2006). Moreover, more studies are encouraged to examine the association between psychosocial traits and longevity, relative to biologically based studies (Poon and Perls 2007). This entry uses the large-sized sample of the CLHLS to investigate how psychological traits are associated with longevity and subsequent health condition, which echoes the new initiatives above and adds new evidence highlighting the importance of psychological factors to exceptional longevity.

However, due to space limit, details about the role of other psychosocial factors to longevity were not discussed, although many of them were already included in the models as covariates. The interactions between psychological traits, environmental factors, and genetics in determining longevity were also not investigated. As Poon and Cheung (2012) pointed out, to eventually unearth the secrets of longevity, there is still much unexplored on what, how, and why some individuals survive to age 100 with good health. By the end of 2015, only a very small portion of studies focuses on centenarians out of 450 peer-reviewed publications in English, Chinese, and 76 Ph.D. and M.A. theses/dissertations that used the CLHLS data since 1998.

One limitation of the present study in analyzing centenarians’ psychological traits and its association between subsequent survival is the way of coding of those who were not able to answer the psychological trait questions. In the case of always positive affect, they were classified into the group of those who did not always experience positive affect. In the case of never negative affect, they were classified into the group of those who never experienced negative affect. Such a coding system may somewhat underestimate the psychological traits in centenarians. As a consequence, the association between good psychological traits and subsequent survival among the centenarians may be somewhat biased. Nevertheless, as the majority of these respondents were in a very poor health condition, such biases would be only mild. Some researchers adopted an alternative approach by excluding those who were unable to answer the questions in the analyses (e.g., Zeng and Shen 2010). However, since

those who were not able to answer the questions were not missing at complete random, the exclusion approach may overestimate centenarians' good psychological traits to some extent. More research on this issue is clearly warranted.

In sum, more studies on centenarians are warranted in this field, and the CLHLS has been becoming an important resource for scholars in this field with a large and representative sample size of respondents at extremely old ages in a longitudinal context plus the voluminous psychosocial and biological data.

Acknowledgments Yi Zeng's work is supported by NIA grant (R01 AG023627), National Natural Science Foundation of China (71110107025, 71233001, 71490732), and National Key Basic Research Program of China (2013CB530700). We thank Dr. Huashuai Chen for his assistance in calculating the sample distribution of the 2014 wave.

Clinical Issues in Working with Older Adults

Definition

“Clinical issues” are the aspects that should be taken into consideration when performing clinical interventions with older adults. The term “clinical” is here used primarily for those professionals who work in behavioral health (i.e., nonsurgical, nonmedication), both at an assessments and intervention level, with older individuals.

Background

Don't tell us, show us (Moreno's Psychodrama Dictum)

The importance of giving attention to clinical issues in working with older adults has been well

emphasized in the last years in emblematic articles (Knight 2004) and in psychological association professional practice guidelines. A representative example is the *Guidelines for Psychological Practice With Older Adults* originally developed by the Division 12, Section II (Society of Clinical Geropsychology) and Division 20 (Adult Development and Aging) Interdivisional Task Force on Practice in Clinical Geropsychology and approved as an American Psychological Association (APA) policy in August 2003. Their main aim is to assist psychologists and gerontology practitioners in evaluating their own readiness for working with older adults, and in seeking and using appropriate education, training, and supervision to increase their knowledge, skills, and experience thought to be relevant for this domain of practice. The specific goals of these professional practice guidelines are to provide practitioners with (a) a frame of reference for engaging in clinical work with older adults and (b) basic information and further references in the areas of attitudes, general aspects of aging, clinical issues, assessment, intervention, consultation, professional issues, and continuing education and training relative to work with this age-group.

The APA Guidelines for Psychological Practice With Older Adults are organized into six sections; the third concerns “Clinical Issues” and comprises three specific guidelines: The first is Guideline 7, which states that “Psychologists strive to be familiar with current knowledge about cognitive changes in older adults.” According to this guideline, from a clinical perspective, one of the greatest challenges facing practitioners who work with older people is acknowledging when to attribute subtle observed cognitive changes to an underlying neurodegenerative condition versus normal developmental changes. Multiple moderating and mediating factors, like lifestyle, contribute to age-associated cognitive changes, maintenance, or decline within and across individuals.

Guideline 8 states that “Psychologists strive to understand the functional capacity of older adults in the social and physical environment.” Here it is strained that the majority of older adults maintain high levels of functioning, suggesting that factors

related to health, lifestyle, and the match between functional abilities and environmental demands more powerfully determine performance than does age (Baltes and Smith 2008). The degree to which the older individual retains “everyday competence” (i.e., the ability to function independently vs. rely on others for basic self-care) determines the need for support in the living environment. In adding aids in the older adult’s living environment, it is important to balance with the person’s need for autonomy and active and safe quality of life. Changes that have impact in functional capacity may immediately lead to modifications in social roles and may place emotional strain in the individual and informal carers. Older people must deal not only with the personal implications of these losses but also with the challenges of finding meaning in a more limited lifestyle. For some older adults, spirituality and other belief systems may be particularly important in dealing with these losses (Ribeiro and Araújo 2013).

Guideline 9 states that “Psychologists strive to be knowledgeable about psychopathology within the aging population and savvy of the prevalence and nature of that psychopathology when providing services to older adults.” This last guideline stresses that although the majority of older adults have good mental health, it should be taken in consideration that approximately 20–22% of older adults may meet criteria for some form of mental disorder, including dementia. For those living in a long-term care setting during their later years, estimates are much higher, with almost 80% suffering from some form of mental disorder. Older adults may therefore present a broad array of psychological issues for clinical attention. These issues include the majority of the problems that affect younger adults and those experienced due to late life events and tasks. These represent challenges that are specific to late life and include developmental and maturational issues and social demands. As examples of developmental issues we can mention the decrease of sensory acuity and increased likelihood of losing significant people and, as a social demand, retirement.

Knight and Poon (2008) proposed CALTAP (Adult Lifespan Contextual Theory for Adapting Psychotherapy) with the aim of providing a

metatheoretical framework to guide an integrated psychotherapeutic approach with the elderly. In this theory the author advocates that an intervention with older people should take into consideration the positive (i.e., cognitive and emotional complexity) and negative (i.e., physical decline) factors of the maturation process of the client, as well as specific sociocultural environments (i.e., values and beliefs), the surrounding context (i.e., living in an institution vs. community), the cohort effect (i.e., influences like education that affect the members of a particular generation), and the challenges of old age (i.e., chronic disease). Together, these contextual and individual factors contribute and influence the problem presented by the older client and his/her expectations and degree of involvement in psychotherapy, as well as to the options of intervention appropriate to a particular case. It is therefore crucial to recognize the intricate interaction between the older adult and his/her environment.

Therapeutic Relationship with Older Clients

To rightly respond to functional, personal, social, cognitive, and psychopathological challenges of older clients it is indispensable to establish a meaningful therapeutic relationship. For the therapeutic process with older adults to successfully unwind theoretical and technical expertise are also necessary. However, independently on the orientation of the intervention, the therapist must have the ability to establish a deep connection with the client – the therapeutic relationship (Fagan and Shepherd 1970; Duffy 1999; Haley 1999; Zarit and Knight 1996). Regardless of the elderly intervention context, the communication skills of the therapist are one essential ingredient to the success of the intervention (Woolhead et al. 2006). Listening and responding accordingly is always important, requiring more attention when the older person has hearing difficulties. Speaking in a simple, direct, clear, and objective way, taking into account the nonverbal communication and without using technical language, is essential. It is also important to be present in the relationship,

“not paddling against the current,” with the therapist open to the flow of experience, recognizing their limits as professionals and with attention to their own prejudices.

Accordingly, geropsychologists must work to actively reduce ageism. Ageism as a pervasive discrimination against older adults is widespread. The nondominant group (older adults in this case) is viewed as homogeneous and portrayed as having a variety of negative characteristics. People in old age are viewed stereotypically as alike; alone and lonely; sick, frail, and dependent; depressed; rigid; and unable to cope (Frazer et al. 2011). This pervasive view portrays all older adults in a negative light, ignoring the incredible heterogeneity of aging and old age and the strengths and positive attributes of older adults. Those geropsychologists working in clinical settings must be particularly cognizant of their own ageist thoughts and beliefs, and acknowledge its impact and try to prevent and minimize them within the therapeutic relationship. Rogers (1951) formulated this issue in a fundamental way: Can the therapist meet with this other individual as a person in the process “of being,” or will he stay tied to his own past or the client’s past? If the therapist relates to the older client as old, rigid, limited, immature, ignorant, unstable, or sick, each of these concepts will limit the relationship. Confirm means accepting the potential totality of the other. If the therapist accepts the other as something fixed, as “diagnosed and classified,” as shaped by the past, he will be doing his part to confirm this restrictive hypothesis. On the other hand, if he accepts the client as in process of “becoming,” he will be doing what he can to confirm or make real the potential of the individual.

Instead of giving unconditional positive regard, most of us give “value conditions,” depending on the satisfaction of our needs and expectations. When we care and we have no qualifications or conditions, there is the “unconditional positive regard.” Rogers (1951) argued that this quality of absoluteness, along with congruence and empathy, would be essential to foster a more confident human being capable of enjoying life more fully. It is then the therapists’ responsibility to create these favorable conditions

for the flourishing of the older client. In this sense, the quality of the relationship has a major weight (though, certainly, other variables such as the therapeutic setting, client motivation, theoretical soundness, and the training and experience of the therapist are also important). By “quality of the relationship” it is meant the ability to establish good contact, i.e., the ability to listen to the other (literal and latent meanings), to produce a real action that can enhance change in the other, and to detect central aspects that can be worked through with the client with the aim of fostering well-being. The therapist’s attitude is based on empathy, willingness to help, and mostly on accepting the patient’s experience without judgment.

Fagan and Shepherd (1970) in a classic text on Gestalt Therapy refer to five aspects that the therapist should take into account for the clinical relationship to be effective: (1) accurate assessment and diagnosis; (2) having control of the therapeutic session (i.e., it is the therapist who wields the session for the client’s benefit); (3) solid theoretical and practical knowledge; (4) humanity and compassion toward the client; and (5) commitment and openness to continue learning. To make a therapeutic intervention involves the therapist as a whole person and constitutes therefore a challenge. Nevertheless, it is a condition for fostering the well-being of the client and will enable the older client to build self-support skills and a more realistic and adaptive view of life.

Working with Older Adults

The therapist working with older adults should be able to work “outside the box,” i.e., be more flexible concerning place, duration, and frequency of sessions and to have the ability to take on multiple roles (Haley 1999) in order to respond to customers that often have multiple physical and psychosocial problems and diverse and complex needs. Before starting a clinical intervention, the geropsychologist should pay attention to the entire therapeutic setting – i.e., all the details concerning the environment, the physical layout

of the room, and the prevention of possible interruptions (Frazer et al. 2011). If these aspects are attained and an environment where there is trust, openness, and acceptance is provided, patients will express themselves without fear of censorship and engage actively in the therapeutic process. This is why it is important to identify resistances, make them explicit, and not pretend they do not exist. The resistance decreases when people take responsibility for how the interaction functions (Egan 1986).

Depending on the case and on the theoretical framework of the therapist during the therapeutic process several techniques (e.g., challenging, clarification, breathing and body awareness techniques) may be used to explore the material provided in favor of the natural course of the session and, therefore, consolidate and increase awareness and individual power and responsibility, even when the older client is very frail and this seems nearly impossible. Techniques are means not ends and should not divert the therapist from the creative and unique relationship with the older client and from the attention required to the emerging themes and needs in a session. In this sense, there are no “recipes” that the therapist should follow but tools and flexible guidelines that can be used. Moreover, the use of techniques can often mask the quality of a relationship.

Change, support, and problem solving are not made only on the basis of technical aids but come mainly from the relationship between the therapist and the patient. It is the quality of the relationship that will dictate (adduced to the sensitivity of the therapist) the time to use certain techniques (e.g., role play). Accordingly, the personal qualities and advocated values of the therapist are the most important and powerful tools regarding the ease of the therapeutic process. In this sense, the therapist should trust in his/her intuition and be authentic, since the techniques are received in the light of the attitudes of the facilitators that employ them (Egan 1986; Corey et al. 1983; Corey 1990). In short, the techniques are valuable and important but should be used with caution (Yalom 2005; Corey et al. 1983). If the therapist has a solid background and supervised experience, it is less likely to abusively use the

techniques (Corey et al. 1983). Those therapists working with older people also benefit in being more flexible in their roles (i.e., feeding the patient, helping to call for other people, fostering other relationships) and more active and participatory (i.e., speak about themselves, give examples) (Knight 2004).

The conceptual framework and the therapist's personality often dictate the choice of which technique to use, but this is also influenced by the link established with the client. There is always a huge variability of possibilities (i.e., the use of animals for people with dementia (Crowley-Robinson et al. 1996)), depending on age, purpose, and level of functioning of the patient but also on the expertise and creativity of the therapist. However, the therapist should recurrently question the appropriateness of a certain technique. When it is possible and meaningful, it is important to ask the client their willingness to participate and to acknowledge any possible resistance. The clinical/therapeutic setting is a field for authentic human interaction and learning. In this sense, the techniques should not be seen as tricks but tools to be used in support of patient needs.

The therapist's countertransference analysis (“how I feel with what the client said/did? What does it mean to me?”) is crucial in a relationship that is often regulated by unusual changes on the therapeutic context. For instance, in many intervention cases the older client is bedridden (Altschuler and Katz 1999; Smith 2006). However, the transference and countertransference, which depend on the previous relationships of the client and of the therapist, may lead to therapeutic impasse and resistance to treatment (Knight 2004). Taboos (e.g., certain themes should not be spoken with older or younger people) and the complexity of the institutional contexts (e.g., the clinician can have different roles in the same institution; different professionals dealing with the client make clinical decisions more complex) can make the management of this dynamic an enormous challenge. In this sense, the therapist has the responsibility to examine personal prejudices in relation to age, disease and gender, and any beliefs or conflicts with their own parents and grandparents that he may bring as relational

patterns to the therapeutic relation. If this does not happen, the therapist may be limiting the possibilities of helping clients to develop. In general, the therapist is blocked where he/she often has difficulties as a person (Perls 1976).

When clients are considered experts in their own lives, they feel mobilized and encouraged to use their resources toward their goals (Smith 2006) and to be active and interventional agents in their own change process (Smith 2006). This perspective about patients as being a repository of resources, rather than being seen as a confluence of problems, favors the therapeutic alliance. To promote the quality of life of the elderly – in face of the complex amount of problems, difficulties, diversity of personality profiles, and the multiple needs and desires people often have to deal with in the last phase of their life cycle – the availability of a wide range of therapeutic possibilities is crucial. Numerous psychological therapies have been demonstrating their effectiveness in supporting older people. Attention to issues concerning education, training, and supervision are therefore core aspects in providing all the technical capacity to the therapist and in helping to understand each person within a biopsychosocial framework. It is also important to acknowledge that all geriatric care occurs within a team context (see the “► [Interprofessional Care](#)” entry for this purpose) and that integrated care is the preferable model. Clinical geropsychologists should additionally know how to use multiple methods of assessment, including brief assessment tools.

The focus on the relationship, the “meeting” that the encounter between two persons (therapist and client/group) allows, updates some of the principles that have been repeatedly confirmed by research and due to the vicissitudes of the context or of daily life therapists tend to forget. Such principles allow human flourishing and can be summarized in the importance of humanization of health services and interventions, the imperative need of adequate training and supervision in interventions with older patients, the importance of empowering and giving personal responsibility to the individual, and the crucial role of both creativity and dignity interventions. The answer to the wish to grow in all stages and contexts of

life can be the authentic creative encounter that the therapeutic relationship enables and therefore should be promoted.

Definition

This entry reviews the literature on the prevalence of dementia among centenarians, the cognitive function in centenarians without dementia, as well as risks and protective factors of cognitive function in very late life. Dementia prevalence among centenarians might be substantially higher than that among younger older individuals; however, the exact prevalence rate among centenarians is unclear. First, we examine the methodological problems to be considered in future studies. Large representative data sets and similar protocols across studies are needed to clarify the inconsistent results. Second, we discuss the characteristics of domain-specific cognitive functions

in centenarians without dementia. In the future, an important goal is to further clarify the nature of cognitive changes among centenarians. Finally, we summarize risks and protective factors that might influence cognitive decline or dementia in centenarians. Findings from genetic, biomedical, and psychosocial perspectives can help clarify the mechanism of cognitive aging throughout the life span.

Taking into account the changing demographic structure in aging societies, the proportion of individuals aged 75 years and over is expected to increase substantially. As a consequence, the number of individuals presenting cognitive decline with and without dementia is also expected to increase. The World Health Organization and Alzheimer's Disease International (2012) reported an overview of the epidemiology of dementia and policy and plans in the world. It is estimated that the number of people aged 60 years and over with dementia worldwide doubles every 20 years, from 35.6 million in 2010 to 65.7 million in 2030 and 115.4 million in 2050 (World Health Organization and Alzheimer's Disease 2012). Thus, coping with dementia is a common challenge in aging societies. Dementia has received attention as one of the key health threats and social issues in the twenty-first century.

One of the major predictors of dementia is age. The age-specific prevalence of dementia nearly doubles every 5 years from 60 to 95 years old (Hofman et al. 1991). The Leiden 85+ study (Heeren et al. 1991) found that the prevalence of dementia was 15.2% in the 85–89-year-old age group, 32.5% in the 90–94-year-old age group, and 41.2% in the ≥95-year-old age group. Although the total number in the ≥95-year-old age group in the study was only 14, these findings suggested that the probability of a dementia diagnosis seriously increases in very old age.

In this entry, we focus on two topics relating to cognitive function among centenarians. Centenarian studies could provide information on the characteristics and degree of aging-related cognitive changes until the final stage of human life. At first, we will give an overview of dementia prevalence in centenarians; however, the exact

prevalence rate among centenarians is unclear. We will also state the methodological problems to be considered in future studies. Second, we will present the characteristics of domain-specific cognitive functions in centenarians, although there are few existing studies on this. Finally, we will summarize significant risk and protective factors that might influence cognitive decline or dementia in centenarians from genetic, biomedical, and psychosocial perspectives.

Prevalence of Dementia

Dementia prevalence among centenarians has been reported over the past 20 years in various countries. Three review papers on centenarians' dementia prevalence have been published (Calvert et al. 2006; Gondo and Poon 2007; Slavin et al. 2013). All three papers pointed out that dementia prevalence varies across studies, due to methodological problems. Based on the estimation of the age-specific prevalence of dementia (Hofman et al. 1991), prevalence among centenarians is assumed to range between 60% and 70%. Following reports of prevalence in previous reviews, we can roughly divide these findings into the following three categories: considerably lower than the estimated prevalence (e.g., less than 50%), almost within the estimated range (e.g., around 60%), and much higher than the estimated prevalence (e.g., more than 70%). Table 1 gives a detailed overview of 11 centenarian studies reporting on dementia prevalence. These studies showed that the dementia prevalence ranged from 33% to 100%, and the average prevalence was 62% (males; 48.5%, females; 66.1%). The study that presented the highest prevalence, the Dutch Centenarian Study (Blansjaar et al. 2000), included only 17 centenarians. On the other hand, the study with the lowest prevalence, the Finnish Centenarian Study (Sobel et al. 1995), excluded mild dementia. Except for one study, the Yamanashi prefecture study (Asada et al. 1996) showed only slightly more than 70%, and the other prevalence ranged from 50.7% to 67.6%. These results suggested that dementia prevalence

among centenarians was very high, but there were dissociations in the prevalence across studies.

The varying prevalence of dementia across studies might indicate ethnic or cultural influences on the progression of dementia with aging. However, before we go on to discuss this issue, two essential problems need to be pointed out. One is related to methodology, and the other is gender differences. The methodological problems include sampling, definition of dementia, and assessment procedures in centenarian studies. Gender differences refer to the issue that the dementia prevalence in centenarian samples varies depending on the ratio of female and male centenarians.

A small sample size can lead to an overestimation or underestimation of results and yield inconsistent dementia prevalence among centenarians. Previous centenarian studies include sample size ranging from 17 to 304 (Table 1). Furthermore, there are often wide individual variations and possibilities of large amounts of missing data in cognitive tests on centenarians. A total number exceeding hundreds of participants might therefore be required for reliable statistical analyses and valid estimations (Calvert et al. 2006). In addition, researchers have to make an effort to obtain representative data and to carefully interpret results having a potential selection bias.

The definition of dementia is one of the fundamental problems in the comparison of results from different studies. Most studies have used standardized diagnosis criteria for dementia. However, these criteria emphasize different dimensions considered for evaluation, to enable identification of dementia. The third edition revised and fourth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-III-R, DSM-IV) have often been used for the diagnosis of dementia. Pioggiosi et al. (2004) explored the variation in dementia prevalence among 34 nonagenarians and centenarians using four common diagnostic criteria. They found different prevalence rates applying these criteria to the same participants. The prevalence of dementia was 47.1% with the use of the DSM-III-R; 41.2% with the DSM-IV; 29.4% with the World Health Organization's International Classification of Disease, 10th revision (ICD-10); and

38.2% with the Cambridge Examination for Mental Disorders of the Elderly (CAMDEX). The ICD-10 criteria for dementia yielded the lowest rate of dementia among the four criteria. This dissociation appears to be due to requirements for evaluation. The ICD-10 criteria always required impairments in three executive functions. On the other hand, the DSM-III-R criteria, leading to the highest rate, required at least one or more impairments in abstract thinking or judgment or impairment of higher cortical functions or personality changes. The DSM-III-R is less restrictive than the DSM-IV in assessing cognitive function except for memory. Consequently, the DSM-IV criteria, including impairments in executive function or condition of having central nerve damage, such as aphasia, lead to the second highest rate. The CAMDEX, with the second lowest rate, has different characteristics in requirements of progressive deterioration for the diagnosis and of impairments in behavioral and emotional functions. This is why the proportion of dementia by the ICD-10 seems to be lowest among these criteria. As mentioned in a later section, centenarians tend to show large dissociations in the decline of different cognitive domains. This characteristic might increase the chances of variations occurring as a result of the use of different definitions.

Differences in exclusion criteria of cases with questionable dementia were also observed. Some studies, for example, excluded in their reports cases where the criteria to identify dementia were not sufficient and the diagnosis was uncertain. In the Longitudinal Study of Danish Centenarians (Andersen-Ranberg et al. 2001), a comprehensive survey was conducted on all individuals living in Denmark who were aged exactly 100 during the survey period. One-hundred sixty-two out of 222 women and 45 out of 54 men participated in this study. According to the criteria of ICD-10 and the Clinical Dementia Rating scale (CDR), the identified prevalence rate of dementia, including mild, moderate, and severe dementia, was 51% in 100-year-old individuals. They excluded cases with the probably no dementia cases and the questionable cases. If they had treated these cases as the category with dementia, the prevalence would have increased. Some studies have also considered individuals with visual or

hearing disabilities as questionable cases. These sensory impairments are very common in very old age and are likely to hinder the understanding or following of instructions of the cognitive tests, which may result in overestimating the cognitive issues in centenarians. Thus, dementia prevalence is influenced by how researchers define and use these questionable cases in their studies (e.g., considering them as part of the dementia group will lead to an increase of the prevalence, while treating them as a part of the group without dementia will decrease the prevalence).

Gender differences can also result in varying prevalence. The Northern Italian Centenarian Study (Ravaglia et al. 1999) reported different prevalence rates, depending on gender and severity of dementia. Their reports on dementia prevalence were based on the DSM-IV criterion and included questionable cases. At 69.6% (N = 39/56), dementia prevalence among women was higher than that among men, at 50.0% (N = 18/36). However, there was no significant difference in prevalence rate and severity of dementia between female and male centenarians, likely due to the small case number in each subgroup. Using a larger sample of 304 individuals, the Tokyo Centenarian Study (Gondo et al. 2006) reported different prevalence rates for dementia according to gender. In this sample, the ratio of women to men was roughly 1:3.6, which was almost similar to the total centenarian population in this research area. They showed that the dementia prevalence was 61.8% (188/304) of the total, 67.4% (161/239) among women, and 41.5% (27/65) among men, based on a CDR score with the range of 1–5 to determine dementia. The findings showed clear differences in prevalence between female and male centenarians. The higher the percentage of female centenarian sample, the higher the dementia prevalence in the overall sample. Thus, gender-specific data should be reported to interpret results while taking into account the gender ratio.

Currently, the direct comparison of dementia prevalence across centenarian studies is problematic due to the issue mentioned above. For precise comparisons, researchers should collect data from larger representative samples, with uniform

procedures and definitions of dementia. Adopting this kind of careful assessment procedures would reduce errors in identification of dementia among centenarians. Otherwise, discussion of cohort, regional, and cultural differences in dementia prevalence among centenarians is likely to lead to questionable conclusions.

Cognitive Function in Non-demented Centenarians

As described above, there is a very high prevalence of dementia among centenarians. Most centenarian studies have assessed cognitive function, using dementia screening tests such as the Mini-Mental State Examination (MMSE), CDR, or the Global Deterioration Scale (GDS). The mean of MMSE scores among 244 individuals aged 98–108 years old was 16.2 ± 8.80 (SD) (Dai et al. 2013), indicating that mean cognitive function in non-demented centenarians was much lower than that among younger older individuals. Considering 68 centenarians who had a CDR score of 0, the mean of MMSE was 22.3 ± 3.32 (Inagaki et al. 2009). These findings showed global cognitive function in centenarians to be equal to or only slightly lower than the established clinical cutoffs in younger older individuals. At the same time, large individual differences were reported among non-demented centenarians.

To date, no study has reported trajectory of domain-specific cognitive aging from younger older individuals to centenarians. Descriptions of domain-specific conditions in centenarians can contribute toward an understanding of normal, aging-related cognitive change and stability in very old people. Few studies mentioned this issue. The Georgia Centenarian Study provided norm data of domain-specific abilities in verbal abstract reasoning, fluency, and memory (Mitchell et al. 2013). They reported that centenarians obtained cognitive performance averages that were lower than those of octogenarians. Moreover, age differences in verbal abstract reasoning, fluency, and recognition were smaller than those in immediate and delayed recall. Using data from the Tokyo Centenarian Study, Inagaki

et al. (2009) compared the scores of centenarians and younger controls on five cognitive domains, as measured by the MMSE. They reported that concentration, language and praxis (i.e., reading and obeying, listening and obeying, writing a sentence, copying pentagons, and naming), and repetition among centenarians were not lower, compared to those of individuals in the younger age groups. Both studies showed small age differences in the domain relating to language, but large age differences in episodic memory. These findings might indicate that a fundamental characteristic of intellectual aging, namely, a smaller decline in the pragmatic domains and a larger decline in the mechanic domains are well-known phenomena, was still preserved among centenarians.

The Georgia Centenarian Study examined the role of intelligence, memory performance, and problem-solving ability in cohorts aged from 60 to 80 and to 100 years old (Poon et al. 1992). The study showed that centenarians had maintained their everyday problem-solving abilities, measured by the nine real-life problems encountered at home on an everyday basis. Furthermore, the study also showed that problem-solving abilities had an effect on mental health as well as personality and coping. Moreover, centenarians with high cognitive function obtained high levels of activity of daily living. These findings suggested that the maintenance of the mechanic domains of cognitive function might be possible in centenarians and that it might enable them to manage and cope with old-age adversity.

Risk for Cognitive Decline and Dementia in Centenarians

Recently, the risk factors for dementia and cognitive decline among individuals in very old age have received increasing attention. The disclosure of risk factors might contribute toward the development of strategies for a healthy long life. To date, few centenarian studies have addressed this issue. Interestingly, limited findings suggest that centenarians and younger older people may not

have the same risk factors. Complex and mutual relationships among risk factors for cognitive decline and dementia are still not clear, even for the younger older adults. Findings from centenarian studies might help clarify these conundrums. We will describe this issue by focusing on brain aging in centenarians from genetic, biomedical, and behavioral viewpoints.

Genetic Factor

The apolipoprotein E (*APOE*) gene, recognized for its important roles of transporting and delivering lipids, is one of the most commonly investigated gene polymorphisms. Among three common alleles, including $\epsilon 2$, $\epsilon 3$, and $\epsilon 4$, the $\epsilon 4$ allele might facilitate ineffective repair and protection from neuronal damage. The presence of the $\epsilon 4$ allele has been identified as a major risk factor for the development of AD in younger older adults (Ashford and Mortimer 2002). However, whether the *APOE* $\epsilon 4$ has an effect on cognitive function among individuals in very old age is still controversial. While there was a significant negative association between the $\epsilon 4$ allele and cognitive function among 103 Korean centenarians (Choi et al. 2003), this association was not observed in 179 Finnish (Sobel et al. 1995) and 33 Japanese centenarians (Asada et al. 1996). Compared to younger older people, centenarians tend not to have the $\epsilon 4$ allele. Thus, the survival effect for individuals with the *APOE* $\epsilon 4$ might hamper the evaluation of the effect of the *APOE* on cognitive function in centenarians.

Cardiovascular Factors

Hypertension, a cardiovascular disease, is a significant risk factor for cognitive impairment. However, some centenarian studies have shown higher blood pressure (BP) to be associated with better cognitive performance and survival. Richmond et al. (2011) showed that systolic BP (SBP) positively correlated with the MMSE score

in centenarians ($r = 0.37$, $p = 0.001$), also showing a pulse pressure (PP) range that was narrower in individuals with dementia, as compared to those without it. Moreover, Szewieczek et al. (2015) reported that centenarians with $SBP \geq 140$ mmHg and with diastolic BP (DBP) ≥ 90 mmHg had higher likelihood for a subsequent 180-day survival. The association between SBP and MMSE scores was expressed in an inverted-U-shaped curve, whereas that between DBP and MMSE scores was best in a liner curve. These results indicate an association between high BP and good cognitive function, depicting a contradictory relationship to that found among individuals in younger older age. Centenarians with moderately high BP might show better cognitive performance.

Nutrition Factors

As factors related to metabolic activities of the brain, we must focus attention on nutrition in old age. The Georgia Centenarian Study examined the role of diet for cognitive function in centenarians (Johnson et al. 2013). Significant relationships were observed between cognitive performance and dietary carotenoids, including serum lutein, zeaxanthin, and β -carotene in the serum and brain. However, these relationships differed from those observed in other studies for the younger older population.

Arai et al. (2015) showed that well-nourished centenarians who showed high serum albumin levels had significantly higher MMSE scores. In addition, the study found that high serum albumin levels and inflammation suppression were associated with low CRP and IL-6 levels among centenarians. Although the nutritional status in the blood serum shows a relationship with cognition, no study has shown a direct relationship between food intake and cognitive function among centenarians. They speculated that inflammatory reactions occurring along with aging might lead to a low nutritional status and low cognitive function in very old age. In the future, there is a

need for a comprehensive study focusing on the associations between food intake, nutrition level in the blood serum, and cognitive function among centenarians.

Psychosocial Factors

In addition to the factors mentioned above, recent gerontology studies have started considering psychosocial factors as pathways to maintenance of cognitive function in old age. Specifically, studies examined the effect of life antecedents, such as education, work, and leisure activities, on late-life cognition and the risk of dementia. Studies addressing the complexity of work engaged throughout their main lifetime reported that highly demanding work was associated with a low risk of cognitive impairment in younger older age. A review paper showed the positive effects of high control and work complexity on cognition in late life (Then et al. 2014). Moreover, many findings support the notion that physical activities, social engagements, and intellectual stimulation in leisure activities could promote cognitive function in old age (Hertzog et al. 2008). There is a need to examine whether complexity of work in midlife and engagement in leisure in old age could affect cognitive function among centenarians.

A prospective study is recommended for such research topics; however, it is not feasible in centenarian studies. In one centenarian study, centenarians and their proxies were interviewed, with their lifelong engagements in cognitive activities retrospectively evaluated (Kliegel et al. 2004a). The study demonstrated that higher education and the number of intellectual activities engaged in predicted higher cognitive function in centenarians. Moreover, the number of intellectual activities that adults engaged in mediated the association between childhood education and cognitive function in centenarians. A prior active lifestyle might be an important predictor of cognitive ability, even in centenarians. Further retrospective studies assessing the activities performed during their 80s and 90s, in order to link these to the cognitive

performance when reaching centenarian status, are necessary to enable a better understanding of healthy cognitive aging in very old age.

Summary and Future Directions

This entry has summarized findings on the prevalence of dementia among centenarians, the cognitive function levels in non-dementia centenarians, as well as risk and protective factors of cognitive function in very late life. Findings suggest that dementia prevalence among centenarians was substantially higher than that among younger older individuals and that women tended to have higher prevalence rates than men did. However, large differences in dementia prevalence rates across different studies have also been observed. A large representative database and similar protocols are needed to clarify the inconsistent results previously obtained. Furthermore, researchers should examine the influence of genetic, biomedical, and environmental factors on cognitive function and dementia among centenarians. As protective factors, nutrition in the serum and an active lifestyle across the lifespan might maintain cognitive function until very old age; however, few studies relating to this have been conducted. In addition to the abovementioned issues, the following topics will also be important in clarifying the nature of cognitive aging among centenarians.

Gene–Environment Interaction

More recently, the role of gene–environment interactions in older adults' cognitive function has gained interest. Wang et al. (2012) reported that higher education might modify the effect of the *APOE* $\epsilon 4$ on the risk of dementia among participants aged ≥ 65 years. In the study, among the $\epsilon 4$ allele carriers, if they had more than 7 years of education levels, the risk of dementia was reduced by half, compared to those with less than 8 years of education levels. Environmental factors must be controlled for, to enable

clarification of the effect of genetic factors on cognitive function even in very old age.

Neuropathology in the Brain and Cognition

Autopsy studies in very old age suggest that there is some level of dissociation between the neuropathological change of the brain and cognitive performance. The prevalence of neuropathology associated with AD ranged from about 20% to about 40% when individuals met at least several criteria for AD-related neuropathology (Price et al. 2009). The result suggests that some people in very old age might be in the pre-stage of AD, although they had not yet exhibited clinical expression.

The Sydney Centenarian Study was designed to relate cognitive function with neuropathological parameters assessed via magnetic resonance imaging in centenarians (Sachdev et al. 2013). Future findings might indicate the uniqueness of the relationship between neuropathology and cognitive function in very old age. Gondo and Poon (2007) proposed the following four phenotypes in centenarians, based on the level of cognitive function and pathological condition: supernormal (i.e., no symptoms of brain pathology and higher cognitive status), cognitive reserve, late-onset dementia, and early-onset dementia. Considering neurological and cognitive aspects simultaneously may provide a useful model of cognitive aging in very old age.

Micro-longitudinal Studies

Longitudinal assessment and neuropathological examination of the brain are recommended, in order to improve our understanding of centenarians' cognitive status. For instance, the Iowa Centenarian Study examined mental performance status and changes therein over time, using Pfeiffer's Short Portable Mental Status Questionnaire. The study examined the individual level of change and found four patterns of short-term longitudinal performance, including stability,

enhancement, decrement, and variability in scores across the 8-month testing period (Margrett et al. 2012). Examining intraindividual changes or patterns of cognitive changes would be recommended because it might prove more sensitive to cognitive impairments than would a one-shot assessment of cognitive performance.

Acknowledgments This study was funded through a grant from the Grant-in-Aid for Scientific Research (B) (No. 26310104), allocated by the Japan Society for the Promotion of Science, and one from the Human Science Project at Osaka University.

The Challenge of Demographic Change

A recent report from the World Health Organization on world population prospects forecasted an unprecedented demographic shift in human history: the number of people aged 65 or older will outnumber children under the age of 5 before 2020. In most developed countries, the average life expectancy at birth has increased from about 45 years in the 1800s to above 75 years in the twentieth century. This remarkable 30-year gain in physical health is, however, not necessarily accompanied by cognitive fitness and mental well-being into old age. Faced with the rapid growth of aging populations worldwide and an ever-expanding prevalence of dementia and other aging-related neuropathologies, understanding basic mechanisms of the still preserved cognitive and brain plasticity in old age in order to uphold and delay functional declines of the aging mind has become a key challenge for cognitive neuroscience, psychology, and gerontology in the 21st century.

As foreshadowed in the quote from Baltes et al. (2006) above, cognitive interventions and brain plasticity are closely interwoven. This brief review will first introduce theoretical concepts of plasticity that are pertinent for geropsychology, followed by a selected overview about cognitive plasticity in key domains of cognition, focusing specifically on episodic memory, working memory, and executive control. Using memory plasticity as an example, dopaminergic neuromodulation, the frontal–parietal circuitry, and neurogenesis involving the brain-derived neurotrophic factor (BDNF) will be highlighted as intermediate mechanisms that link brain and cognitive plasticity. In the last section, plasticity in populations with aging-related neuropathologies as well as potential noninvasive brain stimulations as additional intervention approaches beyond cognitive and physical fitness interventions will be reviewed.

Theoretical Propositions of Developmental Plasticity

The concept of plasticity has a long history in psychology and neuroscience. In his classical volume, *The Principles of Psychology*, William James (1980) considered neural mechanisms of the mind to be endowed with substantial potentials to be influenced by experiences and learning. Around the same time, Santiago Ramón y Cajal (1894) in neuroscience also contemplated about the possibilities of mental exercises as means for facilitating the connections between neural networks.

Among modern concepts of plasticity, in our view, the following propositions are particularly relevant from the perspectives of lifespan development and geropsychology. First is the concept of *developmental reserve capacity* in old age (Baltes 1987): notwithstanding declines in their neurocognitive resources, older adults still possess considerable latent reserve capacity, such that if suitable environmental supports or interventions could be provided, their performance could be maintained or even improved. This concept underlies much of the training and intervention research conducted over the past decades, which aims at maintaining or enhancing cognition in old age by cognitive and/or physical fitness training and lifestyle enrichments (see Hertzog et al. 2009 for a review). A second notion is that prolonged mismatches between task demands and supplies of neurocognitive resources can trigger alternations in cognitive and brain processes (Lövdén et al. 2010). Recognizing that the demand–supply balance is an important factor in driving plasticity implicates that programs or methods for enriching older adults' cognitive and physical experiences need to closely adjust the balance between task demands and individual abilities during the course of training for optimal intervention results. A third proposition is that flexible adaptations to declines in neurocognitive resources and increases in task demands can lead to reorganizations of cognitive processes (Li et al. 2004), and brain mechanisms (Park and Reuter-Lorenz 2009) that go beyond effects on the levels of performances or functions. Indeed, the

correlations among sub-facets of intellectual functioning (e.g., perceptual speed, reasoning, memory, and verbal knowledge) or basic cognitive processes (e.g., working memory and episodic memory) are higher in old age than in early adulthood, indicating dedifferentiation in the organization of cognitive processes in old age (Li et al. 2004). At the brain level, extant evidence also indicates that, relative to young adulthood, brain processes of various cognitive functions in old age tend to activate more diffused networks or recruit additional brain regions (see Park and Reuter-Lorenz 2009 for a review).

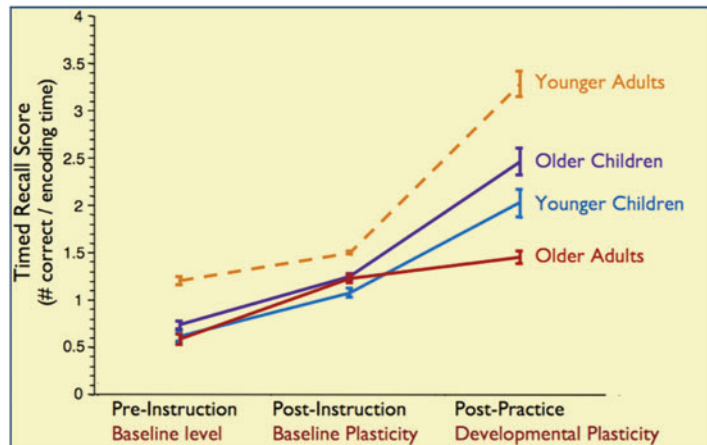

Cognitive Plasticity

Notwithstanding evidence for developmental reserve capacity in old age, cognitive intervention research over the past decades also revealed that the potential for training gains is more limited in old age relative to other periods of the lifespan. The degree of plasticity limitation, however, varies between cognitive domains. In terms of the extent of training gains in episodic memory, evidence from research that applied mnemonic strategies for training the encoding and retrieval of associative memory revealed substantially reduced plasticity in old age relative to younger adults and children (Brehmer et al. 2007; Shing et al. 2008). Specifically, the so-called baseline plasticity – i.e., the potential to benefit from being instructed with memory strategies (e.g., method of loci or paired associates) – was comparable between different age groups, whereas the plasticity in implementing those respective memory strategies through practice to strengthen associative memory was much more limited in older adults compared to younger adults and children (see Fig. 1; Brehmer et al. 2007). In contrast, the plasticity of working memory and executive control functions seem to be less age dependent. A recent meta-analysis (Karbach and Verhaeghen 2014) revealed comparable effect sizes (around 0.6) of training gains in these two domains of functions in younger and older adults.

Beyond training or practice gains, whether the training benefits would transfer to other untrained

Cognitive and Brain Plasticity in Old Age,

Fig. 1 Lifespan age differences in episodic memory plasticity (Data adapted from Brehmer et al. (2007) with permission; copyright American Psychological Association 2007)

tasks is an additional indicator that is of practical relevance when considering interventions for maintaining or improving older adults' daily cognitive competence. Results from a meta-analysis showed that in older adults transfer of training benefits at the level of specific tasks is usually in the range of moderate effect sizes (0.2–0.4) for working memory or episodic memory functions (Karch and Verhaeghen 2014). Relatedly, a unique extensive cognitive intervention study (Schmiedek et al. 2010, the COGITO study) compared transfer effects of an intensive training on multiple domains of cognitive functions (i.e., over 6 months of 1-h daily practice of perceptual speed, working memory, and episodic memory tests). Of note, in both younger and older adults, transfer effects were not only observed with respect to individual tests but also for cognitive abilities represented as latent factors. This indicates that training benefits can be observed at the level of cognitive abilities, instead of just at the level of specific tests. However, the transfer effects at the level of latent cognitive abilities were more limited in older than in younger adults.

Other than cognitive interventions, aerobic physical fitness trainings have been shown to yield transferrable benefits to cognition, beyond physical functions. Specifically, a recent review of physical intervention research over the last decades (Prakash et al. 2015) points to positive cross-domain transfer effects of enhancing aerobic physical fitness on executive control and memory functions in older adults. Similar to

cognitive intervention effects, the effects of physical fitness training on older adults' cognitive performance also differed between domains of functions, with executive control processes (e.g., working memory, inhibition, and multitasking) showing the largest training benefit (Colcombe and Kramer 2003; see Fig. 2).

Linking Levels of Memory Plasticity: From Brain to Cognitive Plasticity

This section focuses specifically on plasticity of working memory and episodic memory to highlight the multiple levels of mechanisms involved, from neurobiological to behavioral plasticity. A number of relevant neurochemical mechanisms have been identified. Specifically, neurotransmitters such as acetylcholine, norepinephrine, and dopamine are implicated in the modulation of long-term potentiation (LTP), which is an important molecular mechanism of memory (Squire and Kandel 1999). Given that dopamine and other neurotransmitters are involved in affecting synaptic plasticity, lifespan age differences in the efficacy of neuromodulation thus would have direct implications on experience-dependent tuning of synaptic connections. Over the past two decades, studies investigating the impact of aging on the brain's neurochemical processes have yielded the consensus of substantial age-related declines in the efficacy of various neurotransmitter systems. Of particular interest here are aging-related

Cognitive and Brain Plasticity in Old Age,

Fig. 2 Effect sizes of aerobic fitness training on cognitive performance in older adults for different types of cognitive tasks. Plotted are mean differences in pre- and post-training cognitive performances of the training and control groups (Data adapted from Colcombe and Kramer (2003) with permission; copyright American Psychological Society 2003)

declines in different components of the dopaminergic system. Estimates based on currently available cross-sectional evidence indicate about 10% decline in dopamine receptor functions per decade starting from the age of early 20s (see Bäckman et al. 2006; Li and Rieckmann 2014 for reviews).

Frontal–striatal dopamine signaling is closely involved in regulating working memory and executive control functions. In healthy young adults, better working memory performance has been associated with higher capacity of striatal and extrastriatal dopamine synthesis (see Li and Rieckmann 2014 for review). Regarding aging, a recent study (Rieckmann et al. 2011) showed that functional connectivity between the prefrontal and parietal cortices, key regions of the network that underlies working memory, was reduced in older compared to younger adults. Importantly, in older adults, interindividual differences in the frontal–parietal connectivity correlated positively with striatal caudate D1 receptor density: those older adults whose D1 receptor availability was higher relative to same-aged peers showed higher frontal–striatal functional connectivity during working memory. These results suggested that age-related losses in striatal DA receptors could contribute to age-related decline in functional brain dynamics of working memory.

Of particular interest, two recent positron emission tomography (PET) receptor imaging studies established the first empirical links between

memory training and changes in dopamine signaling in various brain regions that are crucial for working memory functions. In younger adults, working memory training over 5 weeks was associated with changes of dopamine D1 receptor binding potential in the prefrontal and parietal cortex (McNab et al. 2009) as well as D2 receptor binding in the striatum (Bäckman et al. 2011). Furthermore, individuals who showed larger performance improvements as a function of working memory training also exhibited a greater training-related change in receptor binding potential (McNab et al. 2009).

The direct effect of aging-related decline in dopaminergic modulation on memory plasticity has thus far not yet been empirically established, but a theoretical link has already been suggested for more than a decade. Modeling aging-related decline in dopaminergic neuromodulation by stochastically attenuating the gain control of the sigmoidal activation function that models presynaptic to postsynaptic input–response transfer, computational stimulations results accounted for the reduced associative memory plasticity and working memory capacity in old age (Li et al. 2001; see also Li and Rieckmann 2014 for a recent review). Although without direct measures of dopamine synthesis or binding, a recent functional brain imaging study showed that reduced striatal activity may contribute to reduced transfer effects of working memory training in

Cognitive and Brain Plasticity in Old Age,

Fig. 3 (a) The left dorsal frontal cortex and the left occipitoparietal cortex showed increased activity after the “method of loci” memory training relative to a pretest baseline. (b) Group differences in the comparison of “method of loci” use with pretest. The younger and the improved older adults, but not the unimproved old, activated the left occipitoparietal cortex. (c) Age differences in the comparison of “method of loci” use with pretest. The young but not the old adults activated the left dorsal frontal cortex (Data adapted with permission from Nyberg et al. (2003); copyright the National Academy of Sciences, USA, 2003)

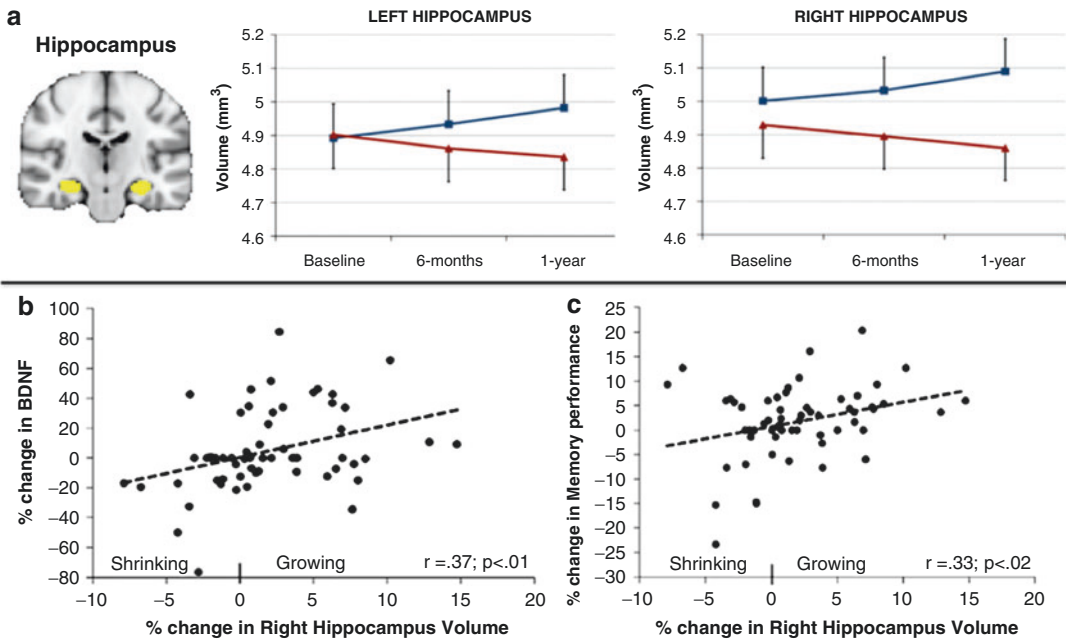

older adults (Dahlin et al. 2008). Given that dopamine pathways extensively innervate the striatum, this finding hints at the possibility that aging-related decline in transfer effects of working memory training may be related to impaired striatal dopaminergic modulation.

Regarding brain correlates of episodic memory plasticity in old age, the plasticity of the frontal–parietal network as a function of memory training has also been investigated (Nyberg et al. 2003). After being instructed to use the method of loci as a mnemonic strategy, increased brain activities in frontal as well as occipitoparietal regions were observed in younger adults. In contrast, accompanying their reduced episodic memory plasticity as indicated by the reduced training gain, older adults did not show training-related increase in frontal activity, and only those older adults who benefited from the memory training showed increased occipitoparietal activity (see Fig. 3). A recent study further investigated

effects of dopaminergic modulation on episodic spatial memory in a crossover pharmaco (ON/OFF)-behavioral design. Using Parkinson's disease as a model disorder which is characterized by severe and progressive degeneration of nigrostriatal dopamine, the authors showed that dopaminergic medication facilitated striatum-dependent spatial learning based on cue-location associations. A positive medication effect on hippocampus-dependent spatial memory relying more on relations between object locations and a local spatial boundary depended on prior experience with the navigation task (Thurm et al. 2016). Given these results, aging-related decline in the dopamine system might differentially affect spatial memory plasticity and transfer effects of navigation trainings might depend upon the task-relevant underlying brain structures.

Turning to effects of aerobic physical fitness training on episodic memory (see Prakash et al. 2015 for a recent review), a study of

Cognitive and Brain Plasticity in Old Age, Fig. 4 (a) Effects of aerobic fitness training on hippocampal volume in older adults. (b) Positive effects of exercise on increased serum BDNF level are correlated with increased hippocampal volume in older adults. (c) Increased hippocampal

volume is correlated with memory performance improvement in older adults (Data adapted from Erickson et al. (2011) with permission; copyright the National Academy of Sciences, USA, 2011)

particular interest (Erickson et al. 2011) showed that aerobic exercise (3 days/week over 1 year) increased the volume of the hippocampus in older adults by 2%, thus effectively reversed the age-related loss in hippocampal volume by 1 to 2 years (see Fig. 4). Moreover, the increase in hippocampal volume was associated with improved spatial memory performance and with greater serum levels of brain-derived neurotrophic factor (BDNF). The hippocampus is central for episodic and spatial memory and is rich in BDNF, which is a putative mediator of neurogenesis and dendritic expansion. Early animal studies showed that voluntary wheel running enhances BDNF gene expression, neurogenesis, and cell proliferation in the hippocampus of mice and rats (Adlard et al. 2005; Neeper et al. 1995), decreases beta-amyloid plaque load in the brains of transgenic Alzheimer mice, and increases the animals' spatial memory performance (van Praag et al. 1999). Thus, the findings of aerobic fitness training increasing the level of circulating BDNF and

hippocampal volume suggest that cell proliferation or increased dendritic branching might contribute to the training-related increases in hippocampal volume and memory function in older adults (see Erickson et al. 2011 for review).

Cognitive Plasticity in Aging-Related Neuropathology

A range of neuropathological conditions are age associated. Therefore, this section focuses on cognitive plasticity in populations manifesting aging-related neuropathology. Mild cognitive impairment (MCI) refers to a transitional zone between normal and pathological cognitive aging. Older adults with MCI or caregivers of individuals with MCI usually report subjective memory deficits. Furthermore, cognitive declines in these populations have been objectively confirmed by neuropsychological tests in at least one cognitive domain (Winblad et al. 2004). In general, daily

functioning of older adults with MCI remains intact, and they do not yet fulfill clinical criteria of dementia. However, older adults with MCI have an increased risk of developing Alzheimer's disease (AD). About 10–15% of those seniors with classified MCI convert to AD within 12 months compared to only 1–2% of the general, age-matched population (e.g., Petersen et al. 1999). AD is the most common form of dementia in late life with complex multifactorial pathogenesis. AD leads to progressing memory deterioration and further exacerbates deficits in other cognitive domains, including executive functions and visuo-motoric, visuospatial, and language abilities that impair independent living and quality of life. Idiopathic Parkinson's disease (PD) is another aging-related neurodegenerative disease, which in its initial stages is rather recognized by motor than cognitive deficits. PD is associated with a drastic degeneration of dopaminergic neurons, especially in the substantia nigra pars compacta (SNc) and its terminals in the dorsal striatum (caudate and putamen). With disease progression, the loss of dopamine further affects the ventral tegmental area (VTA) and its terminals in the ventral striatum (nucleus accumbens) as well as the mesolimbocortical dopamine system (Agid et al. 1993).

Many cognitive intervention studies targeting the training of either compensatory cognitive strategies or specific cognitive abilities in older adults with MCI and AD reported performance improvements in the trained tasks but failed to provide relevant long-term transfer effects on other cognitive functions or abilities needed in daily life (e.g., Belleville et al. 2006; Davis et al. 2001). More recent neuroplasticity-based cognitive trainings have yielded promising results in some studies with healthy older adults, but yielded contradicting results in older adults with increased risk of dementia and MCI (e.g., Barnes et al. 2009). Cognitive training and intervention studies with PD patients provide a similar picture with small to moderate improvements mainly in trained fronto-striatal tasks (e.g., Nombela et al. 2011), without transfer to other untrained functions. Taken together, randomized controlled cognitive training or intervention studies in MCI,

AD, and PD are few and inconclusive at the current stage.

Outlook

In light of aging- and pathology-related decreases in training gains and transfer effects, it is important to investigate other options for improving cognitive and brain plasticity in old age. Repetitive transcranial magnetic stimulation (rTMS) and anodal transcranial direct current stimulation (atDCS) are noninvasive brain stimulation methods that could have transient facilitative effects on cognitive function (see Freitas et al. 2013 for a recent review). Very recently, a few explorative studies have begun to use noninvasive brain stimulations in older adults. Some preliminary successes in terms of ameliorating cognitive aging deficits could be demonstrated. For instance, atDCS applied over the left inferior frontal gyrus improved performance in a semantic word generation task that implicates frontal cognitive control and working memory in old adults. Moreover, atDCS also reduced the nonspecific recruitment of the right prefrontal regions in older adults, thus modified functional brain activity of older adults to more resemble those observed in younger brains (Meinzer et al. 2013). Regarding effects on episodic memory consolidation, atDCS over the right temporoparietal cortex further improved object-location learning and delayed free recall after one week in old adults (Flöel et al. 2012).

Research over the past decade indicates that the facilitating effects of rTMS or atDCS on cognition might not be restricted to healthy young and older adults. Application of rTMS improved face-name association memory in older adults with subjective memory complaints and amnesic MCI (e.g., Turriziani et al. 2012). In AD patients with early to more advanced cognitive deficits, rTMS and atDCS have been shown to improve memory functions (e.g., Cotelli et al. 2014). In PD patients, atDCS stimulation has also been shown to improve working memory (Boggio et al. 2006). These initial progresses notwithstanding, further research is needed to gain better understandings

about the underlying mechanisms of noninvasive brain stimulations, their long-term effects, and potential risks, in order to develop appropriate protocols for gerontological applications.

Definition

Cognitive behavioral therapy (CBT) refers to a psychotherapeutic framework in which cognitions and behaviors are theorized to be the underlying core factors in the development and maintenance of psychological distress. According to the CBT model, maladaptive cognitions, or schemas, about the world and oneself result in emotional distress and problematic behaviors in the individual. The goal of cognitive behavioral therapy is to alter an individual's maladaptive cognitions and problematic behaviors, which result in the alleviation of psychological distress.

Introduction

Cognitive behavioral therapy (CBT) is a psychotherapeutic intervention focused on the alteration of maladaptive cognitions and behaviors in the alleviation of psychological distress. CBT blends elements from both behavioral and cognitive therapies into a cohesive intervention in which both behaviors and thoughts are theorized to effect, and to be effected by, an individual's emotional state. CBT is considered an evidence-based treatment for a multitude of mental disorders, including anxiety, depression, bipolar disorder, eating disorders, anger control, insomnia, and substance abuse, and there is growing evidence for the use of CBT with personality disorders and schizophrenia (Sorocco and Lauderdale 2011; Hofmann et al. 2012). In the treatment of depression, CBT has been found to be at least as efficacious as medication alone. A combination approach of medication and CBT has growing support to be considered as the most effective approach for short-term changes in mood, although CBT continues to demonstrate the most enduring results for mid-life samples (Sorocco and Lauderdale 2011). There is growing evidence for the effectiveness of CBT in geriatric samples. Recent studies have demonstrated the efficacy of CBT in treating older adults suffering from depression, anxiety, insomnia, and pain (Sorocco and Lauderdale 2011), although the effects found for insomnia may not be as long lasting in older adults

as in mid-life adults (Hofmann et al. 2012) and there is some debate about the effectiveness of CBT for anxiety disorders when compared to other treatment modalities.

Outline of CBT

CBT interventions often occur in three main phases: psychoeducation, skills acquisition, and relapse prevention (Sorocco and Lauderdale 2011). Psychoeducation involves teaching the patient about the CBT model for their particular disorder or symptoms and may take place over one or several sessions. Psychoeducation for older adults may take longer than for younger adults due to an increased unfamiliarity with psychosocial interventions (Sorocco and Lauderdale 2011).

Next, therapy moves on to teaching new skills. Skill acquisition involves teaching and demonstrating tools related to both maladaptive cognitions and behaviors (Sorocco and Lauderdale 2011). For example, maladaptive cognitions are altered through the use of cognitive techniques like cognitive restructuring (e.g., replacing maladaptive automatic thoughts with more realistic thoughts) and the downward arrow technique (e.g., asking the individual to describe the meaning of their thoughts until the individual uncovers a core belief about themselves). In the CBT model, an individual's thoughts or interpretation of a situation is theorized as the mediating factor between the situation itself and the individual's subsequent emotional response. The alteration of one's automatic thoughts to the situation allows the person to alter their emotional response as well, thus decreasing distress. The relationship between thoughts, behaviors, and situations is typically monitored through the use of "ABC" worksheets, where "A" represents the "activating event," "B" is the "belief" or automatic thought held by the patient, and "C" represents the "consequence" or emotional reaction to the situation as the result of the automatic thought (Sorocco and Lauderdale 2011). The worksheets used to monitor thoughts may vary based on the patient's symptoms and cognitive ability. Different types of thoughts are captured within the worksheet.

Automatic thoughts are themselves the result of an individual's underlying schemas, or their way of viewing the world. These kinds of thoughts are reflected in the belief portion of the worksheet. Deeper thoughts or themes, known as schemas, develop over the course of an individual's life as the result of an interaction between genetic predispositions and learned responses over time. The therapist and patient can look for common themes in the worksheets to identify schemas.

Maladaptive behavior patterns also develop over time and can exacerbate psychological distress by decreasing the opportunities for individuals to receive positive reinforcement from their environment (Sorocco and Lauderdale 2011). Behavioral problems related to psychological distress are altered through the use of behavioral activation, in the case of depression, and exposure exercises, in the case of obsessive-compulsive spectrum, trauma, and anxiety disorders. Modification of maladaptive behaviors typically starts with activity monitoring worksheets, where the patient monitors his or her activities and mood over the course of a week. This allows the patient and the clinician to assess for patterns related to the patient's behaviors and subsequent mood. Next, the clinician and the patient work together to incorporate pleasurable activities throughout the patient's week. Problem solving and social skills training are also often incorporated into behaviorally based interventions in order to decrease the obstacles faced by patients during this process (Sorocco and Lauderdale 2011). With respect to exposure exercises, patients must face the stimulus that they are repeatedly avoiding. This can be done through imagery or actually engaging with the fear-provoking stimulus. Finally, clinicians and patients work together to create maintenance plans for the patients to decrease the likelihood of their symptoms returning. Relapse prevention in the treatment of older adults is typically done over multiple sessions and possibly includes planning for follow-up sessions either in person or over the phone (Sorocco and Lauderdale 2011).

A case conceptualization process is typically utilized as a necessary component of a CBT model (Sorocco and Lauderdale 2011). The case

conceptualization process starts at intake but is modified repeatedly throughout as new information develops. The conceptualization allows for clinicians to hypothesize about the cognitive, behavioral, and situational factors that may be contributing to an individual's current psychological distress (Sorocco and Lauderdale 2011). Clinicians are able to consider the effect of possible age-related factors, such as cognitive decline and social situation, when creating a treatment plan for geriatric patients.

Anxiety and Obsessive-Compulsive Spectrum Disorders

Up to 27% of older adults may suffer from anxiety-related symptoms and up to 10% of community-dwelling older adults may meet criteria for an anxiety disorder (Petkus et al. 2014). The prevalence of anxiety disorders in late life may be even higher in medical settings (Goncalves and Byrne 2012). Generalized anxiety disorder (GAD) and specific phobia are the two most common anxiety disorders found in late life (Petkus et al. 2014). Older adults suffering from anxiety disorders are likely to prefer psychotherapy to either medication or a combined psychotherapy-medication approach (Goncalves and Byrne 2012). Further, older adults report being more satisfied with a CBT-based protocol than a discussion group intervention (Ayers et al. 2014a).

There is currently a debate in the literature about the most effective treatment for anxiety disorders in older adults, which may be due to a dearth of large treatment trials studying late-life anxiety (Goncalves and Byrne 2012; Gould et al. 2012). While some studies suggest that CBT does not surpass other active treatments of geriatric anxiety, including relaxation training (Hofmann et al. 2012; Petkus et al. 2014), there is also evidence that CBT is equal to or surpasses other treatment modalities, including relaxation therapy, supportive therapy, or psychodynamic therapy (Hofmann et al. 2012). Further, some literature suggests that although CBT may be an effective treatment for late-life GAD, the effect may be less significant than what has been

observed in younger samples (Petkus et al. 2014; Ayers et al. 2014a; Gould et al. 2012). There are multiple reasons why CBT may be less effective in older adults than it is in younger adults. Most notably, older adults with GAD are likely to have maladaptive schemas and behaviors that have been reinforced over several decades, resulting in a psychopathology that is more highly ingrained than in younger adults (Petkus et al. 2014). Further, age-related difficulties with cognitive restructuring may result from increased levels of cognitive dysfunction and reality-based worries (e.g., worries about health and finances) (Petkus et al. 2014). Because CBT requires relatively intact executive functioning in order to be fully engaged in traditional CBT exercises, cognitive dysfunction may serve as a moderator for CBT treatment response in older adults (Ayers et al. 2014a). There may also be additional confounding factors which could have affected the generalizability of the results of many of the major investigation of CBT for late-life anxiety, including self-referral, concurrent unregulated pharmacotherapy, and a lack of control of nonspecific therapeutic effects (e.g., social support) (Gould et al. 2012).

Obsessive-compulsive disorder (OCD) is less frequent in older adults than anxiety-related disorders, only effecting 1.5% of older adults (Ayers and Najmi 2014). The first line of treatment for OCD is Exposure and Response Prevention (ERP), a form of CBT; however, there has been little systematic investigation of the efficacy of ERP in older adults with OCD beyond assorted case studies (Ayers and Najmi 2014). Hoarding disorder, an obsessive-compulsive spectrum disorder with strong ties to anxiety disorders, may be as prevalent as 15% in geriatric samples (Ayers and Najmi 2014). Hoarding disorder has also received poor results when treated with CBT in geriatric samples, with few individuals responding to treatment and no evidence of long-term effects of treatment (Ayers et al. 2014b). Treatment of late-life hoarding is further complicated by low insight, executive functioning problems, and decreased levels of social engagement (Ayers et al. 2014b).

Modified CBT protocols may show more promise than traditional CBT-based interventions for late-life anxiety. Interventions involving

increased problem solving skills and teaching strategies may help to increase long-term outcomes for anxiety disorders (Ayers et al. 2014a). Similar results have been found for hoarding disorder when using a CBT-adapted protocol that focused on compensatory cognitive training and exposure and response prevention (Ayers et al. 2014b). Compensatory cognitive training focuses on skills related to prospective memory and planning, attention and vigilance, learning and memory, and cognitive flexibility, and problem solving. This enables patients with executive functioning problems to work around their deficits when engaging in treatment (Ayers et al. 2014b).

Mood Disorders

The prevalence of mood disorders in late life rivals that of anxiety disorders: as many as 25% of community-dwelling older adults have reported experiencing symptoms related to depression (Shah et al. 2012). Older adults with a late onset of depression symptoms are more likely to have a poor prognosis and greater disability associated with their symptoms than are individuals with early-onset depression (Sorocco and Lauderdale 2011). The CBT model of depression postulates that depressed mood is a combination of maladaptive cognitions, social isolation, and decreased performance of pleasurable activities (Shah et al. 2012). In the treatment of mood disorders, CBT has been found to be equally effective as other treatment modalities, such as interpersonal therapy and behavioral therapy (Sorocco and Lauderdale 2011; Shah et al. 2012), and may even surpass other treatment models in the maintenance of long-term results (Hofmann et al. 2012). Research suggests that a combined CBT and medication approach in late-life samples does not increase the effectiveness of either approach alone (Hofmann et al. 2012). CBT-based protocols for older adults with depression are often modified to take into consideration age-related changes in cognition and memory, as well as physical limitations (Sorocco and Lauderdale 2011; Shah et al. 2012). Typical modifications include using telephone or

home-based therapy, incorporating breaks within sessions, the simplification of thought records, increased use of handouts, and booster sessions (Sorocco and Lauderdale 2011). The majority of sessions in a typical CBT intervention for geriatric depression are focused on both the identification of maladaptive cognitions and the generation of more helpful alternative thoughts as well as behavioral activation and the introduction of pleasurable or positively reinforcing activities (Sorocco and Lauderdale 2011). Problem solving skills may be introduced in later sessions and can help to increase the mastery felt by geriatric individuals (Sorocco and Lauderdale 2011).

Bipolar disorder, a mood disorder characterized by alternating manic and depressive states, is estimated to be prevalent in 0.1–0.5% of community-dwelling older adults (Sorocco and Lauderdale 2011). CBT is considered the treatment of choice for bipolar disorder, especially in light of the high rates observed for patient noncompliance (40–50%) for pharmacological treatments (Sorocco and Lauderdale 2011). Unfortunately, there is little research on the efficacy of CBT for bipolar disorder in geriatric patients (Sorocco and Lauderdale 2011).

Adaptations for Geriatric Samples

Older adults may be more likely to seek therapy due to external pressures from their medical doctors or children and may be less likely to attend treatment for self-motivating reasons (Sorocco and Lauderdale 2011). Consequently, it is especially important for geriatric mental health professionals to assess motivation for treatment and to engage in motivational interviewing when necessary (Shah et al. 2012). This may be especially important for older adults exhibiting low levels of insight into their symptoms, as is often witnessed in geriatric hoarding disorder (Ayers et al. 2014b). Older adults may also have increased obstacles to treatment, including transportation or financial issues (Sorocco and Lauderdale 2011; Ayers et al. 2014b). Because geriatric patients may be unfamiliar with psychological services, extra time may need to be spent to socialize late-life patients

to the CBT framework (Sorocco and Lauderdale 2011). This includes explaining the purpose and benefits of homework, the organization of treatment sessions, and an overview of the CBT model (Sorocco and Lauderdale 2011). Finally, clinicians working with older adults should be especially mindful of suicide risk and assess for suicidal ideation throughout the therapeutic process, as older adults are more likely to have increased risk factors, such as social isolation (Sorocco and Lauderdale 2011).

As individuals age, their opportunities for positive reinforcement, such as interacting with friends or exercising, may decrease due to changes in available resources and their own physical health (Sorocco and Lauderdale 2011). Cognitive impairment may also decrease the ability of older adults to fully engage in some of the core facets of CBT, such as cognitive restructuring or behavioral activation. When constructing lists of pleasurable activities for geriatric patients to incorporate into their daily lives, clinicians should consider how activities that individuals used to enjoy could be altered to be appropriate for their current levels of functioning (Sorocco and Lauderdale 2011). For example, if an older adult enjoyed kayaking but is no longer able to perform due to a medical illness, they might consider walking in the park to be a suitable alternative to incorporate into their daily routine. Clinicians may want to consult with patients' primary care providers before suggesting any new physical activities be added to patients' daily routines.

Older adults who have difficulty with cognitive restructuring due to possible cognitive impairment may benefit from the use of coping cards, which rely on recognition rather than recall memory (Sorocco and Lauderdale 2011). Patients write down common maladaptive cognitions and alternative thoughts on coping cards and then refer to them as needed, rather than having to generate alternative thoughts spontaneously. Other alterations that may increase the efficacy of CBT for geriatric patients include a lengthened course of therapy, increased structure, and an increased use of examples (Sorocco and Lauderdale 2011). Clinicians should also consider the incorporation of booster sessions every 3–6 months to decrease the

occurrence of re-emerging symptoms (Sorocco and Lauderdale 2011) or reminder calls in between sessions to help increase homework compliance (Ayers et al. 2014a). Because older adults may report feelings of guilt at homework noncompliance (Ayers et al. 2014b), booster calls may also increase the therapeutic alliance between the patient and the clinician. Emphasizing the behavioral aspects of CBT over the cognitive skills may also lead to increased outcomes for older adults (Ayers et al. 2014a). For instance, more time is spent doing behavioral activation and in vivo exposures as opposed to cognitive therapy techniques. In summary, accommodations can be made to address cognitive and physical issues.

Future Directions

Although depression and anxiety disorders are often comorbid in older adults, little research has been done on the effectiveness of CBT for comorbid late-life anxiety and depression (Ayers et al. 2014a). Some evidence suggests that CBT for anxiety may also decrease depression symptoms (Gould et al. 2012). Depression may also be more effectively treated by CBT than are anxiety disorders, further suggesting the need for increased research into alternative therapies (Gould et al. 2012).

Cognitive Compensation

Allison A. M. Bielak

Department of Human Development and Family Studies, Colorado State University, Fort Collins, CO, USA

Synonyms

Cognitive plasticity

Definition

The ability to maintain everyday functioning despite quantifiable age-related decline in

cognitive ability (i.e., memory, attention, executive functioning, speed of processing information). Compensation can be achieved in a number of ways, including reliance on pragmatics or experience, strategy use, task modification, cognitive plasticity or growth, and cognitive reserve (i.e., education, activity engagement).

Overview

It is well established that as adults age, they experience decline in various cognitive capacities, including certain types of memory, executive functioning, attention, and processing speed (Schaie 1996; Hultsch et al. 1998). Given the size of these deficits, one might expect that older adults must substantially revise how they complete day-to-day tasks, or require considerable assistance carrying out chores such as managing finances, meal preparation, and taking care of grandchildren. However, the changes in cognitive ability do not tend to translate over to noticeable declines in the ability to complete everyday tasks. Rather, older adults continue to go about their daily lives with the same levels of vigor and proficiency as when they were younger. They may even make achievements that they were not capable of when they were younger. For example, the majority of CEOs for Fortune 500 companies are between their late 40s and early 60s (Salthouse 2012). There are no parallel declines in everyday functioning because older adults can compensate for cognitive decline in a number of ways, including reliance on pragmatics or experience, strategy use, task modification, cognitive plasticity or growth, and cognitive reserve (i.e., education, activity engagement).

Reliance on Pragmatics

There are two general categories of cognition: fluid intelligence and crystallized intelligence (Horn and Cattell 1966). Fluid intelligence uses cognitive abilities that rely on biology and are termed the “mechanics” of cognition. Fluid intelligence involves all of the basic processes needed to complete higher-order cognitive tasks or solve novel problems. It includes domains such as

processing speed, spatial skills, working memory, and reasoning. A person is completing a task based on fluid intelligence when the task requires “adaptation to new situations for which prior education or learning provide little advantage” (Berg and Sternberg 2003, p. 105). On the other hand, crystallized intelligence involves experience, expertise, or “pragmatics” (i.e., practical knowledge). This includes abilities such as general and procedural knowledge, skills, strategies, verbal knowledge, occupational expertise, and the ability to solve real-life problems such as counting change.

To further illustrate this distinction, imagine a bicycle. The mechanical or basic entities of the bicycle would be the wheels, chain, pedals, handlebars, and frame. If there is deterioration in the mechanics of the bicycle, such as if the air in a tire is low, the bike can still function, but it becomes harder to pedal. Similarly, a decline in the basic mechanics of cognition, such as processing speed, would make completing a task that relies on fluid intelligence more challenging. In contrast, if a person is cycling down a hill, their practical knowledge or experience would let them know that they do not have to continue pedaling down the hill but can use their momentum and coast to reach the bottom of the hill. The mechanics of their bicycle, deflated tire or not, would not be at play in this scenario, and the person can rely on their experience in riding the bicycle to efficiently manage the hill.

The distinction between fluid and crystallized intelligence is relevant to cognitive compensation because the two types change differently across the lifespan. Fluid intelligence begins to decline soon after age 30, while crystallized intelligence increases until the mid-40s and remains stable until the 70s (Li et al. 2004). Therefore, even though an individual experiences decline in fluid intelligence with age, they can compensate for this deficit by relying more on their crystallized intelligence (i.e., acquired knowledge, pragmatics, expertise, and experience) to complete tasks.

Everyday Life is Different from Cognitive Tests

Another key factor related to cognitive compensation is that the tests used in the laboratory to

assess cognitive change are very different from the tasks essential to everyday life. Hess (2005) described laboratory-administered memory tasks as “relatively stripped down in terms of familiarity or meaningfulness” (p. 383), as a person rarely has to memorize a list of unrelated words or discover the pattern among sets of letters in the real world. Because of this, tests have been developed that attempt to assess a person’s proficiency in completing tasks required in their daily life. These measures provide participants with real-life stimuli like nutrition labels, medication labels, or appliance instructions and ask them to complete tasks designed to assess everyday problem solving or cognition (i.e., balancing a checkbook, reading a bus schedule). Tests of everyday ability show moderate correlation with standard cognitive test scores (Allaire and Marsiske 1999), indicating that while there is overlap between successful completion of both types of tasks, the ability to solve everyday problems is distinct from typical cognitive tasks. However, tests of everyday ability still do not provide a precise measure of how well an adult can actually function in the real world.

Salthouse (2012) discussed facets of our everyday lives that may help to explain why there are not greater consequences in real life as a result of age-related cognitive decline. First, successful fulfillment of daily activities only require one’s typical level of functioning, whereas academic cognitive tests assess maximum effort and ability. It may be that cognitive decline with older age is only noticeable when attempting to achieve the upper echelons of human cognitive ability (i.e., on cognitive tests), and the level of cognitive exertion required in our daily lives is not sensitive to detect age-related cognitive deficits. Second, day-to-day tasks are likely only slightly different over time, limiting the amount of novel tasks and situations encountered in daily life and allowing the majority of one’s daily function to be solved by relying on past solutions. Consequently, everyday tasks that rely purely on fluid intelligence, which declines with age, would be an exception rather than the rule and experienced only rarely in daily life.

In addition, Park and Gutchess (2000) described that everyday tasks become automatized and require little cognitive effort to fulfill. While the effortful component of memory declines with age, the processes that rely on automatic cognitive processing that occur without conscious awareness or effort do not (Jacoby et al. 1996). Therefore, age-related declines in processing abilities will only be apparent in situations that need mental effort. It is important to note that the automation of tasks is very specific to an individual, and the same situation that requires little cognitive demand for one older adult may involve effortful processing for another (e.g., driving into a large city can be effortful for a tourist versus being rather automatic for a local) (Park and Gutchess 2000). Overall, although it may appear that older adults are engaging in substantial compensation for cognitive decline, an alternative explanation is that the tasks they complete everyday are fundamentally different than the tasks used in the lab that repeatedly demonstrate age-associated cognitive decline.

Strategy Use and Task Modification

If necessary, cognitive compensation can also be achieved through explicit strategy use or modification of the task to accommodate cognitive decline. Possible internal strategies include rote rehearsal (e.g., repeating a name or word multiple times), mental imagery (e.g., recalling ingredients by picturing the finished dish one plans to make), method of loci (i.e., mentally placing items to be recalled in familiar locations, then “walking” through the location to assist in recalling the items), or mental retracing of past steps or events. However, older adults tend to be less likely to spontaneously use such strategies and continue to perform worse than younger adults even when instructed on how to use them (Cavanaugh and Blanchard-Fields 2011). Rather, it is common to rely on external aids such as lists, address books, calendars, notes, or smartphones to aid memory in everyday contexts. A well-known strategy is to use medication organizers or pillboxes to assist with medication adherence, although the efficacy of this aid is inconsistent (Bosworth and Ayotte 2009). Collaborative cognition, where two or

Cognitive

Compensation,

Fig. 1 Interkey interval for choice reaction time and typing tasks across adulthood (Salthouse, TA. Effects of age and skill in typing. *Journal of Experimental Psychology: General*, 113(3), 345–371, 1984. American Psychological Association. Reprinted with permission)

more people work together to complete a cognitive task, can also be an aid in everyday life. This method can be particularly effective when the other person is one's family or friend as they can have a shared past and familiarity with one another that allows them to tailor their reminder cues to their partner (Rauers et al. 2011).

Extensive practice with the task at hand can also benefit older adults. For example, older adults who are given very large numbers of practice trials (i.e., at least 500) on attention-based tasks can perform just as well as younger adults (Cavanaugh and Blanchard-Fields 2011). Older adults may also simply need more time to complete a task, or perform their best when no time limits are imposed.

Individuals may also begin to approach the same cognitive task differently with age, allowing them to compensate for any possible declines in basic processing resources. Salthouse (1984) completed a seminal study demonstrating this phenomenon. Experienced typists between 17 and 72 years of age completed a range of typing-related tasks. As can be seen in Fig. 1, choice reaction time, a test of basic processing speed, was slower with age. However, even though typing presumably involves similar skill,

there was no correlation between age and typing speed. Rather, Salthouse determined that older typists had increased their anticipation span, or were looking farther ahead in the text to be transcribed, and this allowed them to compensate for their slower processing speed.

Similarly, having greater domain-specific knowledge (i.e., crystallized intelligence) for a task or being an expert appears to positively impact performance. Studies have evaluated expertise in a wide range of abilities, including flying, music, chess, bridge, graphic design, and the game of Go. In general, being an expert in a task appears to attenuate but not eliminate age effects on performance and only for tasks specific to the area of expertise (Hess 2005).

Cognitive Plasticity and Training

Improving our cognitive performance despite age-related cognitive changes is another way cognitive compensation is possible. Cognitive plasticity refers to the idea that cognition can be trained or improved. In other words, our cognitive ability is not set in stone and can be changed or show growth over the lifespan.

Numerous studies have attempted to improve older adult's cognitive performance via intense

training or practice of various cognitive skills. One seminal investigation was the Advanced Cognitive Training for Independent and Vital Elderly (ACTIVE) trial, a multisite intervention that involved 2832 adults aged 65–94 years (Ball et al. 2002). Participants were randomized to receive training in either processing speed, reasoning, or memory ability over ten 60–75 min sessions over 5–6 weeks or were assigned to a control group. All training conditions involved strategy instruction and extensive practice, with tasks becoming more challenging over time. The training conditions involved the following: processing speed training focused on visual search skills, particularly when attention was divided; reasoning training focused on identifying the pattern in various real-life (e.g., travel schedules) and laboratory sequences (e.g., the next letter to appear in a series); and memory training involved recall for word lists, text, and stories, in terms of both real-life (e.g., shopping lists) and laboratory-like (e.g., recall a paragraph) tests. Immediately after the training period, participants who received the training sessions performed better on cognitive tests than the control group, but only in the same domain as the training they received (e.g., the memory training group performed better on memory tasks only). This demonstrated that cognitive ability can be improved in older age, but the training gains were task specific and did not generalize to other types of cognition. Impressively, the training gains were maintained even 10 years later for the speed of processing and reasoning groups (Rebok et al. 2014). Moreover, after 10 years participants in each training group reported less difficulty in completing tasks of everyday living. Therefore cognitive training not only resulted in immediate cognitive compensation but also extended to helping participants be more effective in their daily lives.

Despite the remarkable cognitive gains shown from the ACTIVE trial, the success of interventions that involve extensive practice of tasks or training of particular strategies is not entirely clear. In some studies, improvements are limited to the cognitive domains that were targeted (Ackerman et al. 2010; Owen et al. 2010), whereas other interventions do

find generalized improvement to untrained tasks (Schmiedek et al. 2010; Smith et al. 2009). Few studies evaluate intervention effects on everyday function, and the follow-up time of training studies is relatively short (i.e., mostly immediate posttest or months later), putting the durability of effects into question.

Another way to enhance cognitive performance is with interventions that involve increased activity rather than specific practice in cognitive tasks. For these interventions, stimulation is achieved via an intellectually and socially complex environment or particular activity (Park et al. 2007). Older adults who have been assigned to learn theater performance (Noice et al. 2004), competed in team problem-solving tournaments (Stine-Morrow et al. 2014), or participated in an intense elementary school volunteering program have shown significant gains on various cognitive tests (Carlson et al. 2008). Although the novelty of the activity may be relevant to instituting cognitive growth, it may be critically important as to whether the activity requires the acquisition of new skills or involves productive engagement (Park et al. 2007). This is in contrast to activities that rely only on existing knowledge or receptive engagement. Park and colleagues (2014) demonstrated the importance of this distinction by finding that older adults who learned to design and sew quilts, practice digital photography, or a combination of the two over a 3-month period improved on episodic memory tasks compared to those who were assigned to the two receptive engagement conditions. One condition provided only novelty but not skill acquisition (e.g., field trips), and the other involved traditional mental activities (e.g., completing puzzles).

The longevity of the cognitive changes resulting from engagement-based interventions is unclear, but these interventions have the potential of being more easily integrated into everyday life compared to those assigning cognitive training. However, given the documented cognitive growth from both methods, each method holds potential benefit. It remains to be seen if the two intervention techniques are only additive or if cognitive improvement can be maximized by introducing both techniques.

Finally, it is important to note that there also appear to be limits to the cognitive plasticity available to older adults. Although older adults do show cognitive gains from training and activity engagement, the magnitude of possible improvement is smaller than that for younger individuals (Nyberg 2005) even if this varies by cognitive domain (Schmiedek et al. 2010). Therefore, although one method of cognitive compensation may be to increase cognitive capacity via intensive training or engagement, it is unlikely that this method can completely rescind age-related cognitive declines.

Cognitive Reserve

Another way cognitive compensation can occur is via cognitive reserve. The concept of cognitive reserve was created because there is not a direct relationship between the severity of neurological insult or disease and a person's level of cognitive functioning. Rather, individuals may continue to perform at a level higher than expected or show no obvious signs of neurological disease despite diagnosed pathology such as Alzheimer's disease. In other words, older adults appear to be compensating for neurological decline. Stern (2002) described cognitive reserve as the ability of the brain to maximize performance by either using neural networks more efficiently or recruiting alternate neural pathways or cognitive strategies. Cognitive reserve is also known as active reserve, in that the brain actively compensates for pathology, compared to passive brain reserve which is determined by brain volume or the number of synapses. Cognitive reserve is believed to be acquired by engagement in lifestyle activities and educational and occupational attainment. Individuals with more of these resources or reserve are consequently better able to tolerate higher levels of brain pathology before showing signs of clinical impairment (Stern 2002). Each of these potential sources of reserve and their link to cognition is briefly described.

It is well established that older adults who engage in more physical, social, and cognitive activities such as jogging, talking with friends, or playing board games perform better on cognitive tests than less active individuals (Hertzog

et al. 2009). Active older adults also have a reduced risk of developing dementia (Wang et al. 2006; Wilson et al. 2002). It is unclear whether lifestyle engagement slows the rate of age-associated cognitive change per se or simply increases cognitive ability level to a higher starting point and that advantage is maintained with age (Salthouse 2006; Bielak et al. 2014). The precise mechanisms for the association with cognitive performance are unclear and vary by activity domain (Bielak 2010).

It is hypothesized that physical exercise may increase blood flow to the brain, positively impact hormone levels, or increase synaptic connections. Moreover, those who frequently exercise are more likely to have other healthy lifestyle behaviors (e.g., adequate sleep and nutrition) and health status (e.g., healthy weight) that can have repercussions for their cognitive health. Social engagement can enhance emotional well-being through decreasing stress and providing opportunities for instrumental and emotional support which can decrease the physical toll on the body and brain. Finally, stimulating cognitive activity may be neurologically beneficial by increasing cerebral blood flow, increasing the number of synapses, or allowing optimal neurochemical compositions. Exposure to cognitive activity may also produce a feedback loop that encourages further engagement in similarly challenging environments and activities. The environmental complexity hypothesis also proposes that exposure to complex environments offer opportunities for intellectual flexibility and practice that in turn enhance cognitive performance (Schooler and Mulatu 2001).

Greater years of formal schooling are also associated with less cognitive decline compared to those who receive fewer years of education, but the relation appears to vary by cognitive domain (Kramer et al. 2004). Low levels of education are a well-established risk factor for Alzheimer's disease, but higher levels do not appear to attenuate the rate of cognitive change (Zahodne et al. 2011; Wilson et al. 2009). Greater exposure to formal education settings would provide high levels of cognitive stimulation, and highly educated individuals are likely more confident completing tasks that challenge their cognitive skills and may seek

out similar environments. Educational attainment is also highly correlated with socioeconomic status, and individuals with greater education are more likely to partake and experience other activities known to be beneficial for cognitive health including good nutrition, holidays to relieve stress, and knowledge of healthy lifestyle behaviors. Consequently, it is unclear to what extent education per se is influencing cognitive reserve versus other related factors.

The complexity of the tasks one completes in their occupation has been linked to cognitive performance. Those who worked in occupations that had greater environmental complexity, or an environment that involved diverse stimuli, having to make many decisions and having to make decisions that had many factors and contingencies showed greater intellectual functioning in older adulthood than those whose paid work was not substantively complex (Schooler et al. 1999). Specifically, it may be greater complexity with people (e.g., mentoring compared to taking instructions or serving) and data (e.g., synthesizing compared to copying or comparing) at work that is associated with better cognitive performance (Andel et al. 2015) and reduced risk of dementia (Andel et al. 2005). Similar to the effects associated with educational attainment, occupation is associated with many other factors that may also indirectly affect cognition (e.g., nutrition, exercise).

Cognitive reserve acts to boost cognitive ability by allowing the brain to be better able to compensate for impending or already existing declines in functioning. However, the various sources of cognitive reserve may not be purely additive. Rather, the potential gains may be modest when multiple other sources of reserve have already been acquired. For example, the benefit of completing complex work was no longer significant to late-life cognition when participation in social activities was also high (Andel et al. 2015).

Conclusion

Compensation for age-associated cognitive decline is possible in various ways. Some of the

methods involve explicit compensatory techniques or training, while others are achieved indirectly through participation in other activities or passive reliance on other skills. Despite these various sources, older adults do not appear to be able to achieve the same level of performance on cognitive tests as younger adults. However, the relevance of this limitation is negligible given that age-associated cognitive decline does not have a significant negative impact on everyday life for older adults.

Synonyms

Executive control; Self-control

Cognitive control and self-regulation are key determinants of goal-related behavior and known to be highly susceptible to increasing age. This entry provides an overview about new insights into the geropsychology of cognitive control and self-regulation. In two sections, each concept is briefly defined in combination with existing knowledge about their neuronal underpinnings. Then, empirical evidence on age differences in cognitive control and self-regulatory abilities as well as on how these can be improved by cognitive interventions will be summarized.

Definition of Cognitive Control

The term *cognitive control* refers to a set of higher-order processes that regulate basic sensory, motor, and cognitive operations for planning, guiding, and coordinating goal-directed behavior in everyday life (Miller and Wallis 2009). As these higher-order cognitive processes are assumed to

allow pursuing internal goals and flexibly adapting to external changes, cognitive control is regarded as being critical to intelligent behavior.

Evidence from cognitive neuroscientific studies suggests that the mechanism of cognitive control can be attributed to a distributed brain network with the prefrontal cortex (PFC) taking a critical role. Due to its extensive connectivity, the PFC seems to be strongly activated whenever multimodal information from sensory and motor systems and subcortical structures needs to be integrated and maintained in a highly accessible state (Miller and Wallis 2009). Specifically, this PFC activation ensures the maintenance of goal-related information against distraction and serves the top-down guidance of neuronal activation in other brain areas required for the execution of controlled behavior. Advancing age is characterized by a marked neuronal deterioration particularly affecting the integrity of the PFC (Raz 2005). This neuronal alteration in the healthy aging brain has been linked to a pronounced decline of performance in tasks assessing cognitive control processes.

Age Differences in Components of Cognitive Control

Researchers suggested three key components of cognitive control that are assumed to be interrelated but separable abilities: (1) the updating and monitoring of working memory (WM) representations, (2) the inhibition of predominant response tendencies, and (3) the flexible switching between cognitive tasks (Buitenweg et al. 2012). At the theoretical level, aging researchers investigating cognitive control aimed at determining whether age differences in these abilities reflect process-specific limitations or whether they can be explained by age differences in one single general factor reflecting age-related changes in speed of cognitive processing (Kray and Eppinger 2010). At the applied level, aging researchers become more and more interested in assessing the extent to which these abilities can be improved by cognitive interventions (Kray and Ferdinand 2014).

In the following, evidence on both levels will be reviewed for each of the three key components of cognitive control.

Working Memory. There is now ample empirical evidence that WM is a crucial determinant of age differences in cognitive control. In its traditional conceptualization, WM includes domain-specific buffers for short-term storage of visuospatial and verbal information along with central executive processes that monitor and manipulate the storage contents in the service of controlled, goal-directed operations (Hale et al. 2007). The large number of existing WM tasks distinguishes tasks that measure storage capacity, generally termed simple-span tasks (Reuter-Lorenz and Jonides 2007), from tasks that assess both storage capacity and central executive processing, generally termed complex-span tasks. For instance, digit-span tasks can be classified as simple-span tasks. They are assumed to assess the individuals' ability to actively store a number of visually or auditorily presented items and to recall them in the correct order. In contrast, complex-span tasks assess not only storage processing but also the manipulation of the stored information or the processing of a secondary task (Reuter-Lorenz and Jonides 2007). For instance, reading-span tasks require the processing of a sequence of sentences and deciding for each sentence whether it is meaningful or not. At the same time, individuals have to encode the final word of each sentence and to remember these until the end of the task (Reuter-Lorenz and Jonides 2007).

Researchers investigating age differences in simple-span tasks found a differential decline in the performance on visuospatial and verbal WM tasks in older relative to younger adults, indicating larger deficits in visuospatial relative to verbal WM tasks (Hale et al. 2007). Other studies show that age differences are even more pronounced in complex-span tasks, tapping both storage and executive processes, than age differences in storage measures per se. While some researchers tried to separately investigate storage and executive processes of WM in order to identify process-specific limitations in old age, others argued that this separation is artificial, as even storage tasks

might require executive control processes, particularly in older adults (Reuter-Lorenz and Jonides 2007). Evidence for this view comes from studies using functional magnetic brain imaging (fMRI) data. Older adults recruit regions of the PFC associated with cognitive control even in simple storage tasks, while these brain regions are not significantly activated in younger adults. These findings suggest that the recruitment of the PFC serves as a compensatory mechanism to maintain good performance in older adults, as assumed by the *Compensation-Related Utilization of Neural Circuits Hypothesis* (CRUNCH) (Reuter-Lorenz and Jonides 2007). However, as task complexity increases, and thereby the demands on executive control, older adults perform poor on WM tasks because their control processes are already taken up by lower storage demands (Reuter-Lorenz and Jonides 2007).

It is now well known that age differences in WM tasks are particularly pronounced with increased cognitive control demands. A critical question from an applied perspective is whether WM can be improved by cognitive interventions even in elderly individuals. In the last decade, a variety of training studies aimed at improving WM performance by means of computerized training programs (Klingberg 2010). These programs often used adaptive training schedules to optimally adjust training demands to individuals' performance levels. Results of these studies indicate that a variable amount of training on visuospatial and verbal WM tasks results in considerable training gains not only in the trained task but also in closely related but untrained WM tasks (Buitenweg et al. 2012; Klingberg 2010). Less consistent evidence is reported on the extent to which these training gains can be maintained over a longer period of time and can be generalized to other cognitive tasks (Buitenweg et al. 2012; Klingberg 2010). These inconsistencies might be due to differences in the duration of the training interventions as well as in the type of training. For instance, it has been shown that practice of explicit memory strategies leads to WM improvements in older adults, but these strategies are not easily transferred to other memory tasks. In contrast, adaptive, process-oriented WM training sometimes also leads

to performance gains in other cognitive tasks (Buitenweg et al. 2012).

Inhibition. Pronounced age differences have also been demonstrated in cognitive control tasks requiring the ability to inhibit irrelevant responses and predominant actions (Buitenweg et al. 2012). One frequently used task to measure the efficiency of inhibition processes is the Stroop task (Kray and Eppinger 2010). This task consists of color words either printed in a compatible color (i.e., “red” printed in red ink) or in an incompatible color (i.e., “red” printed in blue ink) (Kray and Eppinger 2010). Subjects are usually instructed to perform the less-practiced color naming and to inhibit the more-automatized reading of the word meaning. Results typically show longer reaction times and larger error rates in cases in which the word reading interferes with the color naming, that is, on incompatible stimuli relative to compatible ones. This so-called Stroop interference effect is usually larger in elderly adults than in younger adults. Results from a meta-analysis suggest that the larger Stroop interference effect in older adults can be fully explained by age differences in general speed of processing as a general underlying factor (Kray and Eppinger 2010) and not by specific limitation in inhibitory processing. However, when the demands on controlled processing are increased, for instance, by manipulating the frequency of trials on which subjects have to inhibit automatic responses, older adults tend to show larger deficits in inhibitory control than younger adults. The greater need to flexibly recruit cognitive control on less frequent conflict trials, inducing higher demands on cognitive control, lead to pronounced impairments in inhibition tasks in the elderly, similar to the reported findings on age differences in WM tasks (Kray and Eppinger 2010).

Despite the existing age-related decline in measures of inhibition, studies that aim to enhance inhibitory control in old age are lacking (Buitenweg et al. 2012), although there is some evidence for practice-related improvement in the Stroop tasks in older adults. Whether these training gains also transfer to other inhibitory control tasks or even to improvements in other measures of cognitive control remains to be examined (Buitenweg et al. 2012). It has also been

suggested that older adults show better inhibitory control in the morning than in the evening, based on circadian arousal patterns for inhibitory processes that predominantly peak in the morning in the elderly (Hasher et al. 2007). In addition, there are some first results indicating that physical fitness is linked to better inhibitory control that is explained by increased prefrontal oxygenation. In this regard, it has been shown that 8 weeks of moderate aerobic training can improve performance on an inhibition task in older adults (Berryman et al. 2014).

Task Switching. Age differences in cognitive control are also obtainable in tasks assessing the flexible switching between task rule representations. In these types of tasks, subjects are required to alternate between two or more simple categorization tasks such as deciding whether a stimulus belongs to the category of fruits or vegetables (picture task) or whether it is gray or colored (color task). Results of a meta-analysis on age differences in task switching show larger general (or global) switching costs in older than younger adults when two tasks are performed in an alternating order on a task-switching block relative to performance on a single task block (also termed mixing costs) (Kray and Ferdinand 2014). These age-related deficits seem to map on age differences in WM as a key determinant of cognitive control, as age differences in the implementation of a task switch within a task-switching block, termed specific (or local) switching costs, are less pronounced than age differences in general switching costs (Kray and Ferdinand 2014). Importantly, age effects in these costs remain reliable after controlling for age differences in processing speed, suggesting process-specific limitations in the ability to maintain and select task sets.

Further evidence for this view comes from aging studies measuring the neuronal activity during task preparation and response selection by means of fMRI and event-related potential (ERP) data. For instance, if the upcoming task in a task-switching paradigm is announced by a preceding task cue, changes in neuronal activity suggest that older relative to younger adults tend to update the appropriate task representations in

WM after task-cue presentation all the time, even if not required, i.e., when the response rules are exactly repeated compared to the previous task. Moreover, older adults seem to recruit a larger proportion of the PFC than younger adults even in single task blocks in which no task switching is required. Similar to age differences in WM, this finding may reflect that older adults tend to compensate for difficulties in maintaining task rule representations by activating a larger network of prefrontal brain areas (Kray and Ferdinand 2014). Together, the results of task-switching studies favor process-specific limitations, as behavioral and psychophysiological measures suggest age differences in the representation and selection of task goals in WM that cannot be attributed to processing speed as a single underlying factor. In contrast, the switching process itself seems to be relatively preserved in old age (Kray and Ferdinand 2014).

Despite these age-related limitations, recent intervention studies revealed substantial plasticity in task-switching abilities among older adults (Buitenweg et al. 2012; Kray and Ferdinand 2014). Strategy-based interventions, for instance, employed labeling strategies such as verbalizing the next task to promote the planning and preparation of the upcoming task switch and thus to facilitate goal-directed behavior. Results on these kinds of interventions show a substantial benefit of verbal self-instructions on switching costs particularly in older adults, indicating language processes to offer a promising approach to support action control in old age (Kray and Ferdinand 2014). Process-based interventions aim to enhance cognitive control by the practice of the underlying cognitive control processes involved in task switching. Recent studies reported a considerable reduction in switching costs for younger as well as older adults, indicating substantial potentials to improve switching ability (Buitenweg et al. 2012). Both age groups also showed larger performance gains in an untrained but structurally similar switching task, and these gains were even more pronounced in the older than in the younger age group. Importantly, training gains also generalized to untrained cognitive

control task (e.g., inhibition, WM (Kray and Ferdinand 2014)), suggesting the training of cognitive control processes, and in particular, the training of maintaining and selecting (biasing) of tasks as required in dual-task-like situations is a promising approach to induce broader transfer to other cognitive domains (Buitenweg et al. 2012; Kray and Ferdinand 2014).

A Theoretical Framework for Explaining Age Differences in Cognitive Control

In sum, age-related differences in cognitive control have been shown in WM, inhibition, and switching tasks. Recently, the dual mechanisms of control (DMC; Braver et al. 2007) theory proposes that age differences in all of these tasks can be explained by age differences in one common mechanism, namely, the ability to process context information. Context information is described as the internal representation of task-relevant information such as rules, goals, or instructions within WM that is maintained and updated to serve controlled, goal-related behavior. Within this framework, context processing relies on the interaction between the dorsolateral PFC (DL-PFC) and the midbrain dopamine (DA) system. More precisely, sustained neuronal activity of the DL-PFC provides the online maintenance of context information in order to bias the activity in posterior and subcortical brain regions responsible for goal-related behavior in accordance with the current context representation. At the same time, phasic DA projections toward the DL-PFC in response to new, salient, or reward-predicting context cues are proposed to act as a gating mechanism, i.e., ensuring the appropriate updating of context information in the DL-PFC (Braver et al. 2007). Hence, sustained activity within the DL-PFC ensures the stability of goal-directed behavior against distraction, whereas the DA-guided gating mechanism simultaneously allows for the flexible adaptation to changing task demands. Given the well-known age-related neurobiological changes observed in the PFC and the midbrain DA system, deficits are expected in both the active maintenance and the

gating of new context information that in turn impairs performance on a variety of cognitive control tasks. For instance, the active maintenance of task-relevant context information serves to protect information against interference, and disturbances therein particularly affect WM capacity. In a similar vein, deficits in actively maintaining context representations may also impair the ability to inhibit predominant response tendencies, as the maintenance of a contemporary task rule is thought to enable the activation of a weaker, task-relevant response against a stronger but task-irrelevant response. Finally, phasic DA responses to the DL-PFC indicating the need for updating context representations are particularly important in task switching. Therein, context information represents the currently relevant task rule, and deficits in the gating mechanism might impair the updating and flexible attention shifting between cognitive tasks. These examples outline that instead of separating age differences in cognitive control into a decline of subprocesses such as WM, inhibition, and attention shifting, the DMC theory considers age differences in the neurobiological basis of context processing to be fundamental to account for age deficits in subcomponents of cognitive control (Braver et al. 2007).

Recent behavioral and neuroscientific studies on testing the assumptions of the DMC theory show that changes in the interplay between the PFC and the DA system inherent to healthy aging predominantly affect the time course of updating context information. Younger adults exhibit an early, proactive manner of context updating by the time context information is presented and hence update context information to prepare for an upcoming task in advance. In contrast, older adults show a late, reactive manner of context updating, only when needed such as when interference is detected in a reactive fashion (Braver 2012). While the temporal shift of context updating in a pro- versus reactive manner with increasing age has been supported on the basis of fMRI and ERP data (Braver 2012; Schmitt et al. 2014), age differences in maintaining context information have revealed mixed results and seem to occur only under specific task conditions. However, the DMC theory is promising as

temporal differences in context updating seem to account for age differences in inhibition, WM, and task shifting that are often regarded as separable components of cognitive control (Braver et al. 2007).

Age-related differences in context updating have been shown to be susceptible to different training regimes. In two training studies, the AX continuous performance task (AX-CPT, Braver 2012) was applied in order to measure an individual's ability to process context cue information required for correct responding to a subsequent probe stimulus. It has been demonstrated that both extended practice and directed strategy training toward the use of cue-based, proactive control in the AX-CPT reduced context processing deficits in older adults, indicating process- and strategy-based interventions to benefit context updating in old age. Moreover, the behavioral improvements in the AX-CPT in older adults were accompanied by increased PFC activation to the presentation of contextual information (Braver 2012). These results correspond to a recent training study showing training-related alterations in PFC activity to underlie the transfer of training gains to untrained cognitive control tasks (Bamidis et al. 2014). In this study, older adults performed an adaptive multitasking video game training offering a large stimulus variability and continuous feedback. The multitasking approach in particular encompassed the need for resolving task interference in the dual-task situation. Training gains were larger after multitask training than after training both tasks in isolation, transferred to other untrained cognitive control tasks such as WM and attention, and remained stable at a follow-up measurement 6 months after the training. Moreover, robust correlations between multitasking ability and changes in activation patterns of the PFC predicted the transfer gains to the untrained cognitive control tasks. Hence, process-based training interventions, such as multitasking training, that aim at improving cognitive control can result in alterations of the neuronal recruitment of the PFC in elderly individuals that may also generalize to other cognitive tasks relying on cognitive control networks (Bamidis et al. 2014).

Definition of Self-Regulation

The concept of *self-regulation* refers to the individual control of own actions, thoughts, and emotions toward the achievement of desired outcomes and intentions (Bauer and Baumeister 2011). It is very loosely defined and considered as a conglomeration of abilities, consisting among others the capability to override automatic habits, basic affects, and impulses, to control and monitor performance, to achieve distal aims, and to resist short-term temptations to the benefit of long-time goals. Accordingly, failures of self-regulatory ability affect both flexible behavior and social adaptation that can be observed in a broad range of psychological phenomena such as gambling, addiction, eating disorders, underachievement, prejudice, aggression, and so on (Bauer and Baumeister 2011).

In general, self-regulatory processing is considered as a system of feedback loops in which individuals concurrently monitor the discrepancy between the actual behavioral outcomes and feedback and the individuals' goal and intentions (Bauer and Baumeister 2011). Whenever there is a discrepancy, individuals automatically or consciously engage in self-regulatory abilities to minimize the discrepancy until the goal is achieved. Hence, similar to the concept of cognitive control, self-regulation is highly important to adaptive, goal-directed behavior (Bauer and Baumeister 2011). For instance, it has been shown that individuals with better cognitive control ability, such as higher WM capacity, also tend to show better self-regulatory skills, such as less mind-wandering or more resistance toward the temptation of eating candy (Hofmann et al. 2011).

Neuronal Underpinnings

Recent research has also identified subprocesses of cognitive control to play an important role in the mechanisms of self-regulation (Wagner and Heatherton 2011), in particular the self-control aspects of self-regulation. This view is supported by evidence that akin to the mechanisms of cognitive control, a broader range of self-regulatory

abilities depend on a network of specialized prefrontal brain regions, including the lateral PFC (L-PFC), the ventromedial PFC (VM-PFC), and the anterior cingulate cortex (ACC) (Wagner and Heatherton 2011). The L-PFC is highly related to other prefrontal regions, especially to motor cortices, the VM-PFC, and the ACC, and is assumed to contribute to the mere self-control processes involved in self-regulation, such as inhibiting inappropriate behaviors, maintaining multiple goals in WM and flexibly selecting between them, dealing with distraction, and carefully planning the sequence of goal-directed actions (Wagner and Heatherton 2011). In contrast, the VM-PFC is highly connected to subcortical structures involved in affective processing (e.g., the amygdala, the hypothalamus, the insula, and the ventral striatum). Therefore, the VM-PFC is seen to be particularly important for regulating affective and appetitive processes and adapting to social norms (Wagner and Heatherton 2011). This assumption has been supported by case reports showing patients with damage to the VM-PFC to exhibit drastic personality changes such as aggressive, socially inhibited behavior and a particular inability to respect social norms (Wagner and Heatherton 2011). Despite their functional differences, both the L-PFC and the VM-PFC are interconnected with the ACC that shares many connections with subcortical (e.g., the ventral striatum) and motor regions. Patient studies show that due to its close connection to motor cortices and subcortical structures involved in reward processing, damage to the ACC may result in general apathy, loss of motivation or interest, and an inability to generate behavior (Wagner and Heatherton 2011). Moreover, given its anatomically strategic position, neuroscientific research regards the ACC as a neuronal correlate of a conflict detection mechanism, signaling the need for increased control toward the L-PFC whenever performance errors are detected. This role closely reflects the conceptualization of self-regulation as a system of feedback loops (Wagner and Heatherton 2011).

The strong anatomical and functional overlap between control processes (e.g., inhibition of temptations and automatic behaviors) attributable

to both the concepts of cognitive control and self-regulation has led to systematic investigations of their interaction. In the *Strength Model of Control and Depletion* (Bauer and Baumeister 2011), it has been argued that these control processes depend on a limited, domain-general physiological resource that – once depleted – results in impaired performance on task relying on this resource. Dieters, for example, whose resource for self-regulatory control on eating behavior was stressed by inhibiting temptation from nearby food, showed impaired performance not only in a subsequent task on self-regulation (i.e., eating ice cream) but also on a cognitive control task (i.e., WM) relative to non-dieters and dieters whose self-regulation was not additionally depleted by tempting foods (Bauer and Baumeister 2011). Likewise, participants who were required to take part in a difficult cognitive control task (i.e., attentional control) showed impaired self-regulatory control (i.e., emotion regulation) compared to control participants who did not complete the cognitive control task (Wagner and Heatherton 2011).

Age Differences in Self-Regulation

Age-related deficits in self-regulation have been strongly associated with impairments in cognitive control and in particular with impairments in inhibitory control (Von Hippel and Henry 2011). On the one hand, due to a failure to inhibit and control automatically activated thoughts and temptations, older adults seem to express more social stereotypes (i.e., race-related prejudices), exhibit more socially inappropriate behavior (i.e., talking about private issues in public and generating gratuitous comments), and engage more in risky gambling (i.e., larger perseverance in the absence of reward) than younger adults (Von Hippel and Henry 2011). Interestingly, individual differences in inhibitory deficits (as measured with standard cognitive control tasks) seem to directly mediate the extent of self-regulatory failure in older adults (Von Hippel and Henry 2011). Moreover, these inhibitory deficits have been shown to be sensitive to circadian

rhythms, with smaller deficits obtained in the morning than afternoon based on biological changes in the underlying neuronal resource. Therefore, older adults showed more risky gambling and socially inappropriate behavior when they were tested in the afternoon relative to when the experiment took place in the morning (Von Hippel and Henry 2011). On the other hand, evidence exists that older adults are able to manage self-regulatory deficits and inhibit expressing stereotypes or inappropriate behaviors when they are aware of it. For instance, if older adults are forewarned about an upcoming, irrelevant stereotypical situation or if they know beforehand that they have to suppress a socially inappropriate action later on (Von Hippel and Henry 2011), they do not differ in the appropriateness of their behavior relative to younger adults. This suggests that older adults may prepare for potential inhibitory control deficits, and hence, can exert conscious control over their self-regulatory abilities.

Furthermore, there are also findings suggesting *increased* self-regulatory skills in older adults than in younger adults (Von Hippel and Henry 2011). For instance, in the domain of emotion regulation, it has been shown that older adults focus more on positive than negative or neutral information in order to voluntarily enhance their emotional well-being. This phenomenon, known as the *age-related positivity effect* (Mather 2006), has been explained in the framework of the *socio-emotional selectivity theory* (Mather 2006). This theory posits that personal goals have to be regarded within future time constraints. In the case that individuals value future time horizons as enduring, they will focus on goals related to the future, such as gaining knowledge. In contrast, if individuals recognize future time as restricted, just as it occurs in older age, they will focus on immediate, meaningful goals, such as emotional regulation and gratification (Mather 2006). Accordingly, relative to younger adults, older adults expressed higher emotional stability and skills of emotion regulation, showed more effective social problem-solving, focused more strongly on positive relationships with others, and reported less self-conscious negative emotions (Mather 2006). Similar to the controlled

compensation of inhibitory deficits, the age-related positivity effect seems to be more pronounced when older adults are forewarned and for older adults with better cognitive control ability. In contrast, when cognitive load is increased or cognitive control abilities are impaired as in pathological aging, older adults are less able to invest in controlled processing of emotional information and the positivity effect vanishes (Mather 2006).

Apart from the stable or even improved ability of emotion regulation in the elderly, there are only a few studies that have investigated whether self-regulatory skills can be improved by cognitive interventions. These studies show that already a limited amount of practice in self-regulatory control, for instance, by controlling eaten food or engaging in regular physical exercises, is able to translate into improvements in key aspects of self-control in laboratory tasks and also transfers to self-regulatory skills in everyday life (e.g., decreased consumption of cigarettes, alcohol, and unhealthy food) (Bauer and Baumeister 2011). So far these studies have mainly been conducted in younger or middle-aged individuals and largely neglected the effect of self-regulatory practice in older adults (Hofman et al. 2012). However, given existing evidence for self-regulatory failures in old age (e.g., problematic gambling), it might be especially important to create successful self-control trainings and to investigate any potential transfer to measures of self-regulation in this age group. In this respect, it is also interesting to note that improvements in self-control have been demonstrated via training of cognitive control functions. In a study on middle-aged problem drinkers, WM training transferred to self-regulatory improvements, i.e., reduced alcohol consumption for more than 1 month after training (Hofman et al. 2012). Given the functional relationship between cognitive control and self-regulation, these improvements may draw back on the underlying neuronal process resource common to cognitive control and self-regulation. Thus, as cognitive interventions have already demonstrated significant potential to improve different facets of cognitive control in old age (see previous section on

cognitive control), future research studies in older adults might investigate whether and to what extent these interventions are able to transfer to self-regulatory skills. Finally, these studies might also turn to training-related changes in the underlying brain network of self-regulation and cognitive control.

Summary

There is now accumulated evidence for age-related limitations in cognitive and self-regulatory control that are associated with alterations in different underlying neuronal networks. Age differences in cognitive control occur in tasks requiring high demands on WM, inhibitory control, and task switching that can be explained by a recent neurobiological theory on context processing. Age differences in self-regulation primarily concern self-control, while emotion regulation is relatively preserved. Intervention studies have revealed considerable plasticity in cognitive control in elderly individuals, while the potential benefit of training in self-regulation is not known yet. Given that cognitive control and self-regulation partly rely on similar neuronal networks, it will be an important challenge for future research to determine whether training in either of these abilities will lead to improvements in the corresponding other one.

Inconsistency; Inconsistency resolution

Definition

In its original definition, cognitive dissonance is a state of arousal caused by having co-occurring cognitions such that one follows from the obverse of the other. Dissonance is experienced as an unpleasant tension-like state and needs to be reduced. A cognition is an individual piece of knowledge about the world or about one's internal states.

Cognitive Dissonance

Cognitive dissonance is a ubiquitous aspect of human social life. Introduced into the scientific literature by Leon Festinger (1957), the concept was defined as a state of arousal caused by inconsistency among a person's cognitions. In Festinger's view, people abhor inconsistency. When faced with discrepancy among cognitions, people experience a motivation akin to hunger or thirst. It is an uncomfortable drive-like state that we are motivated to reduce. We resolve our inconsistencies in myriad possible ways that are designed to alleviate the tension state and restore equanimity.

Festinger (1957) offered a set of hypothetical examples that helped to describe some of the circumstances that might lead to the arousal of dissonance. Among those circumstances are choosing to smoke when you know that smoking is damaging to your health, making a statement contrary to your true opinions, choosing one commodity or action from a set of attractive alternatives, holding an opinion that is inconsistent with more general values or opinions, or observing events that are inconsistent with past experience.

Despite our preference for consistency, there are numerous times in our daily lives in which we are confronted with a set of inconsistent cognitions. Because the perception of inconsistency leads to an uncomfortable state of arousal, we have developed ways to reduce the inconsistency. We may respond to inconsistency by changing a cognition to make it fit with other cognitions we hold. We can also change the importance of a cognition or act to avoid noticing the inconsistency altogether.

Aging may affect the dissonance process. At the very least, the cognitions that people find to be important change with age. Young children may be invested in the toy they are allowed to choose; young adults may be profoundly affected by the cost of attending university; older adults may be most interested in the types of leisure activities they can choose or the age of retirement from their careers. More profoundly, changes in memory and emotional processes may also affect the quality and magnitude of dissonance arousal, and

changes in mental and physical health status may also affect the way that dissonance is experienced in people's lives.

The plan of this entry is to describe the basic tenets of cognitive dissonance theory and the focal areas that have received the preponderance of research attention. Alternative formulations of dissonance will be examined as will the accompanying evidence for those alternatives. Changes in mental processes and brain activities that characterize passage into older age will be presented along with a discussion of the ways that such changes affect the arousal and reduction of cognitive dissonance.

Cognitive Dissonance as Function of Choice

Our lives are replete with choices. We choose a breakfast cereal to begin the morning, we choose the clothes we put on, and, possibly, we choose the means of transportation we use to shop or go to work. If we have been fortunate in our lives, we have chosen the job we currently have or the school that we attended. What is little noted in all of these choices is the fact that choices create the conditions for the arousal of cognitive dissonance. Imagine a couple that has recently retired and decided to change their living accommodations from a private home to a retirement community. They have narrowed their choice to two facilities that they view as highly attractive. One community offers excellent recreational activities but comes at a steep cost. Another may have a dearth of recreational facilities but has excellent food and costs appreciably less. The choice is an important one for it has implications for future lifestyle and happiness.

Cognitive dissonance theory predicts that these retirees will experience cognitive dissonance as soon as they decide which facility to join. Prior to the choice, the many facets of the decision were examined carefully and objectively. In the pre-decision period, people try to make the very best decision possible and consider their options without bias. However, once the decision is made, then every attractive feature of the unchosen alternative stands in contradiction to the choice that was made. So, too, does every unattractive feature of the chosen alternative. For example, if the

retirees decide to join the facility that had the best recreational activities, they will be comforted by the fact that recreation – as well as all other positive features of this choice – fit with their decision. They can envision hours on the treadmill, or the golf course. On the other hand, the cost of the facility will make it less feasible for them to travel for holidays or family visits. Moreover, by choosing the facility with the better recreational activities, the couple will not be able to savor the excellent meals at the second facility.

Cognitive dissonance theory predicts that, once having made a choice, all of the consequences of that choice that are inconsistent with the selected alternative become grist for the dissonance process. The perception of inconsistency – for example, foregoing the excellent food at the rejected community and paying the steep price at the chosen community – creates the aversive feeling state of cognitive dissonance. In order to reduce the aversive state of dissonance, the couple is motivated to reevaluate the components of their decision in order to support the conclusion they came to. They can decide that they did not really want to be saddled with the burden of having to go to the rejected community's elaborate dinners and that traveling is not a highly prized activity after all. They might also engage in selective memory by recalling all of the consequences consistent with their choice while forgetting those that are inconsistent. In the end, dissonance theory predicts that the couple will become more satisfied with their choice than they were when they made their selection. In brief, the inconsistency created by making a difficult choice between alternatives arouses the uncomfortable tension state of dissonance. In order to reduce dissonance, the chosen alternative is seen as more attractive and the rejected alternative becomes less attractive. This is known as the "spreading of alternatives," one of the signature predictions of cognitive dissonance theory.

Numerous laboratory studies have supported this prediction (Cooper 2007). In the first empirical investigation of the consequences of free choice, Brehm (1956) asked adult consumers to rank a number of appliances in terms of how attractive they would be to own. The consumers were

then given an opportunity to select one of two highly attractive items. The choice was a difficult one because the items had been ranked similarly in attractiveness. Brehm found that, following the choice, the participants came to feel that the item they had chosen was even more attractive than it had been prior to the choice and the item they had rejected was rated as less attractive. The spreading of alternatives following a choice has been replicated with children and adult participants and is robust across cultures (Cooper 2007).

Cognitive Dissonance and Induced Compliance

Induced compliance is the name given to the social situation in which someone is induced to argue for a position that is contrary to the person's own beliefs. In the first experiment of its type, Festinger and Carlsmith (1959) asked participants to engage in a performance task in the laboratory that was designed to engender a negative attitude. It was tedious, boring, and apparently without purpose. Participants were then induced to lie to a person who was waiting to take part in the experiment. They were asked to convince the alleged next person that the performance task was fun, engaging, and enjoyable. Because the statement was clearly contradictory to the participants' attitudes, it aroused cognitive dissonance. In order to reduce the arousal of the unpleasant tension state, participants changed their attitudes to make them more consistent with their behavior – that is, they came to agree that the task was interesting.

Dissonance has a magnitude (Festinger 1957). People who hold cognitions that are incompatible can experience dissonance to different degrees. Some of the variance is due to individual differences in tolerance for inconsistency (Cialdini et al. 1995). Most of the research on the magnitude of dissonance, however, has focused on situational differences in the inducement for counterattitudinal behavior. For example, asking people to make a counterattitudinal statement for a small, or no, incentive creates more dissonance than making the same request for a substantial incentive. Festinger and Carlsmith predicted and found that making attitude-discrepant speeches in

return for a small incentive (\$1) created more attitude change than making attitude-discrepant speeches for a large incentive (\$20).

The situation that Festinger and Carlsmith employed in their research was well controlled but somewhat artificial. Enjoyment of a specific laboratory task is not a concern in most people's lives. Nonetheless, there are instances in people's lives in which they may find themselves advocating positions that they do not fully endorse and these may lead to the arousal of cognitive dissonance. Imagine that a special interest group hires a retiree to advocate for privatization of a pension or retirement system. Although the retiree does not endorse privatization, he consents to advocate on behalf of this plan. Consistent with dissonance theory predictions, the retiree is likely to change his attitude in favor of privatization. The less he is paid for his advocacy, the greater the dissonance and the greater the attitude change in favor of the privatization plan.

Empirical research has supported the prediction that people change their attitudes toward important issues that affect their lives. People have been induced to change their attitudes about banning controversial speakers, students have changed their attitudes toward raising tuition, and taxpayers have changed their attitudes about raising taxes after being induced to make statements contrary to their attitudes. And, as in the laboratory, the less the incentive, the greater the dissonance and the more the attitude change (Cooper 2007).

An additional feature of the induced compliance situation critical for the maximization of dissonance is that the attitude-discrepant behavior must lead to an unwanted consequence. If a retiree makes a statement advocating privatization of pension plans, the statement will lead to dissonance if there is a consequence to his behavior. The likelihood that someone will be convinced by the counterattitudinal statement facilitates maximal cognitive dissonance and will lead to attitude change.

Effort Justification

People often engage in effortful activities in order to achieve a goal. In the literature on effort

justification (Aronson and Mills 1959), effort is considered to be any activity that is difficult and unpleasant or would otherwise not be engaged in. Imagine that a person hopes to join a book discussion club at a neighborhood senior citizen center. Imagine, too, that the group has requirements that could be considered onerous. In order to join, members have to pay a deposit as a precaution against damages, must read and write reports on several books so that their reading and intellectual abilities can be assessed, and agree to lead more than their share of group discussions. Assuming that the deposit, the extra reading, and reports are unpleasant or effortful, then engaging in them arouses cognitive dissonance. If they were engaged in for the purpose of joining the club, then the club ought to be a very good one in order to justify the amount of effort expended. Suppose that objectively it is only mediocre. In that case, the effort expended to join the group is inconsistent with the group's quality. This increases the amount of dissonance. The unpleasant arousal state can be reduced by distorting the perception of the quality of the group. Rather than viewing the book club as mediocre, people can alter their attitude to believe that the group is wonderful, thereby justifying the effort and expense they paid to join.

Alternative Models of Dissonance

The New Look Model. Cooper and Fazio (1984) proposed an alternate model for the basis of cognitive dissonance. They outlined a theory in which dissonance is caused by assuming responsibility for a behavior that results in a potentially unwanted consequence. In the New Look model, dissonance is not aroused by inconsistent cognitions per se but is rather a coping strategy to deal with one's responsibility for bringing about aversive events.

The New Look model raises an important issue that affects many people as they age. Any number of unwanted consequences may occur as a function of growing older. People may need to retire because of failing health or because of arbitrary age restrictions. Home environments may need to be modified or people may need to move to special care facilities. These consequences of aging

are often unwanted and aversive, which seem suited to evoking the arousal of dissonance. Dissonance often works to the advantage of people who must make difficult decisions about retirement or health because it typically serves to make them feel more positively about the decisions they have made. The critical factor that determines whether the unwanted consequences of aging lead to dissonance is whether people feel personally responsible for the occurrence of the aversive events. In principle, if dissonance is aroused, it will lead to cognitive activity designed to reduce the dissonance. If moving to a senior facility leads to something objectively unwanted, people will experience dissonance and take action to reduce it. It would be reasonable to predict that people will be motivated to like their new living facilities as a way to reduce dissonance – but only to the extent that they feel personal responsibility for their choices. If they feel retirement has been forced on them or they had no role in a decision to move to a new facility, then dissonance will not occur and there will be no motivation to raise their evaluations.

The Action-Based Model. Harmon-Jones (1999) proposed a functional approach to the motivation for cognitive dissonance. The action-based model suggests that people are motivated to reduce inconsistency because the negative arousal interferes with people's distal motivation to prepare for unequivocal action. Because inconsistent cognitions imply inconsistent actions, the discrepancy needs to be resolved.

Self-Esteem Approaches. Aronson's self-esteem model (Aronson 1968) and Steele's self-affirmation theory (Steele 1988) suggest that the central motivation for dissonance arousal and reduction is to maintain a high sense of self-esteem. Acting inconsistently threatens people's self-worth. Therefore, restoring consistency is at the service of reestablishing a self-worth and global self-esteem.

Self-Standards Model and the Role of Self-Esteem in Aging. Stone and Cooper (2001) proposed a resolution of the role of self-esteem in dissonance. They showed that the effect of the self in the arousal of dissonance is moderated by the standards that are used to evaluate the

consequences of behavior. When people behave, they assess the valence of the consequences by comparing them to a particular standard of judgment. Stone and Cooper's self-standards model proposes that the choice of standards of judgment moderates the role of the self in the dissonance process. When people are motivated by situational or dispositional factors to assess their behavior against normative standards of judgment, such as "How would most people assess this behavior?", then self-esteem does not factor into the dissonance process. However, when people evaluate their behavior by using a personal standard of judgment, then self-esteem is very much a part of the dissonance process. As a general rule, the higher the self-esteem, the greater is the dissonance.

What can we expect about the role of self-esteem in the aging process? To the extent that dissonance is based on personal standards of judgment, an aging population will experience more or less dissonance depending on changes in their self-esteem over the life span. Research concerning the self-esteem of the elderly leans toward the conclusion that older adults have a lower sense of self-esteem than younger adults (Robins et al. 2002), which would suggest that dissonance may be less acute with an aging population. On the other hand, self-esteem of older adults tends to be related not only to chronological age but also with their ability to assimilate into their social environment and to manage difficult life events (Alaphilippe 2008). Self-esteem of the elderly also shows fewer fluctuations than the self-esteem of younger adults. Empirical research has not yet addressed the role of aging as a moderator of the role of self-esteem in the dissonance process but it is likely that self-esteem is a complex factor of chronological age and social circumstances.

Neuropsychology of Dissonance. Dissonance is accompanied by the psychological experience of discomfort (Elliot and Devine 1994) and by autonomic physiological arousal as assessed by elevated skin conductance responses (SCR) (Croyle and Cooper 1983; Losch and Cacioppo 1990). In the brain, research has associated cognitive dissonance with increased neural activity in

the right inferior frontal gyrus, the medial frontoparietal regions, and the ventral striatum and decreased activity in the anterior insula (Jarcho et al. 2011). Such processes are found to engage quickly at the moment of decision without extensive deliberation. Van Veen et al. (2009) found that attitude change associated with cognitive dissonance engages the dorsal anterior cingulate cortex and the anterior insula. More broadly, greater left frontal activity appears to be activated in the dissonance process, linking it to other negative, approach-oriented motivations such as anger (Harmon-Jones 2004).

Dissonance in the Aging Process

Numerous changes occur during aging that affect dissonance. The magnitude of dissonance is influenced by factors that undergo change during the life span. For example, when making a choice between alternatives, a person's age may determine the importance of the choice and therefore the magnitude of dissonance. More fundamentally, increased age brings with it changes in psychological functioning and neurological integrity. These changes are likely to affect cognitive dissonance in fundamental ways.

Older adults experience deteriorations in neural areas important for executive functioning. The prefrontal cortex is one of the areas most affected by aging. With increasing age, the prefrontal cortex responds more slowly than, for example, the limbic system, when processing emotional stimuli (Gross 2013). The vmPFC shows marked structural decline after the age of 60 (Asp et al. 2012). Neuronal density in the frontal gyrus is measurably different when people enter their 70's. Yet, despite the atrophy in structure, activation in areas associated with dissonance and decision making remain strong in older age. Activations in the dorsolateral prefrontal cortex and the ventral medial frontal cortex remain strong, as do the parietal areas.

There are decreases in explicit memory with age, but the decreases are not associated with diminished ability to process or respond to dissonant information. Explicit memory does not

appear to be necessary for dissonance reduction. Lieberman and colleagues (2001) tested amnesiacs whose explicit memory was impaired and compared them to normal adults in a free-choice dissonance situation. In the experiment, amnesiacs and normals were asked to make a selection between attractive alternatives. Lieberman et al. found that amnesiacs engaged in choice-supportive reevaluation of the alternatives despite their having no explicit recollection of the initial choice. Consistent with dissonance theory, and similar to the responses of normal participants, amnesiacs spread the attractiveness of the choice alternatives to support the initial decision they had made.

Older adults are more averse to negative affect than are younger adults. For example, they are more likely to rate highly arousing negative stimuli as more negative than do younger adults and are vigilant to minimize the occurrence of negative experiences. Older adults concentrate on avoiding regret and boosting contentment (Carstensen and Hartel 2006). When asked to report their emotional experiences, older adults report as many positive emotional experiences as younger adults but report fewer negative experiences (Carstensen et al. 2000). In general, older adults spend more time and resources regulating emotional experiences, both in laboratory research tasks and in daily life tasks, and do so with a bias that leads to emotional satisfaction (Scheibe and Carstensen 2010).

As people age, they become more proficient at knowing the emotional effects of future events and have the enhanced ability of tailoring their emotion-regulatory strategies to meet contextual demands (Scheibe and Carstensen 2010). Thus, the future emotional implications of decisions may be weighted heavily by older adults, suggesting that because the elderly are concerned with their view of self, decisions and actions that go against their attitudes and views may intensify their experience of dissonance. This effect in the elderly can be further understood through the life-span theory of control (Heckhausen & Schulz 1995), which suggests that people's capability to regulate their environments and attain their growth-related goals declines in older adulthood. Therefore, older

adults increasingly use secondary control tools, such as emotion regulation, which is aimed at changing the self to be able to adjust to a given situation, instead of relying on primary control strategies that change the situation itself.

The increase need for emotion regulation combined with diminished structural integrity of frontal brain activity suggest that older adults devote more of their cognitive resources to regulating emotion, with particular emphasis on avoidance of negative states. Because cognitive dissonance is experienced as a specifically negative emotional state, older adults are motivated to engage in dissonance reduction, consistent with their orientation to avoid negative emotional states. Mather and Johnson (2000) examined people's recollections of the positive and negative features of choice alternatives in a free-choice (Brehm 1956) situation. Older adults (64–83) and younger adults (18–26) were given the option to choose an alternative in a set of two-choice options. Choices included selections of which of two houses they would prefer or about which of two candidates they would select for a job. Several positive and negative attributes of each alternative were described. Following their choice, participants were asked to recall as many of the attributes as they could remember. The older participants showed more choice-supportive memory than the younger adults. Older adults remembered more positive attributes and fewer negative attributes of the alternatives they selected. They also recalled more negative and fewer positive aspects of the alternatives they rejected. Older participants also misattributed attributes of the alternatives in a choice-supportive manner. When given the opportunity to attribute positive and negative features to the alternatives that had not been mentioned in the original list, they made errors of memory in the same choice-supportive fashion.

In order to assess the crucial role played by emotion regulation, participants were either asked to remember the facts or remember how they felt when making their decisions. Younger adults did not show choice-supportive memory when asked for a factual review. They manifested the choice-supportive memory effect only when asked how they felt. Older adults showed the

choice-supportive memory effect regardless of condition, indicating that they used selective and distorted memory as ways to adjust negative feelings that were aroused by dissonance.

In Mather and Johnson's research, participants were also administered a neuropsychological test battery to measure frontal brain region pathology. The results showed poorer overall memory among people identified with neuropathological disorders but found even greater ratios of choice-supportive memory in this subpopulation. This is consistent with the notion that the weakening of cognitive executive function causes people to put more of their available resources toward the goal of regulating emotion by becoming more emotionally satisfied with the choices they made (Mather and Johnson 2000).

Further research (Mather and Johnson 2000) confirmed that the distortions of memory are consistent with dissonance theory predictions. Participants either chose one of the alternatives or were assigned one of them. Results confirmed that choice-supportive memory distortions occurred only in the free-choice conditions known to produce cognitive dissonance (Brehm 1956) but not in conditions in which the alternatives were merely assigned.

Conclusion

Cognitive dissonance is a state of aversive arousal that occurs when people perceive inconsistency among their cognitions. Although dissonance was not theorized to be age related, empirical work on dissonance had been primarily focused on convenience samples of young adults. Recent research suggests that, to the extent that gerontological factors influence the course of cognitive dissonance, older adults may be particularly sensitive to dissonance effects. With increasing age, changes in psychological functioning imply different needs, goals, and abilities. Although regions of the brain associated with memory and executive function show structural and functional decline with age, regions associated with cognitive dissonance show no consistent pattern of decline. Instead, research in emotion regulation suggests that the need to achieve positive emotional states increases with age along

with the concomitant sensitivity to potential negative threats. Cognitive dissonance is a potential threat. Reducing it in a choice-supportive manner appears to be an increasing priority of the aging process.

Definition

While physical changes are obvious with age, cognitive neuroscience sheds light on the structural and functional changes that occur in the brain throughout the lifespan. Using behavioral and neural measures, cognitive neuroscience suggests that with increasing age, there are not only cognitive deficits, but also the potential for reorganization and stability of these underlying cognitive processes.

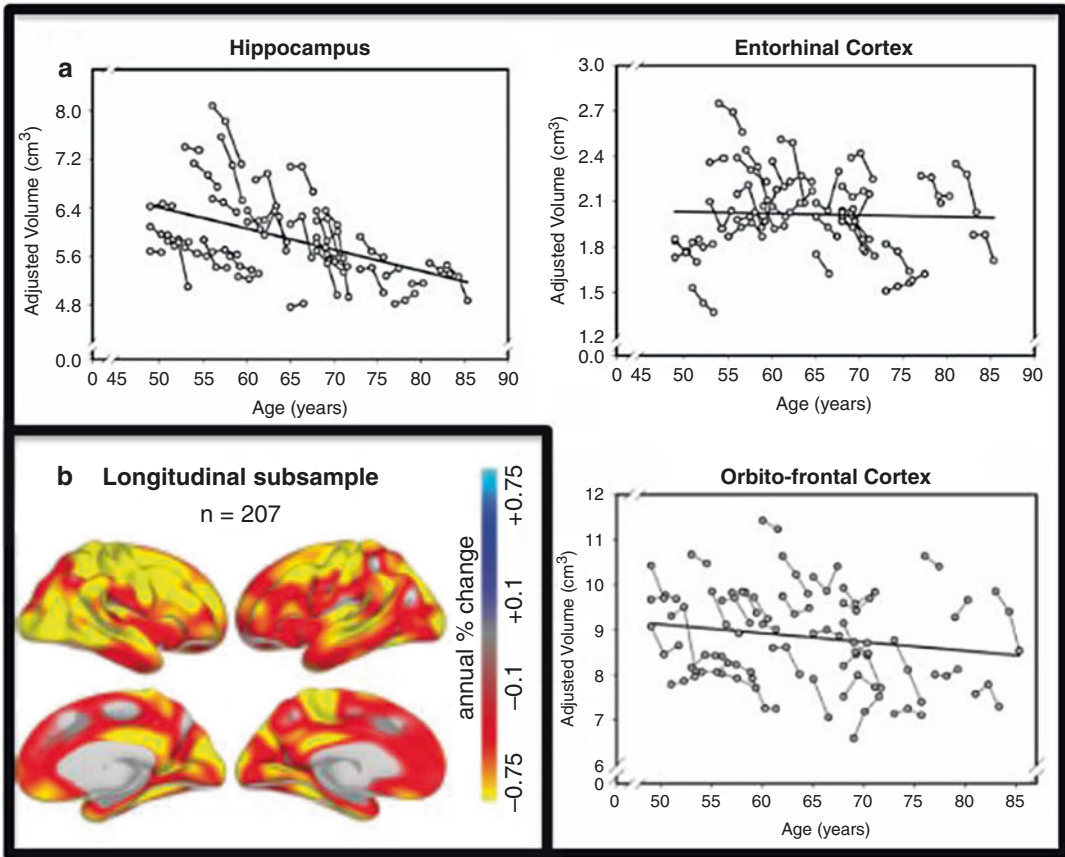

Introduction

Much of the previous behavioral research has focused on losses with age – the senses become less sharp, performance worsens on tasks, and it is easier to become distracted and forgetful. While aging brings readily apparent changes to areas such as physical appearance, health, and stamina, it also brings significant changes to the brain. Cognitive neuroscience has greatly impacted the way in which aging is understood by probing these internal changes. New methods have shown that aging leads to alterations in multiple aspects of the brain, including structure, integrity, and active engagement of neural regions. The physical anatomy of the brain changes in terms of both gray matter (as assessed with methods such as magnetic resonance imaging, MRI) and white matter (as assessed with method such as diffusion tensor imaging, DTI). Determining *functional* activation in the brain, such as how different regions are engaged during demanding

cognitive tasks, is accomplished via methods such as functional magnetic resonance imaging (fMRI). These are just some of the many methods used in cognitive neuroscience research, but these are the methods that will be predominantly discussed in this entry. Studies employing these methods begin to uncover how age-related changes to the brain impact behavior, including not only how neural regions support cognitive function with age but also the overall efficiency in engaging processes. Importantly, the application of cognitive neuroscience methods has shown that aging is not simply deterioration of the brain, but it also reveals evidence for reorganization and compensation underlying cognitive processes. For example, some research illustrates how an older brain is able to adapt to physiological changes to perform a task comparably well as a younger brain, albeit not as efficiently. Much of the literature argues that older adults recruit additional activation in brain areas that were not activated in younger adults performing the same task. While the function of these activation changes is still greatly debated in the field, it indicates, at the very least, flexibility in the brain recruitment of older adults. Cognitive neuroscience has helped progress the field by seeking to understand the behavioral impairments on a neural level and how brain plasticity attempts to compensate for these changes.

Structural Changes in Aging

With aging, the brain typically undergoes widespread cortical thinning. The gaps (sulci) between the cortex widen, while the volume of the folds of the cortex (gyri) decreases, as evidenced with methods such as MRI. However, certain regions are more prone to atrophy than others, and individuals vary widely in their extent of change. For example, the hippocampus, orbitofrontal cortex, and entorhinal cortex have all been shown to decrease in volume over time, whereas regions like the primary visual cortex, putamen, and pons remain relatively intact (see Fig. 1a; Raz et al. 2010). Longitudinal studies of cortical thickness have also shown that regions such as the

Cognitive Neuroscience of Aging, Fig. 1 Atrophy in the aging brain is exhibited by overall cortical thinning of the cortex. (a) Volume was measured twice, 15 months apart, in individuals aged 49 and older. This is depicted by two measurements, connected by a line for each individual. Most individuals show decreases in volume, even in this short time frame, with the vast majority of lines connecting the two points showing a downward trend. The overall trend line reflects that the volume of the region tends to decline after age 49. (b) Annual percentage change in cortical thickness was measured in a longitudinal sample

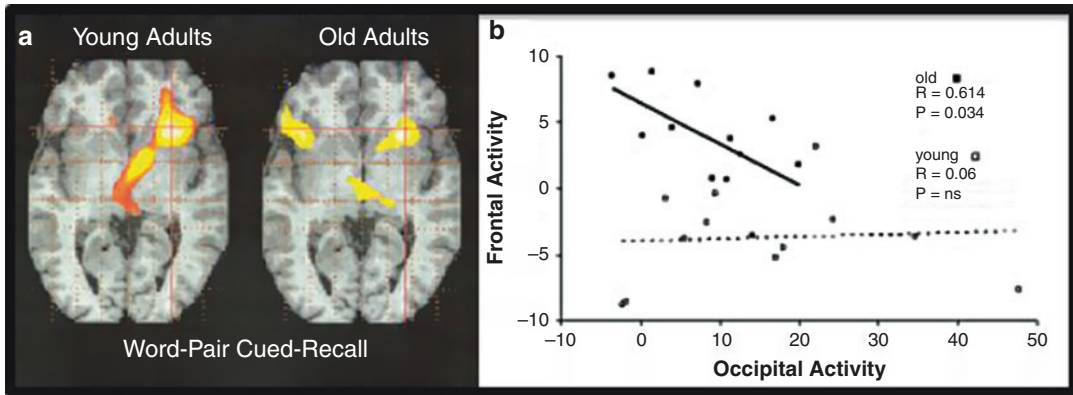

aged 60–93. This is represented by a color-coded brain map where percent decrease in cortical thickness is represented by *yellow* and *red*, appearing as lighter and darker *gray* in the grayscale version. The longitudinal sample showed a mean annual change of -0.59% across the cortical surface. This reduction was especially seen in regions such as the lateral frontal, temporoparietal, and lateral occipital cortices (Source: (a) adapted from Raz et al. (2010) with permission; (b) adapted from Fjell et al. (2014) with permission)

lateral frontal, temporoparietal, and lateral occipital cortices all exhibit an increased mean annual percent change with age (see Fig. 1b; (Fjell et al. 2014)).

Although there is much interest in linking structural measures of the brain with performance on cognitive tasks, there is not always a straightforward link between these measures. However, relationships have emerged for some regions, such as the entorhinal cortex. The cortical thickness of this region is associated with memory

performance and shows substantial atrophy both in Alzheimer's disease and in normal aging (Fjell et al. 2014). A role for entorhinal cortex in memory is consistent with its location in the medial temporal lobes near the hippocampus, an important structure for memory.

Classically, atrophy in the brain has been studied by examining gray matter, which is the tissue that contains the cell bodies and dendrites of neurons. However, cognitive neuroscience has revealed that it is also important to study the

Cognitive Neuroscience of Aging, Fig. 2 Changing brain activation patterns with aging. (a) Support for the HAROLD model reveals that prefrontal cortex activation during a cued-recall task (e.g., studied *parents-piano*, presented with *parents-???* at test) was right lateralized in younger adults but bilateral in older adults. Activation appears as a *yellow/orange* blob, *gray* in the grayscale version. Concurrent with HAROLD and reductions in hemisphere asymmetry, older adults recruited two hemispheres to complete a task that only required recruitment of one hemisphere for younger adults. (b) Correlations

between occipital and frontal activations in younger (depicted as *circles*) and older (depicted as *squares*) adults. Consistent with the PASA model, older adults (relative to younger adults) showed less occipital activity concomitantly with increased frontal activity. This suggests age-related deficits in sensory processing that require recruitment of regions involved in organization and reconstruction of information (Source: (a) adapted from Cabeza (2002) with permission; (b) adapted from Davis et al. (Davis et al. 2008) with permission)

connections between regions of the brain formed by white matter, the tissue that contains the axons of neurons and that is necessary for communication and coordination between regions (Gunning-Dixon et al. 2009). One metric used in DTI is fractional anisotropy (FA), which characterizes the presence of white matter fiber tracts by studying how much water diffuses in one direction. Intact fibers restrict the flow of water, increasing the measure of FA. Research using this method has shown that aging causes deterioration of tissue microstructure, decreasing FA (Gunning-Dixon et al. 2009). As a result, there is no longer an exclusive focus on just gray matter. White matter changes with aging can be profound and may explain much of age-related cognitive decline (Gunning-Dixon et al. 2009).

Age-Related Differences in Neural Activity

While structural measures of gray and white matter largely reveal a pattern of decline, research with functional measures can reveal different

patterns. For many tasks, older adults can activate more brain regions than younger adults (Park and Reuter-Lorenz 2009). This includes patterns of bilaterally recruiting the same region in both the left and right hemispheres and shifting from activating regions largely in the back of the brain to those in the front (Cabeza 2002; Davis et al. 2008). Several models have sought to understand the causes and functions of these age-related changes in activation.

The *Hemispheric Asymmetry Reduction in Older Adults (HAROLD)* model looks at how younger adults activate a region in one hemisphere when performing a task, whereas older adults have a tendency to activate the same region in both hemispheres (see Fig. 2a; Cabeza 2002). This pattern of bilateral activity, or reducing the asymmetry of hemispheric activations, can sometimes be linked to better cognitive performance, suggesting that additional bilateral recruitment may support older adults' performance to be on par with that of younger adults.

While HAROLD considers patterns of activation across hemispheres, the *posterior-anterior shift in aging (PASA)* model studies a different

pattern with aging – changes in activation from the back of the brain to front. Specifically, decreases in occipital lobe activation occur concomitantly with increases in frontal lobe activity (see Fig. 2b; Davis et al. 2008). The occipital lobe is involved in sensory-related processes that become deficient with age (e.g., difficulty organizing sensory input of a previously seen image). PASA suggests that older adults try to offset sensory deficits and underrecruitment in these areas by overrecruiting in frontal regions. This change may reflect greater reliance on high-order cognitive processes responsible for directing sensory input or reconstructing poor signals coming from sensory cortices, also known as top-down processing (Davis et al. 2008).

Like HAROLD, another pattern of activity known as *dedifferentiation* illustrates a decrease in the specialization of regions with age (Park et al. 2004). In contrast to HAROLD or PASA, which emphasize the location of the brain areas recruited differently with age, dedifferentiation usually emphasizes the specialization of the process. For example, parts of the brain that respond specifically to seeing faces in younger adults may respond less distinctly to faces but also respond to other images, such as places or words, for older adults (Park et al. 2004). This loss of specialization in activity can occur even in brain regions that do not show atrophy with aging, such as the ventral visual cortex (Park et al. 2004).

Within the literature, there is much debate over whether these increased patterns of activation are actually compensatory, helping to improve older adults' performance. If this is the case, older adults could be bringing "online" additional cognitive resources in response to task demands. One theory has focused on how changing task demands (e.g., increasing or decreasing difficulty of task) can alter activation in older adults. The *compensation-related utilization of neural circuits (CRUNCH)* hypothesis suggests that making a task more difficult should proportionally increase neural activity for older adults at levels of difficulty that would not be considered strenuous for younger adults (Cappell et al. 2010). Building off of that theory, the *scaffolding theory*

of aging and cognition (STAC) shows older adults compensate with task difficulty by recruiting additional regions, creating new connections, and enhancing neural systems to improve cognitive performance (Park and Reuter-Lorenz 2009). Cognitive neuroscience methods have helped develop important theories like STAC to advance our understanding of aging. Unlike other theories, STAC actually accounts for both cognitive decline as well as the ability to utilize additional resources to improve performance with age. STAC incorporates the possibility that while cognitive declines may be inevitable with age, interventions such as cognitive training or physical exercise could help subside some of the age-related challenges to cognition.

Theories of Cognitive Aging

Thus far, this chapter has reviewed ways in which cognitive neuroscience has led to new ways of thinking about aging. However, data using these methods have also substantiated or enriched classical theories of cognitive aging originally based on behavioral data.

Speed of processing. Slowing in older adults is true both physically and mentally, as our ability to process information slows with age. Known as speed of processing, this ability is assessed by how many judgments can be made in a short period of time (Salthouse 1991). Performance declines with age because older adults are slow to complete initial cognitive tasks and processes within a trial, and this prevents them from completing later stages of tasks (Salthouse 1991). Underlying neural regions involved in executive function, such as the prefrontal cortex, have been shown to decrease with age leading to increased response time and inaccuracy in tasks specifically measuring speed and efficiency (Rypma et al. 1999). As previously mentioned, cognitive neuroscience helped establish the importance of studying white matter pathways. It has now been shown that damage to connections between the prefrontal cortex and other regions formed by white matter tracts can largely account for such cognitive slowing (Gunning-Dixon et al. 2009).

Memory. There are two major subtypes of memory, both of which are affected by aging. Working memory manipulates and stores information “online,” such that it can be stored, retrieved, or transformed at the same time (Craik and Byrd 1982). Looking up a phone number, keeping it active in mind, and dialing it a few minutes later would be an example of this. The ability to manipulate information decreases with age. Research suggests older adults require additional cognitive resources to maintain information in mind as task demands increase (e.g., remembering a string that is three numbers vs. nine numbers long). In line with the PASA model, older adults try to counteract deficits in underrecruited sensory regions by recruiting higher-order cognitive processes mediated by frontal regions (Cabeza and Dennis 2012). This leads to a pattern of prefrontal overactivation in older adults as additional resources are needed. Interestingly, a similar pattern of activation happens for younger adults too, but not until they reach seemingly higher memory loads (Cappell et al. 2010). This suggests that older adults are using compensatory processes but require them at lower levels of task difficulty than younger adults.

Aging also affects long-term memory or lasting storage of information. As previously mentioned, structural deficits to regions involved in memory processes have been shown to occur with age and accelerate in Alzheimer’s disease (Fjell et al. 2014). One consideration within this type of memory is true versus false recollection of items. True recollection, or correctly remembering an event in enough detail to feel as if it were being reexperienced (rather than feeling only generally familiar), is associated with age-related decreases in occipital activation and increases in prefrontal cortex activation (Dennis et al. 2014). Despite recruitment of different neural regions, older and younger adults have similar behavioral rates of true recollection. This pattern of activation therefore suggests an age-related inability to retrieve perceptual details and a greater reliance on familiarity and gist (e.g., general meaning that lacks distinct features) for older adults to complete the task (Dennis et al. 2014). On the other hand, false recollection

is associated with age-related decreases in prefrontal cortex activity, parahippocampal gyrus, and occipitoparietal cortex (Dennis et al. 2014). Unlike the comparable memory performance for true recollection, older adults have higher rates of false recollection. The resulting activation then suggests a reduced ability to reconstruct perceptual details leading to increased false memories (Dennis et al. 2014).

Inhibition. Older adults’ difficulty with speed of processing and memory could be largely connected to breakdowns in inhibition with age. Inhibition, or the ability to focus on important target information and inhibit attention to irrelevant information, becomes increasingly difficult with age (Hasher et al. 1991). Successful versus unsuccessful “ignore” trials have revealed differences in brain activation. When told to ignore certain words, younger adults activated rostral prefrontal cortex and inferior parietal cortex more than older adults, and activity in these regions was negatively correlated with priming for distracting words (Campbell et al. 2012). Younger adults remembered fewer of the “ignore” words than older adults. Besides activating the rostral prefrontal cortex less during to-be-ignored trials, older adults also had reduced functional connectivity within the frontoparietal network. These results suggested that increased distractibility could be due to decreased engagement of this cognitive control network and impairment in how this network works together with other networks involved in ignoring information (Campbell et al. 2012).

Socioemotional Information and Aging

This chapter has shown that aging brings changes to structural integrity of the brain and the cognitive processes necessary to carry out various tasks. Aging can also impact the ways in which one interacts with the environment. The application of cognitive neuroscience methods to social psychology has allowed researchers to understand the neural changes involved in social domains and emotional responses. Importantly, the inclusion of aging into social and affective neuroscience

research highlights how age-related differences in social cognition, similar to cognitive function, are not just about loss.

Changes in social cognition. Social neuroscience research has revealed a variety of activation patterns. Some patterns are consistent with the cognitive literature, showing that age-related declines in cognitive processes may also contribute to social domains. Other patterns, however, suggest that social domains may be more preserved with age. One ability that seems to be largely preserved with aging is self-referencing. In these tasks, participants must reference words or items to oneself or to another person, and this process can enhance the memorability of information. When comparing activation between younger and older adults, it was found that both groups engage the medial prefrontal cortex similarly (Gutchess et al. 2007). This finding was interpreted as evidence for preserved social functioning, and corresponding neural activity, with age.

Other research, however, suggests that patterns of activation in social cognition are consistent with the functional deteriorations seen in the cognitive literature. Processes like inhibition and speed of processing which decline in age may contribute to changes in social cognition by way of their contribution to executive function. For example, executive functions are necessary for regulation of bias, specifically toward stigmatized individuals (e.g., individuals with facial deformities, homeless people). It has been shown that high-functioning older adults, who had relatively preserved levels of executive function, activated areas of lateral prefrontal cortex more than younger adults and low-functioning older adults (Krendl et al. 2009). On the other hand, younger adults had greater activity in medial prefrontal cortex than older adults in response to stigmatized individuals that were considered less negative (Krendl et al. 2009). Because high-functioning older adults and younger adults showed similar attitudes toward stigmatized targets, the differences in the groups' neural activity suggest high-functioning older adults and younger adults rely on different underlying processes (Krendl et al. 2009). High-functioning older adults may have exerted greater cognitive effort,

relying on executive function, to achieve the same behavioral results.

Changes in emotion. In contrast to the other abilities reviewed thus far, emotion regulation, or the ability to control reactivity to valenced stimuli, seems to improve with age. Unlike other areas of the brain that undergo large amounts of atrophy, the amygdala is relatively preserved with age (Nashiro et al. 2012). Further, aging seems to affect the way in which valenced information is processed in which older adults show a positivity effect, whereby they spend more time viewing positive items and less time viewing negative items. As a result, older adults remember relatively less negative information and more positive information (Mather and Carstensen 2005). Behavioral theories suggest that the positivity effect seen with aging is due to a greater focus on regulating emotions and required cognitive processes (Mather and Carstensen 2005). This cognitive control theory predicts that prefrontal emotion regulation processes diminish amygdala responses to negative but not positive stimuli (Nashiro et al. 2012).

Using cognitive neuroscience methods, one can examine the ways in which different regions in a network operate together to contribute to this shift in emotional processing with age. Research suggests that emotional processing differences are the result of age-related changes in encoding processes when viewing positive stimuli only. In these instances, the connectivity between the ventromedial prefrontal cortex, amygdala, and hippocampus was stronger during encoding of positive trials only (Addis et al. 2010). There were no changes in connectivity between regions during encoding of negative trials (Addis et al. 2010). This suggests that aging may not weaken emotional network connections (as in the negative stimuli) but rather strengthen them (in relation to the positive stimuli), allowing for increased attention and memory for positive information.

Conclusion

The growth of cognitive neuroscience has changed the way aging is studied and understood. Brain volume and cortical thickness decrease, and

important connections between regions lose integrity as white matter tracts deteriorate. In aging there are also general brain activation patterns that change, such as reduced hemispheric asymmetry and overrecruitment of frontal regions. Importantly, cognitive neuroscience has shown that aging is not just a downward spiral of loss but can include compensation by bringing additional regions “online” and reorganizing neural circuits. Despite the increased appreciation for malleability in neural circuits with age, changes in the brain do affect cognition, causing older adults to process information slower, demonstrate short- and long-term memory problems, and experience difficulty attending to important information while ignoring irrelevant information. In regard to social cognition, research is split on whether social domains may be preserved in aging. Some aspects appear to be affected by underlying cognitive processes that are known to deteriorate, whereas other abilities seem to be unaffected. Age-related differences are also seen in emotional processing, with older adults exhibiting a positive bias when viewing and remembering information. Research has shown this change could be the result of a greater focus on emotion regulation with aging or altered connections between neural regions, allowing for the emphasis on positive information over negative. Ultimately, developments in cognitive neuroscience have shown that aging is not as clear-cut as previously thought – there are both age-related deficits and alterations that reveal the ability of the aging brain to adapt to change through compensation. Advances in cognitive neuroscience methods seek to better understand the physiological changes that occur through aging and how these neural changes ultimately influence behavior.

Definition

Cognitive rehabilitation refers to therapy designed to restore, substitute, or compensate for cognitive abilities lost due to injury or illness. Cognitive rehabilitation typically refers to training targeting improvement of skill by regaining (reestablishing or strengthening) abilities that were intact prior to the loss. The other focus of cognitive rehabilitation is developing compensatory strategies for lost abilities when they cannot be regained. In contrast, the term cognitive intervention refers to targeted training of a particular cognitive skill or domain for the purpose of enhancement regardless of the baseline state of cognitive abilities. As such, many cognitive interventions target healthy functioning individuals. Distinct from rehabilitation and intervention, cognitive stimulation therapy refers to a brief psychological intervention used to provide general stimulation of cognitive abilities in individuals with mild to moderate dementia.

The techniques used in cognitive rehabilitation can be applied to any individual who experiences cognitive loss due to an injury or illness. Most commonly, cognitive rehabilitation is used with stroke victims and traumatic brain injury patients. Additionally, while less common, cognitive rehabilitation techniques and programs have been designed for elders with cognitive decline due to normal aging, mild cognitive impairment (MCI), or neurodegenerative disease (Attix and Welsh-Bohmer 2006; Camp 2010).

History of Cognitive Rehabilitation in Old Age

As the name suggests, cognitive rehabilitation represents a diverse set of therapeutic interventions aimed at restoring, substituting, or compensating for cognitive abilities impacted by injury or illness through the use of specific strategies or adaptations. These interventions are nonpharmacological and nonsurgical and are aimed at remediating the cognitive capacities (Prigatano 2005). Historically, cognitive rehabilitation has focused on specific kinds of acquired brain injury

such as traumatic brain injury (TBI) and stroke (Parente and Stapleton 1996). While injury severity necessarily limits the extent to which cognitive rehabilitation can be effectively utilized, age is also a significant factor contributing to the efficiency (e.g., time, cost) of cognitive rehabilitation for acquired brain injury (Flanagan et al. 2005) as well as later-life cognitive impairment and dementia.

To combat the effects of cognitive decline in older adults, cognitive rehabilitation was born out of plasticity research in the 1970s, which conceptualized the cognitive aging process as both multidimensional and multidirectional (Verhaeghen 2000). At that time, the “performance-potential” divide associated with cognitive aging spurred the search for modifiability, which would later be described as plasticity. Baltes and Willis (1982) defined plasticity as “the range of intellectual aging under conditions not normally existent in either the living ecology of older persons or in the standard assessment situation provided by classical test of psychometric intelligence.” While early experiments focused on the enhancement of performance on tests of intelligence, plasticity research with elders quickly branched out into the domain of episodic memory function and has since expanded to include nonspecific cognitive stimulation targeting a variety of cognitive domains (Smith et al. 2009). As the construct of brain plasticity has matured, it has come to stand alongside, if not over shadow, cognitive rehabilitation training programs focused on strategy use. This is in part due to the lack of generalized gains from direct strategy instruction outside of the specific cognitive tasks related to the training. Additionally, it can be difficult for older adults to continue learning new approaches to cognitive processing, as use of specific strategies require.

One of the dominant theories underlying current understanding of neuroplasticity in cognitive aging is known as the scaffolding theory of aging and cognition (STAC; Goh and Park 2009). STAC posits that the aging brain responds to neural insults (e.g., volume reduction, white matter degradation) through the recruitment of additional brain regions to achieve adequate function. Barulli and Stern (2013) identify STAC as a

more generalized theory of neural compensation within which the concept of cognitive reserve remains an important factor associated with better neural compensation. Such additional brain recruitment has been observed in both structural and functional imaging studies. For example, Ilg and colleagues (2010) investigated practice-induced neural activation associated with mirror reading and found that short-term gray matter signal increase was associated with task-specific processing. Similarly, Steffener and colleagues (2009) investigated age-related changes in working memory using an fMRI paradigm. They found that while decreased regional volume in the primary neural network was associated with increased secondary network utilization independent of age, only older adults demonstrated increased activation in the secondary neural network as working memory load increased. Whether this recruitment represents neural compensation in the facilitation of task completion remains debated (Park and Reuter-Lorenz 2009).

Preventative Cognitive Training

Increasingly, however, targeting healthy older adults before symptoms of impairment develop has been a focus of research. Shatenstein and Berberger-Gateau (2015) have recently posited four categories of modifiable cognitive risk or protective factors for older adults: (1) collective societal factors, (2) individual psychosocial factors, (3) lifestyle factors, and (4) cardiometabolic factors. Within these four categories, seven individual modifiable factors account for 28% of the risk of developing Alzheimer’s disease: diabetes, obesity or hypertension in middle age, low physical activity, depression, smoking, and low educational level. Within this model, Shatenstein and Berberger-Gateau identify primary prevention as reduction of the occurrence of specific risk factors, with secondary prevention aimed at early prevention of disease by identification of clinical or biological markers that could lead to early detection and treatment of at-risk individuals.

Historically, cognitive interventions have been used to remediate intellectual decline in normal

older adults. In a longitudinal study conducted by Schaie and Willis (1986), their findings suggest that decline is associated with the disuse of cognitive abilities overtime. With the implementation of cognitive training, two thirds of the participants were able to improve their intellectual functioning. Specifically, 40% of the participants that had shown significant decline over a 14-year period were able to return to their pre-decline performance (Schaie and Willis 1986). Furthermore, the outcomes of this cognitive training were shown to be long-lasting, with the benefits persisting 7 years after training in comparison to controls (Schaie et al. 1994).

The potential benefits of targeting healthy older adults have been rigorously demonstrated in the recent Advanced Cognitive Training for Independent and Vital Elderly (ACTIVE) study. The ACTIVE study was a randomized, controlled single-blind trial ($n = 2832$) with three intervention groups and a no-contact control group to determine the effects of cognitive training on cognitive abilities and everyday function over a 10-year period. Each of the three intervention groups targeted a specific cognitive domain: memory, reasoning, and speed-of-processing. The intervention consisted of an initial ten-session training (60–70 min per session) for one of the three cognitive domains, with some participants receiving a four-session booster training at 11 and at 35 months after training. Outcome measures included both objective measures of memory, reasoning, and processing speed and functional measures of IADLs.

At the conclusion of the study, all groups showed declines from their baseline tests across cognitive domains. Interestingly, individuals who received training in reasoning and processing speed evidenced fewer declines than those in the memory and control groups. Results of the cognitive tests after 10 years reported by Rebok and colleagues (2014) demonstrated that nearly three quarters of those individuals that received reasoning training were still performing reasoning tasks above their pretrial baseline level. In contrast, only 62% percent of control participants showed above pretrial performance. Similarly, 71% of those receiving the processing speed intervention

were performing comparable or better than their baseline level compared to 49% of controls. Memory performance was comparable between the intervention and control groups after 10 years. With respect to IADLs, individuals across all three intervention groups endorsed less subjective difficulty with IADLs than control participants; however, performance on objective measures of functional abilities was comparable across intervention and control groups.

In summary, ACTIVE was the first multisite clinical trial to test the effects of cognitive training interventions on cognitive abilities and daily function in healthy functioning older adults. The relative success of the ACTIVE trial provides support for preventative cognitive interventions in this population and has significant economic implications given the aging of the US population. Interventions that reliably extend healthy cognitive aging trajectories could significantly reduce the economic burden associated with cognitive impairment and dementia.

Cognitive Rehabilitation for Mild Cognitive Impairment

MCI is often described an intermediate stage between cognitive decline due to normal aging and dementia (Huckans et al. 2013). Criteria for MCI diagnosis are (a) evidence of modest cognitive decline from a previous level of performance in one or more cognitive domains including memory, language, attention, visuospatial functioning, and executive functioning, or as documented by standardized neuropsychological testing, (b) cognitive deficits do not interfere with capacity for independence in everyday activity, (c) cognitive deficits do not occur exclusively in the context of a delirium, and (d) it is not better explained by another mental disorder and does not meet criteria for dementia (American Psychiatric Association 2013). Although many people with MCI live independently, declines in subjective and objective memory and cognition impact quality and degree of independence in daily life. Deficits may impact scheduling, transportation, or financial management. Functional impact may be

greater for those struggling with multiple domain MCI rather than in a single domain (Huckans et al. 2013). Within the older adult population, the prevalence rate of MCI is estimated to range from 3% to 42% (Ward et al. 2012). However, it is estimated that 14–40% of people with MCI return to normal cognitive functioning (Ganguli et al. 2004) and others maintain MCI functioning without progressing to dementia (Manly et al. 2008). The use of cognitive rehabilitation in this population may have particularly beneficial outcomes (Huckans et al. 2013), as gains will not be obscured by progressive decline.

A large proportion of patients (35–85%) with MCI have additional psychiatric comorbidities, such as depression, anxiety, irritability, apathy, disinhibition, and sleep disorder (Monastero et al. 2009). Therefore, effective management of MCI will not only focus on cognitive decline but also incorporate strategies to address neuropsychiatric symptoms and lifestyle.

Although many cognitive rehabilitation programs exist to treat MCI, there are several strategies and interventions that are consistent across programs. The first and most directive approach to address cognitive impairment is restorative cognitive training. The aim of this technique is to enhance or restore cognitive abilities through neuroplasticity mechanisms. This is most commonly done through the utilization of structured and repeated practice of specific cognitive tasks and mental exercises (Huckans et al. 2013). These tasks are tailored to the individual's ability level and in the domain that is impaired, such as memory or attention. The exercises have the potential to improve or maintain functioning in these cognitive domains with the goal to improve performance that will generalize beyond the immediate training task. However, the impact and the duration of task repetition remain unclear (O'Sullivan et al. 2015). Belleville and colleagues (2006) demonstrated that instruction in episodic memory strategies is effective in improving memory performance in individuals with MCI. More recently, Gagnon and Belleville (2012) reported that individuals with a single-domain executive function deficit benefit from an attentional control cognitive intervention.

A different approach is to train cognition through the development of new processing approaches. Here, cognitive training draws on internal strategies to work around the deficit when the impairment cannot be improved through repetition. Examples of such cognitive training strategies include visual imagery, chunking information, storytelling, and creating acronyms to remediate memory difficulties. Other strategies such as structured problem solving and planning methods can be used to address specific executive deficits (Huckans et al. 2013). Teaching mindfulness to double check and develop habits and routines may also be helpful for some individuals (O'Sullivan et al. 2015). Compensatory techniques can also involve external aids such as day planners, calendars, and personal notebooks (Kurz et al. 2009). Navigation devices can be helpful for those with visuospatial compromises. Additionally, environmental strategies may be used, such as setting up a quiet workspace in order to avoid distracting visual and auditory stimuli (Huckans et al. 2013). Quinn and colleagues (2015) recently reviewed three self-management interventions for individuals with MCI that focused on information, communication, social support, and skills training. They concluded that continued study of this intervention is necessary to test the efficacy of self-management techniques in an MCI population.

Treatment benefit will likely be maximized if additional treatment modifiers, such as mood and lifestyle factors, are also addressed (Attix and Welsch-Bohmer 2006). Education about MCI as a risk state, rather than prognostic indicator, can be quite helpful. Information about lifestyle practices that involve protective factors (e.g., diet, exercise, and cognitively stimulating activities) and risk factors (e.g., smoking, heavy substance use) is also relevant. This can be done through direct behavioral engagement or through the use of motivational interviewing with patients (Huckans et al. 2013; Kurz et al. 2009). Lastly, psychotherapeutic interventions are utilized to treat the neuropsychiatric symptoms that frequently accompany MCI. For example, relaxation exercises and deep breathing can be taught to reduce anxiety, and cognitive-behavioral

interventions can be utilized to address negative thoughts and feelings related to MCI (Kurz et al. 2009; O'Sullivan et al. 2015; Huckans et al. 2013). While not every patient will need cognitive retraining, compensatory strategies, modification of lifestyle interventions, and psychotherapy, these interventions are each part of a comprehensive treatment model to improve overall quality of life in patients with MCI.

Cognitive Rehabilitation in Dementia

Due to the progressive nature of neurodegenerative diseases, many do not believe that cognitive rehabilitation is a suitable treatment for people with progressive dementias such as Alzheimer's disease, progressive vascular disease, and Lewy body disease. However, when the goal is to improve quality of life rather than return to premorbid cognitive ability, cognitive intervention can be a proactive approach to improve overall functioning (Marshall 2005). Dementia is a relatively common condition in older adults aged 65 and older, affecting approximately 5% of the population (Jolley 2005). Alzheimer's dementia (AD) has an insidious onset and progressive cognitive decline, predominately in the domain of episodic memory, and is most evident in the ability to register and retain new information. However, people with AD tend to maintain the ability to recall stories from early in their lives, as well as habits and skills performed over decades (Jolley 2005) until late stages of the disease. Cognitive intervention is primarily used in individuals with dementia to help them utilize their remaining memory functioning most effectively, learn how to compensate for difficulties, and create environmental adjustments to reduce the need for memory (Mountain 2005). In other words, cognitive intervention aims to assist patients and families discover new ways to handle problems that arise due to cognitive decline and help the individual maintain the ability to engage in pleasurable activities and interact with loved ones for as long as possible (Clare 2005). The treatment should be client-centered, recognize the changing role identities of the patient, and facilitate coping and

effectiveness. Attix and Welsh-Bohmer (2006) detail the importance of the initial clinical evaluation in maximizing the effectiveness of cognitive interventions through careful incorporation of relevant patient data. These variables include goals, motivation, neuropsychological evaluation, insight, affective status, unique patient and environmental factors, and current compensatory methods and activities.

Cognitive rehabilitation techniques for people with more significant deficits in dementia include reminiscence therapy, reality orientation, and validation therapy, among others. Reminiscence therapy encourages individuals to recall past events and life experiences through stimuli that evoke memories, such as photos, objects, music, and videos. These sessions typically take place in a group setting in order to stimulate conversation about common subjects (Mountain 2005). Reality orientation is a technique that presents orientation information such as time, place, and person-related. The goal of providing information about the surroundings is to improve the quality of life in confused individuals by increasing their sense of control. Bianchetti and Trabucchi (2001) found that this therapy was able to delay entry into extended-care facilities and slow cognitive decline when administered over an extended period of time to people in early- to middle-stage dementia. In contrast, validation therapy provides a way to communicate with older individuals with dementia in a way that is opposite to reality orientation. Instead of helping the individual understand the truth of their surroundings, this communication style validates rather than corrects the individual's erroneous sense of reality (Neal and Briggs 2003). The purpose of these three therapeutic orientations aims to compensate for decline rather than attempt to reverse it. This approach can ultimately lead to greater acceptance and increased quality of life for people with dementia (Mountain 2005). Importantly, however, this therapeutic approach has received criticism with respect to its underlying evidence base. Moreover, in their 2003 review of the effects of validation therapy, Neal and Barton concluded that there is insufficient evidence from rigorous studies (e.g., randomized control trials) to

substantiate claims of efficacy for people with dementia or cognitive impairment.

Alternatives to compensatory orientations include self-management interventions, which equip people to manage the symptoms and lifestyle changes present over the course of chronic health conditions. Self-management interventions for individuals with dementia focus on psychoeducation, social support, and specific skills training. Quinn and colleagues (2016) recently reported modest effects of a randomized controlled trial of a self-management intervention for individuals with early-stage dementia and their caregivers.

Adaptations to existing methods of developmental learning have also been successfully employed in individuals with dementia. For example, Camp and colleagues developed Montessori Programming for Dementia (MPD), which provides a framework for the translation of Montessori principles into meaningful activities for individuals with dementia (Camp 2010). MPD has been used effectively within long-term care settings as well as in intergenerational care programs where programming is administered to older adults and preschool-aged children in a shared location (Camp and Lee 2011; Camp et al. 2002).

Future Directions

While interventions on individual modifiable risk factors associated with cognitive decline will continue to be investigated, multidomain approaches for the prevention of cognitive decline are strategic. This is, in part, due to the multifactorial nature of late-life dementia (Richard et al. 2012). Additionally, the majority of preventative studies to date have focused on the prevention of dementia, rather than less severe forms of cognitive impairment. The recent results of the Finnish FINGER study (Ngandu et al. 2015) provide proof-of-concept for the efficacy of multidomain interventions targeting modifiable vascular and lifestyle-related risk factors associated with mild cognitive deficits. Several other randomized clinical trials are employing multidomain approaches,

including the US ENLIGHTEN trial, the Prevention of Dementia by Intensive Vascular Care (preDIVA) study, and the Healthy Aging through Internet Counseling in Elderly (HATICE) program, which focuses on the management of modifiable risk factors in older people using an Internet-based platform (Shatenstein et al. 2015).

Conclusions

While cognitive rehabilitation interventions will continue to be developed and used in older adult populations with acquired brain injury (e.g., TBI, MCI), MCI, and dementia, preventative interventions to extend healthy aging cognitive trajectories are well positioned to be more widely disseminated. Efforts to build cognitive reserve and thereby extend the course of healthy cognitive aging trajectories have significant economic implications. For example, total annual per-person payments for Medicare beneficiaries with dementia are more than three times greater than payments for those without dementia (Unpublished tabulations based on data from the Medicare Current Beneficiary Survey for 2008. Prepared under contract by Julie Bynum, November 2011). Total payments in health care, long-term care, and hospice for individuals with neurodegenerative disease are currently estimated at \$214 billion, and over the next 25 years, the cumulative cost of care for individuals suffering from neurodegenerative diseases such as Alzheimer's disease has been estimated at over \$1 trillion (Alzheimer's 2014). These costs underscore the economic benefits associated with the prolongation of healthy cognitive aging trajectories even over relatively short amounts of time.

Definition

The term *cohort* refers to a group of people born at about the same time.

In geropsychology, the term *cohort* refers to a group of people born at about the same time. While it has long been considered a nuisance variable for age-based developmental studies, cohort is an important variable for many researchers in the social and health sciences because it provides evidence of secular changes. Studies of cohort effects on intelligence, reasoning, memory, and other cognitive abilities have garnered recent attention in both the academic and lay communities (Schaie et al. 2005; Williams 2013). A cogent example is the *Flynn effect* (Flynn 1987), which is the observation that generation by generation, people are becoming smarter with respect to intelligence test scores.

Cohort Effects,

Fig. 1 Cumulative cohort differences for the primary mental abilities in the Seattle Longitudinal Study. Excerpted from Schaie (2005) (Reprinted with permission from Oxford University Press.)

This entry will focus on cohort effects on cognitive performance primarily in adulthood and older age. After reviewing some of the methodological issues that affect the measurement of cohort and age effects, several important findings on cohort differences in cognitive performance including the Flynn effect will be reviewed. Finally, the issue of whether cohort differences continue into later life will be discussed.

Methodological Issues

Cohort is often contextualized in the metric of years, decades, or generations. Decisions about defining an appropriate time metric to assess cohort effects are important because the gap between cohorts needs to be large enough to detect statistical differences, yet not too large as to miss meaningful changes or turning points. Decisions about the range of birth years to be included in a sample are best made before initiating a study but are often constrained to the parameters of previously collected data in studies that were not specifically designed with the measurement of cohort in mind (Schaie et al. 2005).

Cohort-sequential longitudinal studies and time-lag studies have been used to assess the

effects of cohort for a variety of measures and for a variety of research questions (Schaie and Hofer 2001). *Cohort-sequential studies* (AKA panel studies), which include two or more longitudinal panels of participants derived from different birth cohorts, are able to assess cohort effects in two important ways. First, they can be used to measure changes in cognitive performance over birth cohort. As shown in Fig. 1, Schaie and collaborators (Schaie et al. 2005) have often used this approach to examine cohort changes in performance for psychometric measures of cognition. The figure shows that psychometric performance can be mapped over birth cohorts yielding evidence of cohort trends. For example, one can see from Fig. 1 that there have been marked increases in inductive reasoning performance in more recent birth cohorts. Second, cohort-sequential studies can be used to assess cohort differences in time-based or age-based analyses of measures of cognitive performance. As shown in Fig. 2, Zelinski and Kennison (2007) demonstrated this approach when they assessed cohort differences in mean level functioning and in age-related changes of performance in a list recall task. The cohort difference observed from ages 56 to 74 weakens from ages 74 to 86.

Cohort Effects,

Fig. 2 Estimated longitudinal changes for list recall for earlier-born (*solid line*) and later-born (*dashed line*) cohorts. The chart was created from the parameters reported in Table 5 of Zelinski and Kennison (2007)

A classic example of a cohort-sequential study is the Seattle Longitudinal Study (SLS), which includes multiple longitudinal sequences (panels) initiated approximately 7 years apart currently providing the potential for 7, 14, 21, 28, 35, 42, and 49 year cohort comparisons (Schaie et al. 2005). Some of the other studies that have used this approach are the Victoria Longitudinal Study (Dixon and de Frias 2004) and the Long Beach Longitudinal Study (Zelinski and Kennison 2007).

An alternative method used to assess cohort effects in longitudinal studies is the practice of replacing lost subjects with new ones who are matched on baseline age but born to a later cohort. An example of this approach can be found in the Health and Retirement Study (2015), which replaces participants lost to attrition. In addition, as the HRS has progressed, it has included panels that represent different cohort groups.

The other approach that is often used to study cohort effects is the *time-lag design* (Twenge 2010). In time-lag studies, groups of participants are tested at about the same age but at different points in time. The participants used in the different data collections are not the same, so the approach is not longitudinal. Like cross-sectional studies, time-lag studies are less expensive and easier to conduct than longitudinal studies. However, time effects are confounded with cohort effects making it difficult to uniquely attribute causality; possible causes are either specific

historical events or the accumulation of life experiences nested within a broader historical period (Twenge 2010; Salthouse 2015).

The important design features of a valid cohort study have been debated. Jensen in a personal communication sent to and reported by Flynn (1987) identified four elements needed to conduct a reasonably valid cohort study. He stated:

- (a) The possibility of sample bias should be eliminated by comprehensive samples, such as mass testing of draft registrants; (b) tests should remain unaltered from one generation to another and estimates of trends should be based on raw score differences; (c) particular emphasis should be placed on culturally reduced tests like the Ravens Progressive Matrices Test, as distinct from tests with items that might easily be learned from one generation to another; and (d) particular emphasis should be placed on using mature subjects, subjects who have reached the peak of their raw score performance.

While these criteria are generally desirable, aspects of each have been challenged. On the first criterion (a), the best methods for selecting subjects such as random sampling from a well-defined population are difficult and costly to achieve. Many of the most consequential longitudinal studies that have reported on cohort effects have used convenience samples including the Victoria Longitudinal Study, Seattle Longitudinal Study, and Long Beach Longitudinal Study (1, 5, and 7, respectively). Even the use of representative sampling is flawed because samples are likely to become less representative as subject

attrition occurs over time and testings (Schaie et al. 2005). Criterion (b), while it was originally one of the central tenants of longitudinal methods, has become somewhat less important with the development of item response theory methods (Embretson 1996), which allow tests and measures to be equated. Criterion (d) states that subjects should have reached maturity before inclusion into the study, however, this does not allow for the assessment of cohort differences in the age at which maturity is reached (Schaie et al. 2005).

In recent years, many of the existing and retired longitudinal studies have archived their data for use by other investigators. According to the Maelstrom Research webpage (Fortier and Ferretti 2015) there are currently 115 active or completed cohort-based studies worldwide and most of those studies include one or more measures of cognitive performance. Many of the databases can be found on the Maelstrom website (www.maelstrom-research.org) or on other websites such as the National Archive of Computerized Data on Aging (NACDA) in the USA.

Cohort as a Nuisance Variable

In the developmental sciences, research studies are not able to achieve pure measures of age, cohort, or time-of-measurement (AKA period effects), which are likely to be the primary measures of interest. That is, the experimental designs that are currently available are problematic such that two of three time-varying measures, age, cohort, and time, are always confounded with one another, and the so-called “ACT problem” is intractable (Horn and Donaldson 1976). However, as statistical modeling methods continue to advance, there is the likelihood that the magnitude of the three effects can be estimated and that these estimates can be confirmed within and across studies. If reliable estimates can be determined then they can be statistically controlled for.

In *cross-sectional studies*, which are the most popular type of study used to examine cognitive performance (Salthouse 2015), age is the variable of interest but cohort confounds its measurement

(Horn and Donaldson 1976). In such studies, the performance of different age groups is compared to determine whether age differences exist among those groups. However, compared to a younger age group, an older age group’s participants are not only older but they are also born into an earlier birth cohort, and thus any conclusions about observed age differences are potentially confounded by cohort differences. Depending on the nature of the cohort effect, age group differences in performance can either be inflated, which is the norm, or reduced (Schaie et al. 2005; Zelinski and Kennison 2007). Yet, even when the direction of a cohort effect is not clear or is inconsequential, additional cohort-related noise is likely to be introduced into cross-sectional data, which may affect estimates of variability.

While many cross-sectional studies are performed in the highly controlled environment of a research laboratory, the potential for birth cohort contamination is not directly knowable from the data collected. The implicit assumption of many researchers has been that cohort effects are small and that they have only trivial effects on conclusions about age differences (Salthouse 2015). However, such assumptions are not always well founded and are contradicted by findings from the cohort-based results of cohort-sequential longitudinal studies, which have shown that many of the most studied measures of cognitive performance are indeed affected by birth cohort differences (Schaie et al. 2005; Zelinski and Kennison 2007). Matched sampling, in which the younger and older aged participants are matched on variables such as education or health can be used to reduce potential cohort effects, but such matching strategies are not likely to be entirely effective because such variables do not fully account for observed cohort effects (Williams 2013; Flynn 1987). While it is the case that cohort contamination is usually acknowledged as a limitation of cross-sectional study designs, cohort effects are scarcely considered in discussion sections.

As shown in Figure 1, positive cohort trends, whereby later-born cohorts outperform earlier-born cohorts, have been observed for measures of inductive reasoning, episodic memory, spatial

reasoning, and vocabulary (Schaie et al. 2005). Such findings suggest the likely existence of cohort contamination in cross-sectional studies of age-related cognitive performance, and they indicate that conclusions about age differences are likely to be overstated. Findings of cohort differences have been mixed for some measures such as verbal fluency and numerical ability, and so the potential for cohort contamination is less clear but not necessarily inconsequential (Schaie et al. 2005).

Salthouse (2015) in an intriguing study investigated the validity of longitudinal and cross-sectional results in light of the Flynn effect. The Flynn effect, the observation that more recently born cohorts score higher on IQ measures compared to earlier-born cohorts, has largely been confirmed with time-lag studies, in which both time-of-measurement and cohort effects are measured together and therefore confounded. If the Flynn effect is at least partially a product of historical changes, then longitudinal results may be contaminated by the Flynn effect. Salthouse studied Flynn effect biases in both cross-sectional and longitudinal comparisons and concluded that "...there were similar time-of-measurement increases in cognitive scores at different ages, which were accompanied by nearly constant cross-sectional age differences, but positively inflated estimates of longitudinal age differences." Thus, he showed that longitudinal studies are not immune to secular changes in performance and in some cases may be more biased in the measurement of age effects than cross-sectional studies. Others have shown that cohort effects can alter both cross-sectional and longitudinal results (Zelinski et al. 2009).

Research Findings on Birth Cohort and Cognitive Function

Gains in intelligence. The so-called *Flynn effect* is the observation that there has been a strong, positive trend of increasing intelligence scores from one generation to the next for nearly a century (Flynn 1987). Rundquist in 1936 (Rundquist 1936) and Tuddenham in 1948 (Tuddenham

1948) were among the first researchers to document the phenomenon in the early to mid-twentieth century in American samples. Tuddenham (1948), for example, observed gains over an 11 year gap from 1932 to 1943 in an American sample, and he attributed the gains to advances in health, nutrition, education, and test-taking abilities. It was not until the 1980s, however, that the phenomenon gained its current traction and a name, when it was reported by Richard Lynn in 1982 and James R. Flynn in 1984 (Lynn 2013). It was Flynn's detailed investigation and description that led to the phenomenon being labeled the "Flynn effect" (Lynn 2013). Although this is the term popularly used, some refer to it as the Flynn-Lynn effect to recognize Lynn's 1982 contribution, whose publication preceded Flynn's and who like Flynn has published extensively on the topic (Lynn 2013).

In the United States, intelligence scores have risen by about three IQ points per decade from 1932 to 2002 on various versions of the Stanford-Binet and Wechsler IQ tests (Flynn and Weiss 2007). Similar strong gains have been recorded in countries all across the globe, including developed (Flynn 1987; Flynn and Weiss 2007) and developing nations (Williams 2013). These gains have been observed in both verbally based IQ measures as well as for Raven's Matrices and other matrix reasoning tests, which are believed to be less affected by cultural and educational influences (Flynn 1987).

A recent meta-analysis evaluated average IQ gains from 1909 to 2013 for a combined sample created from 271 individual samples representing 31 countries of over four million participants. They reported IQ gains of 4.1 points per decade for measures of fluid abilities (Pietschnig and Voracek 2015). Somewhat more modest gains were observed for spatial abilities (IQ gain = 3.0 points/decade), full scale IQ (IQ gain = 2.8 points/decade), and crystallized abilities (IQ gain = 2.2 points/decade). While IQ gains have been observed across most of the twentieth century, there is a growing body of evidence that these gains have slowed or even reversed around the turn of the twenty-first century for some countries. Teasdale and Owen (2008), for example,

found losses of 1.5 IQ points over a 5 year period from 1998 to 2003 in a Danish sample.

The magnitude of gains has been observed to be larger in people with lower IQ scores, but this finding is not universal (Williams 2013). Observed gains have also been larger for urbanites than for rural samples (Williams 2013).

The largest gains have usually been found for fluid ability measures such as inductive reasoning, word recall, and spatial reasoning (Schaie et al. 2005; Zelinski and Kennison 2007). Somewhat smaller gains have been observed for crystallized abilities such as vocabulary (Schaie et al. 2005; Zelinski and Kennison 2007), and in some cases no gains have been observed (Lynn 2013). The observed increases in fluid abilities have sometimes been taken as evidence that the gains represent real gains in intelligence as opposed to gains in knowledge. Yet, the inconsistent correlation in the rise of IQ scores around the globe and the small fluctuations in reports of gifted individuals have led Flynn (1987) to conclude that IQ tests have a weak but not inconsequential relationship to the construct of intelligence.

So what explains the rather extraordinary gains in IQ performance observed over the past century? Several non-mutually exclusive explanations have been proposed and at least partially supported, including increases in educational quality and attainment (Alwin and McCammon 2001), exposure to technology and media (Williams 2013), the benefits of better health and healthcare (Williams 2013; Gerstorf et al. 2011), and reductions in poverty and malnutrition (Flynn, 2008), among others (Lynn 2013). However, none of these explanations individually or in combination fully explain the observed gains. In addition, Lynn (2013) has demonstrated that cohort-based IQ gains have been found in infants, which brings into question explanations that are likely to occur in later development, including education-based explanations. Thus, the question of cause remains open and the search for a comprehensive explanation continues to remain elusive.

Cohort effects in older adult samples. It is well established that there are large age-related declines in many aspects of cognitive performance.

For example, declines in fluid intelligence abilities (e.g., inductive reasoning, memory, and word fluency) have been observed to begin soon after human maturity is reached, around age 30, with increasingly large age-related declines thereafter as confirmed in both cross-sectional and longitudinal analyses (Schaie and Hofer 2001). Given these persistent declines and the expanding size of the older adult population relative to other age groups, questions about whether cohort-based positive gains in intellectual abilities will offset or partially mitigate anticipated declines in present and future generations are well worth considering (Zelinski and Kennison 2007).

Most studies that have examined cohort effects in psychometric measures have done so by examining mean level differences in cognitive performance, whereby participants from different cohorts are matched on age and their average performance is compared to determine whether cohort differences exist (Schaie et al. 2005). Such comparisons have usually indicated that a later-born cohort outperforms an earlier-born cohort (Schaie et al. 2005; Williams 2013). Fewer studies have examined cohort differences in the rate of age-related changes (Schaie et al. 2005; Zelinski and Kennison 2007; Gerstorf et al. 2011). Such studies typically employ growth modeling, whereby a model is “fit” to the data. At least two results are typically reported: (1) cohort differences in mean level performance (intercept) and (2) cohort differences in the rate of change (slope).

Zelinski and Kennison (2007) examined cohort differences in the Long Beach Longitudinal Study from ages 56 to 86 for two cohorts born 16 years apart on five measures of cognition including inductive reasoning, list recall, text recall, spatial reasoning, and vocabulary. Piecewise growth models consisting of two linear slopes – one for young-old age (ages 56–74) and the other for old-old age (ages 74–86) – were fit to each measure of cognition. The results indicated that mean level cohort differences favoring the later-born cohort were found for all measures except vocabulary. No differences in the rates of decline were found for inductive reasoning or spatial reasoning. However, for the two memory measures, list and text recall, the rate of decline for

Cohort Effects, Fig. 3 Cohort differences in inductive reasoning from age 50 to age 80. Later-born cohorts (*solid lines*) outperformed earlier-born cohorts (*dashed lines*) at age 70 and also showed shallower rates of cognitive decline. Excerpted from Gerstorf et al. (2011) (Reprinted with permission from the American Psychological Association)

the old-old age slope (age 74–86) interacted with cohort such that the advantage of the later-born cohort disintegrated with advancing age. This result can be seen in Fig. 2 for list recall.

Similar findings have been reported by Gerstorf et al. (2011), who examined age-related performance on five cognitive measures from the Seattle Longitudinal Study including inductive reasoning, spatial reasoning, word fluency, numerical ability, and vocabulary. Separate growth models were fit for age-related changes and for time-to-death changes. The five age-related change models each showed that a later-born cohort outperformed an earlier-born cohort and that the gap increased from 50 to 80 years of age. Figure 3 demonstrates this finding for inductive reasoning. Yet, the time-to-death models showed that the cohort advantage enjoyed by the earlier-born cohort receded as death approached. Figure 4 shows the collapse of the advantage in performance of the later-born cohort compared to the earlier-born cohort as death nears.

Possible explanations for the reduction of cohort effects in very old age include: (1) greater selectivity

Cohort Effects, Fig. 4 Cohort differences in terminal decline for inductive reasoning. Mortality-related models suggest no evidence for positive secular trends in inductive reasoning. Later-born cohorts (*solid lines*) showed steeper mortality-related declines than earlier-born cohorts (*dashed lines*). Excerpted from Gerstorf et al. (2011) (Reprinted with permission from the American Psychological Association)

in the oldest segment of the sample or (2) that the protective effects of cohort recede at the upper reaches of the lifespan. While greater selectivity is a possibility in the results reported by Kennison and Zelinski (2007), the Gerstorf et al. (2011) time-to-death results reduces selectivity as a possible explanation for their results because all of their participants were followed to their deaths. They concluded that “[the] results are in line with the idea that mortality-related mechanisms and the progressive processes leading toward death (e.g., deteriorating health) are so pervasive that they override historical, cohort-related effects that were apparent earlier in life.” Thus, these results suggest that cohort effects, while quite robust, may not persist across the entire lifespan, especially at the upper reaches of the lifespan.

Still there is considerable evidence that birth cohort differences favoring the later-born cohort exist in older samples, and this suggests that the

effects of early developmental experiences are likely to be long lasting, even into old age. There is also growing and compelling evidence that cognitive, social, and physical engagement among adults enhances level of cognitive functioning (Hertzog et al. 2008). These findings combined with findings that later-born cohorts are more likely to engage in such positive health behaviors (Baltes et al. 2006) suggests that the level of age-related declines that are seen in today's older adults are likely to be smaller for future generations (Skirbekk et al. 2013).

Conclusion

The cohort-based findings reviewed in this entry have far reaching societal and institutional implications as they have been linked to secular changes in education, technology, health, health care, etc. Yet, a comprehensive explanation of the observed positive cohort trends remains a work in progress. While methodological constraints persist, much progress has been made towards understanding age, cohort, and time effects and their interactions by employing a variety of different study designs, sampling frames, and statistical techniques. The cognitive performance advantages enjoyed by later-born cohorts are likely to persist into old age, however, as death approaches, these advantages may recede. Finally, the findings reviewed here give hope that the typical cognitive declines seen in older adults today are likely to be smaller and less intrusive in future generations of older adults.

Synonyms

Common cause hypothesis; Common cause factor; Dedifferentiation; Shared age-related variance; Shared influence models

Definition

The common cause theory of cognitive aging hypothesizes that age-related declines in cognitive, sensory, and sensorimotor functioning can primarily be attributed to a domain-general neurobiological mechanism. It predicts an increasing association between cognition and sensory acuity with advancing age and was originally proposed as a broad third variable explanation to account for shared variance between age, cognitive, and noncognitive variables.

Historical Context and Background to the Common Cause Hypothesis

Since Galton's early work in the late 1800s (Galton 1883), psychologists have long attempted to draw conceptual and empirical links between sensory discrimination and intelligence, particularly those adopting an individual differences perspective (Deary 1994). For example, sensorimotor abilities have been identified as important structural components in hierarchical models of human intelligence (Carroll 1993). In more recent times cognitive scientists, guided by an information processing framework, have recognized that cognition and sensation do not operate in isolation, but constitute an integrated system in which top-down and bottom-up processes are intrinsically intertwined. Of interest to geropsychology is the way in which the coupling between these two domains changes with age. While there is no evidence to suggest that sensory functioning is strongly linked to cognitive performance in early life or mid-life, a small number of studies conducted sporadically during the latter half of the 1900s consistently demonstrated an association between cognition and sensory functioning (particularly hearing ability) in older age-groups (Schaie et al. 1964; Anstey et al. 1993; Rabbitt 1990a; Granick et al. 1976). These cross-domain interassociations were important from the viewpoint of life-span developmental psychology as they appeared to emerge during later life and therefore provided an example of discontinuity in life-span development (Lindenberger and Baltes 1994). They also indicated that dedifferentiation may extend beyond the cognitive domain (Anstey et al. 2003a) and were relevant to theoretical debates concerning the extent to which age-related changes in a variety of domains could be accounted for by a broad and general mechanism, rather than a number of unrelated domain-specific factors (Salthouse and Czaja 2000).

Despite the significance of these findings for theories of cognitive aging, it was not until the mid-1990s that there was a concerted research program seeking to understand why cognitive and noncognitive variables are increasingly

Common Cause Theory in Aging,

Fig. 1 Schematic of mediation model analogous to those tested by Lindenberger and Baltes (1994) and Anstey (Anstey and Smith 1999; Anstey et al. 2001). *Sensory functioning is generally found to be a stronger predictor of age-related individual differences in cognition than processing speed

related at older ages. At the start of the decade, Rabbitt (1990b) strongly argued that cognitive scientists with an interest in late-life phenomena should indeed be interested in lower-level sensory systems. Critically, this period coincided with a greater appreciation of the underlying role that degeneration of the central nervous system plays in driving age-related declines in sensory acuity (Baltes and Lindenberger 1997). That is, age-related sensory decline could be attributed to neuronal deterioration beyond the level of the end organ. It was therefore timely for geropsychologists to consider joint contribution of “brain aging” to cognitive and sensory decline (and more broadly to motor functions), and this culminated with a proposal by Lindenberger and Baltes for a “common cause hypothesis” (Lindenberger and Baltes 1994).

Shared Age-Related Variance

Motivated by previous empirical findings and their potential implications for cognitive aging theory, Lindenberger and Baltes (Lindenberger and Baltes 1994; Baltes and Lindenberger 1997) conducted two studies using baseline data from the Berlin Aging Study to investigate the roles of vision and hearing in explaining age differences in

intellectual (or cognitive) abilities. In the first study (Lindenberger and Baltes 1994), visual acuity and auditory pure-tone thresholds explained 49% of the total variance and 93% of the age-related variance in a second-order general intelligence factor comprising perceptual speed, reasoning, memory, verbal fluency, and knowledge. In addition, vision and hearing fully mediated the effects of age on intelligence – that is, after adjusting for sensory functioning, there were no direct effects of age on intelligence (see Fig. 1). Importantly, excluding participants with suspected dementia or severe sensory impairment did not alter the pattern of results. The explanatory power of sensory functioning was then compared to that of processing speed, which had been identified as a potential broad mechanism underpinning cognitive aging. These analyses indicated that vision and hearing were at least as powerful as processing speed in predicting age-related individual differences in an intelligence factor defined by reasoning, memory, verbal fluency, and knowledge (i.e., excluding speed). Moreover, while sensory functioning subsumed all the age-related variance in processing speed, processing speed was unable to account for 15% of the age-related variance in vision and 9% of the variance in hearing. This finding was later supported by comparable analyses of other datasets (Anstey

Common Cause Theory in Aging, Fig. 2

Venn diagrams depicting cohort differences in shared variance patterns among age, sensory functioning (visual acuity and pure-tone audiometry), fluid cognitive mechanics (speed, reasoning, and memory), and crystallized cognitive pragmatics (knowledge and fluency). Overlapping areas reflecting proportions of shared variance are approximated from results reported in Baltes and Lindenberger (1997) and Anstey (Anstey and Smith 1999); however, the schematic is illustrative only and not based on actual data

et al. 2001). Lindenberger and Baltes (1994) argued that of the two, sensory functioning was the more powerful predictor of general intellectual abilities. Their conclusion was significant because speed of information processing was considered an important cognitive primitive and central to resource-based accounts of cognitive aging. Such theories included the generalized slowing and processing speed hypotheses, which had been proposed in various forms by Birren, Cerella, and Salthouse (for review see Hartley 2006).

The link between intellectual abilities and sensory acuity was later reexamined in a larger composite sample that augmented the baseline sample of participants from the Berlin Aging Study with newly recruited younger participants (Baltes and Lindenberger 1997). Rather than modeling the indirect effects of age on a second-order general intelligence factor, each cognitive ability was examined individually. Vision and hearing were more strongly associated with individual differences in the five cognitive abilities within the older cohort (ages 70–103), relative to the younger cohort (ages 25–69). But there remained a significant proportion of shared age-related

variance among the younger participants, thus replicating their previous findings across a broader age range. A more nuanced pattern of results emerged when the cognitive abilities were classified according to a dual-process model of intellectual functioning. (Dual process models of intellectual development across the life-span make a distinction between cognitive mechanics (also referred to as fluid intelligence) and cognitive pragmatics (referred to as crystallized intelligence). Cognitive mechanics are content poor, have a strong neurophysiological basis, and typically undergo age-related declines throughout adulthood. Cognitive pragmatics reflect knowledge acquired through experience, are culturally shaped, and increase with age.) There were no cohort differences in the proportion of age-related variance shared by vision or hearing and variables reflecting fluid cognitive mechanics (speed, reasoning, and memory). In contrast, while sensory functioning predicted age-related variance among variables reflecting crystallized cognitive pragmatics (fluency and knowledge) within the older cohort, this was not the case within the younger cohort (see Fig. 2).

The Common Cause Hypothesis and Alternative Explanations

Overall, the key findings from these studies were that (a) there was considerable shared variance between age, general intelligence (primarily in fluid abilities), and sensory acuity and (b) sensory functioning fully mediated age-cognition associations. Lindenberger and Baltes offered etiological and functional explanations to account for age-related covariation between cognitive and sensory functioning. These included the neurological *common cause* hypothesis, *sensory deprivation* hypothesis, and *cognitive load on sensory performance* hypothesis. A brief description of each of these hypotheses is provided below, but interested readers may like to refer to Schneider and Pichora-Fuller (2000) who provide a thorough overview of these hypotheses and additional explanations.

The *common cause hypothesis* maintains that a domain-general mechanism is responsible for a substantial amount of the age-related decline in cognitive, sensory, and sensorimotor functions. It was argued that the emergent association between sensory and cognitive function in late life reflected “an expression of the physiological architecture, or the mechanics, of the [aging] brain” (Lindenberger and Baltes 1994, p. 339). Clearly the original intention of the hypothesis identified the underlying etiology as being neurological in nature. Though often construed as a single determinant, it was recognized that as a third variable explanation, the common cause factor could reflect an ensemble of senescent processes affecting brain structure, physiology, and function. In addition, other third variables such as “bodily functions” were not discounted (Baltes and Lindenberger 1997). The common cause hypothesis was consistent with contemporaneous views offered by researchers interested in operationalizing functional biomarkers as an index of primary aging. For example, after reporting that a bioage factor (a latent variable reflecting biological age; Anstey 2008) comprising measures of sensory acuity and physical functioning mediated the relationship between age and fluid intelligence (Gf), Anstey and colleagues

(1993) concluded that sensorimotor functioning was an important indicator of intellectual decline, and this “may be interpreted as evidence for a decline in Gf related to biological changes in the brain, central nervous system, and motor systems” (Anstey et al. 1993, p. 568). Such broad explanatory mechanisms implied by common cause factors are attractive to cognitive aging theorists because they are parsimonious and reduce the search for potential mechanisms to a single or small number of underlying causes.

Whereas the common cause theory hypothesizes an underlying etiology, other explanations propose more functional and directional causal pathways between cognitive and sensory aging. The *sensory deprivation* hypothesis identifies reduced sensory functioning as a long-term antecedent of cognitive decline, linking the two via social engagement. Specifically, declining sensory acuity creates communication and mobility difficulties, increasing the likelihood of social withdrawal and disengagement from intellectually stimulating activities, which over an extended period (spanning years to decades) will eventually result in the lowering of levels of general cognitive ability. Thus, according to this view, age-related sensory impairment initiates an upward cascade of effects that ultimately impact on central cognitive functioning. Such explanations had previously been described by Sekular and Blake who referred to the process as “protracted sensory underload” (1987; cited in Lindenberger and Baltes 1994) and Rabbitt (1990b) who noted that sensory loss in late life can inhibit “social interaction, employment, enjoyment of life, learning new skills, and cognitive engagement” (p. 231) and have secondary “knock-on” effects on everyday memory and comprehension. These accounts therefore invoke the notions of brain reserve or cognitive reserve, which posit that novel and mentally stimulating activities are important for maintaining cognitive ability levels (or at least attenuating rates of cognitive decline) by promoting neuroplasticity which creates a buffer against the impacts of accumulating neuropathology.

Alternative upward cascade models have also been proposed. The *perceptual degradation*

and *cognitive permeation* hypotheses place age-related sensory decline as a driver of poor cognitive performance, but over a more immediate time frame (Schneider and Pichora-Fuller 2000; Valentijn et al. 2005). According to the perceptual degradation explanation, encoding errors of degraded sensory inputs impinge on higher-level cognitive processing. Similarly, the cognitive permeation hypothesis maintains that greater attentional, executive, and working memory resources must be allocated to processing of low-fidelity sensory inputs, thus compromising cognitive functioning by diverting cognitive resources away from higher-order processes (Lindenberger and Ghisletta 2009). A key prediction of such explanations is that correcting for sensory loss should moderate the association between sensory and cognitive function. A popular approach to testing this hypothesis has been to examine the effect of cataract surgery on cognitive function. While some studies have been argued to demonstrate that cataract surgery is associated with lower levels of cognitive impairment after surgery, these investigations have been limited by small sample size, lack of appropriate control groups, failure to assess baseline cognitive function, or inadequate control for confounding factors (Hall et al. 2005). Studies employing more rigorous research designs have failed to show that removal of cataracts improves cognitive function (Hall et al. 2005; Anstey et al. 2006).

The *cognitive load on sensory performance* suggests that deterioration of cognitive abilities such as attention and processing speed adversely affect the control and execution of simple sensory tasks. For example, deficits in sustained attention may diminish an individual's capacity to detect auditory or visual stimuli. It is important to note that these explanations are not mutually exclusive, but are related and likely to operate interdependently in a cycle of cumulative and reciprocal effects. For example, if cognitive resources become more limited and sensory acuity declines due to "brain aging," this may increase the cognitive load for basic processing of sensory information. This increases the likelihood of social withdrawal and reduced participation in mentally stimulating activities, which

limits opportunities to moderate the adverse impacts of brain aging.

As the original analyses of the Berlin Aging Study employed observational and cross-sectional research designs, it was not possible to rule out any of the proposed explanations. Baltes and Lindenberger (1997) also acknowledged that each of the hypothesized causal pathways was potentially related. Nevertheless, they argued that a common cause explanation was most consistent with their results for the following reasons. Firstly, sensory functioning had weaker associations with experientially based cognitive abilities, whose development was considered to be more reliant on an enriched social environment. Secondly, it was expected the impacts of protracted sensory underload would be more pronounced among individuals with greater levels of sensory impairment, yet there was no evidence of a curvilinear relationship between sensory and cognitive functioning. Finally, sensory measures were thought to mediate age-cognition relations because they were assumed to provide a more reliable and direct measurement of brain aging (Lindenberger and Baltes 1994). Similar arguments were made by those who adopted a biomarker mediation model of cognitive aging, whereby sensorimotor variables were conceptualized as functional biomarkers that indexed primary (normative) aging processes with greater reliability than chronological age (Anstey et al. 1993; Anstey and Smith 1999).

Evidence for Common and Domain-Specific Factors

Even though these studies arose from opportune circumstance and were framed as being exploratory (Lindenberger and Baltes 1994; Baltes and Lindenberger 1997), their clear rationale and robust findings meant they quickly became a catalyst for rigorous conceptual, methodological, and empirical examination of the interassociations between age, cognition, sensory perception, and other indicators of physical ability. Because of the emphasis placed on a common cause interpretation, this theory became the main focus of subsequent

investigations. In particular, debate centered on quantifying the degree of interdependency across a variety of functional domains and whether it was reasonable to infer that a common cause was primarily responsible for age-related declines.

The common cause theory was originally concerned with cognitive and sensory domains, with a focus on visual acuity and pure-tone audiometry; subsequent investigations broadened the explanatory scope of the theory to include other functional domains that also exhibit declines in performance with age. Studies have examined age-related associations with cognition for a range of sensory variables such as contrast sensitivity, central auditory processing, proprioception, vibration sense, and balance. The general finding has also been extended to motor and physiological functions including grip strength, lower limb strength, walking ability and gait, lung function, and blood pressure (Schneider and Pichora-Fuller 2000; Anstey and Smith 1999; Li and Lindenberger 2002; Clouston et al. 2013; Krall et al. 2014), though blood pressure has not always been shown to load onto a common factor (Christensen et al. 2001). All such cross-sectional studies have typically reported moderate to large interassociations with age. However, it has been suggested that the magnitude of the age-related associations between different pairs of cognitive and sensorimotor variables may vary. For example, data from the Australian Longitudinal Study of Aging indicates that vision and hearing are more strongly linked to episodic memory than other general cognitive abilities (Anstey et al. 2001).

It was not unusual for cross-sectional evidence of shared age-related variance to be interpreted as suggestive of a broad explanatory mechanism (Salthouse and Czaja 2000). Early studies employing structural equation modeling or hierarchical regression analyses generally identified sensory functioning as the mediator of age-cognition associations as depicted in Fig. 1. In these cases, a common cause interpretation relied on the assumption that sensorimotor functioning was a more direct indicator of the integrity of the central nervous system. A more formal approach to assessing common cause factors is to define latent variable that reflects shared

variance across cognitive and noncognitive variables and regress age onto the common factor as well as each of the individual domains or indicators. This approach, when applied to multifactorial data, is depicted in Fig. 3 and typically involves the comparison of (at least) three nested conceptual models, namely, (i) an independent factor model (no common cause factor) which only includes direct effects of age on each domain, (ii) a hierarchical common factor model with indirect age effects mediated by a common cause, and (iii) a hierarchical common factor model with both direct and indirect age effects (see Allen et al. (2001) for a detailed description of each of these conceptual models and some additional variations). An alternative depiction of these shared variance models is presented in Fig. 4.

When studies were designed to test common cause factor models following procedures outlined in Fig. 3, it quickly became apparent that there were both direct and indirect effects of age on cognitive and sensorimotor variables (Salthouse and Czaja 2000; Anstey et al. 2001; Christensen et al. 2001; Salthouse et al. 1998; Salthouse and Ferrer-Caja 2003). Thus, these analyses demonstrated that there were shared and unique portions of age-related variance among cognitive and noncognitive variables. Sensorimotor variables have also been reported to correlate with cognitive variables independent of age (particularly variables reflecting crystallized cognitive pragmatics) (Anstey and Smith 1999). Consequently by 2003, there was a broad consensus that age-related declines in cognitive and sensorimotor functioning could be attributed to both a broad common cause factor and separate domain-specific mechanisms, tempering the earlier emphasis placed on common cause interpretations. In an important appraisal of the common factor methods used to support broad mechanisms, Allen and colleagues (Allen et al. 2001) argued that many analyses failed to adequately assess the comparative fit of all competing models. They demonstrated that hierarchical common factor models did not always fit the data better than independent factor models, particularly when independent factors were allowed to have correlated disturbance terms.

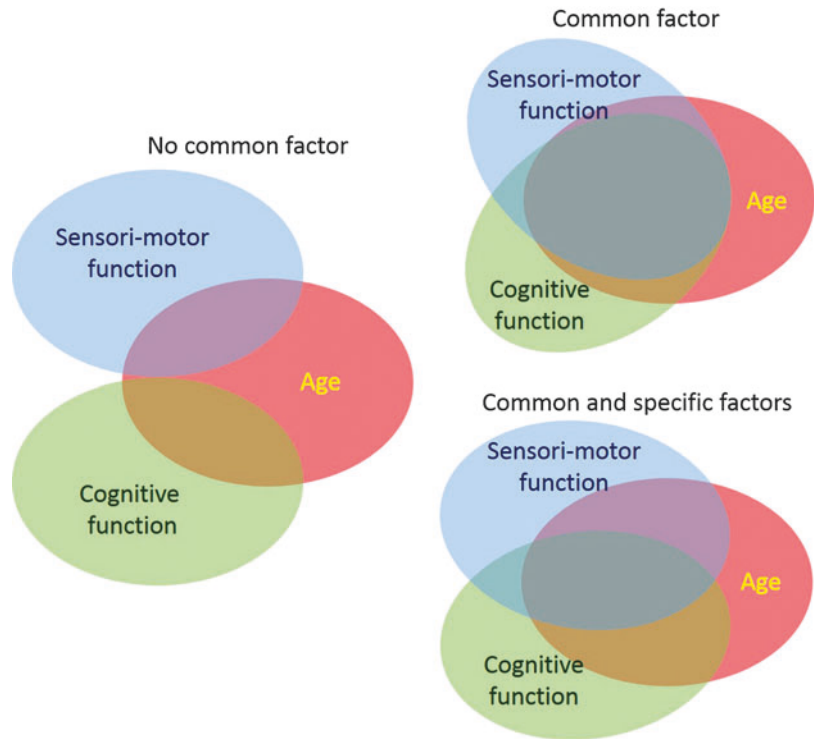

Common Cause Theory in Aging, Fig. 3 Top: Independent factor model with direct age effects. Bottom Left: Second-order (hierarchical) common factor model with indirect age effects, Bottom Right: Second-order (hierarchical) common factor model with direct and indirect age effects (Figures adapted from Salthouse and Czaja (2000) and (Allen et al. 2001))

Sensorimotor variables have also been described as “functional biomarkers” (Anstey et al. 1993; Lindenberger and Ghisletta 2009)

Longitudinal Evidence for the Common Cause

Recognizing that longitudinal designs were necessary to properly examine within-person coupling of cognitive and noncognitive variables (Hofer and Sliwinski 2001), a number of research groups employed multivariate latent growth curve (and related) techniques to test covariation in levels and rates of change between cognitive and sensory measures (Anstey et al. 2003a, b; Lindenberger and Ghisletta 2009). Importantly, these studies demonstrated only modest associations between rates of sensory and cognitive decline (e.g., 9% shared variance between change in memory and vision; Lindenberger and Ghisletta 2009), as well as providing support for domain-specific factors. Again, it was argued that the evidence for a common cause factor was strongest for memory and vision and for memory and speed, which were the only inter-domain pairings to have correlated rates of change in the Australian Longitudinal Study of Ageing (Anstey

et al. 2003b). Bivariate dual change score models have been used to test bidirectional time-ordered associations between cognition and sensory function (Ghisletta and Lindenberger 2005). In these analyses, levels of visual acuity were predictive of subsequent declines in processing speed, and conversely, levels of processing speed were predictive of subsequent declines in visual acuity. Consistent with other studies, large domain-independent effects were reported. Ghisletta and Lindenberger (2005) framed their discussion of this dynamic link between cognitive and sensory functioning in relation to common cause, biomarker mediation, and cascade hypotheses. Each of these longitudinal studies provides a complex picture of the interdependent nature of cognitive and sensory aging, but overall supports the notion that there are both common and independent factors driving declines in cognition and sensation. In addition, the modest interassociations suggested that initial enthusiasm for the overarching importance of a common cause factor was overstated. The divergence in findings from earlier studies

demonstrates the importance of longitudinal data for modeling time-dependent processes that are inherent to theories of psychological development and aging. Longitudinal designs enable direct examination of age changes and covariation in rates of change – which is necessary to test predictions made by the common cause hypothesis. Indeed, it has been well documented that age changes are confounded with age differences and population trends in cross-sectional data, and this can produce positively biased correlations between variables that actually share no association, or even a negative association, in their developmental trajectories over time (Hofer and Sliwinski 2001; Lindenberger et al. 2011; Lindenberger and Potter 1998).

Limitations of the Common Cause Theory

The common cause theory has both conceptual and methodological limitations that constrain its overall attractiveness as a comprehensive explanation for cognitive aging. Although common factor models often provide good fit of cross-sectional associations between cognitive and noncognitive variables and are often interpreted as reflecting broad explanatory mechanisms (Salthouse and Czaja 2000), simulation studies have shown that common factor models cannot always be rejected even when they are false (Allen et al. 2001). Many of the analytic strategies employed provide supporting evidence of a common factor rather than conduct critical hypothesis testing of the common cause theory.

One of the main challenges for the theory is that it implicates a wide range of psychological and physical functions with no obvious candidate (s) for the ensemble of common causes. A broad range of measures including peripheral hearing, visual acuity, reaction time, grip strength, lung capacity, processing speed, and episodic memory have all been shown to converge onto a common age-related factor to varying degrees, yet there is no well-defined system that is known to directly underlie performance across all of these domains

(Christensen and Mackinnon 2004). Thus, at the time the common cause was attracting peak research attention, it was not possible to specify the broad mechanism (Salthouse and Czaja 2000). In the words of Ghisletta and Lindenberger (2005), the common cause theory is “empirically and theoretically under-identified” (p. 580). Indeed, when conjecturing about the common cause, proponents have cast a wide net when naming candidate mechanisms. These have ranged from general notions of “brain aging” and “integrity” of the central nervous system to more specific etiology such as structural changes or atrophy, white-matter loss or hyperintensities, gray-matter loss, impaired frontal circuitry, dopaminergic neuromodulation, inflammation, oxidative stress, telomere length, and genetic expression (Salthouse and Czaja 2000; Ghisletta and Lindenberger 2005; Christensen and Mackinnon 2004). Unfortunately, many studies examining the common cause theory have lacked direct measurement of any of these mechanisms. It is for these reasons that the latent variable reflecting a common factor should be distinguished from a putative common cause mechanism (Christensen and Mackinnon 2004).

Conclusion

Understanding relations between functional domains is an important step to developing a complete description of human life-span development. Cognition, sensation, and motor functioning are broad ability domains that are central to the study of human aging. Their age-related associations demonstrate the importance of considering cross-domain interdependencies in human development. The common cause hypothesis shone a spotlight on this important field and stimulated research into shared mechanisms underlying sensory and cognitive aging. It remains plausible that a common etiology underlies some of the age-related declines in both cognitive abilities and sensorimotor function (Li and Lindenberger 2002; Christensen and Mackinnon 2004), but it is clear that a comprehensive account of cognitive

aging must also include domain-specific factors. According to relatively recent evaluations, it is reasonable to expect that substantial portions of decline across a range of domains can be attributed to a small number of causal pathways (Lindenberger and Ghisletta 2009). Common causes are likely to draw from some of the central processes underpinning brain aging, such as systemic inflammation affecting vascular health, oxidative stress, and genetics. It is important that future research directly assesses the role(s) of candidate common causes.

Communication with Older Adults

Mary Lee Hummert

Communication Studies Department, University of Kansas, Lawrence, KS, USA

Synonyms

Aging and communication; Elderspeak; Intergenerational communication; Language and aging; Patronizing talk; Person-centered communication

Definition

Communication with older adults refers to face-to-face or mediated interactions between individuals or within groups in which at least one of the individuals meets – or is perceived to meet – the cultural standard for classification as an “older adult.” The specific standard varies across cultures and is generally based on chronological age (actual or perceived) or another demographic factor such as retirement status.

Communication with others – whether in family, social, or institutional contexts – is important to the psychological well-being of older adults. Communication is the means through which older adults achieve and maintain personal control as well as the social, familial, and professional relationships that are essential to their emotional health, life satisfaction, and general well-being. From the perspective of the life span theory of control (Heckhausen and Schulz 1995; Hummert and Nussbaum 2001; Fowler et al. 2015), communication may become the sole avenue to exercising personal control for those older adults in declining health. Although normal aging is associated with changes in hearing and cognition (e.g., name recall) that can affect language and communication, the extent to which individual older adults experience these changes varies widely and most develop coping strategies that

enable them to maintain their communication skills (Kemper et al. 2015). Yet negative age stereotypes about the communication competence of older adults create challenges for them and their communication partners across contexts. This relationship between negative age stereotypes and communication carries implications for not only the psychological and social, but also the physical, well-being of older individuals.

The Communication Predicament of Aging

Age stereotypes can be positive (e.g., the wise and loving perfect grandparent) as well as negative (e.g., the bitter and demanding shrew/curmudgeon), but negative stereotypes are more accessible and numerous than positive ones (Hummert 2011). Even in East Asian cultures that traditionally have placed a strong value on filial piety, negative age stereotypes predominate and play a role in intergenerational communication (Giles and Gasiorek 2011). Negative age stereotypes include beliefs about the physical, cognitive, and psychological characteristics of older adults that have implications for their communication competence. Examples are hard-of-hearing, sick, inarticulate, slow-thinking, forgetful, sad, lonely, inflexible, and demanding (Hummert 2011). Drawing on communication accommodation theory, the *communication predicament of aging* model (CPA; Ryan et al. 1986) illustrates how these stereotypical beliefs contribute to a negative feedback cycle in communication with older adults.

According to the CPA model, when a younger person meets an older person, recognition of the physical signs of age (grey hair, wrinkles, etc.) may activate these stereotypical beliefs and result in a communication style that accommodates to the presumed needs of the older person. That is, the younger person may speak slowly and loudly, use short sentences and simple language, employ exaggerated intonation for emphasis, and/or call the older person by first name or a diminutive (e.g., honey, dearie), all in an effort to communicate effectively. This stereotype-based, age-adapted

communication style, or elderspeak, constitutes *patronizing talk* because it implicitly (or in some cases, explicitly) questions the competence of the older person. In doing so, it challenges the older individual's autonomy to control his or her behavior and decisions (Savundranayagam et al. 2007).

Although control is an element in all patronizing talk, the degree of control can vary from moderate to high and the accompanying emotional tone may be warm or cold (Hummert et al. 2004). Three examples of moderate control illustrate variations in emotional tone from warm to cold: (1) "Here's the form, dear. Let me explain it to you"; (2) "Mom, don't overdo it – you're not as young as you used to be"; and (3) "Tom, as your physician, I think that I know what's best for you." Two high control forms of patronizing talk are also distinguished by emotional tone. The first form, directive talk ("I said to take your pill *NOW*"), lacks any hint of warmth that might soften the control message and indicate concern for the recipient. The second high control form is called secondary baby talk ("Now, sweetie pie, it's time to take our pill.") due to its similarity to the intonation patterns, warm emotional tone, and simple language used with infants (Caporael 1981). Older adults express their dissatisfaction with patronizing talk, and both middle-aged and younger adults evaluate it as disrespectful and controlling (Giles and Gasiorek 2011; Hummert et al. 2004).

In addition to capturing the antecedents that lead to patronizing talk, the CPA model outlines the consequences that create a feedback cycle with negative outcomes for older adults and their communication partners (Giles and Gasiorek 2011). These include unsatisfactory intergenerational relationships, avoidance of intergenerational contact, and reinforcement of negative age stereotypes in the younger and older individuals in the conversation. Ultimately, to the degree that the older person internalizes and conforms to the negative stereotypes as a result of such interactions, declines in physical functioning may follow (Hummert et al. 2004; Hummert 2012). Experimental studies and analysis of longitudinal data sets by Levy and colleagues (Levy 2009) have identified an association between negative self-stereotyping and an

increased risk of illness or death for older adults. The relationship between patronizing talk and negative stereotyping has been documented in numerous studies, but a recent study links patronizing talk to both cognitive performance and physiological stress, a risk factor for health problems. Hehman and Bugental (Hehman and Bugental 2015) randomly assigned older and younger participants to receive instructions for a cognitive task in either a patronizing or nonpatronizing style. Analysis of performance and stress responses revealed that older participants exposed to patronizing talk had poorer performance and higher stress responses in comparison to older participants in the nonpatronizing condition and young participants in both conditions.

Context and the Risk of Patronizing Talk

Communication with older adults occurs in a wide variety of contexts such as family, social, institutional, organizational, and medical. Although patronizing talk and its consequences as illustrated in the CPA model can occur in any context, it is more likely to occur in contexts which make negative age stereotypes salient than in other contexts (Giles and Gasiorek 2011; Hummert et al. 2004). Three contexts assume prominence due to their importance to the psychological and physical well-being of older persons: institutional, medical, and family.

Institutional and medical settings in particular evoke negative age stereotypes of illness, frailty, and decline (Kornadt and Rothermund 2015). In fact, the initial identification of secondary baby talk occurred in observations of nursing home staff interactions with residents (Caporael 1981). Frail older adults in such living facilities may have repeated interactions that involve the more extreme forms of patronizing talk and thus are especially susceptible to the consequences illustrated in the CPA model (Giles and Gasiorek 2011; Hummert et al. 2004; Williams et al. 2009). Community-dwelling older adults may encounter patronizing talk from physicians and other medical staff in both hospital and out-patient settings. Patronizing talk in these

settings can emerge in several additional ways that disadvantage the older patient: not allowing time for the patient to describe concerns, failing to explore comments that hint at health problems, using an authoritative style that precludes the opportunity for questions, avoiding eye contact with the patient, attributing complaints to the patient's age, or directing communication to the patient's companion rather than to the patient (Fisher and Canzona 2014). Institutional and medical settings make age stereotypes salient not only for physicians and staff but also for residents and patients (Miche et al. 2014). Thus, these settings increase resident and patient vulnerability to the declines in psychological and physical well-being that can follow from exposure to patronizing talk (Giles and Gasiorek 2011; Hummert et al. 2004; Williams et al. 2009).

Age is salient within the family context because families are intergenerational by definition. In comparison to institutional and medical settings, the family context is one that is associated with positive age stereotypes about the warmth and wisdom of elders (Miche et al. 2014). At the same time, older family members report that they experience patronizing talk from their adult children (Hummert et al. 2004; Hummert 2012; Hummert *in press*). These problematic interactions primarily take the form of unsolicited advice and/or directives around topics of health, finances, living arrangements, and safety (e.g., driving) (Hummert et al. 2004; Hummert *in press*), all of which are related to negative age stereotypes of decline and incompetence. Within families, these conversations reflect a tension between paternalism (i.e., the desire to protect family members from harm) on the part of the adult child, on the one hand, and autonomy (i.e., the desire to control one's own actions) on the part of the older parent, on the other (Cicirelli 1992). Parallels can be seen in the problematic interactions between parents and adolescents, although in those interactions the expectation is that the adolescents will later achieve independence (Hummert 2012). With older parents, the expectation is that the need for paternalism will increase and the parent's ability to be independent will decline.

Older adults recognize that patronizing talk from their adult children is based on care and concern for their well-being, and so may find it difficult to discount as unwarranted even as they find it dissatisfying. Experiencing patronizing talk from valued family members therefore increases the parents' subjective experience of aging and susceptibility to negative self-stereotyping (Giles and Gasiorek 2011; Hummert et al. 2004; Diehl et al. 2014) and the related negative psychological and physical consequences of the CPA model. Communication between grandparents and grandchildren is also susceptible to the influence of negative age stereotypes and their consequences (Soliz et al. 2006), illustrating that these patterns of talk may be transmitted and reinforced across the generations.

Improving Intergenerational Interactions

Older and younger adults have the opportunity to reduce the impact of negative age stereotypes on intergenerational communication. These opportunities are addressed in the communication enhancement, the age stereotypes in interaction, and communicative ecology of successful aging models, all of which build on the communication predicament of aging model (Fowler et al. 2015; Giles and Gasiorek 2011; Hummert et al. 2004).

The communication enhancement model offers suggestions on ways that caregivers and family members can use communication to empower frail older persons, creating an alternative positive feedback cycle to the CPA model (Savundranayagam et al. 2007; Hummert et al. 2004). In the CPA model, negative stereotypes influence communication with older adults when the recognition of age cues leads to implicit activation of beliefs about the communication needs of the older adult involved and the unconscious or automatic accommodation to those needs that can result in patronizing talk. The communication enhancement model calls for disrupting this process at the outset by conscious focus on the individuality of the older person. Communication can then be modified as

necessary to accommodate needs of the individual, empowering that person as a coequal partner with the provider or family member. The movement toward person-centered communication in caregiving is consistent with the individualized communication envisioned in the communication enhancement model (Savundranayagam et al. 2007; Williams et al. 2009; Storlie 2015). Empowering older adults through individualized communication increases the satisfaction of all parties and optimizes the opportunity for the older person to achieve improved well-being. It also sets in motion a positive feedback cycle by enabling the older person to maximize his or her communication skills and competence. The benefits of the communication enhancement model require conscious commitment, monitoring, and effort on the part of providers and family members. Intervention studies and assessment of training programs demonstrate that use of patronizing talk by caregivers can be decreased and person-centered communication increased to yield benefits for older individuals in residential facilities (Savundranayagam et al. 2007; Williams et al. 2009).

The age stereotypes in interaction (ASI) model considers how older adults themselves can use communication to avoid negative stereotypes at the beginning of an interaction or to redirect an interaction in a more positive direction after it has begun (Giles and Gasiorek 2011; Hummert et al. 2004). According to the ASI model, positive or negative age stereotypes may be salient at the beginning of an interaction with an older adult based not only on the context (e.g., family or medical) as discussed previously but also on the way in which the older adult communicates. Young, middle-aged, and older individuals associate several communication behaviors of older adults with negative age stereotypes (Giles and Gasiorek 2011; Hummert et al. 2004; Hummert 2012): painful self-disclosures (i.e., revealing a distressing personal experience such as the death of a spouse or child to a stranger or acquaintance), off-target verbosity (i.e., rambling and/or redirecting the conversation to a tangential or unrelated topic), self-stereotyping (e.g., referencing one's age or labeling a memory lapse as a "senior moment"), and older-to-younger

patronizing talk (e.g., disapproving/disrespectful talk, over-parenting by offering unsolicited and unwelcome advice, etc.). The ASI model predicts that the association of these communication behaviors with negative age stereotypes increases the likelihood that their use will initiate the negative feedback cycle of the CPA model. Conversely, older adults' ability to tell interesting stories, especially those that put history in context or provide an uplifting narrative to listeners, are associated with positive age stereotypes and a reduced likelihood that the negative cycle of the CPA will follow (Hummert et al. 2004).

The ASI model also considers how older adults can use their communication skills to interrupt and redirect the negative feedback cycle of the CPA through their responses to patronizing talk (Giles and Gasiorek 2011). The challenge for older adults is to respond to patronizing talk in ways that assert their autonomy and establish their competence, but to do so in a manner that builds a mutually respectful relationship with the other individual. Experiments have tested the effectiveness of passive, direct assertive, appreciative, and humorous response styles in achieving this goal. Results show that direct assertive responses, in comparison to passive responses, are better at establishing the competence of the older person but are perceived as more controlling and less respectful. Humorous and appreciative responses emerged as the most effective in establishing the competence of the older speaker in a warm and respectful way (Giles and Gasiorek 2011; Savundranayagam et al. 2007; Hummert et al. 2004).

Increasing older adults' awareness of how their own communication relates to age stereotypes can help them to avoid the consequences of the CPA model and achieve the benefits envisioned in the ASI and communication enhancement models. This awareness is at the center of the communicative ecology model of successful aging (Fowler et al. 2015). The ecology model focuses on the power of older adults to use communication to reduce their uncertainty about aging, increase their self-efficacy, take advantage of new communication technologies, and reach their own definition of successful aging (Fowler et al. 2015).

The three models may be compared on (a) their assignment of agency to older adults or others, and (b) their applicability across contexts (family, social, institutional, organizational, and medical). The communication enhancement model emphasizes the responsibility of caregivers and providers to engage in adapting their communication to the individual needs of older persons in order to support their full engagement in the communication process. Although being sensitive to one's communication partner is good advice in general, the communication enhancement model is particularly applicable in institutional, medical, or family settings in which the frailty or acute health condition of older individuals make it difficult for them to assert their agency without supportive communication partners.

In contrast, the ASI and ecology models assign agency to the older adult, but the former focuses on agency within individual interactions whereas the latter considers agency in communication holistically. In the case of the ASI model, the older adults have the ability to use their communication skills to avoid beginning the negative feedback cycle captured in the CPA model or to interrupt and redirect that cycle after it has begun. Within the ecology model, older adults have the agency to create the communication environment that supports their desired experience of aging. Both of these models apply across all contexts, but within medical and institutional contexts their applicability may be limited by the extent to which older adults' health status affects their communication agency.

Concluding Thoughts

Age-related conditions such as stroke, dementia in its various forms, and Parkinson's disease create specific communication challenges for older adults, their family members, and caregivers. End-of-life communication also has its own unique characteristics and challenges. Neither of these topics is addressed specifically in this entry. However, the communication principles outlined here – the dangers inherent in drawing on negative age stereotypes as guides, the benefits of adopting

an individualized approach, and the importance of older adults using their communication skills to achieve their version of successful aging – provide a useful framework for communication with and by older adults in these special circumstances.

Synonyms

Co-occurring disorders; Dual diagnosis; Multimorbidity

Definition

Comorbidity generally denotes the occurrence of two or more psychiatric or mental health disorders in one person. Two conditions that co-occur are considered to be comorbid regardless of whether the etiology of the disorders overlaps or is distinct, regardless of the chronological development of the disorders (Goodell et al. 2011).

Background

Most older Americans have at least one chronic condition (Administration on Aging: A profile of older Americans 2013) and one in four has two or more chronic conditions (U.S. Department of Health and Human Services 2010). With respect

to physical conditions, approximately three-fourths of older Americans have hypertension, half have arthritis, one-third have heart disease, one-quarter have some type of cancer, and one-fifth have diabetes (Administration on Aging: A profile of older Americans 2013). Older age is associated with the presence of more chronic conditions (Bayliss 2014), which makes comorbidity an essential topic for geropsychologists. Moreover, patients with chronic medical conditions have high rates of depression and other mental illnesses (Bower et al. 2014). The prevalence of psychiatric disorders may be as high as 45% among medical inpatients and outpatients (Kaszniak 1996). Other psychiatric conditions like anxiety or substance abuse are more likely to occur when the index condition of depression is also present. In light of the ubiquity of chronic medical conditions in late life and high rates of co-occurrence of medical and psychiatric disorders, one must assess and manage comorbid conditions when working with older adults. Failure to consider medical comorbidities may dilute treatment effects and confound diagnostic accuracy. Consideration of comorbidities may also refine our psychiatric phenotypes, help us identify the genetic bases of mental health disorder, and reveal their pathophysiological mechanisms. Before considering the identification and management of comorbid disorders, one should first carefully characterize comorbidity.

Defining Comorbidity

The term “comorbidity,” first used by Feinstein in 1970, refers to the coexistence of two or more disorders within one person. One important aspect of Feinstein’s definition was that one of the disorders was the “index disease” being studied (Fortin et al. 2014). The term comorbidity originated in the medical literature but was soon adopted for use in psychiatry. The study of comorbidity became quite important with the 1980 publication of the third edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM) (American Psychiatric Association 1980) because

of the use of polythetic criteria to characterize psychiatric disorders. Polythetic criteria allowed for differing clusters of symptoms to be characterized as the same disorder. Additionally, symptoms such as sleep disturbance may be included in multiple psychiatric disorders.

By the 1980s and 1990s, researchers began using the term multimorbidity (Fortin et al. 2014) to describe the burden of multiple medical conditions. Currently, multimorbidity is most often used when three or more conditions are present. Comorbidity usually has one condition of interest (i.e., index condition), whereas in multimorbidity there is no specific condition of interest. Multimorbidity encompasses the complexities resulting from the presence of multiple conditions, as is often seen in primary care settings (Fortin et al. 2014). When working with patients with multimorbidity, clinicians must sort out different recommendations resulting from the separate clinical management guidelines for each chronic condition. Reconciling different clinical management guidelines often leads to confusion on the part of the patients and polypharmacy and even results in contradictory recommendations. Multimorbidity is an important term to be aware of for clinical geropsychologists, but here, comorbidity is the term that is focused on as specialized fields such as geropsychologists often focus on one presenting problem or one index condition.

Kraemer (1995; Kraemer et al. 2006) defined several distinct types of comorbidity that are especially relevant for those studying aging: clinical comorbidity, epidemiological comorbidity, familial comorbidity, and random comorbidity. The first type, clinical comorbidity, refers to a situation in which the prognosis differs for people who have the index disorder and a second disorder when compared with those who have the index disorder and not the second disorder. The second type, epidemiological comorbidity, occurs when two disorders co-occur more often than one would expect by chance alone. Epidemiological comorbidity may occur when the two disorders share genetic risk factors or if the two disorders are different clinical manifestations of the same disorder. Epidemiological comorbidity is of interest to clinicians and researchers because the presence

of one disorder (e.g., Down's syndrome) may signal that clinicians should screen for another disorder (e.g., dementia). The third type, familial comorbidity, describes comorbidity that occurs when the prevalence of one disorder differs among relatives of patients with a second disorder when compared with relatives of patients without the second disorder. For instance, the occurrence of obsessive-compulsive disorder is higher in relatives of individuals with Tourette syndrome compared with families without Tourette syndrome. Lastly, disorders that do not fit into these other three categories, that may simply co-occur at random, and that have no relevance to clinical decision-making would be called random comorbidity using Kraemer's model (Kraemer 1995). For example, the presence of social anxiety disorder and a completely unrelated condition like shingles could be considered randomly comorbid. Unrelated disorders such as these are considered an example of random comorbidity.

Prognosis and treatment recommendations can vary based on co-occurrence of conditions in clinical comorbidity (Kraemer 1995). This entry, therefore, focuses on issues relevant to clinical comorbidity because it is most relevant to geropsychologists in both clinical practice and clinical research settings.

Diagnostic, Prognostic, and Treatment Implications of Ignoring Comorbidities

Among older adults, age-related physiological and other body system changes can complicate diagnosis and treatment. One disorder may cause another (e.g., hypothyroidism can lead to depression), whereas other conditions may exacerbate one another (e.g., anxiety and chronic obstructive pulmonary disease). Hence, prognosis and treatment recommendations may vary based on the comorbid disorders present.

Sleep disturbance is one of the most frequent complaints among those with depression or anxiety in late life and as such can be thought of as a core-presenting symptom of these two mental health disorders. Nevertheless, sleep disturbance can also occur due to the presence of a

diagnosable sleep disorder, such as sleep apnea, an extraordinarily common sleep disorder in older adults. Failing to adequately assess for and diagnose sleep apnea can mean patients obtain a diagnosis of a psychiatric disorder when in fact they should be given the diagnosis of a sleep disorder. In the example of sleep apnea misdiagnosed as depression, treatment with antidepressants may have modest results at best, whereas augmenting antidepressant treatments with continuous positive airway pressure (CPAP) could alleviate the sleep-disordered breathing while also improving depressive and anxiety symptoms.

With respect to prognosis, a person with an anxiety disorder and breathing disorder may be slower to respond to behavioral treatments because of modifications needed in teaching diaphragmatic breathing or breathing retraining compared with a person with an anxiety disorder and no breathing difficulties. Indeed, it is well documented that the presence of such comorbid disorders such as pain and depression slows the response to pharmacological and psychological treatments for late-life depression. Such examples are very common in geropsychology. Given the considerable implications of many comorbid conditions for diagnosis, prognosis, and treatment, it is imperative that geropsychologists adequately assess for and address comorbid medical and psychiatric disorders in older adults.

Assessing Comorbidities

A critical issue is how best to evaluate and assess a comprehensive range of comorbid disorders. The main challenge to studying comorbidity is the inherent heterogeneity of one's sample. Consideration of this heterogeneity is essential to identifying the effectiveness of evidence-based treatments, yet characterization of comorbid samples is challenging. Frances et al. (1990) highlight several issues that influence how comorbidity is measured and classified. To start, with more disorders included in a classification system, there is more likelihood of comorbidity. Additionally, splitting disorders and using categorical classifications increase the rates of disorders and the rate

of comorbidity. Often in the DSM, which relies on polythetic criteria, there is substantial symptom overlap, which can lead to increased rates of comorbidity; however, the use of a hierarchy in making diagnoses reduces rates of comorbidity.

A commonly reported issue relating to differing comorbidity rates and assessment is the halo effect, whereby an assessment geared toward detecting a particular disorder might also increase the assessor's awareness of a particular disorder. A halo effect also could be a function of the assessor's assumptions about disorders being related (Frances et al. 1990). Another reported issue regarding assessment and comorbidity includes selection of comprehensive versus narrower assessments. A comprehensive assessment, such as the Structured Clinical Interview for DSM (SCID), is more likely to detect the presence of comorbid conditions than would be the case if select measures of specific disorders were used. In the case of structured interviews (e.g., SCID), the assessor is comparing an individual's symptoms to the set list of diagnostic criteria. Assessors likely detect more conditions when using structured interviews compared with using a limited set of selected measures (e.g., depression and anxiety screens) because structured interviews force assessors to consider many different types of psychiatric conditions as the assessor reviews a set list of diagnostic criteria for each disorder. Different settings also affect the likelihood that specific pairs of comorbid conditions will co-occur, such as in an anxiety disorder clinic, where depression may be more likely to co-occur with social anxiety disorder; however in primary care clinics, depression may be more likely to co-occur with chronic medical conditions. The main challenge to characterizing comorbidity in psychiatry is the use of diagnoses based on groups of symptoms rather than etiologically defined disorders (Fyer et al. 1990). Prospective longitudinal studies will elucidate the etiology and course of psychopathology, which is needed to better understand the common pathways and courses of comorbid diseases.

In the medical literature, the burden of multiple conditions (i.e., multimorbidity) is measured using disease counts and established comorbidity

indices such as the Charlson Comorbidity Index (Charlson et al. 1987). These indices and counts do not characterize the specific relationship between an index condition and the associated conditions, as is the focus of comorbidity research. These indices are helpful in predicting negative outcomes such as mortality, but they have less relevance when trying to characterize specific comorbidities.

Personalized approaches to assessment can also be used. This would entail a multimodal assessment including reviews of medical evaluations, cognitive testing, functioning assessments, behavioral observations, and clinical interviews with the patient and an informant if possible. The thorough review of somatic symptoms can help differentiate medical disorders from psychiatric disorders. In the review of somatic symptoms, identifying the onset of symptoms and other factors in the time line is essential. Investigations of whether disparate treatment outcomes occur with different groups of comorbid patients will also help elucidate the relationships among comorbid conditions.

Common Psychiatric Comorbidities

Many aspects of psychiatric comorbidity remain true from younger to older adulthood, although some differences exist. Psychiatric disorders seldom occur in isolation from other psychiatric symptoms or disorders regardless of a person's age. The psychiatric disorders ranked from most (anxiety disorders) to least common (schizophrenia) follow the same pattern in younger, middle-aged, and older persons (Kessler et al. 2001; Zarit and Zarit 2007). The tendency for some psychiatric disorders to occur together more often than others is also somewhat age invariant. The prevalence of psychiatric disorders and subthreshold symptoms, however, differs with age. In particular, the prevalence of any psychiatric disorder decreases with age, but subthreshold anxiety and depressive symptoms are documented as common with as many as 25% of older adults

reporting subthreshold depression (Zarit and Zarit 2007) and 20–29% reporting subthreshold anxiety (Gellis et al. 2014). Researchers have argued for a dimensional approach to understanding psychiatric disorders, rather than a purely categorical one, in order to capture these subthreshold psychiatric conditions (Maser and Cloninger 1990). The rationale for implementing a dimensional approach is all the more salient in older adults given the ubiquity of subthreshold symptoms. Because subthreshold psychiatric disorders are associated with substantial medical and cognitive comorbidity, especially in older adults, documenting and treating them is critical.

Anxiety and depressive disorders frequently co-occur and as such have garnered much of the attention regarding psychiatric comorbidity (Zarit and Zarit 2007). This has led some theorists to propose that anxiety and depression represent different phenotypic (i.e., expressed) manifestations of the same underlying disorder. Others have argued that the lifelong durability and trait-like nature of anxiety disorders increase the risk of developing depressive disorders, which tend to be cyclic over the life span. Older adults with any number of anxiety disorders, such as panic disorder and social anxiety disorder, often suffer from coexisting dysthymic disorder or major depressive disorder. In fact, there has been some suggestion that this overlap of depression and anxiety in older adults is greater than what is seen in younger adults, particularly when subthreshold symptoms are included. Cognitive disorders, namely, minor and major neurocognitive disorders, are much more likely to co-occur in older adults with psychiatric disorders than in older adults without any threshold or subthreshold psychiatric issues.

In addition, comorbid psychiatric issues require additional consideration in clinical situations with older patients, particularly because individuals with coexisting psychiatric problems often have more severe symptoms. The decision to treat one disorder, such as the anxiety disorder as primary versus treating the depressive disorder as primary, has implications for

treatment selection. Behavioral interventions targeting anxiety typically focus on reducing anxiety through relaxation skills training or desensitization through real or imagined exposure to feared situations or objects. Treatments for depression typically work to increase the person's social interactions, activity level, and experience of the environment as positive through a concerted effort to partake in enjoyable activities. These behavioral skills have been successfully used in older patients suffering from psychiatric disorders (Zarit and Zarit 2007). The presence of anxiety and depressive disorders could require a combined treatment approach or staged approach where the more urgent of the two disorders is first treated before treating the second disorder. With regard to pharmacological interventions, both anxiety and depression can be treated with some of the same medications (i.e., selective serotonin reuptake inhibitors or SSRIs), rendering this comorbidity issue potentially less relevant for medication management. Nevertheless, other situations, such as comorbid schizophrenia with generalized anxiety disorder, could require a more complicated medication regimen due to potential interactions and negative side effects of medications that treat the two separate disorders.

Less often discussed, but a critical issue for understanding psychiatric comorbidity in older adults, is the co-occurrence of personality disorders (Mordekar and Spence 2008). These disorders are characterized by long-standing patterns of inflexible and maladaptive behaviors that often go against society and cultural norms. This often leads to disruptions in interpersonal relationships. Again, as with other psychiatric disorders, the prevalence of personality disorders declines with age (Segal et al. 2006). The comorbidity of personality disorders with other psychiatric disorders, however, is quite high in older persons. Mood and anxiety disorders are the most commonly reported diagnoses comorbid with personality disorders. For example, it has been reported that 24% of older individuals with major depressive disorder also meet criteria for a personality disorder. Further, rates of comorbid personality

disorders are notably higher (73%) in older individuals with adult-onset depression than late-life-onset depression (45%) (Mordekar and Spence 2008). With regard to anxiety disorders, comorbid DSM-5 Cluster C personality disorders (avoidant, obsessive-compulsive, or dependent) are frequently observed in individuals of all ages who experience an anxiety disorder. Treatment of an older patient becomes even more challenging, as personality disorders are often associated with poorer prognosis. They complicate treatment delivery and can require a more sophisticated intervention approach and skill level of therapist for older adults seeking help.

Common Medical Comorbidities

Older adults with psychiatric disorders often also have comorbid medical conditions. Psychiatric-medical comorbidity is likely a function of many factors including but not limited to age, poorer self-care, greater disability, and cognitive impairment. When working with older adults who have both psychiatric and medical disorders, one must determine the extent to which the medical disorder contributes to the psychiatric disorder of interest. Additionally, the manner in which the medical and psychiatric disorders are related temporally is important. For instance, chronic conditions may lead to depression, whereas depression itself may be a risk factor for chronic conditions and functional decline (Bower et al. 2014). Moreover, depression may make it more difficult for a patient to be motivated to manage their chronic conditions, leading to poorer outcomes, as may be observed in individuals with comorbid depression and diabetes (Bower et al. 2014).

There are multiple pathways through which psychiatric and medical disorders interact. To illustrate this point, take the example of late-life anxiety disorders. Chronic medical conditions, such as chronic obstructive pulmonary disease, may lead to physiological changes that predispose older adults to anxiety (Zarit and Zarit 2007). Alternatively, an acute illness or hospitalization

may lead to an exacerbation of worry and other anxiety symptoms (Zarit and Zarit 2007). It is also possible that medications such as steroids or anticholinergics prescribed to older adults could exacerbate or even cause anxiety (Zarit and Zarit 2007). The presence of an anxiety disorder prior to the development of a chronic condition may make the management of the medical condition more difficult, such as the presence of agoraphobia would likely interfere with patients' attendance at medical appointments. These are only a few examples of the multiple pathways connecting psychiatric and medical disorders.

In addition to the pathways connecting psychiatric and medical disorders, oftentimes the prevalence of psychiatric disorders may be greater and severity worse among older medical patients. For instance, depression is more prevalent among older adults with medical illness (Zarit and Zarit 2007). Functional limitations associated with medical illnesses, sensory impairments, ambulation difficulties, and pain may limit an older patient's ability to engage in pleasant activities. Behavioral theorists posit that these functional limitations reduce participation in enjoyable activities and thus cause depression.

Psychological stress, experienced by those with psychiatric disorders, may also adversely affect physical health by exacerbating chronic conditions like hypertension (Haley 1996) and preventing immune responses that are important in recovery (e.g., cancer). Individuals with severe mental illness (SMI), such as schizophrenia, die 10–15 years earlier than their counterparts without SMI. These individuals with SMI also have elevated risk of having comorbid medical conditions likely due to multiple factors. The presence of SMI requires substantial management and can result in the psychiatric disorder taking precedence over and obfuscating other problems, which is referred to as diagnostic overshadowing (Bower et al. 2014). Some antipsychotic medications contribute to weight gain, increased risk of diabetes, and metabolic syndrome, whereas other lifestyle choices (e.g., sedentary, poor diet) and comorbid conditions (e.g., substance use disorders) may contribute to the development or

worsening of chronic medical conditions (Bower et al. 2014).

Treating Patients with Comorbidities

Personalized or patient-centered medicine ideally can be used to tailor treatments to patients with comorbidities. Individualized treatments can take into account the patient's medical and psychiatric comorbidities. Individualized treatments allow providers to consider the index condition being treated as well as other factors, such as cognition, which can influence outcomes. Careful assessment provides a strong foundation for tailored, personalized treatments. Additionally, interdisciplinary teams are an essential part of delivering patient-centered treatments to those with comorbidities. The team members can address medical and psychiatric conditions through the collaboration and communication across disciplines.

There is also a need to include patients with comorbidities in randomized control trials (RCTs). Patients with comorbidities are included in large and inclusive RCTs called “pragmatic” or “effectiveness” RCTs rather than the smaller efficacy studies. Effectiveness trials focus on examining the effects of treatment under the usual conditions (i.e., in community practice) rather than under the ideal conditions (i.e., controlled research setting) as is the case for efficacy studies. Moderator analysis (Kraemer et al. 2006) can be used to examine the effect of comorbidities on treatment outcomes. The resulting findings will likely yield information about what treatments work best for which groups of patients. These findings can be used to refine existing treatments, develop new treatments, and inform patient-centered medicine.

Conclusions

Psychiatric and medical comorbidities are common across the life span. Among older patients, high rates of comorbid psychiatric disorders co-occur frequently with chronic medical conditions.

Medical conditions and associated functional impairments may precede and lead to psychiatric conditions. Chronic psychiatric conditions can also affect an individual's physiology and immune responses, lifestyle, and the clinician's assessment (i.e., diagnostic overshadowing). The complex relationship between comorbid psychiatric disorders and medical and psychiatric disorders points to a need to use multimodal assessments to accurately diagnose and treat older patients with these comorbidities. Additionally, more research is needed to determine the manner in which comorbid conditions affect treatment outcomes in older patients. Prospective longitudinal studies and large-scale effectiveness trials could address this issue.

Holistic medicine; Natural medicine; Non-conventional medicine; Unorthodox medicine

Definition

Complementary and alternative medicine (CAM) is an umbrella term used to describe a group of diverse medical and healthcare systems, practices, and products that are not generally considered part of conventional medicine, that have not been part of the public healthcare system or administered by conventional medical practitioners (Adams et al. 2009). There has been a noted increase in CAM use across all populations during the past 20 years (Andrews 2002), including older adults (aged over 65). Depending on how CAM is measured, studies suggest 40–65% of older adults use either some form of CAM therapy and/or over-the-counter CAM products (Cohen et al. 2002). Older adults have been identified as being significant consumers of CAM, and the factors that influence this use are varied and have unique implications compared to other cohorts.

Population Ageing, Chronic Illness, and Health System Responsiveness

Complementary and alternative medicine (CAM) is broadly consumed by older adults and its use is on the rise. CAM, and indeed health care in general, is being influenced by the demographic shift of the ageing population (Adams et al. 2009). It is predicted that there will be 1.5 billion individuals over the age of 65 by 2050, driven by decreasing fertility rates and improved life expectancy

(World Health Organization 2011). This comes at the cost of increased economic and social pressures on a range of systems and infrastructure globally. How health services are consumed and provided is changing across both traditional and nontraditional services.

The ageing population will place particular strain on the health system with disease patterns moving from acute short-term, infectious or parasitic diseases to chronic long-term, noncommunicable diseases (Hale et al. 2007). As longevity increases, frailty and chronic illness rise as physical and cognitive capacities decline at the later stages of life (World Health Organization 2011). In particular, the demand for chronic care, rehabilitation services, and palliative care all increase with the ageing of populations (Hale et al. 2007).

Criticisms have been made of the existing medical system and the difficulty it will face catering to the increased demand on services due to changing disease patterns (Holman 2004). The current health system is typically focused towards treating acute illnesses that are episodic where the health practitioner typically has the majority of control in determining treatment and management approaches, and the patient is largely a passive recipient. It has been argued the traditional medical model of health care (that focuses on biological aspects of disease and illness) is less conducive to treating chronic illnesses where treatment is ongoing and long-term management of symptoms is often the goal, rather than seeking a cure. Due to the ongoing and often personalized experience of chronic illness, it is argued that the roles in treatment need to shift from the health practitioner having full control to provide the patient with more authority over their treatment plan, allowing them more responsibility and autonomy in management of their conditions (Holman 2004). The current model of healthcare delivery offers limited flexibility.

Chronic Illness and CAM Use

The ageing population is at increased risk of chronic health complaints illness (Cherniack

et al. 2001). Older consumers are cognizant of the need to treat these health complaints, and it has been found that as health conditions deteriorate, CAM use increases (Cherniack et al. 2001). Indeed, CAM use is five times higher in the chronically ill population compared to a healthy population. In general, research completed with chronic illness populations have noted that CAM use rates are elevated and typically centered around management of health conditions (Cherniack et al. 2001).

Within the chronically ill population, the use of CAM has been linked to a belief that CAM is a “safer” option than conventional medicine with fewer side effects to conventional medicine (Vincent and Furnham 1996). Furthermore, CAM users have reported strong beliefs in the efficacy of the CAM product/service being consumed (Vincent and Furnham 1996). Practitioners who provide CAM services often have longer consultations and reportedly provide more personalized services than offered by conventional medical systems (Gammack and Morley 2004). This in itself has a therapeutic benefit that can be particularly useful in the treatment of non-life-threatening chronic illnesses.

The Active Consumer

Researchers have noted that the flexibility in services offered through CAM allows the individual to play an active role in the management of their long-term chronic disease (Bishop et al. 2007). CAM offers a different approach to the traditional biomedical model, and studies have shown it can provide a prevention-focused, flexible healthcare model for chronic and degenerative diseases (Bishop et al. 2007). While the need for conventional medicine is still undisputed, the argument that CAM offers a more versatile form of care when dealing with non-life-threatening and chronic ailments has merit and may assist in addressing the need created by the ageing population. This shift appears to be occurring as traditional health systems are not currently structured to cater for the increase in long-term chronic diseases that is occurring across the globe associated

with population ageing (World Health Organization 2011).

Traditional medicine and CAM use are very much rooted in cultural contexts, and the legitimacy of both health treatment options is influenced by sociocultural perspectives (Root Wolpe 2002). The sociocultural context not only influences people’s perceptions of both traditional medicine and CAM but also the illnesses that trigger their use. In the literature surrounding health service provision, there is an expanding body of research attempting to describe a shift towards consumerism and the identity of health users (Milewa 2009). The typical health consumer now interacts with health services as an active participant, picking and choosing the products best tailored and personally suited to their needs rather than being a passive consumer. The ability to make personal decisions, select from a range of options, and make choices based on a sense of personal responsibility and shared decision making are valued by many patients. Patients who adopt this viewpoint are more likely to look for broader healthcare options beyond what is offered by traditional health service providers, including services offered by CAM.

With higher uptake of CAM use, there is increasing pressure for conventional medical practitioners to have knowledge about individual patients CAM usage. Historically, many doctors have not discussed CAM usage with their patients. Research has demonstrated that up to 77% of CAM users did not disclose their CAM use to their treating practitioner (Xue et al. 2007). CAM users who discussed their CAM use with their medical practitioner were more likely to describe themes of acceptance and control whereas CAM users who did not have these conversations were more likely to describe their treating physicians as narrow minded (Vincent and Furnham 1996). To add to this, general practitioners frequently underestimate the extent to which their patients use CAM (Nahin and Straus 2001). This is concerning as studies have additionally shown that patients often have a poor understanding of the effects of CAM. Harmful interactions have been found between some CAM products and conventional medicine

approaches, e.g., herbal therapies and pharmaceutical therapies (Votova and Wister 2007).

The Third Age

Increasing longevity of life has contributed towards a period of time referred to as the Third Age, between postretirement but prior to age-imposed limitations such as illness (Weiss and Bass 2002). This growing generation in general has improved physical and mental health, greater wealth, and higher levels of education, with predicted longer life-spans than their predecessors. The Third Age provides a platform for older adults to explore personal growth, self-fulfillment, freedom, and personal engagement, with a noted increase in the desire to maintain health status and postpone the inevitable decline in health (Weiss and Bass 2002). Indeed, there is often an acute awareness of one's mortality coupled with uncertainty about future health needs (Weiss and Bass 2002). The combination of increased resources and the time to use them has placed older adults in an optimal position to experiment with previously unexplored services and products, e.g., CAM. There is often a sense of responsibility for personal self-maintenance that promotes concepts such as awareness of medical conditions, proactive intervention, wellness techniques, self-care of diet and exercise, and new learning. With this combination of factors, an increase in CAM use among this population is understandable (Andrews 2002).

Antiageing Movements

Antiageing movements through media and marketing have additionally influenced the use of CAM through increased consumerism of antiageing products (Milewa 2009). There exists a marked increase of interest in products and services that are marketed as being able to slow down or even reverse the natural ageing process. Improvements in access and marketing that targets consumers through media such as the press, television, and Internet have contributed to this increased interest. While CAM services have increased broadly, there has been a particular boom in CAM technologies aimed towards antiageing with middle-aged and older adults

being primary consumers (Weiss and Bass 2002). An increased focus on positive frameworks of growing older that include the denial of physical signs of ageing and the promotion of healthy active living has been witnessed. In particular, the chronological process of ageing has been reframed as a transition, emphasizing a distinction between chronological age and cognitive age of individuals.

Personal Motivators of CAM Use

Some researchers have categorized the motivators for individuals choosing to use or not use CAM as being in terms of push/pull influences. Pushes indicate factors that "push" an individual away from conventional medicine. Typically, these experiences are underpinned by dissatisfaction with conventional medicine, e.g., poor communication, adverse side effects, poor treatment options (Sirois and Gick 2002). Pulls in contrast indicate factors that draw the individual towards CAM, e.g., holistic approach, long appointment times, and perceived safety of the approach (Furnham 2005). Typically, there appears to be a mix of motivators that change over time and an interplay factors that influence whether an individual is a CAM user or nonuser. It is often the case that older adults use CAM in conjunction with conventional medicine, as a concurrent service to the management of their health care. Indeed, in some studies CAM users were found to consult with a specialist doctor more frequently than non-CAM users (Adams et al. 2003). The researchers hypothesized that this suggested a pragmatic approach to selecting treatments that "best fit" their health concerns.

Research on push versus pull factors has been varied and there is little consensus in the literature on which variables are consistently associated with CAM use in the past or future. For example, one found that personal control over health and dissatisfaction with conventional medicine were inversely related to CAM use (Testerman et al. 2004). In previous research however, criticisms of the existing medical system have been proposed to influence CAM use (Willison and

Andrews 2001). A more recent study that found dissatisfaction with conventional medicine was positively correlated with past but not future use (McFadden et al. 2010). An important variable that is not always addressed in research is dissatisfaction with conventional medicine treatment versus dissatisfaction with the treating physician. For some individuals, there were high rates of satisfaction with their physician; however, they felt that the use of CAM would assist in relieving symptoms in a way that conventional medicine was not able to provide (Testerman et al. 2004).

A number of attitudinal dimensions have been identified as being related to CAM use. Those who are more likely to seek CAM have been identified as having a heightened awareness and commitment to environmental issues (Astin 1998; Kranz and Rosenmund 1998). Other attitudes that have been linked to CAM use include a belief in personal responsibility towards health and holistic healthcare approaches (Astin 1998). Holistic beliefs include views of the mind–body relationship as being in balance and maintained by self-healing. Some studies have noted that as holistic beliefs and health complaints increased, so too did CAM use, indicating that both personal beliefs about health care and a desire to relieve illness symptoms influence CAM use (Vincent and Furnham 1996). It has been proposed that conventional medicine, through focusing on the physical elements of a disease, fails to account for the person as a whole (Kranz and Rosenmund 1998). For individuals holding this perspective, CAM provides an appealing alternative.

It has been suggested that CAM users perceive that they have increased control over the active management and choices concerning their health (Astin 1998). Previous researchers have hypothesized that a desire for control (Astin 1998) and a sense of personal responsibility towards health and holistic healthcare approaches (Furnham and Kirkcaldy 1996) are important factors that influence an individual's choice to use CAM. The desire to seek holistic, natural, and preventative approaches is often motivators for commencing CAM use (Kranz and Rosenmund 1998). A systematic review explored 94 studies that included themes of control, illness, holism

treatments, natural treatments, and life philosophies and how they related to CAM use (Bishop et al. 2007). The researchers reported that a desire for participation in treatment decisions, active coping styles, and holistic approaches to health were all significantly related to CAM use, however control was not. Many of these studies use a cross-sectional design so directionality cannot be easily established to determine if beliefs about CAM use, active coping styles, and holistic approaches to health were formed before or as a result of CAM use. Other research has found positive relationships between personal control and CAM use for healthy individuals (McFadden et al. 2010). Testerman et al. (2004) did not find such a link but his population was recruited from a medical clinic. These studies demonstrate that the specific relationships between predictor variables are often complicated.

Structural and Sociodemographic Influences on CAM Use

There are also a number of structural and personal sociodemographic influences that influence frequency and type of CAM use (Kelner and Wellman 1997). The physical availability and access to CAM products, personal income, insurance plans, private health care, and distance travelled to access services have all been linked to CAM use (Kelner and Wellman 1997). Studies have consistently shown that CAM use is higher in rural and remote regions compared to urban settings (Robinson and Chesters 2008), and lower in Metropolitan areas compared to nonurban locations (Adams et al. 2003). This is an issue of particular concern to older adults as there are often mobility and driving restrictions that further complicate their access compared to younger cohorts (McLaughlin and Adams 2012). Difficulty accessing conventional health services in rural regions compared to urban areas may be influential in the decision to use CAM (Robinson and Chesters 2008). Indeed, the relationship between geography and location to CAM use is not as strongly established in the literature as other

elements including health status, gender, income, and level of education. Connected elements to geography may include population of available clinicians, proximity of specialist services and range of services, socioeconomic status of the region and policies, and politics of the region (Adams et al. 2011). A number of studies specifically exploring older adult CAM use in rural settings found that CAM is used far more broadly than the treatment of existing health complaints, but also for maintaining current health status and well-being (Adams et al. 2003; Robinson and Chesters 2008).

Conclusion

The ageing population, the antiageing movement, and shifts in consumerism and disease patterns have all contributed to changing the way in which older adults consume traditional health care and CAM. CAM use amongst older adults is an increasing phenomenon that is uniquely impacted on by a number of broader cultural shifts. The combination of the ageing population and the rise of chronic illness requires all health providers, independent of their qualifications or personal beliefs, to recognize and be informed about the processes and factors influencing CAM uptake in the older population. There is a need for future research to investigate directional relationships to explain the mechanisms which influence decisions to adopt and maintain CAM therapies. This information will potentially provide guidance for healthcare service providers who seek to understand how CAM usage interacts with conventional medicine, and will help ensure that the most effective health-related outcomes for those in later life.

Conceptual Model of Habit Reforming to Improve Balance and Prevent Falls

Lindy Clemson and Jo Munro

Ageing, Work and Health Research Unit, Faculty of Health Sciences, The University of Sydney, Lidcombe, NSW, Australia

Synonyms

Automatic behaviors; Challenge your balance; Cues to action; Do more and be safe; Integrate balance and strength training within daily tasks; Load your muscles; Visualize and plan

Definition

Understanding how habitual behaviour can be adapted and changes maintained are core concepts in an applied model of behaviour change to embed balance and strength training into daily life activities and routines with the goal of reducing the risk of falling.

Definition Statement

Habits: automatic behavioral responses to environmental or situational cues developed through repetition in consistent contexts.

Falls: an event which results in a person coming to rest inadvertently on the ground or floor or other lower level (WHO).

Balance: the ability to maintain an upright posture and keep the body within the base of support with minimal postural sway. Maintaining balance involves motor planning and the integration of input from multiple sensory systems.

Functional exercise: training that is performed with purpose to enhance a certain movement, movements, or activity that is closely aligned with daily tasks (Liu 2014; Chou 2012).

Lifestyle-integrated exercise: This is a specific type of functional exercise whereby activities or actions that are designed to improve physical ability, such as to challenge balance or improve muscle strength, are embedded within everyday tasks and routines (Clemson, 2012).

Introduction

This entry outlines a conceptual framework that underpins the adoption of an innovative approach to balance and lower limb strength training to reduce the risk of falls. The Lifestyle-integrated Functional Exercise (LiFE) program, proven effective in reducing falls and improving function in a randomized trial, (Clemson et al. 2012) embeds balance and lower limb strength activities within daily life tasks and routines. Activities are tailored to the person's capacity and their lifestyle. The framework is an applied one and is based on a

habit reforming theory, principles of self-efficacy, and an understanding of occupation-person-environment demand theories.

Functional Exercise Programs That Improve Balance, Reduce Falls, and Improve Function

There is strong evidence for the core role of balance in providing protection from falls for older people with studies demonstrating that balance training is more effective than strength training alone in preventing falls (Sherrington et al. 2008). Further, the evidence for functional exercise training having direct benefit in improving balance, physical function, and the capacity of older adults to perform activities of daily living is growing (Liu et al. 2014). Functional training has been defined as any type of training that is performed with purpose to enhance a certain movement or activity (Liu et al. 2014). Functional exercise appears to be most effective when the training content is specific to the outcome (Liu et al. 2014; Chou et al. 2012) and activities that involve dual or multitasking have a greater capacity to reflect function.

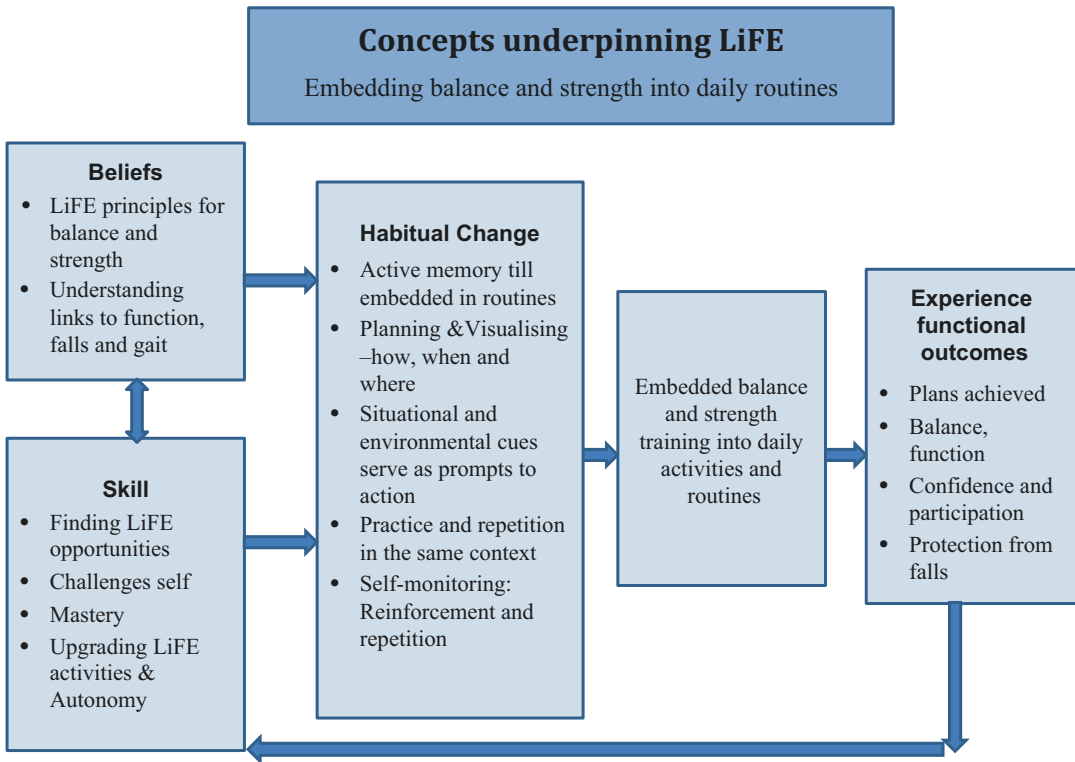

Exercise programs that involve multiple components are suggested as the most appropriate for physically frail older adults because they align more closely with the demands of functional situations (Cadore et al. 2013). Examples of specific functional training programs include a music-based multitask training program which improved gait and balance and reduced falls through activity to music and involved dual tasking (Trombetti et al. 2011). Other approaches to improving physical fitness and capacity to perform daily life activities have tested programs that specifically incorporate activities of daily living. One such program used a multistation circuit approach which mimicked daily functional tasks (Dobek et al. 2007). The Lifestyle-integrated Functional Exercise program (LiFE) (Clemson et al. 2012) is different to these in that it embeds balance and strength training into daily life activities throughout the day and is performed within the participants home and their community environments.

With poor health, slow gait, and unsteady balance predictive of difficulty in long-term engagement in exercise, it is not surprising that the effect of any exercise dissipates after the program ceases (Gine-Garriga et al. 2013). To maintain outcomes, the program needs to have an effect more than just preventing falls, for example, improving functional capacity. Typical positive comments from LiFE participants such as “I can keep catching the buses so I can still get to visit my daughter” or “I can stand up now to put on my trousers” or “I can keep going to the club because I can easily get out of the chair” reflect that personal outcomes must be relevant to the person and their lifestyle. Understanding what enables older people to continue to exercise will also provide guidance as to what features are essential when undertaking training and also what tools are needed to facilitate adoption and personal sustainability.

LiFE Trial Outcomes

LiFE was tested in a three-arm randomized trial (Clemson et al. 2012) where LiFE and a structured exercise program were compared to a control group who received a “sham” gentle exercise. The trial recruited 317 people 70 years or older who had either had two falls in the previous year or one injurious fall. After a 12-month follow-up, there was a 31% significant reduction in rate of falls (IRR = 0.69) for the LiFE participants compared to the control group who received a gentle exercise program. The structured program (balance and strength exercises performed three times a week) showed reduced falls, but this was not a significant difference compared to the control group. In the LiFE program, there were significant and moderate effect sizes for both static balance and dynamic balance and for balance confidence. For LiFE, while there were steady improvements for hip and knee strength, ankle strength was the only strength measure to show a significant effect. LiFE demonstrated moderate to large effect sizes in measures of function and daily activity and in a measure of participation. Adherence was sustained with 64% still engaged in LiFE activities at 12 months.

The LiFE program has been successfully implemented in a restorative home care service showing positive outcomes in a pragmatic

Conceptual Model of Habit Reforming to Improve Balance and Prevent Falls, Fig. 1 Conceptual framework underpinning embedding balance and strength training into daily life activities and routines (Lifestyle-

integrated Functional Exercise (*LiFE*) Program to prevent falls. Trainer’s manual. Clemson, Munro and Fiatarone Singh, 2014 Sydney University Press)

randomized trial (Burton et al. 2013). It has also been incorporated in a group-based program for women at retirement (Fleig et al. 2015).

The Lifestyle-integrated Functional Exercise (LiFE) Conceptual Model

Embedding Balance and Strength Training into Daily Routines

Figure 1 summarizes the main concepts underpinning how to embed balance and lower limb strength activities into daily life activities and routines (Clemson et al. 2014). The LiFE program includes features that enhance beliefs, attitudes, and understanding of the program as well as training in skills specific to the program. A central and core process of change are strategies to encourage habitual change, based on habit re-framing theory (Lally and Gardner 2013). LiFE activities are

linked to specific daily tasks using situational and environmental cues that serve as prompts to action. Planning includes both setting what activities and where and how they will be performed and visualizing doing this in selected situations. They are performed intentionally and consciously until they become habitual and embedded in daily occupation. Feedback, monitoring, and positive reinforcement are strategies used to improve skill and enhance self-efficacy in the performance of the activities. The experience of positive functional outcomes will sustain engagement in the program. These outcomes may include protection from falls, increased function, self-confidence in balance demanding activities, and greater participation in activities and life roles.

Beliefs

When training people to implement such programs, we believe it is important for participants to

understand the principles of balance and strength training underlying the program. Motivation can be enhanced if people are able to link doing the particular activities to specific outcomes. Features of the model are designed to inform and enhance beliefs, attitudes, and understanding of the underlying principles of the program. To engage in an embedded exercise program, it is necessary to have a belief that it is possible to improve balance and strength and that this will have a direct impact and benefit; this may be to reduce fall risk, to improve gait or to improve functional capacity in performing activities of daily living.

LiFE Principles for Balance and Strength

Many people are unaware that they have poor balance. Only 6% of the general older population engages in any balance challenging activities. Being able to safely and functionally maintain posture requires motor planning and sensory input from the vestibular system, vision, and proprioception. Being able to maintain balance is a complex process. Further, the notion that balance is something that a person can improve is a very poorly understood phenomenon. Most people do not understand that they can improve their balance. Nor are they aware how they could do this, that is, by challenging themselves in specific ways that are tailored to their personal capacity. The program outlines several principals for challenging balance (Clemson et al. 2014). The LiFE principles for improving muscle strength are applied to the groups of muscles known to provide protection from falls – hip, knee and ankle muscles. The program does not use weights or resistance bands as these would not be part of the participant's daily routine. Instead it relies on the person using their own body weight (e.g., standing up from a chair slowly to increase quadriceps strength).

The overarching LiFE principles are (i) to improve balance, we must challenge balance and continuously increase the challenge to our balance, and (ii) to improve strength, we must continue to load the muscles.

Understanding Links to Gait, Function, and Falls

Providing brief but targeted explanations about how the type of exercises directly link to

beneficial outcomes can impact motivation. We suggest that there would be numerous opportunities during assessment and training to provide examples which link the exercises to improved function in doing daily living tasks, to improved gait, and how the LiFE activities can provide protection from falling. These examples need to be relevant to the person. This is intended as conversation during training at appropriate moments when the opportunity arises and not intended as a didactic lecture. For example, “moving sideways” or sideways stepping is one of the balance activities. This could be illustrated by referring to how strong hip abduction is important if a sideways stepping response is required to protect from overbalancing. Further, people with a previous hip fracture are more likely to have poor hip abduction strength suggesting the importance of strong hip muscles.

Improving Balance and Strength Can Improve Walking Stability and Strength

Other examples could relate to the ability to walk safely. Understanding how the gait changes and how this impacts fall risk may provide a motivation for older people to engage in balance and strength training which can also improve their mobility. The changes in gait in the older person may be influenced by a variety of factors including musculoskeletal changes such as decreased strength, reduced range of motion at a variety of joints, neurological factors, or low confidence.

Gait analysis is complex. However, a simplified analysis of the gait of older people generally states that older people have a shorter stride length, a wider base of support, and a slower pace. Anecdotally, many older people shuffle. This means that their feet are in contact with the ground for longer periods of time through the phases of the gait cycle. This may make them feel more stable but may not necessarily protect them from falls. The inability to lift the foot to effectively clear an obstacle may make the person more likely to trip and therefore fall.

Improving balance and strength in the legs should translate to an improved ability to walk. For example, strengthening the dorsiflexors may lead to an improved ability to lift the forefoot for

heel strike and less chance of “catching” the toe and tripping. If this is added to better balance while standing on one leg, therefore a more stable supporting leg in the stance phase in the persons gait cycle will be improved. This in turn should lead to safer walking and possibly more confidence walking. The program encourages participants to think about the way they walk, with the heel down and the toe up. That is, they need to concentrate on making contact with their heel and then consciously pushing off with their toe. With improvements in both strength and balance, the person is encouraged to walk with an improved gait and encouraged to scan ahead as they walk (Clemson and Swann 2008).

Balance Challenges While Dual Tasking Can Have a Functional Benefit

LiFE activities often involve tasks that require multiple skills to be used at the same time. This is often referred to as dual tasking as the tasks involve varying combinations of physical movement and upper and lower limb coordination, as well as attention to the task at hand. Examples of dual tasking include a one-legged stand while cleaning your teeth or squatting (bending at the knees) rather than bending at the waist when selecting items from a lower shelf in the supermarket.

By embedding LiFE activities in daily life routines, the person is automatically placed in situations of competing demands. This connects balance and strength training to daily living tasks which naturally adds challenging demands. This can include, for example, selectively paying attention to the environment around them as well as dual tasking as they are doing the LiFE activity.

Having a poor capacity to perform dual tasking in tasks that involve gait variation and demand attention has been shown to predict an increasing risk of falls (Kuptniratsaikul et al. 2011). This risk is increased for repeat fallers (Beauchet et al. 2008). Training in dual-task activities that challenge balance in clinic situations has been shown to improve gait stride and variability and dynamic and static balance (Silsupadol et al. 2009). LiFE has shown that this can be done in everyday situations and that these skills

transfer to other functional tasks. It may be that the tailored and embedded activities of LiFE enhance the integration of skills such as task coordination, postural control, and spatial processing.

Functional Activities Also Involve Planning, Concentration, and Attention

Activities that involve planning, concentration, attention, and strategizing could have a direct impact on function (Liu-Ambrose et al. 2008). Think of what is involved in challenging balance when talking on the phone, carrying things while turning around or going up stairs, or tandem walking down the hall carrying a cup of tea. Liu-Ambrose et al. (2012) propose that it is not just physiological improvements that can be gained from exercise but that executive function and functional plasticity can improve from targeted exercise. They draw on understandings of brain function, evidence from their own and others work in resistance training, and on studies exploring the relationship between fallers’ performance on tasks that demand attention and tasks involving executive function (Anstey et al. 2008). They assert that, along with physiological change, such mechanisms may play an important role in how exercise improves function and reduces fall risk.

Skills

Finding LiFE Opportunities

There are many opportunities throughout the day to embed balance and strength activities. The starting point is to chart a typical day routine over a week. LiFE activities are then matched to specific daily routines or tasks for that individual. Rather than looking for ways to do less, participants are encouraged to look for ways to do more and to add balance and strength activities into more daily tasks.

Challenges Self and Mastery

The concepts of challenging oneself, mastery, and upgrading are interconnected. They are all important skills that underpin most exercise programs. To improve and continue to improve balance, a person will need to practice challenging balance

activities. To improve strength, a person has to continue to load their muscles and continue increasing the load on their muscles. To continuously upgrade their activities, the participant needs to be able to set a goal related to a LiFE activity, determine when they have mastered that activity or achieved the goal, and then set a new, more challenging goal. Self-efficacy refers to the perception of one's ability to reach a specific goal (Bandura 1997). The ability to set realistic, short-term, achievable goals as well as mastering an activity can increase the participant's beliefs about self-efficacy when they prove that they can master the activity.

Mastery refers to the ability to perform an activity at a certain level. Inherent in this concept is the idea that new challenges can always be created once a particular challenge has been met. Mastering a skill involves breaking it down into simple and manageable steps and having incremental goals working toward achieving these steps. In the LiFE program, participants have to master an activity at a lower level before they can safely progress to a more challenging activity. For example, when a participant can stand on one leg with two-hand support, then the goal becomes moving to a one-hand support and then one-hand intermittent support. Participants master the activity and then set a new goal which upgrades their level of activity.

Upgrading LiFE Activities and Autonomy

Upgrading is based on the principles, that is, progressively increasing challenges to balance or increasing load on lower limb muscles within one activity or combining activities that target two or more principles (e.g., sway to limits of stability sideways when standing on one leg and climbing up stairs two steps at one time without using the handrail for support are both very advanced LiFE activities).

Finally, and most importantly, the aim is to give the participants the skills to become autonomous in implementing the program themselves, to understand how to upgrade, and to select appropriate activities that will continue to challenge their balance and load their muscles in safe and correct ways. Thus, planning and setting goals

require joint decision-making, a sense of ownership of the goal, and encouragement to contribute "how, when, and where" more LiFE activities can be undertaken.

Habitual Change

Facilitating habit change requires strategies that transition the novel activity into a routine part of the daily task (Lally and Gardner 2013). That is, LiFE activities need to become habitual. When the activities become habitual, they are more likely to be sustained.

Active Memory Till Embedded in Routines

Habits are automatic actions. So to change a habit requires thinking and planning within active memory until it becomes stronger than the current action and becomes automatic or "embedded." This suggests also that the number of activities chosen to change at one time should be manageable.

While learning the program during the training phase, participants must consciously think about the activities and embed them into daily tasks. That is bringing them into consciousness or active memory. We learn new habits by incrementally processing over time using our active (or procedural) memory. Over time they become habitual and automatically embedded in daily occupation. Habits are routine, goal-directed behaviors that are set in motion by situational or environmental cues (Ronis et al. 1989). These can be automatic and may go unnoticed or may be intentional where the situation needs to prompt us to action.

Changing habits requires time. This is why training in the LiFE program was taught over five sessions, two phone calls, and two booster sessions but which extended over a 12-week period. LiFE requires working with active memory until the activity becomes a stable and enduring habit and is embedded in routine. This is facilitated by practice and repetition in the same context.

Planning and Visualization: How, When, and Where

Holland et al. (2006) stated that planning and visualizing changes were important because they helped formulate the intent to action and acted to strengthen the association between the situation or

environment and the action. Participants in the LiFE program are expected to plan when and where they will perform the activities and to which of their daily tasks they will link the activity. They are also asked to visualize themselves performing the activity while doing their daily tasks. The particular task then becomes the cue for remembering to do the LiFE activity. For example, a participant could practice tandem standing while washing up; then doing the washing up becomes the cue to do the tandem stand. But in addition to practice, they are also encouraged to imagine or visualize themselves in the future doing this.

When they have mastered the skill of performing the desired activity embedded in a specific daily task and are doing this routinely, they should then try to visualize themselves performing it in other daily tasks. Participants can then generalize the activity performance to other contexts. The idea is to be able to transfer the activities to as many tasks and places as possible through their daily routine. They can plan to embed the activity in the new task in addition to the former task.

For example, they might start with bending their knees (squatting) to get the detergent from below the sink. Once this is mastered, they then plan and visualize themselves bending their knees in other situations such as the bathroom to get the toothpaste out of the cupboard or in the kitchen when getting the plates out for dinner.

Visualization is a strategy to assist intent to action and included as a step in planning where the activities can and will be embedded. It also assists participants to generalize the activities to a variety of tasks and places. Recording how, when, and where on the “LiFE Activity planner” is important to clarify steps and to commit to action, but it is the visualizing and planning that are the key features of this process. Such intentions to implement the action and planning will greatly increase the chance of carrying out the action.

Situational and Environmental Cues Serve as Prompts to Action

A planned commitment to a behavioral response occurs within a particular situation and in response to a particular cue. The ability to replace

old habits with new ones is dependent on both conscious planning and the influence of situational cues (Lally and Gardner 2013; Holland et al. 2006; Lally et al. 2011). Changing behavior requires prompts to elicit the desired behavior. In LiFE there are several methods of providing the cues to prompt the desired behavior. There are general prompts that apply to all participants. These include bending your knees if you need to reach for anything below waist height or go on your toes if reaching above waist height.

To facilitate the embedding process, the participants plan which daily tasks the LiFE activities will be linked to or embedded within. These tasks then become the situational cues to prompt the performance of the LiFE activity. Situational cues can be a place and time, for example, the kitchen sink in the morning; a feature of the environment, for example, the doorway between the hall and the bathroom; or a pattern of interaction with the environment, for example, standing in the supermarket line. These cues act as a prompt to elicit the behavioral response – the performance of the LiFE activity.

The program encourages participants to make changes to their environment to facilitate the performance of the LiFE activities such as moving commonly used items to a different place to promote repeated performance. Some examples include moving the detergent to a lower shelf to prompt knee bends and moving the tea cups to a higher shelf to prompt toe raises. The aim is to have participants performing the strength and balance activities without having to consciously think about including them in their daily tasks. This way, they become habitual.

Fleig et al.’s (2015) implementation of LiFE with younger women in a group setting particularly noted the importance of habit theory and how using activity and object-based cues were particularly effective in generating action and automaticity.

Practice and Repetition in the Same Context

Practice and repetition is crucial to habit formation. Lally and Gardner (2013) outline the stages of habit formed in a similar context each day. So rather than planning too many different contexts,

you might start with squatting (instead of bending your back) every time you close a drawer in the bedroom and kitchen. Once habits are formed, this can be generalized to broader contexts such as the supermarket, the garage, or other places that the participant goes.

Planning and practice are both critical in implementing new habits. Participants have to plan to do the activity, visualize themselves doing the activity, and then practice doing the activity consciously and repeatedly until it becomes habit. When a new action is performed, a mental association between situation and action is created, and repetition reinforces and establishes this association in memory.

Self-Monitoring, Reinforcement, and Repetition
Participants engage in planning the changes. The therapists demonstrate the activities and provide opportunity for participants to practice, self-monitor through planning and recording sheets between sessions, and provide feedback and positive reinforcement. To enable habit change, this approach to exercise needs to be taught over a period of at least 8 weeks and preferably 12 weeks. Therapist support is needed to assist in setting session goals initially and then to move to increasing autonomy so participants are planning, setting “how, when, and where” themselves, and monitoring their progress. To change habits, there must be continual repetition and practice.

The power of goal setting, feedback sheets for monitoring exercise that are acknowledged by the trainer, and other forms of encouragement and self-incentives relative to personal goals cannot be overestimated. In resistance training, self-regulation is known to directly contribute to enhanced confidence in maintaining performance at challenging levels, to using correct form and to continual upgrading as one level is mastered (Winett et al. 2009). This requires cognitive (knowing what to do), motivational (wanting to perform and the confidence that you can), and behavioral (being able to do it) factors.

Experience Functional Outcomes

Participants gain intrinsic reinforcement for the performance of the activities in a variety of

ways. If they engage in the planned activities and can upgrade over time, they will achieve improved balance and function and increased confidence in mobilizing and in desired activities and will have more protection against future falls.

In fact, protection from falls alone, although a major outcome, is not going to be an ongoing incentive. Other outcomes are needed, such as better balance and function, in order to enhance motivation sufficiently to adopt and sustain the program.

Applied Theory in Practice

The innovative LiFE program is different to a usual exercise program and may require a shift in thinking or focus for therapists and trainers and the participants. Occupational therapists look for ways of making tasks *easier* for their clients or of having them do *less*. The LiFE program encourages participants to look for ways of doing *more* and seeking out more demanding environments. Physical therapists are more familiar with prescriptive programs where dosage is increased by repetition, weights, or external resistance and performed in sets at regular times each week.

The model is intended to be applied in practice, and providing this framework enables the assessments, planning, and recording tools as well as the training process be conducted such that they integrate the key elements and features of the model. This kind of program requires the participant to spend time implementing the program throughout their day, and it therefore needs to be tailored, relevant, practical, and functional.

The LiFE approach has been shown to work in different settings and provides another choice for a successful fall prevention program with potential to maintain function. Further work could elucidate which groups of people an embedded approach of balance and strength training would benefit the most. In addition, qualitative inquiries would be welcome that can further elucidate the features and mechanisms of the concepts underpinning the program which are essential to successful uptake and long-term sustainability of such programs.

Definition

Workplace conflict emerges when there is a disagreement between two or more parties in the organization or when a person perceives incompatible needs, goals, desires, or ideas with another person (Deutsch 1994). There are two major forms of conflict in the workplace: Interpersonal conflict takes place when a worker perceives that his/her valued outcomes are deprived due to interference from the opposing worker, while intergroup conflict arises when a group of workers perceive a deprivation of valued outcomes due to interference from the opposing group (De Dreu 2011).

Introduction

Conflict is inevitable in the workplace as long as there is social interaction between two or more

parties, including individuals, units, departments, and organizations. It involves cognitive and behavioral reactions toward incompatible goals, competing interest in scarce resources, and interference in goal attainment (Hocker and Wilmot 1991). Depending on one's attitudes, values, and goals, a social situation can be perceived as either a threat to one's interests or an opportunity to cooperate and maximize the benefits of both parties. This behavioral intention in turn determines whether escalatory or de-escalatory action should be taken.

Abundance of conflict research has provided evidence for the detrimental effects of conflict when it is managed poorly. In particular, prior research has found that workplace conflict contributes to reduced job satisfaction and organizational commitment, poorer health and well-being, and disruptive behaviors that are costly to employers, such as absenteeism and turnover (De Dreu 2011). However, although it is undeniable that conflict can result in a number of negative outcomes, research from the past two decades shed light on the positive and constructive benefits of conflict when it is managed appropriately in the workplace. For example, workplace conflict has been found to enhance communication, resolve continuing problems, facilitate team performance, stimulate learning, and promote creative thinking under the condition that the conflict is problem-focused, cooperatively oriented, and involves integrative efforts to achieve optimal solutions (De Dreu 2011). Therefore, effective conflict management is crucial to team effectiveness and work productivity.

The number of mature workers aged 45 and above in the labor force has been growing drastically over the past decade, for example, from 34.9% to 42.9% in the United States (US Bureau of Labor Statistics 2011). The composition of labor force becomes more diverse, comprising mature workers from the baby boom cohorts (1946–1964) and later cohorts from generations X (1965–1976) and Y (1977–1992). The presence of workers from multiple age groups within an organization intensifies the occurrence of conflict because of differences in work values, work ethics, goal orientations, and conflict styles between younger and older workers.

In the face of changing demographic trends, how conflict can be managed effectively is a major concern for many organizations. It is therefore a pressing task to identify and unravel the underlying mechanisms of conflict in the mature workforce. By drawing from various areas of research, valuable insights can be obtained to reveal the influences of motivational orientation, goal orientation, and social identity on conflict strategy preferences among younger and older workers. Effective measures can then be proposed in light of the conditions that are required for conflict to result in positive outcomes. In the first section of this entry, the dual concern model (Rahim 2011) and the theory of cooperation and competition (Deutsch 1994) will be discussed to identify the major determinants of conflict strategy in the workplace. The second section will discuss the socioemotional selectivity theory (Carstensen 2006) and the social identity theory (Tajfel and Turner 1986) and review the empirical findings on age differences in conflict management. Implications and future directions on managing the workplace conflict will be discussed in the concluding section.

Conflict Management in the Workplace

Working adults' responses to conflict can yield diverse consequences. According to the dual concern model, the ways to deal with interpersonal conflict can be categorized into five styles, including obliging, dominating, integrating, avoiding, and compromising (Rahim 2011). The selection of conflict styles is determined by one's motivational orientation, i.e., the degree of attempts to satisfy concern for self and concern for other parties. In particular, obliging strategy is used when concern for self is low and concern for others is high. This involves meeting the needs of the opposing party and giving into his/her demands. Dominating strategy is used when concern for self is high and concern for others is low. This involves forcing the opposing party to accept and give into one's personal views and demands. Integrating strategy is used when concern for self and others are both high. This involves

collaborating with the opposing party in order to reach a mutually agreed solution so that the interests of both parties are satisfied. Avoiding strategy is used when concern for self and others are both low. This involves neglecting the conflict entirely to allow the conflict to dissipate on its own. Compromising strategy is used when concern for self and others are both moderate. This involves a give and take negotiation so that an intermediate position can be reached.

Similar to motivational orientation, another line of research examined goal orientation as the underlying determinant of conflict behaviors. According to the theory of cooperation and competition (Deutsch 1994), goal interdependence, which is the perception of how goals are related, influences social interaction. Specifically, goal interdependence can be grouped into three categories: cooperative goals, competitive goals, and independent goals. These three types of goal orientation are proposed to have a significant impact on the way conflict is handled. For cooperative goals, individuals perceive their goals to be positively related to each other so that successful achievement of one's goal would lead to the successfulness of another in reaching his/her goal. Individuals who are motivated by cooperative goals would avoid the escalation of conflict since working cooperatively as a group would be more effective in achieving the most desirable outcome for both parties. In comparison, for competitive goals, individuals perceive their goals to be negatively related to each other; so increasing the chances of success for one person would diminish the chances of success for another person. Under this win or lose perspective, conflict will most likely be escalated since individuals are motivated to do better than others and behave competitively in order to ensure that they succeed while others fail. For independent goals, individuals perceive their goals to be unrelated to the goals of others; so their personal goal attainment is prioritized, while other people's goals are irrelevant to their concerns and efforts. Motivated by an independent orientation of goals, actions are taken in order to ensure one's personal interests are met, regardless whether the other party is satisfied or not.

Age Differences in Conflict Management

Although the dual concern model and the theory of cooperation and competition are prominent in the literature on conflict management, they generally assume that goals and motivation remain more or less constant over the life span. Applying these two frameworks to the age-diversified workforce would lead to the prediction that a worker's behavioral responses are determined by his/her motivational or goal orientation, regardless of his/her age. For example, an older worker who has high concern for self and low concern for others would be as likely as a younger worker to prefer the use of dominating strategy. However, the literature on life span development stresses that older adults shift their goal orientation from knowledge-related goals to emotional goals when they perceive future time as increasingly limited (Carstensen 2006). Therefore, it is doubted whether these two models can fully explain the patterns of conflict strategy use in an age-diversified workforce.

Socioemotional selectivity theory (SST; Carstensen 2006) can be applied to understand conflict behaviors of older workers since it provides a theoretical explanation for age-related changes in developmental goals and social behavior. According to this theory, the way emotion is regulated is guided by future time perspective, which becomes increasingly limited as the person ages. Younger individuals who are likely to perceive an expansive future time prioritize knowledge-related goals, including knowledge acquisition, career advancement, and expansion of social network. As individuals grow older, they are more likely to perceive limited time and therefore shift their priority to emotional goals such that emotionally meaningful experiences are emphasized and valued. Therefore, the emphasis of emotional goals motivates older individuals to make use of adaptive emotion regulatory strategies that can maximize positive emotional experiences, while younger individuals are less likely to focus on emotion regulation.

When applying SST to predict conflict styles of younger and older workers, it is expected that older workers' emphasis of emotional goals

motivates them to concern for others more than themselves and to cooperate instead of to compete, such that they are more likely to use passive strategies such as obliging or avoiding. Assertive strategies such as dominating style are less likely to be utilized by older workers as these strategies will prevent them from maximizing positive emotional experiences. In contrast, younger workers tend to use more assertive strategies to manage conflict situations as they focus on knowledge-related goals and are concerned for themselves more than others. These speculations are supported by research findings. For example, in a national survey of 1785 working adults in the United States, Schieman and Reid (2008) revealed that among male workers with higher authority, younger workers engaged in more aggressive and competitive conflict behaviors than did older workers. Similarly, Davis et al. (2009) examined behavioral responses toward workplace conflict in a sample of 2513 American working adults. This study demonstrated that both younger and older workers used active-constructive strategies such as perspective taking or creation of solutions to deal with conflict incidents at work, though older workers displayed a greater tendency to utilize passive-avoidant strategies such as yielding or adapting.

Past research on conflict management showed that the selection of conflict strategies varies by role of the conflict partner. For instance, in the study measuring conflict styles of 1219 managers in the United States, Rahim (1986) demonstrated that employees were more likely to use obliging to handle conflict with superiors and utilize compromising with peers. When resolving conflict with subordinates, they tended to use integrating as primary styles and avoiding as backup styles. Both Lee's (1990) and Nguyen and Yang's (2012) experimental studies further support the influence of the role of the conflict partner in the selection of conflict strategies. Specifically, there was a greater tendency to use direct and assertive strategies to resolve conflict with subordinates, compromising strategies to deal with peer conflict, and indirect and harmony-preserving strategies to handle conflict with supervisors. However, these studies did not take age into consideration in

the examination of conflict behaviors. To address the limitation of the prior research, Yeung et al. (2015) measured behavioral responses to workplace conflict in a sample of 280 Hong Kong Chinese managerial and executive employees aged between 22 and 66 years. The participants were asked to recall a personal workplace conflict experience that happened in the past 3 months. They also reported their goal orientations and conflict responses during the conflict situation. Results of this study revealed that relative to younger employees, older employees utilized more avoiding to handle conflicts with supervisors and less dominating with subordinates. These age differences could be explained by the higher level of cooperative goals held by the older workers relative to their younger counterparts, supporting the proposition of SST on the age-related variation in goal orientation.

In addition to the influences of motivational orientation and goal orientation reviewed above, one's social identity can also affect the selection of conflict strategies, especially during intergroup conflict. The social identity theory, which was developed to provide theoretical contributions toward social phenomena such as intergroup relations, stereotyping, and group processes (Tajfel and Turner 1986), is suitable to explain the intergroup dynamics of an age-diversified workforce. Social identity is defined as an individual's self-concept based on his/her perceived membership of relevant social groups that are of value and emotional significance to him/her. In a conflict involving a younger worker and an older worker, the individuals may identify themselves as members of the younger or older age group, which subsequently influences their thoughts, feelings, and behaviors toward the intergroup conflict (De Dreu 2011). Members of an in-group are motivated to enhance positive distinctiveness compared with the out-group members. This in-group-out-group bias is commonly manifested in intergroup conflict where members of opposing parties utilize strategies that favor the in-group and denunciate the out-group. Intergroup conflict is expected to be most severe in organizations with age diversity and distinct group boundaries between younger and older workers, as this can foster intergroup

competition and social conflict, causing a higher likeliness for opposing intergroup relations to be formed (Dencker et al. 2007).

While the social identity theory makes general assumptions about the behavioral responses of conflict, five types of conflict strategy can be predicted by integrating with the dual concern model (Haslam 2004). According to the integrated model of conflict, the two axes of the dual concern model, concern for self and concern for others, can be reconceptualized as the salience of subgroup identity and the salience of superordinate identity, respectively. Salience of subgroup identity refers to one's social identification with a subgroup (younger or older workers), while salience of superordinate identity refers to one's social identification with a superordinate group (employees of an organization). This reconceptualization is possible because concern for self is consistent with the behavioral intentions of subgroup identity, while concern for others is consistent with the behavioral intentions of superordinate identity. As presented in Fig. 1, conflict between younger and older workers is escalated when dominating strategy is utilized by those who have a salient age group identity. In order for the conflict to be reconciled, social identity must be salient on both subgroup and superordinate dimensions so that an integrative solution can be reached.

To test the effect of social identity on conflict behaviors, Ho (2014) examined the relationships among social identity, goal orientation, and conflict strategies in a cross-sectional survey among 380 clerical workers in Hong Kong. Two hypothetical scenarios involving conflict with a younger worker and an older worker were used to stimulate workplace conflict. In response to each conflict scenario, participants were asked to respond to a questionnaire on how they perceived their goals as related to the opposing worker and the type of conflict strategies that they prefer to utilize under the circumstances. Results of the moderated mediation models revealed that organizational and age group identities had a combined influence on conflict strategies through goal orientation, but the pattern differed by the age of the opposing party. In the conflict with a

Conflict Management and Aging in the Workplace, Fig. 1

The integrated model of conflict (Adapted from Haslam 2004)

younger worker, individuals were more likely to use integrating when both of their organizational and age group identities were high. Individuals who were identified as members of the organization but had moderate age group identification were more likely to use compromising toward the younger worker. Furthermore, organizational identification was related to the use of obliging toward the younger worker when age group differentiations were minimal. It was also found that these relationships could be explained by the low level of independent goals held by the respondents.

In the conflict with an older worker, individuals were more likely to use integrating strategy when their organizational and age group identities were high. Individuals who were identified as members of the organization but had minimal age group identification were more likely to use obliging strategy toward the older worker. Furthermore, organizational identification was related to the use of compromising strategy toward the older worker when the level of age group differentiations was moderate. These relationships could be explained by the high level of cooperative goals held by the respondents.

Ho's (2014) study suggests that social identity contributes more to independent goal orientation with younger workers and cooperative goal orientation with older workers. This difference in goal orientation when the age of the opposing party differs may be explained by values deeply rooted in the Chinese culture. According to Confucius'

ideology, it is a virtue to respect senior adults and sacrifice one's own interests to establish and maintain relationships with older people. Therefore, during conflict with older workers, one's cooperative intention is a major determining factor of how the conflict should be managed. Nevertheless, consistent with the findings of the literature on intergroup conflict, in-group membership can diminish conflict of interest and facilitate cooperation between opposing parties.

Implications for Managing an Age-Diversified Workforce

In general, the literature on conflict management in the workplace holds the assumption that the same set of predictive factors of conflict behaviors is applicable to all working adults, regardless of their age. However, as reviewed above, goal orientations change as a person grows older, suggesting that the way older workers deal with conflict incidents may not be the same as those utilized by younger workers. Even though researchers can infer from past aging research on interpersonal tensions to predict conflict responses of older workers, these studies focus largely on conflicts with family members and close friends. Therefore, it remained unclear whether younger and older workers react to workplace conflict differently, as it usually involves coworkers and clients who are not perceived as emotionally close as family members and close friends. The findings of our research tentatively suggest that similar to other nonwork conflicts,

older workers utilize more passive strategies (e.g., avoiding) and fewer destructive strategies (e.g., dominating) to manage workplace tensions than do younger workers (Yeung et al. 2015). Putting research findings from the literatures on life span development and conflict management together, it seems older individuals manage daily interpersonal conflicts in a similar way, regardless of the context. This proposition awaits future investigation to explicitly compare within-individual use of conflict strategies and goal orientations across different life domains to confirm whether the age-related pattern of conflict management is context-specific or not. In addition, by integrating the dual concern model and social identity theory, Ho (2014) further demonstrated that social identity can influence goal orientation, which would in turn influence one's preference for conflict strategy. Specifically, workers with higher organizational and age group identities tend to hold more cooperative goals and therefore use more integrating strategies to handle conflicts with an older conflict partner. Future research should include the assessment of social identity to accurately predict conflict strategies of working adults.

The majority of conflict management research was conducted on Western populations. Past cross-cultural studies on conflict management suggest that Chinese employees, in general, are more likely to utilize non-confrontational strategies (such as avoiding or compromising) than their Western counterparts (Bazerman et al. 2000). Yeung et al.'s (2015) study demonstrated a robust age effect, even in a sample of working adults with cultural norms of non-confrontational conflict approaches. Older Chinese workers displayed higher level of avoiding strategies when handling conflicts with supervisors than did younger Chinese workers. Future studies should replicate this age effect in a cross-cultural comparison study by recruiting both Western and Asian working adults of a wide age range.

In addition to the examination of age variation in conflict management, future studies should also investigate the impact of conflict strategies on work outcomes. Past studies often suggest that avoiding strategies are related to higher work and conflict stress (Friedman et al. 2006) and

reduced job satisfaction (De Dreu and Dijkstra 2004). It is questioned whether older workers' greater preference for avoiding strategies is associated with poorer work outcomes and psychological well-being. However, according to SST, older adults' use of passive strategies is indeed consistent with their developmental goal orientation that emphasizes on emotional goals and interpersonal closeness (Carstensen 2006). Therefore, greater use of passive strategies should contribute positively to their well-being or have a less harmful effect. Cross-sectional studies of Yeung and Fung (2012) and Yeung et al. (2015) have demonstrated that the use of emotional suppression and avoiding strategies is beneficial to the older workers by improving their sales productivity and lowering the level of negative emotions and interpersonal tensions. These findings imply that the use of passive strategies is not always harmful to working adults but depends largely on the age of the users. The long-term beneficial effects of passive strategies on older workers though await future investigation.

Conclusion

Age differences in conflict management are observed, which can be explained by age-related changes in goal orientation and social identity.

Case conceptualization; Formulation

Definition

The Contextual Adult Lifespan Theory for Adapting Psychotherapy (CALTAP) model is a transtheoretical model developed to assist in increasing the understanding of both who the older adult client is and the broad context within which he or she presents for therapy.

Introduction

The Contextual Adult Lifespan Theory for Adapting Psychotherapy (CALTAP) (Knight and Lee 2008) is a model that has been developed with an older adult population in mind. Fundamentally, the model provides a framework within which a holistic and in-depth understanding of older adult clients can be developed. In order to achieve this, the CALTAP model draws on lifespan developmental principles and social contexts (both current and historical and at a cultural and cohort level). The model has also been designed to be transtheoretical in nature rather than being

wedded to any one particular type of therapy (e.g., cognitive behavioral therapy, interpersonal psychotherapy, etc.). The CALTAP model therefore offers the opportunity for the clinician to explore the case history of the client at a broad level and then determine the best therapeutic approach to meet the goals of therapy.

Drawing on Knight's (1996) contextual, cohort-based, maturity-specific challenge (CCMSC) model of psychotherapy, the CALTAP model elaborates on the CCMSC model by outlining a more integrated approach to psychotherapy with older adults and adding consideration of the importance and relevance of culture (Knight and Lee 2008). CALTAP identifies the following factors for consideration in psychotherapy with older adults: context, culture, and cohort. The CALTAP model (like the CCMSC model) is designed to be transtheoretical; that is, the model is not linked to any one particular approach to therapy and as such may be used across approaches to psychotherapy. Regardless of therapeutic focus, the model has the goal of increasing the therapists understanding of the client, outside the context of any one particular type of therapy, by encouraging the importance of understanding and incorporating the depth and breadth of contextual influences (Knight and Poon 2008). Having such an understanding not only guides case conceptualization but provides a frame for selecting and adapting therapeutic modalities, the use of clients' idiosyncratic strengths and challenges, and choice of therapeutic method which avoids reliance on stereotypical beliefs which can be subtle in nature and insidious in effect. For example, while older adults are more likely to experience chronic illness, some cope better with chronic illness than others. The CALTAP model therefore encourages the clinician to explore the client's experience of chronic illness both with respect to their current circumstances and to current and historical contextual factors that may be contributing to their ability to cope. A stereotypical mind-set without guidance from a model such as CALTAP, on the other hand, might assume that all older adults have difficulty coping with chronic illness, resulting in treatment missing the most appropriate therapeutic goal(s).

The CALTAP model also encourages consideration of both strengths and challenges within individual (e.g., maturation, presenting problem), environmental (e.g., context), and social contexts (e.g., culture, cohort). The focus of this model is on exploration and adaptation, encouraging the psychologist to adapt to the needs of the client (based on the information they gather) rather than having the client adapt to the psychotherapy or the underlying beliefs of the therapist. At its broadest level, the model considers both intra- and interindividual factors as they relate to the client. The model also encourages consideration of interpersonal, intergenerational, and intercultural elements. Therefore, the CALTAP model is a tool that encourages a structured approach to gathering information about the client, which is multifactorial in nature and considers the client from a number of different perspectives (e.g., interpersonal, intergenerational, and intercultural). Such a comprehensive method of collecting data guides therapy goals and offers both the therapist and the client a means of understanding who the client is and what they bring to therapy.

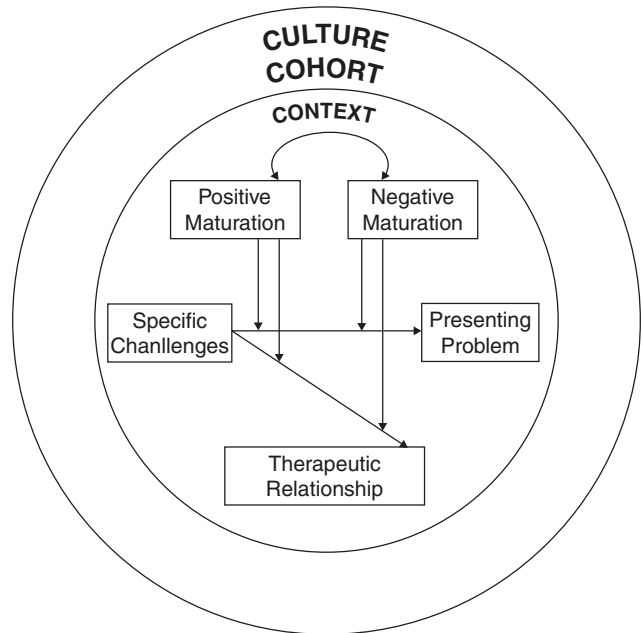

The Elements of the CALTAP Model

The Element of Context

The inner circle of the model (see Fig. 1) focuses on the individual and immediate context. The central diagram (i.e., "positive maturation," "negative maturation," "specific challenges," "presenting problem," "therapeutic relationship") encapsulates intraindividual factors, while the domain of "context" within which this central diagram sits considers both interindividual and interpersonal factors. This portion of the model therefore highlights the importance of consideration of the elements that might be broadly framed as the everyday context in which the client lives, including personal, environmental, and social factors. With regard to personal factors, consideration is given to what the clients themselves bring to therapy and the therapeutic relationship, as well as the interactions between those elements, which are captured via the central diagram within the center circle. In considering environmental

Contextual Adult Life Span Theory for Adapting Psychotherapy (CALTAP) and Clinical Geropsychology,

Fig. 1 Contextual Adult Lifespan Theory for Adapting Psychotherapy (CALTAP) model

and social factors, the focus is on the context in which the individual currently lives and socially engages, including such things as housing and living arrangements, the medical environments in which they engage, recreational settings, interpersonal environments, and family and social settings, for example.

The maturation elements capture lifespan developmental processes, those positive and negative changes that are posited to occur naturally as people age. Positive maturation reflects gains with increasing age, and negative maturation includes decrements in functioning with age, along with those things that people are more at risk of with increasing age (e.g., reduced processing speed, increased risk of illness, etc.). The broad and generic nature of the model also allows for consideration of variations in developmental processes, acknowledging the fact that while the lifespan developmental literature offers insight into normative developmental processes, individual differences in development can and do occur.

“Positive maturation” refers to the elements of cognitive and emotional complexity (Knight and Poon 2008). Cognitive complexity encompasses the accumulation of knowledge and skills across a lifetime, as a result of both structured and

unstructured learning, that result in what can be summarized as maturation in cognition. Emotional complexity refers to the notion that as people age, they become better able to regulate their emotions (Mather and Carstensen 2005) and also experience more complex, as well as less intense, emotions than those perceived to be experienced by younger adults (Ong and Bergeman 2004). “Negative maturation,” on the other hand, encompasses the broad areas of both physical decline and cognitive decline. Physical decline encompasses the idea that as people age, their body and bodily functions tend to become less efficient and less effective, and the risk of illness increases. Variability in decline is influenced by lifestyle choices of the individual as well as the normative changes associated with aging. Cognitive decline refers to the normative changes in cognition as the individual ages. Such changes include decrements in processing speed, attention, and memory (e.g., Kemper et al. 2003; Light 2000; Salthouse and Ferrer-Caja 2003). As with physical decline, and all elements of maturation, the level of decline and/or development (i.e., “negative maturation” and “positive maturation”) will, in part at least, depend on the life that the individual has led and the genetic hand they have been dealt.

The CALTAP model structures a holistic approach, neglecting neither the positive nor the negative aspects of developmental processes – at an individual level – in order to build understanding of the client within a therapeutic context.

“Specific challenges” refer to life circumstances that challenge the individual and therefore can impact on the sense of self and the sense of well-being. Examples of such challenges can include chronic illness, disability, and changes in interpersonal functioning (e.g., dealing with grief, caregiving, role changes, etc.). To illustrate, with regard to chronic illness and disability, not all older adults will develop such conditions, and how much of a challenge such factors are to the individual will depend on a number of elements, not the least of which being the severity of the illness or disability, the coping ability of the individual, and the support available. Grief is another example of a “specific challenge,” which may not only cause the person to think about his or her own existence but can also impact on psychosocial functioning. Length and intensity of relationship, manner of death, coping skills, and support all play a role in how well the individual might cope with the challenge of grief. “Specific challenges” also include role changes such as caregiving. Older adult caregivers can be frail and ill themselves; they may lack support or experience emotional distress as a result of the changes in their partner and themselves. With regard to the challenges that role changes may create, traditional partner roles can be challenged when the person who always saw themselves as the caregiver becomes the care receiver. Like the elements of maturation, there is no clear formula or template here, which is considered a strength of the CALTAP model as it encourages consideration of the individual, in his or her own context and specific circumstances.

As illustrated in the central portion of the diagram via the arrow configurations, the CALTAP model also highlights that the elements of “positive maturation,” “negative maturation,” and “specific challenges” each play a role in shaping the “therapeutic relationship” as well as the “presenting problem.” An individual’s context will necessarily impact on his or her ability to

form relationships, including with a therapist, and will shape the therapist’s ability to form a good rapport with the older client. The direction of the arrows and links they create among the elements within the center circle make intuitive and clinical sense, although such relationships have not been established via research specifically focused on the CALTAP model. One might need to consider at the very least, for example, whether bidirectional arrows should exist between “specific challenges” and “therapeutic relationship” and between “specific challenges” and “presenting problem.” The bidirectional arrow between “positive maturation” and “negative maturation” highlights the interrelationship between these elements as coexisting within lifespan development.

As a group (i.e., the central portion of the diagram), the aforementioned elements are located within the center circle labeled “context.” The construct of “context” itself looks to capture details of the settings within which older adults currently engage, including the environments in which they live, work, and play. It therefore looks to emphasize consideration of what elements of the individual’s living arrangements, work or volunteer commitments, and socializing (at professional and personal levels) might be relevant to the presenting problem and therapeutic intervention choices.

“Context” is an apt name for this central portion of the model given that exploration of such elements provides the psychotherapist with an appreciation of the immediate context within which the client both exists and presents. One of the key strengths of this portion of the model then is to discourage stereotypical beliefs about the older adult and call attention to both environmental and intraindividual influences as a firm basis upon which to begin effectively meeting the therapeutic needs of the individual client. However, the positioning of the central portion of the diagram (which focuses on intraindividual factors) specifically within “context” (which focuses on interindividual factors) can be confusing since intuitively it makes sense to look at each of those factors separately outside the realms of such a model. It may therefore be beneficial for

the clinician to think of the central diagram and “context” as two separate elements, rather than as one embedded within the other.

The Elements of Cohort and Culture

Moving out from the center circle, “cohort” and “culture” form the outer ring of the model and represent consideration of interindividual factors. This is a change from the first iteration of the CALTAP model (Knight and Lee 2008), where the two elements were initially presented as separate rings. The significance of the two elements now being encapsulated within the one ring represents a recognition by the authors that, realistically, cohort and culture are inseparable, with each having an effect on the other, and so now present them together (Knight and Poon 2008). While the illustration of the model does not highlight this point, consideration of both historical and current contextual factors for “cohort” and “culture” is encouraged.

Cohort

At a population level, cohort refers to portions (sometimes arbitrarily determined) of the population thought to share common characteristics as a result of what might be termed shared world experiences. Knight and Lee define cohort, specifically in relation to the CALTAP model, as a group of people, often determined based on when a person was born, who are therefore assumed to have been “. . .socialized into certain abilities, beliefs, attitudes, and personality dimensions, which remains relatively stable with age and distinguishes the group from other cohorts” (Knight and Lee 2008, p. 61). For example, an individual born between the years of 1946 and 1965 is defined as belonging to the baby boomer cohort, a group of people born in the Western world after World War II, when conception rates were high with the arrival of peace. Slight variations in definition can occur depending on, for example, in which country the individual was born. Further, Knight and Lee’s definition implies that to think of someone as belonging to a larger cohort such as baby boomers may risk stereotyping the individual by characterizing the client in terms of the

overarching qualities assumed to be characteristic of a particular population rather than seeing clearly the qualities of the individual. Clinicians are encouraged to avoid pigeonholing their clients within one “popularized” cohort by using information about one fact in the context. Consideration should also be given, therefore, to the potential areas of influence within the cohort portion of the model, which may include such things as intellectual abilities, education level, personality development, historical experiences, norms, and values. As such, the cohort influences are based primarily on life experiences and the impact those experiences have on the development of the individual.

More specifically, cohort encourages the psychologist to explore and gain an understanding of the older adult’s sense of self, which has been developing over a lifetime. As previously mentioned, consideration should be given to both the historical context and the current context in order to understand where the older adult has “come from” and where she or he is now. Cohort influences are historical in nature, which act to build the individual into who they are today and how they interpret their world. A key implication of the cohort portion of the model is that many of the distinctions that can be made between young people and older people at any point in time may be due to cohort influences and the sociohistorical context in which the individual became an adult rather than developmental changes due to aging or of being at different points in the lifespan. Recent discussions regarding the CALTAP model have made it clear that the model is also seen as useful in terms of helping clients understand their own aging processes and the meaning of variations between themselves and younger family members as caused at least partially by differences in cohort rather than age (Knight and Pachana 2015).

Culture

The final element of the CALTAP model is “culture,” which Knight and Poon (2008) describe as twofold, with variations in both cultural values and beliefs, as well as ethnic and racial considerations, being important considerations.

These factors contribute to not only who the clients are but also how others treat them, how the clients interpret psychological distress, and their willingness to seek assistance.

Knight and Lee (2008) offer a definition of culture that encompasses the idea of the individual taking on group characteristics via the process of socialization, expressed as customs, language, beliefs, and behaviors. The element of culture highlights the importance of interpreting each client in the context of her or his own cultural existence, thus refraining from relying on ill-informed or stereotypical beliefs when it comes to exploring the element of culture with the client. Assumptions about culture from such concrete factors as skin color and general appearance miss important factual information with regard to how the client actually interprets themselves under the banner of culture.

Also encouraged is the exploration of the cultural beliefs toward older adults within the client's own environment. The model therefore also encourages consideration of culture from two perspectives, that of the client and that of those around them. The importance of this consideration is that it helps to determine the client's place within her or his environment, potentially highlighting such things as the availability of support and the degree of respect (or place they hold) within the particular environment. As with all the elements of the CALTAP model, such in-depth considerations highlight the need to have an understanding of the individual beyond stereotypical beliefs, one that specifies the individual within the heterogeneous older adult population as a guide toward appropriate and effective treatment decisions.

Summary

As a transtheoretical model, CALTAP offers the psychotherapist the ability to develop an understanding of the individual that can assist in guiding therapeutic approach by focusing the clinician's attention on both intra- and interindividual factors of relevance.

The importance of this is that formulation models (i.e., models for conceptualizing a client's case in order to guide treatment focus) for specific types of therapy often neglect such factors, providing instead only a snapshot of the client as applicable to the needs of the therapeutic approach being used. Contextual factors, however, are an important addition in understanding how to best apply therapy to the case of the individual client. The CALTAP model therefore encourages consideration of both the forest and the trees.

The breadth of scope of the model, however, is also one of its limitations. There is comfort in having small, targeted goals as can be established from formulation models associated with specific types of therapy. The CALTAP model, on the other hand, looks to incorporate much more data, which can lead to lack of clarity with regard to establishing the goals of therapy. However, by exploring the elements of the CALTAP model with the client, the clinician has the opportunity to assist the client in broadening their understanding of their own context, which may in fact help provide for the development of more nuanced goals.

The CALTAP model recently was explored as a useful tool for consideration within the cognitive assessment context as well (Knight and Pachana 2015). Knight and Pachana (2015) expand on the model's utility by highlighting its relevance within the cognitive assessment domain. The authors encourage clinicians to become similarly aware of the depth and breadth of the client's individual context given that such knowledge contributes detail and richness to the data available in the assessment arena, as well as influencing assessment decisions, thereby improving validity overall and allowing for more targeted assessment choices and more individualized recommendation strategies.

The CALTAP model encourages psychologists to consider the range of contexts within which the older adult client presents at the level of the individual, offering a transtheoretical tool to assist in individualizing therapy and to help both the client and the psychotherapist understand the intra- and

interindividual factors of relevance to the presenting problem. Authors of the model primarily leave the decision of how to use the model in practice up to the individual clinician although the model is intended to guide more than the intake interview. CALTAP was designed as a tool to guide case conceptualization and as a broader framework that can guide assessment, selection, and adaptation of therapeutic approaches and identify relevant factors for assessing outcomes.

Creative Aging, Drawing on the Arts to Enhance Healthy Aging

Andrzej Klimczuk

Warsaw School of Economics, Warsaw, Poland

Definitions

The term “creative aging,” in the broadest sense, describes an aging policy idea that focuses on highlighting the creativity of older adults in order to prepare individuals and communities to manage old age. Programs focus on the evolution of creativity over the lifespan and aim to provide meaningful participatory engagement, especially through the arts.

A General History of the Creative Aging Movement and Best Practices

The history of professionally led creative aging programs may be traced back to the origins of the constructs of successful aging and healthy aging. These gerontological concepts were developed in the 1960s in opposition to the prevailing construct at that time, namely disengagement theory. At the same time, aging interest groups emerged which promoted cultural and lifestyle issues for older adults.

Some of the well-known creative aging programs started in the 1970s in the United States (USA) with combining art and activities for older adults. These programs were led by professional artists, such as Susan Perlstein (the founder of Elders Share the Arts) and Liz Lerman (the founder of the Dance Exchange). Also, organizations such as the Society for the Arts in Healthcare, founded in 1990, and Generations United, established in 1986, began various activities and programs related to the creativity of older adults in the context of health care, intergenerational programs, and public policies.

Cutler (2009) describes the creative aging movement also emerging in Europe in the 1970s. However, at that time similar early initiatives

related to the arts and aging were usually described as part of the community arts movement. Examples in the United Kingdom (UK) include the Plymouth Arts Centre and community arts funding initiatives of the Calouste Gulbenkian UK Trust. More specialized programs emerged in the 1980s, such as the Age Exchange (a center of reminiscence and intergenerational arts). Moreover, in Europe various initiatives were (and still are) established through the Universities of the Third Age movement, such as courses, workshops, and debates focused on the arts and humanities.

In recent years, the creative aging movement became widespread around the world. There is a growing diversity of activities, but the arts remain at the core of initiatives. In the USA in 2001, Gene Cohen and Susan Perlstein established one of the best-known such organizations, the National Center for Creative Aging (NCCA) by building a partnership with the National Council on Aging and the National Endowment for the Arts (NEA), in affiliation with George Washington University. The organization advocates on issues concerning the arts and aging, promotes combining of the arts and aging policy, organizes events and conferences, provides training and e-learning courses and toolkits, and maintains databases of resources and best practices.

Creative Aging Programs

Creative aging programs aim to foster older persons' social engagement, skills, and opportunities for creative expression ("Creative Aging Toolkit for Public Libraries" (2016)). Three forms of creative aging practice include: (1) health and wellness programs (e.g., use of art therapies in institutionalized settings for older adults with dementia); (2) community engagement programs that focus on civic involvement of older people through the arts (e.g., volunteering, mentoring, and intergenerational programs); and (3) lifelong learning (LLL) programs that aim to improve the quality of life of older adults by building skills during various courses. Thus, creative aging programs are not simply synonymous with art

workshops for seniors and tend to be delivered by professionals in diverse settings (e.g., long-term care facilities, public libraries, senior centers, and non-governmental organizations that focus on education, culture, heritage, and socialization).

Creative aging programs may also be considered as examples of new healthcare services that deliver enjoyable and fun activities in safe environments. As Hanna and Perlstein (2008) argue, creative aging may also provide a new perspective that encourages and promotes the potential (capital) of older adults rather than emphasizing their problems. To achieve this, creative aging programs should be aimed at increasing morale and passing on a legacy to younger and future generations of older adults as a means of sustaining the culture (a cultural and symbolic capital), improving physical health (human capital), and building relationships (social capital). In other words, such programs provide the basis to foster the empowerment of older adults by the promotion of emancipation or social justice, democratic citizenship, and human capital (Payne 2012).

Creative Caregiving

Creative caregiving techniques and exercises mainly draw on creative and art therapies to enhance the quality of life in both older people and caregivers, the latter including both informal (e.g., family) and professional caregivers ("NCCA Creative Caregiving Guide" 2016). In addition to the arts, creative approaches can draw on culture, science, business, and technology. Artistic creativity, for example, involves exploring new ways of interpreting the world that can produce texts, sounds, and images in response to stimulating thought-provoking questions. Creativity can also result from innovation and design. The innovation may involve the translation of ideas into new products, services, management models, or social processes. The design includes processes integrating creativity and innovation, leading to useful solutions in a caregiving context. Creative caregiving is congruent with "older-person-centered and integrated care" promoted by the World Health Organization (2015).

Creative Aging Policy

Creative aging policy can be used both as theories (descriptive models) and as ideologies or strategies (normative models) that provide frameworks for constructing positive responses to population aging. This form of policy is typically considered in the context of other aging policies ideas such as successful aging, productive aging, healthy aging, active aging, positive aging, aging in place, and intergenerational policy.

Creative aging policy aims to engage older adults in creative activity and involves a shift away from highlighting problems of aging to promoting the potential of older adults (Klimczuk 2015). It focuses on providing opportunities, technological innovations (gerontechnologies), and social innovations for all older adults, not only those who have had careers within cultural and creative industries. It supports a creative approach to leisure time in old age, regardless of whether the focus is on professional or amateur activities.

There is a complementarity of creative aging policy to the official United Nations active aging policy and thus to the related concept of healthy aging, both referred to in the 2002 “Madrid International Plan of Action on Ageing” (MIPAA). A “glocalization” of policy ideas, that is, translating and implementing general policy ideas from international organizations’ policies to the local level (cities and communities) and regional level, is also implied.

Selected Theories and Research on Creativity and Aging

There are two contrasting frameworks – the “peak and decline model” and the “lifespan developmental model” – that provide frameworks to understand creative aging as a means of constructing positive responses to population aging.

The “peak and decline model” is based on the Western cultural definitions of creativity that highlight production, quantity, and novelty (Levy and Langer 1999). These features can be evaluated through use of psychometric and

productivity tests that usually lead to the conclusion that with age, people tend to lose their creative abilities. This model has been criticized for excessive attention to results from standardized tests of creativity, which may not tap creativity as it is expressed throughout the lifespan. In contrast, the “lifespan developmental model” (also known as the continuity model) relies more on the qualitative measurement of creativity, with a greater focus on mechanisms leading to growth, change, and the evolution of creativity over the lifespan (Reed 2005).

Research conducted by Gene D. Cohen is considered groundbreaking in the field of arts and aging. Cohen has focused on the development of the brain in old age and its relation to creativity. His studies explore the hypothesis that maintaining a high level of creativity in old age requires not only appropriate external stimulation but also the inner need to solve increasingly complex problems with the use of creativity, and that this leads to positive health outcomes.

According to Cohen (2009), creativity in old age may be presented as the creativity equation ($C = me^2$). Here creativity (C) may be seen as the result of one’s mass (m) of knowledge, which is multiplied by the effects of one’s two dimensions of experience (e²). These dimensions include an individual inner world experience (emotions and personality), and the outer world (experience and wisdom). From this perspective, aging has a positive influence on creativity due to the accumulation of knowledge and experience. Thus, the aging brain is still developing with new experiences and learning (Cohen 2001, 2005). These activities lead to the creation of new brain cells between our early 50s and late 70s. Thus, with proper stimulation and good health, further intellectual development is possible. Moreover, with age, brain functioning becomes more balanced in the areas responsible for emotions, and the brain’s two hemispheres are more evenly used. These changes allow older people to be more creative.

Cohen and his team (2006) carried out a study of the impact of community-based cultural programs on the physical health, mental health, and social activities of older people (aged 65 and older). The research sample consisted of 166

older people from the region of Washington, DC. Participants were divided into two groups – an intervention (chorale program) and comparison (usual activity) group. These groups were assisted by researchers at the beginning of the project, after 12 months, and after 24 months. The programs included artistic activities such as painting, ceramics, dance, music, poetry, theater, and talks on material culture and spoken histories. The research demonstrated that the cultural program participants reported a better overall degree of physical health, fewer doctor visits, less medication usage, fewer falls, and fewer other health problems than the comparison group. Advantages in sociological terms were primarily better morale, increased activity, and less loneliness than the control group. In other words, the intervention helped in reducing the risk factors that may increase the necessity for long-term care services. This is potentially due to an increase in a sense of control and meaningful social engagement.

Potential Personal and Societal Benefits of Creative Aging

The literature about the arts and creative aging programs provides various examples of effects that may be achieved by the arts and creative expression intervention programs. For example, Moloney (2006) and Ehler et al. (2010) proposed several groups of beneficiaries from such programs. First, older adults themselves may achieve personal fulfillment, a sense of meaning, new competencies to cope with daily challenges, new social relationships, and opportunities for maintaining and improving health. Second, organizations that are developing and implementing programs, particularly within the arts sector, may find benefits including engagement of older artists, access to new audiences, the development of learning communities, and changes in program funding opportunities. Third, the health sector may benefit through increased health benefits for older adults, such as fewer visits to doctors and lower levels of depression (Castora-Binkley et al. 2010). Moreover, the engagement of older adults in creative activities in

care settings may lead to increased quality of life for staff, improved retention of personnel, facilitation of points of communication for visitors, increased social cohesion, the development of volunteering, and the establishment of new programs of activities. Finally, benefits may also accrue to the general public. Positive outcomes include here the promotion of intergenerational solidarity, the development of positive older role models, the establishment of cooperation between different sectors of society, and the provision of new strategies to reach diverse groups of older adults.

Conclusion and Future Directions

In recent years, the dissemination of creative aging practices has appeared across the globe (Bloom 2014). However, at this point, barriers and challenges remain for the development of creative aging programs. These observations may be at the same time considered as potential directions for further research.

One set of challenges concerns insufficient dissemination among the public and healthcare professionals about outcomes from arts and aging programs. In addition, there has been only limited development of standardized techniques for evaluating the use of the arts in healthcare programs and identifying best practices (e.g., Thomas and Lyles 2007). Use of the knowledge and skills of professional artists in engaging with older adults within the community and healthcare settings remains limited. Aside from creative aging's greatest advocate, Gene Cohen, there is limited promotion of knowledge about the benefits of creative aging. There is a need for greater research efforts and a common language concerning creative aging. Finally, funding for interdisciplinary strategies in healthcare regarding the arts remains scarce.

Cross-Cultural Aging

Yang Fang*, Xianmin Gong*, Minjie Lu* and Helene H. Fung
 Department of Psychology, The Chinese University of Hong Kong, Hong Kong, China

Synonyms

Aging in different cultures; Cross-cultural differences in aging

Definition

In the current entry, cross-cultural aging is defined as cultural differences in aging of human psychology, including cognitive aging, socio-cognitive aging, and socio-emotional aging. The scope of cultural difference in the extant literature focuses mainly on comparison between East Asian and Western (North American and Western European) cultures.

Introduction

Population aging is a worldwide phenomenon. This entry provides an overview of extant research on how age differences in cognition, affect, and behavior vary across cultures. While this inquiry is driven by the need for science to understand the relative contributions of culture in explaining the impact of aging on human

* Author contributed equally with all other contributors.

psychology, it also underscores the importance of recognizing the role of culture, in a world growing in its awareness of cultural diversity. The contents of this entry are thematically organized into cognitive aging, socio-cognitive aging, and socio-emotional aging with a focus on differences between Eastern (typically East Asian) and Western (typically North American) cultures.

Age Differences in Cognition Across Cultures

Cognition has long been theorized to comprise two components: one is the biologically based hardware of basic cognitive functions, supporting speed of processing and working memory, for example, and the other is the culturally based software of cognitive functions, supporting language and decision-making. These components of cognitive functions have also been characterized as fluid and crystallized intelligence, cognitive mechanics, and cognitive pragmatics, as well as primary and secondary processes.

This division provides a possible framework to understand cultural differences in age-related cognition. Specifically, biologically based hardware of basic cognitive functions declines with age and does so equivalently across cultures, whereas culturally based software of cognitive functions could be cultivated by culture and be more resistant to the effects of aging (Park et al. 1999). According to this view, few cultural differences would be detected in the hardware of cognition in either younger or older adults. In contrast, one might expect more profound cultural differences in the life-span developmental trajectory of the software of cognition.

Recent evidence, however, suggests that culture also moderates the aging of the hardware of cognitive processes (Park et al. 1999). For instance, Hedden and colleagues found superior performance in Chinese versus American younger adults on auditory digit span task (a working memory measure), but no difference in Chinese and American older adults (Hedden et al. 2002). Park et al. posited that culture might bias people at the very beginning phase of cognitive encoding to

attend to certain types of information at the expense of other information (e.g., context-object bias). This, in turn, has a major influence on follow-up cognitive processes of the selected information (including those that were once thought of as basic processes) (Park et al. 1999). Therefore, cultural differences in cognitive aging may not neatly follow the dichotomous characterization of cognitive processes.

To better comprehend the interplay of age and culture in cognition, Park, Nisbett, and Hedden developed a new theoretical framework, based on a distinction between culture-invariant and culture-saturated cognitive tasks and measures (Park et al. 1999). These authors asserted that the effects of culture and age on cognition were task dependent. On culture-invariant cognitive tasks, individuals from different cultures would perform similarly, and age-related declines on the tasks would happen at an equivalent rate across cultures. On culture-saturated cognitive tasks, however, individuals' performance would vary as a function of culture. Specifically, cultural differences would increase with age if the differences are based on automatically activated processes and would decrease (termed as cultural convergence) with age if they are based on effortful, strategic cognitive processes. Accordingly, age-related cultural convergence could result from the leveling effects of biologically based functional declines on basic cognitive processes, influencing one's cognitive resources. On a resource-demanding task, older adults would have insufficient resources to support flexible use of strategies, resulting in cross-culturally equivalent task performance.

According to Park et al.'s framework, culture is more likely to interplay with age on culture-saturated than on culture-invariant cognitive tasks and measures. To understand this influence, it is necessary to identify culture-saturated cognitive measures and then discuss the interaction effects of culture and age on these measures.

Holistic-Analytic Thinking

Previous literature has well documented a preference for holistic thinking in collectivistic Eastern cultures and a preference for analytic

thinking in individualistic Western cultures. Individuals with holistic thinking tend to attend to contextual information, emphasize relationships and group functions, make relatively little use of natural categories, and rely on intuitive, dialectical reasoning. Individuals with analytic thinking, however, attend to objects, emphasize individual functions, readily make use of categorical information, and rely on rational, logical reasoning (Masuda et al. 2008).

Context-Object Bias

The cultural divergence on holistic-analytic thinking results in different attentional biases in Easterners and Westerners. Easterners normally pay greater attention to contextual information (e.g., a picture's background) and tend to bind context and object together, whereas Westerners normally pay greater attention to objects, even when they are embedded in the background (Masuda et al. 2008).

Cultural differences in context-object bias have been found to diminish with age. For example, some studies find that younger East Asians are more sensitive to the context of facial expressions than younger North Americans. However, this cultural discrepancy disappeared in older adults (Ko et al. 2011; Masuda et al. 2008). The results of these studies are consistent with Park et al.'s framework in which they assert that cultural differences in cognition could decrease with age on tasks that require effortful and controlled processing. In these studies, it was highly resource consuming to integrate contextual and facial information, making both Asian and American older adults unable to complete the tasks well and leading to age-related cultural convergence (Park et al. 1999).

Categorical Processing of Information

The divergence on holistic-analytical thinking also leads to differences in categorization strategies used by Easterners and Westerners. First, Easterners typically make less use of natural categories compared to Westerners when categories are not highly salient. Second, Easterners use more thematic categorization, whereas Westerners use more taxonomic categorization when categories are salient enough to be accessed (Park et al. 1999). Taxonomic information refers to

similarity of features and attributes among objects, whereas thematic information refers to causal, spatial, and temporal relationships among objects (Ji et al. 2004). For example, in the "chicken-cow-grass" test (Chiu 1972), Westerners tend to pair the chicken and cow together due to their shared taxonomic similarity (i.e., both are animals), while Easterners tend to categorize the cow and grass together due to their functional relationship (i.e., cows eat grass).

These cultural differences in processing of categorical information become amplified with age. For example, cultural differences in memorizing categorical information are larger among older than younger adults, and the age-related decline in memorizing categorical information is more pronounced in Eastern versus Western cultures (Gutchess et al. 2006; Yang et al. 2013). These interaction effects could be interpreted within Park et al.'s framework. Specifically, limitations in cognitive resources make it increasingly difficult for older Easterners to employ an unfamiliar strategy (i.e., categorization), and therefore Easterners may suffer more severe age-related loss in using categories. In contrast, cultural preferences and prolonged experience make it less resource demanding for older Westerners to categorize, and therefore their age-related decline in category processing may be reduced (Gutchess et al. 2006).

In short, divergent thinking styles make people from Eastern and Western cultures process information differently. The cultural differences in cognition are especially evident in measures of context-object bias and categorical processing of information – all of which appear to be readily accounted by Park et al.'s theoretical framework of the interaction between age and culture on cognition.

Age Differences in Social Cognition Across Cultures

Attributions of Social Behavior

A well-established finding in social psychology is errors of attribution error. People tend to explain causal relationships in terms of dispositional (e.g., personality traits), rather than situational forces

(e.g., social pressure). This bias manifests as the correspondence bias, which refers to one's lack of awareness of situational constraints, leading to insufficient correction for these constraints when making dispositional inferences.

Besides social psychologists, life-span psychologists have also focused on social attributions in the context of aging. With an American sample, Blanchard-Fields and Horhota (Blanchard-Fields and Horhota 2005) found that older and middle-aged adults displayed the correspondence bias to a greater extent than did younger adults (Blanchard-Fields and Horhota 2005). The difference between older and younger adults was eliminated only when a plausible motive (but not other situational constraints) for the actor's behavior was made salient. The researchers attributed this finding to cognitive decline and insufficient motivation of older adults to consider the situation faced by the actor if they were not prompted to consider the actors' plausible motives.

The cross-cultural difference in susceptibility to the correspondence bias is well established. People from relatively individualistic cultures, such as the United States, Canada, and Western Europe, are more susceptible to this bias than people from relatively collectivistic cultures, such as East Asian countries including Japan, Korea, and China. This tendency is chiefly explained in terms of East Asians' subscription to the holism – the notion that nothing is isolated and everything is connected and their tendency to take constraints faced by individuals – imposed by the social collectives and situational contexts they are embedded in into account (Nisbett et al. 2001). Blanchard-Fields, Chen, Horhota, and Wang inquired into cultural differences in correspondence bias at different ages by comparing adults from two age groups, younger and older, in two cultures, American and Chinese (Ko et al. 2011). In addition to finding a cultural difference (the Americans showed stronger correspondence bias than the Chinese regardless of age group), they found that this cultural difference was affected by age – older Americans demonstrated a stronger correspondence bias than younger Americans (replicating prior findings), whereas older Chinese showed a weaker bias, albeit statistically

insignificant, than younger Chinese (Blanchard-Fields et al. 2007). The researchers suggest that age-related changes in susceptibility to the correspondence bias are not driven by decline in cognitive processing capacity but rather by “lifelong accumulation of cultural experience,” which helps older adults to “internalize cultural-specific models of attribution.”

Implicit Theories and Their Consequences: Dialecticism and Holism

Another psychological domain investigating the effects of culture on age concerns the lay theory of naive dialecticism (often simply referred to as dialecticism). Naive dialecticism is a “constellation of lay beliefs about the nature of world” whose roots can be traced to folk Taoism, with influences from Buddhist thoughts (Spencer-Rodgers et al. 2009). The beliefs related to naive dialecticism revolve around three themes: that everything is related to one another (*holism*), that change is cyclical, and that we should be tolerant of contradiction. These themes are endorsed by members of a number of East Asian cultures, including Japan, China, and Korea. Dialecticism influences cognition, affect, and behavior in a number of ways. For example, members of dialectical cultures are more likely to prefer dialectical proverbs to nondialectical proverbs, reason more dialectically about social contradictions, and perceive emotions of opposite valence as compatible with each other (Spencer-Rodgers et al. 2009).

As the culture-specific influence of dialectical beliefs on emotional experience and well-being across the life-span will be covered in another entry, this section will focus on how dialecticism influences self-concept and cognitive-behavioral tendencies in older adults. Zhang and his colleagues examined age-related changes in dialecticism (and its close conceptual counterpart, *holism*) cross-culturally (Zhang et al. 2014). Comparing younger and older adults in Hong Kong and America, they found distinct age-related changes in self-reported dialecticism and a behavioral measure of holism, the framed-line test (FLT). Specifically, while older people reported being less dialectical than younger

people in both cultures, only Chinese older adults, not their American counterparts, exhibited stronger holistic tendencies on the behavioral measure of holism, the FLT. These findings suggest a potential for the influence of culturally endorsed implicit theories to grow with age, but such growth is likely to be domain specific.

Age-Related Changes in Personality Across Cultures

Personality is characterized by habitual patterns in behavior, thought, and emotion. This section reviews some models of personality and examines their manifestation in younger and older age groups in different cultures.

Big Five and Indigenous Models of Personality

Often regarded as the most influential model of personality, the five-factor model (FFM) has been supported in cross-sectional and longitudinal studies in multiple cultures (McCrae et al. 1999). The model comprises five dimensions of personality – extraversion, openness to experience, neuroticism, agreeableness, and conscientiousness. Evidence further suggests that, across cultures, older people are more conscientious, more agreeable, less neurotic, less open to experiences, and less extraverted than younger people (McCrae et al. 1999).

However, some personality psychologists have argued that the FFM is culturally biased and is insufficient when it comes to explaining personality variability in cultures outside of North America and Western Europe. This sentiment has spurred an emic (indigenous) approach to the study of personality. In China, this has resulted in the development of the Chinese Personality Assessment Inventory (CPAI) (Cheung et al. 2001), which argues that a sixth personality construct, interpersonal relatedness, should be added to increase its relevance to the Chinese context. Interpersonal relatedness comprises harmony (avoidance of interpersonal conflict), Ren Qing (abiding by the rules of social exchange),

face (concern of others' opinion of oneself), and flexibility (seeing others' views or methods). Notably, these CPAI personality factors, which include interpersonal relatedness, replicate fairly well in European American populations, hence supporting the CPAI applicability in cross-cultural personality research (Lin and Church 2004).

Interestingly, when measured across the life-span, changes in interpersonal relatedness showed cross-cultural variation. Fung and Ng found that interpersonal relatedness is higher among older Chinese than younger Chinese, but this age difference is not found among European Canadians (Fung and Ng 2006). This suggests that Chinese exhibit culturally valued norms and traits more strongly as they age. The same trend is also observed in the domain of dispositional optimism: Americans (who live in a culture that value optimism) become more optimistic with age, whereas Hong Kong Chinese (who live in a culture that value optimism considerably less) become less optimistic with age (You et al. 2009).

Collectivistic and Individualistic Tendencies

Research on personality development across the life-span using nonfactor-based approaches has corroborated the aforementioned finding that age-related differences in personality across the life-span can vary among cultures. In Labouvie-Vief, Diehl, Tarnowski, and Shen's exploratory study, they examined how 20 "folk concept" scales of personality – taken from the California Psychological Inventory – changed over the life-span in Americans and Mainland Chinese (Labouvie-Vief et al. 2000). They discovered that older Chinese, compared to younger Chinese, expressed increases in self-control and good impression, together with a reduction in self-acceptance and flexibility. These results suggest that "collectivistic tendencies," which are related to norm orientation, are stronger among older Chinese, whereas "individualistic tendencies," characterizing extraversion and individual initiative, are weaker among older Chinese, compared to younger Chinese. In general, the age-related patterns found in the Chinese sample

are either absent or less pronounced in the American sample.

Taken together, findings from these cross-cultural studies suggest that aging can strengthen the endorsement and expression of traits and characteristics valued in one's culture (e.g., social reciprocity and collectivistic tendencies in the Chinese culture and optimism and individualistic tendencies in the American culture).

Age-Related Gains in Wisdom Across Cultures

Most cultures tend to agree that we gain wisdom as we age, though recent evidence shows that age-related gains in different aspects of wisdom vary as a function of culture. With three age groups (younger adults, middle-aged adults, and older adults), Grossmann and his colleagues examined wise reasoning (e.g., acknowledging multiple perspectives, recognizing likelihood of change, perceiving flexibility in conflict development) about interpersonal and intergroup conflicts in Japanese and Americans aged 25–75 years (Grossmann et al. 2012). They found that younger and middle-aged Japanese, compared to their American counterparts, showed greater use of wise reasoning strategies only for reasoning about interpersonal conflicts, but not for intergroup conflicts, and this cultural difference did not extend into old age. In terms of intergroup conflicts, while Japanese and Americans started out at a similar level of intergroup wisdom at a younger age, only Americans exhibited age-related growth in this type of wisdom. The findings were interpreted as evidence for interpersonal wisdom to emerge at a younger age among Japanese than Americans, due to the relevance of wise reasoning to keeping harmonious relationships with others. Conversely, age-related growth in wise reasoning about intergroup conflicts is only observed in America. This may be because of the United States' relatively higher ethnic diversity that calls for wisdom in the intergroup domain. This finding suggests that although wisdom is a psychological quality that shows age-related growth across cultures, the trajectory of the growth

is influenced by domain-specific importance of different types of wisdom in each culture.

Age Differences in Emotion and Well-Being Across Cultures

Emotion Perception

As people grow older, they tend to show preference for processing positive information rather than negative or neutral information. This effect was coined as “positivity effect” (Charles et al. 2003). For example, Charles and colleagues found that, while young participants demonstrated a negativity dominance during memory tasks (remember negative images better), such an effect was less pronounced among older adults, suggesting a reduction in negativity with increasing age. However, recent cross-culture studies suggest that this aging-related positivity effect might not be universal. In Western cultures, positive information is perceived as more emotionally useful because it helps individuals maintain optimism and self-esteem, which in turn fulfills culturally endorsed values of autonomy and uniqueness. In East Asian cultures, social harmony and interpersonal relationships are more important than individual uniqueness or autonomy. Thus, to maintain social harmony and avoid social mistakes, individuals may pay attention to different social cues from the environment, including both positive and negative information, and then provide appropriate responses accordingly. Hence, in these cultures, negative information may not be perceived as less important as positive information. This may, in turn, lead to a cultural difference in the aging-related positivity effect, such that the bias for processing positivity is not generalized to interdependent cultures.

Evidence showing this cultural difference comes largely from comparisons of Western and the Hong Kong Chinese cultures – studies conducted in Korea demonstrated the same age-related positivity bias as in Western cultures (Ko et al. 2011). For example, Fung and her colleagues found that, although older participants remembered positive information better than

neutral information (positivity enhance effect), they also remembered negative images as well as the neutral images (no negativity reduction effect) (Fung 2013). In another study, older adults recognized an announcement that conveyed negative emotions better than an announcement that conveyed neutral emotions. Using eye tracking methodology, Fung and colleagues demonstrated that Chinese older participants looked away from positive stimuli (Fung 2013).

Later, Fung and colleagues tested whether the cultural value of interdependence held by individuals moderated the age-related bias for positive information (Fung 2013). In both studies with memory tasks and attention tasks, results suggested that the age difference in negativity reduction effect was only observed among participants with lower levels of interdependence, similar to the result that has been demonstrated by Western samples. Yet, among Chinese participants with higher level of interdependence, no age difference was found.

To summarize, accumulated evidence has demonstrated the cultural variation in age-related positivity effect. Individuals from Chinese culture, who value interdependence more than Western individuals, may not regard negative information as more important than positive information and thus exhibit the age-related positivity effect to a lesser extent.

Emotional Experience and Well-Being

In the Western literature, previous findings have demonstrated that older people exhibit a higher level of emotional well-being (more positive emotions and fewer negative emotions) compared to their younger counterparts (Shiota and Levenson 2009). The same pattern was found in the Chinese culture. Pethtel and Chen compared the emotional experience among a group of Mainland Chinese participants and found that older adults reported lower levels of negative emotions than did younger adults (Pethtel and Chen 2010). However, some recent studies observed a different pattern in other Asian cultures. Grossman and colleagues argued that although emotional well-being might be a universal goal, the way to achieve it might vary

across cultures (Grossmann et al. 2014). In Western cultures, well-being might be enhanced by experiencing more positivity and less negativity, and research shows that this is what Westerners tend to pursue, being more strongly motivated to maximize their positive emotional feelings and minimize negative one. However, in East Asian cultures that encourage tolerance for contradictions and changes, well-being is defined by a dialectical way of mixing positive and negative experience. Based on this dialectical belief, maintaining positive feelings and avoiding negative feelings may become less important for East Asians; they might instead prefer to strive for a balance between the positive and negative (Grossmann et al. 2014). Indeed, in Grossman's study, older Japanese participants reported a higher level of positive emotions than did their younger counterparts. Yet they reported the same level of negativity as did their younger counterparts, including the intensity of negative emotions, the focus on past negative experience, and the proportion of perceived negative interpersonal relationships. In another study conducted in Hong Kong, a similar pattern was found, such that age was associated with more positive emotions, but there was no correlation between age and negative emotions (Yeung et al. 2011).

In summary, in both Western and Eastern cultures, aging correlates with an increase in positive emotions, while a decrease in negative emotions is more frequently observed in Western cultures.

Emotional Regulation

As outlined above, older people tend to report higher emotional well-being. Urry and Gross proposed that the underlying mechanism might be that older adults become better at regulating their emotions (Urry and Gross 2010). More specifically, to regulate emotions, older adults may tend to employ antecedent-focused strategies (e.g., cognitive reappraisal, attentional deployment) more than response-focused strategies (e.g., expression suppression) (Carstensen et al. 1999). The former is also associated with healthier outcomes. For example, as abovementioned, compared to younger adults, older adults pay more attention to

positive information and stimuli, suggesting they tend to use the strategy of attentional deployment. Given that the antecedent-focused strategies downregulate the negative emotions before they are full-blown, preventing individuals from negative and stressful experience, they tend to be associated with healthier outcomes.

Cross-culturally, age differences in emotion regulation only partially hold true in East Asian cultures. During the SARS outbreak in Hong Kong, Yeung and Fung found that compared to young participants, older participants reported more emotional-focus coping and lower levels of anger both at the peak of the SARS epidemic and at its end, suggesting that older people were more successful in managing their negative emotions under stressful situations (Yeung and Fung 2007). In another study conducted in Hong Kong, Yeung and colleagues found that an age-related increase in using cognitive reappraisal partially accounted for the age differences in positive feelings (Yeung et al. 2011). These data support the hypothesis that older people are better at antecedent-focused emotion regulation.

However, in the same study, no age difference in suppression was found. Yeung and colleagues speculated that because Asian cultures emphasized interpersonal harmony, suppressing one's emotions to avoid social conflict was always encouraged across different life periods (Yeung et al. 2011). Hence, older adults exhibited the same level of suppression as younger adults. In another study, older adults benefited from suppressing emotion. This emotional suppression was positively correlated with a lower intensity of negative emotion and better work performance among older adults but not younger adults (Yeung and Fung 2012).

Interestingly, although most of the aforementioned evidence suggests that older adults tend to control their emotions to preserve their social relationships, a study found that in Mainland China, where the hierarchy within family was emphasized, older adults were more likely to express anger to their kin to preserve their authority in the family hierarchy (Fung and You 2011).

Conclusion

This entry provides an overview of how age-related changes in cognition, affect, and behavior vary as a function of culture. It should be acknowledged that most “cross-cultural” comparisons reported in this entry are mostly “East versus West” comparisons – in other words, imprecise depictions of the rich cultural diversity in our world. This bias in current research on culture should be an inspiration for researchers to broaden the scope of inquiry of age differences into cultures that are, at present, underrepresented. Similarly, most of the reported studies are cross-sectional (reflecting existing aging research in general), and their conclusions may be confounded by cohort effects. Despite these limitations, our review suggests that aging does take different forms, or at least manifest in different ways, in some domains across cultures. Examining the intersection of aging and culture may reveal important mechanisms about adult development.

Crystallized Intelligence

Patrick Rabbitt
 Department of Experimental Psychology,
 University of Oxford, Oxford, UK

Humans have recognized the difference between having knowledge and being able to use it for at

least 2,000 years. In 1963, Raymond B. Cattell was the first to propose a psychometric model for these distinct abilities (1963). Horn and Cattell (1966) further developed his theory and Horn (Horn 1968, 1982; Horn and Noll 1997) applied it to changes in cognitive abilities in old age. Horn showed that our abilities to solve problems rapidly and accurately (and so achieve high scores on intelligence tests), to respond fast to simple signals, and to quickly learn unfamiliar material such as lists of random words peak in our early twenties but decline as we grow older. These changes are slight from our 30s through our 50s but accelerate throughout our 60s, 70s, and 80s. Horn and Cattell termed these “fluid abilities” or “fluid intelligence” (gf) because they are not specific to particular problems but support performance in all mental tasks. In contrast to waning fluid abilities, Horn showed information that we have learned throughout our lives is relatively age robust. Following Cattell, Horn called such bodies of acquired information “crystallized intelligence” (gc). Their choice of the word “intelligence” emphasizes that Cattell and Horn did not regard gc only as a mental archive of semantic information, such as vocabulary, or collections of names of birds or trees, or athletic records but also as tool kits that we have invented or learned to carry out “procedures.” Some examples of these procedures might be constructing grammatical sentences, doing algebra, working out lines of play in chess or go, or managing a bank, a business, or a kitchen. This distinction is clear in Horn’s discussions but while his experiments do show that vocabulary and other kinds of semantic knowledge can survive well into old age with little loss, he did not systematically explore how far this is also true of complex procedural skills that we have learned over our lifetimes. Horn’s early experiments and discussions also do not make the important point that, in contrast to “fluid intelligence” or “fluid abilities,” the “crystallized” skills are intensely “domain specific.” That is, mastery of a particular skill may be of little help in learning or using others, even if these may seem quite similar. An analogy from information technology is that computer programs written to efficiently carry

out particular tasks are usually useless for any others.

Horn and Cattell’s distinction also implies a contrast between the difficulty of inventing, learning, and using a difficult procedure for the first time and its easy and automatic deployment once it has become familiar. This applies to cultural as well as individual accomplishments. Clay tablets, papyrus, libraries, and the World Wide Web can all be envisaged as means of “crystallizing” and indefinitely preserving semantic and procedural information that most individual humans could not discover or invent on their own: For example, it took Leibniz and Newton years of hard thought to invent the Calculus that schoolboys can now easily learn from textbooks in a few weeks.

The Cattell/Horn distinction raises interesting practical questions as to how we should view our likely trajectories of competence in our everyday lives throughout our lifespans. Though our fluid intelligence declines as we get older, can we still continue to practice demanding professions supported by information and skills that we have learned throughout our lives and still retain in our old age? An associated question is whether some kinds of crystallized abilities may be more age robust than others so that professional competence based on these durable abilities can be maintained longer than on more age-fragile skills?

A key issue is that retaining effective procedures is one thing, but carrying them out is quite another. Another helpful metaphor from information technology is the difference between developing and storing a program that is ideal to perform a particular task and having a system that is adequate to run it. As the “benchmark” bandwidth and memory capacity of an information processing system reduce, so will the maximum complexity of the programs that it can run. For humans “working memory” (*see also entry Crystallized Intelligence in this volume*) is a convenient term coined by Alan Baddeley and Graham Hitch (1974) as a blanket label for our abilities to rapidly shift attention from less to more important information, to process new information and to relate it to other information that has been recently registered or held in memory for many years, and to reorder all of this old and

new information so as to decide and implement what we should do next. All of the abilities implicit in the general concept of “working memory” are, in Cattell and Horn’s terms, “fluid” and age fragile. However, without a well-functioning “fluid” working memory system, we cannot manage to do complicated things for which we, long ago, learned reliable procedures: e.g., to produce a long, grammatical sentence, to understand and solve a complex business problem, to cook a complicated dish, or to plan and carry out apt sequences of moves in chess. So, as the efficiency of working memory sharply declines with age (Salthouse et al. 1989), we may still be able to perfectly describe effective procedures for completing complex tasks but become unable to meet the demands these make on our diminishing working memory capacity when we attempt to put them into practice.

A neat illustration of this is Susan Kemper’s (1990) analyses of diaries written by citizens of Kansas during the late nineteenth and early twentieth centuries. These often covered 40 or 50 years of their authors’ lives. As diarists aged the ranges of words that they used only slightly reduced (as Horn and Cattell’s empirical results predicted). Nevertheless, although their youthful diary entries were often long sentences and complex grammatical constructions, as they grew old, their sentences became shorter and their grammatical constructions increasingly simple. Retaining large numbers of words and retaining the ability to assemble them into complex sentences are different things.

This raises the interesting practical question whether some “crystallized abilities,” that is, kinds of learned knowledge and skills, can survive later in life than others. In 1935 Lehman (1935) pioneered studies of the ages at which distinguished mathematicians, scientists, poets, novelists, musicians, and artists had made their most remarkable contributions (Lehman 1942; Lehman and Ingerham 1939). Ages of greatest productivity and achievements were the early 20s and 30s for mathematicians, physicists, and chemists; the 40s and 50s for historians, philosophers, and novelists but might be as late as the 60s, 70s, or even 80s for some visual artists and musicians.

Does this mean that some skills are more age resistant than others?

Lehman pointed out that his data were not ideal to address these questions. Many of the careers documented took place in the eighteenth and nineteenth centuries when life expectancy was much shorter and career trajectories were very different. Recent studies confirm early age-related losses in scientific productivity but suggest that these now happen much later than in the historical periods for which Lehman collated data. Studies of British psychologists in the 1970s and 1980s (Over 1982); of large groups of less eminent physicists, geologists, physiologists, and biochemists in 1989 (Levin and Stephan 1989); and of the careers of economists and other scientists (Cohen 1991; Bayer and Dutton 1977), all found that, as they grow older, all academics publish less and in less prestigious journals. Recent studies of average or slightly above-average scientists find that their plateaux of greatest productivity last more than a decade longer than Lehman’s analyses suggested. Studies of artistic productivity also revise his conclusions. A 1999 analysis of the number of paintings produced by 739 graphic artists, works by 719 musicians, and books by 229 authors found that, like most contemporary scientists, their periods of maximum output were in their 30s and 40s. Unfortunately literary skills are not immune to changes that come with old age and with approaching death. Suedfield and Piedrahita (1984) analyzed the late work of distinguished novelists and found that the quality of writing in their correspondence declined during the 10 years before they died.

Other recent studies find that while the learned skills of bankers and business executives allow them to competently do their jobs in late middle age and even give them some advantage over younger colleagues with less experience, their ability to correctly analyze and cope with novel problems tends to have decline by their late 40s and 50s (Colonia-Willner 1998, 1999).

The current consensus is that while competence, even at learned and highly practiced skills, does decline with age, these changes are much smaller and slower than the earliest surveys suggested. The contrast between “early flowering

and early decline” in the hard sciences and “late flowering and late decline” in the humanities and visual arts now seems less clear-cut. One problem is finding comparable standards across different disciplines. Assessments of quality in the arts are much more contentious and differ sharply between various kinds of achievement. Standards of comparison are more elusive than the earliest studies assumed. For example, a tally of the year 2000 market value of paintings by 51 modern US artists found that for painters born before 1920, the average peak age for the valuation of their paintings was 50.6, but for those born after 1920, it was only 28.8. Changes from a cautious to a speculative market account for similar discrepancies (Colonia-Wilner 1999). From current sale prices, we might conclude that artists who are now elderly are painting much better (or at least much more profitably!) than their young contemporaries or, indeed, than themselves when young.

Ideal data to examine differences between “fluid” and “crystallized” abilities would be the achievements of large numbers of extremely gifted people on the same, difficult, mental skill on which they can be compared against each other in terms of a common objective standard. The careers of chess masters are as close to this as we get. Chess requires high levels of both fluid abilities, such as working memory and intelligence. It also requires crystallized knowledge because it has been so exhaustively researched and documented that, even for young prodigies, success at the highest levels needs long and intensive study. Chess play requires an ability to simultaneously hold many variables in mind and to recognize, as rapidly as possible, how patterns of relationships between these variables will alter if particular moves are made. Clearly there is a “natural talent” for chess because some prodigies play at a remarkably high standard at ages as early as 6–12 years. However, a study by Charness and colleagues found that even maintaining success at much lower levels than “grandmaster chess” requires 5,000 or more hours of deliberate practice over 10 years (Colonia-Wilner 1999). In terms of John Horn’s dichotomy, chess mastery requires both considerable fluid intelligence and a

formidable body of learned crystallized knowledge of tactics and strategy.

Statisticians such as Arpad Elo developed very sensitive and reliable systems for rating the relative strengths of different chess players. Because these have been used and validated for at least 50 years, even small changes in the playing strengths of individual grand masters can now be tracked from their 20s through to their 70s. Elo’s initial studies (Charness et al. 2005) found that nearly all the careers he compared showed improvements until 30s or 40s, a plateau of the best achievement until the late 50s or, in some few cases, early 60s but then a significant decline. During the historical spans of this and later analyses, chess at the highest level evolved so rapidly that players could not keep or improve their ranks unless they continually revised a vast body of theory on openings and end games. It is cheering to find that gifted individuals can, though perhaps with gradually increasing effort, remain at the very peak of an extraordinarily demanding profession until their seventh decades. Evidently, acquired knowledge and endless practice can support even a skill that is, essentially, computational and demanding of fluid intelligence until late in life. We must also remember that long after they had retired from competitive chess, these remarkable people could still play at a level that most humans cannot hope to reach at any age. We should also remember the wise comment of Gary Kasparov, perhaps the greatest player yet: “Excelling at chess has long been considered a symbol of more general intelligence. That is an incorrect assumption in my view, as pleasant as it might be.” Crystallized intelligence is intensely task specific.

Decision Making

Rui Mata

University of Basel, Basel, Switzerland

Synonyms

Choice; Inference

Definition

Decision making is the process by which a course of action is chosen from among two or more alternatives. This definition is broad enough to span different decision types and domains, from fast, habitual decisions to complex, life-changing ones. The extent to which such disparate decisions share or not the same underlying cognitive processes and are differentially affected by age-related change is an ongoing topic of research.

Historical Background

There are a number of different traditions in psychology, economics, and related disciplines to describe and formalize decision-making processes. The perhaps most prominent approach comes from expected value theory and related views, which describe decision making as the

computation of expected value, that is, the weighting of the value of possible outcomes by their probability of occurrence (Bernoulli 1954). Variations of this principle introduce the idea of subjective value/utility and probability functions that may vary as a function of individual characteristics or situations, but such approaches typically do not make reference to the specific cognitive architecture underlying these calculations. One example of such a theory is cumulative prospect theory (Tversky and Kahneman 1992). A second approach, strongly anchored in cognitive science and psychology, tries more explicitly to link descriptions of decision processes to cognitive functions of attention, learning, and memory. The models associated with such an approach may also describe the computation of value and probability but often will make stronger assumptions about information search and updating of information. For example, sequential-sampling and reinforcement-learning models make assumptions about information sampling and updating to describe decision making. Other related approaches attempt to describe decision making at the algorithmic level by making assumptions about the series of computational steps required for search, stopping, and deciding (Gigerenzer and Brighton 2009). Third, and finally, a more recent approach investigates the neural basis of decision making, often making links to some of the formal and computational theories described above (Glimcher and Fehr 2014).

Decision Making,

Fig. 1 Depiction of an estimate of the number of publications on aging and decision making as well as the corresponding percentage relative to all publications on decision making in the past 40 years. The search was conducted using the terms “aging” and “decision making” in *all fields* in PubMed

The question of how decision making changes across the life span and, in particular, with aging, has received some attention. Yet, the field of aging and decision making represents less than 2% of all work in decision making, albeit there has been an increase in the relative proportion of decision research focusing on aging (see Fig. 1).

Key Research Areas

There are a number of reviews on aging and decision making that emphasize how different aspects of age-related change can influence decision making, including affective and motivational (Samanez-Larkin and Knutson 2015), as well as cognitive and ecological, factors (Mata et al. 2012a). A complete understanding of the impact of aging on decision making will likely require the integration of different perspectives (Hess et al. 2015). Crucially, the ecological perspective suggests that there is no domain-general answer to the question of how changes in motivational or cognitive capabilities impact decision making. For example, the impact of age-related cognitive decline should depend strongly on the demands of specific task environments, such as memory demands. In other words, the quality of decisions made by people of all ages is the result of how task

demands and affordances interact with particular cognitive strategies. To better understand this interaction, one needs to describe the structure of decision environments and the cognitive or affective components that such environments exploit (Mata et al. 2012a). In what follows, the specific key research areas that have received most attention in the past are described with the goal of exemplifying the importance of age-related changes in cognitive and motivational components and the moderating role of ecological (i.e., task) characteristics on decision making.

Perceptual Decision Making

Perceptual decision making refers to low-level decisions about immediately presented stimuli, with most research on aging having been carried out on visual discrimination, such as discrimination between different letters (E vs. F) or varying levels of brightness in stimuli presented very briefly on a computer display (e.g., for less than 1 s). The state-of-the-art approach is to use sequential-sampling models (e.g., diffusion models) to describe both reaction times and accuracy of responses simultaneously and account for possible speed–accuracy trade-offs. The latter models are able to distinguish between different components, such as motor components, response criteria components, and evidence accumulation

components, because each makes different predictions about the shape of the reaction time distribution of correct and error responses. Key results in this area are that older adults do seem motivated to perform well and show motivational adaptations by adopting more conservative decision criteria than the younger adults. Older adults are also overall slower in noncognitive (e.g., motor) components. However, the quality of evidence accumulation driving the decision process is significantly lower for older relative to younger adults in some but not all tasks (Ratcliff et al. 2007), suggesting that task characteristics, such as the nature of the stimuli, can be crucial in engendering age differences in perceptual decision making. The extent to which the results from perceptual decision making can be directly translated or are correlated to performance in higher-level decisions is yet to be investigated.

Multiple-Cue Decision Making

The bulk of decision-making research has focused on problems in which decision makers have to integrate different pieces of information (i.e., cues, attributes) and deliberately decide between two or more options. The nature of information presentation may vary dramatically from those cases in which it is conveniently summarized in a table or, alternatively, needs to be retrieved from memory. A major distinction in this field concerns the existence of an objective criterion that determines the correctness of the decision, such that decisions amount to inferences, and those cases for which no objective criterion exists – decisions thus represent expressions of individual preferences. Some work on aging and multiple-cue decision making has artificially created objective criteria and examined the strategies selected by younger and older adults in inferential decision making (Mata et al. 2007). Strategies can be defined as sequences of operations or processes that are goal directed, that is, are aimed at accomplishing a particular task and, therefore, mediate task performance. The strategy concept has been used to describe cognitive processes and mechanisms of human cognition in many domains, including memory, arithmetic, and decision making. In particular, the strategy approach

has a long tradition in decision research with various strategies having been proposed, each with its particular cognitive demands and domain of execution (Shah and Oppenheimer 2008). For example, some strategies, like take-the-best (TTB), ignore significant amounts of information because they infer which of the two alternatives has the higher value on a criterion by (a) searching through cues in order of validity (i.e., how much the cue is correlated with the criterion), (b) stopping search as soon as a cue discriminates between decision alternatives, and (c) choosing the alternative this cue favors. In turn, other strategies, like weighted-additive strategy (WADD), consider all information by (a) multiplying each cue value by the respective cue weight (i.e., a measure of how important this cue is to the prediction), (b) summing up the results for each alternative, and (c) choosing the alternative with the highest sum. TTB does well in environments with many redundant cues or in which search is costly, the opposite being true for WADD. In the inference domain, there is some inherent difficulty in distinguishing age-related changes in preferences from the impact of age-related cognitive decline on the selection and application of specific decision strategies that impact the search and integration of information. Overall, work on inferential decision making suggests that older adults tend to search for less information prior to making a decision (Mata and Nunes 2010) and use simpler strategies that ignore some information (Mata et al. 2007) or strategies that do not rely heavily on memory (Mata et al. 2012b) to integrate information, possibly due to age-related cognitive decline. There are, however, other aspects related to age-related changes in motivation and preferences that can affect decision making. The work on the impact of aging on preferential decisions is summarized below for a number of areas in which age differences have been investigated, such as in the domains of risky, intertemporal, and social decision making.

Risky Decision Making

Conceptions of risk and risk taking abound, with economists viewing risk as the variance or probability of possible outcomes, whereas

psychologists and lay people often emphasize the link between risk and the possibility of losses. There are a number of measures and tasks that attempt to capture individual and age differences in the tendencies to decide for or against risky courses of action. Some behavioral tasks provide explicit information about outcome magnitudes, whether outcomes are positive (gains) or negative (losses), as well as their respective probabilities (decisions from description), but others require individuals to learn about probability and outcome information over time (decisions from experience). A review of the literature suggests that the pattern of age differences in risky decision making is heterogeneous and may depend heavily on task characteristics (Mata et al. 2011). In particular, in decisions from experience, age-related differences in risk taking seem to be a function of decreased learning performance: Older adults may be more (or less) risk seeking compared to younger adults depending on whether learning leads (or not) to risk-avoidant behavior. In decisions from description, younger and older adults may show more similar risk-taking behavior at least when the cognitive demands of the task are low. The exact decision strategies used by younger and older adults in these tasks have not been fully investigated, thus making it difficult to disentangle the role of age-related changes in risk preferences due to motivational factors and more cognitive factors, such as the changes in strategy use due to age-related cognitive decline (Depping and Freund 2011). One interesting avenue for future research is to investigate which behavioral tasks can best capture the underlying risk preferences of older adults as captured in commonly used self-report measures.

Intertemporal Decisions

Many important life decisions require trading off immediate rewards against future ones, such as the choice between spending and saving. This type of decisions is typically studied empirically using monetary decisions between smaller-sooner and larger-later amounts of money, for example, \$10 today or \$20 in 1 week. Overall, humans seem to deviate from the assumption of economic theory, which assumes exponential discounting

(i.e., constant discounting per time period). Instead, humans typically show a present bias by showing valuations that fall rapidly for small delay periods, but slowly for longer delay periods. The empirical literature concerning age differences in intertemporal decisions is mixed (Rieger and Mata 2015; Samanez-Larkin et al. 2011). However, the majority of existing studies seem to suggest a pattern, whereby older adults are more patient, by showing choices indicative of either less steep discounting rates or increased neural responses to later rewards (Samanez-Larkin and Knutson 2015).

Social Decision Making

Aging is traditionally perceived as being associated with increased wisdom, including an increased ability to navigate the social world. But do older adults deal more or less strategically and prosocially relative to younger adults in social contexts? Standard economic theory assumes that people are, perhaps exclusively, motivated by material self-interest and thus do not care about the well-being of others. A number of studies have rejected this assumption and suggested that individuals of all ages have prosocial motivations (Engel 2011). The typical measures used to assess prosocial motivations consist of having individuals (i.e., players) make decisions in the context of groups in which other individuals may or not be anonymous. For example, individuals may be asked to allocate monetary amounts to themselves and others, with the amount assigned to the social partner being used as an indicator of prosocial motivation. The economic games include the dictator, ultimatum, and trust games, among many others (Rieger and Mata 2015; Engel 2011). The literature on age differences in social preferences in such games is relatively scarce and most work has only considered age as a nuisance variable. Some work does suggest an increase in prosocial motivations with increased age (Engel 2011), but there is evidence that such patterns may not hold across tasks or populations (Rieger and Mata 2015). More empirical studies investigating a more culturally and age-diverse set of participants are still needed to characterize age differences in such strategic social interactions.

Another area of research that has received some attention concerns decision making and problem solving in a social context. Such abilities are typically assessed by tallying the number and quality of solutions participants generate to deal with everyday problems, for example, the course of action to take under financial distress or how to handle a social conflict between members of a couple. A meta-analysis of such problems concluded that there is a decline in effectiveness of everyday decision making (Thornton and Dumke 2005), with a medium effect size difference between younger and older adults (Hedge's $g \approx 0.4$). However, moderator analyses revealed that age differences were reduced when problems were of a social nature (Hedge's $g \approx 0.2$). Overall, the literature suggests that there may be changes in social decision making, but it remains an open issue whether these are due to motivational or cognitive factors.

Future Directions

An important avenue for future work concerns evaluating the consequences of basic age-related changes in motivational and cognitive changes on real-world decisions. There is some evidence for an inverted-U-shaped function of age and financial decision making in the real world (Agarwal et al. 2009). Yet, the exact mechanism for this pattern remains unknown, and it could be a function of age-related changes in financial knowledge, numeracy, fluid cognitive abilities, motivation, or all of the above. Prospective and longitudinal studies of decision making that include real-world outcomes are yet to be conducted but are sorely needed to distinguish such different possibilities.

The area of consumer decision making provides an interesting future test-bed for different theories because it likely conflates different influences, including cognitive and motivational factors (Yoon et al. 2009). One important principle to keep in mind in such work is that age-related cognitive decline may not always be associated with poor choice outcomes. For example, simple strategies that ignore information can lead to

satisfactory choices in many real-world consumer environments (Mata and Nunes 2010).

In sum, aging seems to be associated with changes in decision making, from simple perceptual decisions to complex social ones. The motivational and cognitive mechanisms leading to such changes still need to be uncovered, as do the task characteristics that foster or hinder successful choices by aging decision makers.

Assessment; Competency; Decision-making

Definition

The necessary cognitive and functional abilities required to perform a specific task or make a specific decision.

Introduction

The term *capacity* refers to a person's ability to perform a specific task or make a specific decision. Determinations of capacity have historically been made by clinicians in clinical settings. This is in contrast to the legal term *competency*, which is a determination made by the court. At times these terms have been used interchangeably; however, for the purposes of this section, we henceforth use the terms “clinical capacity” and “legal capacity.”

Psychologists are increasingly called upon to make determinations of capacity. The reasons for this are multifactorial. It is widely cited that the number of older adults worldwide has grown exponentially. And while not all older adults develop dementia, they may experience physical and mental changes as they age that place them at risk for impaired capacity. There has also been shift of wealth from the World War II generation to the baby boomers and now to the Generation X, in increasingly diverse families that are separated geographically. Consequently, probate courts are seeing an increase in contested wills and guardianship proceedings (Moye and Marson 2007). The probate law has also shifted from a global and absolute view of capacity towards a more task- or decision-specific standard of capacity, recognizing a person can have capacity in one area but not another. Thus to meet the current legal standard of capacity, the capacity evaluation has also evolved to include neurocognitive, psychological, and functional assessments. Psychologists are often trained in these assessments thus are well suited to conduct capacity evaluations (Lichtenberg et al. 2015).

Yet while psychologists may have the appropriate training to address the functional, cognitive, and mental health components of the evaluation, they are often less familiar with the term capacity or the interventions available to persons with

diminished capacity. To further complicate the issue, professionals who often work with the probate laws surrounding capacity (i.e., lawyers and judges) may be less familiar with the unique needs of and challenges in working with older adults. So in 2003, the American Bar Association (ABA) and the American Psychological Association (APA) formed a workgroup to develop educational materials and handbooks for lawyers, judges, and psychologists. The intent of this workgroup was to provide a framework for professionals to draw upon in capacity determinations as opposed to more rigid standards of practice. The workgroup produced the first handbook, *Assessment of Older Adults with Diminished Capacity: A Handbook for Lawyers*, in 2005. The second handbook, *Judicial Determination of Capacity of Older Adults in Guardianship Proceedings: A Handbook for Judges*, was published in 2006. The final handbook, *Assessment of Older Adults with Diminished Capacity: A Handbook for Psychologists*, was published in 2008. These handbooks are available online at www.apa.org/pi/aging and www.abanet.org/aging (American Bar Association and American Psychological Association Assessment of Capacity in Older Adults Project Working Group 2008).

The following sections will detail the evolution of the legal capacity and guardianship laws; the core ethical principles inherent in decision-making capacity; the requisite functional abilities for determinations of capacity; the role of culture in capacity evaluations; a framework for capacity evaluations; and future directions for the field.

Evolution of Legal Capacity and Guardianship

Over the past 65 years, the legal aspects of capacity evaluations have undergone significant change in the United States and internationally. In essence, there has been a shift towards increased autonomy and limited guardianship, resulting in various legal reforms. Historically, the concept of capacity was global and absolute in that a person deemed incapacitated would have his or her legal rights revoked in a broad range of legal domains (American Bar Association and American Psychological Association Assessment of Capacity in Older Adults Project Working Group 2008).

This has shifted over time and current legal practice uses the term “capacity” to refer to a person’s ability to complete a specific task or decision (Bailar-Heath and Moye 2014), thus recognizing that a person can have capacity in one area (e.g., medical decision-making) but not another (e.g., driving). Another relatively recent change has replaced the term “incompetency” with the term “incapacity” as the determination of these have evolved to integrate clinical findings into legal findings in a multidisciplinary manner (American Bar Association and American Psychological Association Assessment of Capacity in Older Adults Project Working Group 2008). This shift is in keeping with the view of capacity as being decision relevant, which holds that judgments of capacity are for specific abilities at specific time in a specific context and relevant to a specific decision (Buchanan and Brock 1989).

The past few decades have yielded significant reform in legal practice pertaining to adult guardianship in the United States. The ABA defines guardianship as legal decision-making power given to an outside entity or person in response to a determination of incapacity. The term itself is often used interchangeably with “conservatorship” depending on the state or country in which the determination is being made and may be used in reference to guardianship of property specifically (American Bar Association and American Psychological Association Assessment of Capacity in Older Adults Project Working Group 2008; Bailar-Heath and Moye 2014). Criteria for guardianship fall under state and not federal regulation, and thus there is variability across states in how guardianship determinations are made. These decisions are defined by either statutory or case law and are transaction specific. Examples of transaction-specific capacity include testamentary capacity, donative capacity, contractual capacity, capacity to execute a durable power of attorney, and capacity to consent to medical care. Despite the inconsistency in legal definition, basic guidelines for determining diminished capacity include disabling condition, functional behavior, cognitive functioning, and consideration of the least restrictive alternative. These guidelines are commonly expanded upon by state law (American Bar

Association and American Psychological Association Assessment of Capacity in Older Adults Project Working Group 2008).

As part of the recent capacity reforms, 32 states have passed comprehensive reform bills, and 261 separate capacity laws have been passed. Currently, more than 30 states now require clinical evaluation for capacity to determine whether an adult may qualify for guardianship (Bailar-Heath and Moye 2014). Further, the majority of US states have done away with the global and absolute determination of incapacity in favor of the relatively recent model of limited guardianship. In the limited guardianship model, a guardian is appointed on for the areas in which the person has been deemed to lack capacity (American Bar Association and American Psychological Association Assessment of Capacity in Older Adults Project Working Group 2008). In determining whether a person is in need of guardianship, all states begin with the assumption of capacity and put the burden of proof on the party attempting to establish guardianship. In other words, every person is assumed to have capacity until established otherwise.

In contrast to the variability of laws pertaining to capacity determinations based on state jurisdiction in the United States, international law offers a more unifying standard. Since the 1960s, guardianship law has been of particular concern in many countries. In 2006, the Convention on the Rights of Persons with Disabilities (CRDP) marked a major international milestone in the legal rights of persons deemed to have diminished capacity. The CRDP brought significant changes to the laws of member nations to protect the legal rights, status and autonomy of incapacitated adults, and to provide support to this legally vulnerable population (Bailar-Heath and Moye 2014). Among other things, these changes mark an increase in the emphasis on autonomy and independence, cultural sensitivity, and the consideration of least restrictive alternatives (Doron 2002).

Within the broader legal standards outlined in the CRDP, the laws regarding capacity determinations vary by country. Canada, the United Kingdom, and Portugal define incapacity using the

benchmark of an individual's ability to care for "person or property" (Bailar-Heath and Moye 2014). In Germany, the guardianship model has shifted focus towards a "care and assistance" model that allows the individual to be appointed with a caretaker who carries out specific tasks as defined by the court, protecting the incapacitated individual from losing his or her legal rights. Sweden offers two possibilities for legal support for incapacitated persons. In both, the individual is appointed an administrator, mentor, or trustee that is responsible for assisting him or her. Additionally, the person may forfeit legal capacity in specified domains only or may not lose any of his or her legal rights. Israel is gradually transitioning from guardianship laws that eradicate the legal rights of the individual in all domains, to the appointment of a guardian and retention of legal competence (Bailar-Heath and Moye 2014).

In Hong Kong, the courts that determine guardianship appointment are multidisciplinary panels made up of lawyers, someone who has personal experience with incapacitated individuals, and either physicians, psychologists, or social workers. The structure of the panels in Hong Kong illustrates the shift towards a psycholegal construct of capacity that has been the recent trend in numerous countries. Similarly, Australian guardianship tribunals include members of the community as well as legal professionals, and various provinces in Canada require collaboration of legal and clinical professionals (Bailar-Heath and Moye 2014).

The legal aspects of capacity evaluations are complicated by variance in laws according to country and state jurisdiction. However, recent reforms both in the United States and internationally point to a shift in consciousness towards providing those who are legally determined to be incapable of safely making decisions about their person or property the least restrictive guardianship and preserving many of their legal rights. By including clinical assessments in legal proceedings that determine capacity, the system is beginning to allow for a more holistic view of the individual's abilities as opposed to the historically broad revocation of legal rights.

Principlism in Health Care

The concept of capacity spans the fields of health care and law. Yet health-care ethics is a third area which is central to the concept of capacity. Principlism is system of ethics deployed in health care that based on four moral principles of: (1) respect for autonomy, (2) beneficence, (3) nonmaleficence, and (4) justice.

The principle of respect for autonomy, also referred to as self-determination, is the person's ability to make his or her own decisions. This principle is rooted in the longstanding belief of the importance of personal freedom and individualism. Health-care providers are tasked with ensuring that autonomous decisions are intentionally made, with substantial understanding, and free from coercion (Beauchamp 2007; Beauchamp and Childress 2011).

Beneficence may be viewed as a group of principles that both prevents harm and also provides benefits that outweigh costs and risks. This principle reflects the moral obligation to act for the benefit of others and is often considered a foundational value in health-care ethics. It could be argued that the obligation to promote patient welfare is of the utmost importance in medicine. Beneficence obligates health-care providers to assist older adults in furthering their interests, often by removing or minimizing risk and harm to the patient (Beauchamp 2007).

The principle of nonmaleficence prevents providers from causing harm to others, or put simply is the "do no harm" principle. While beneficence includes the prevention of harm or reduction of risk for the ultimate benefit of the patient, nonmaleficence is the intention to avoid unnecessary harm or injury to the patient. As noted by Beauchamp (Beauchamp 2007), nonmaleficence is one of the most frequently cited codes in health-care ethics. Some have advocated to place the greatest emphasis upon this obligation, even if that is to the detriment of other obligations, including the respect for autonomy. Nonmaleficence obligates providers to inflict the least amount of harm to achieve a beneficial outcome.

Finally, the principle of justice requires the fair distribution of benefits, costs, and risks (Beauchamp 2007). Put another way, this principle

obligates providers to act on the basis of unbiased decision-making in the face of competing claims. Thus the principle of justice extends beyond equitable access to treatment, as it obligates providers to be aware of their own biases to ensure the fair distribution of health-care resources.

These four principles are not hierarchical; thus clinicians have an obligation to uphold each of them. While this is the ideal, ethical clinical practice dictates that the clinician must examine the balance of these principles by examining their respective weights on a case-by-case basis. Thus to weigh the respective weights is to carefully evaluate the risks involved in the situation. There are no hard and fast rules that dictate that one principle take precedence over another. To further complicate the matter, different professionals may place a greater emphasis on different principles. When faced with the same clinical case, providers may recommend different treatments based on their evaluation of the potential risks and benefits involved. For example, a provider may recommend an older adult with a history of falls and mild cognitive impairment be discharged to home with the assistance of home health aides in order to promote the respect for the patient's autonomy. However, another provider, when presented with the same clinical scenario, may recommend the patient be discharged to an assisted living facility in order to promote the principle of beneficence (i.e., prevent the patient from sustaining future harm). As is highlighted in this example, determinations of capacity are often a balancing act between these foundational principles of health-care ethics.

Essential Functional Abilities

Assessment of functional abilities is a core component of capacity evaluations. In the field of geropsychology, the concept of functional abilities often refers to a person's ability to perform activities of daily living (i.e., bathing, grooming, eating) and instrumental activities of daily living (i.e., shopping, bill payment, household chores). Yet in capacity evaluations, the legal concept of functional abilities also refers to the intact decisional abilities that are generally agreed to convey capacity (Lichtenberg et al. 2015). These abilities,

which are drawn from case law, include *understanding*, *appreciation*, *reasoning*, and *expressing a choice* (Grisso 2003; Smyer 2007).

In the context of capacity assessments, *understanding* refers to the ability to comprehend the nature of a proposed decision, including an awareness of its risks and benefits. The ability to adequately understand a proposed decision is impacted by several factors including the person's intelligence, educational level, and the method by which the information is presented to them. The risks and benefits of a decision must be presented to a person in a manner that promotes their understanding.

While there are different interpretations of *appreciation*, it is generally thought to refer to the ability to understand the relevance or applicability of a decision to the older adult. At the most basic level, older adults must recognize that a decision must be made, that they are the decision-maker, and it is their life that will be affected by the decision. Thus it is not surprising that appreciation is greatly impacted by the degree of patient insight, as well as the type of decision to be made and the complexity of that decision.

Reasoning entails the process of rationally comparing different treatment options or proposed solutions in a consistent manner. Older adults must demonstrate that they can weigh the risks and benefits of the proposed choices as well as the possible consequences. The ability to reason directly impacts understanding and appreciation. If a person cannot rationally reason or logically manipulate the presented information, it is not possible to fully understand or appreciate the issues in the decision (Grisso and Appelbaum 1998).

Older adults must also be able to *express a choice*; those who are unable to outwardly communicate a choice or who waver in their choice are seen as lacking capacity (Lichtenberg et al. 2015; American Bar Association and American Psychological Association Assessment of Capacity in Older Adults Project Working Group 2008; Grisso 2003). That choice should be consistent with the person's value or beliefs; however, it is accepted that a person's value and beliefs may change over time. The importance of expressing

a choice should not be minimized as there are situations in which a person may be able to understand, appreciate, and rationally reason about a decision; however, due to a physical condition, such as stroke, is unable to express a choice. In situations such as this, it is impossible to know what that person's preference or desire would be.

In addition to these four functional abilities, *the role of values in the determination of capacity cannot be overstated*. The ABA and APA Assessment of Capacity in Older Adults Project Working Group (American Bar Association and American Psychological Association Assessment of Capacity in Older Adults Project Working Group 2008) defined values as "an underlying set of beliefs, concerns, and approaches that guide personal decisions." This definition is useful as it not only defines values but also highlights the relationship between values and decision-making. As highlighted in Moye (Moye 2007), the "extent to which a person's expressed choice is consistent with their values is an indicator of capacity"; thus, it is an essential component to the assessment of these functional abilities. An understanding of a person's values will also greatly assist in the development of appropriate treatment recommendations. Providers should also be aware of their own values so that any inherent biases regarding the decision at hand can be appropriately addressed.

The Role of Culture in Capacity

In addition to being one of the fastest growing segments of society, older adults are one of the most culturally diverse groups. That diversity is projected to continue to expand in coming years as evidenced by recent US census data. In 2014, 14% of the adults in the United States were age 65 or older. A closer analysis of this census data reveals that within this older segment of the US populace, approximately 1 in 7 (14%) sampled identified as a racial minority. That percentage of racial minorities is projected to steadily grow to 18% by 2030 and 23% by 2050 (U. S. Census Bureau 2014). As noted by Karel (2007), within these racial groups are further subgroups (denoted by their countries of origin) with their own values and beliefs. These values and beliefs are often the

foundation for their views on aging, health care, family and familial roles, finances, and end-of-life. Among older White Americans, there are further ethnic, regional, and religious subgroups. And not surprisingly, these subgroups have strong values and beliefs that influence their views on many of the abovementioned issues.

There are also cross-cultural differences within the aforementioned principles of health-care ethics. In Western cultures, the principle of respect for autonomy or self-determination is strongly valued. This is evident in the widespread use of advance care directives and durable powers of attorney, which are designed to foster patient autonomy in situations where patients are unable to make their own decisions. This emphasis on patient autonomy is unique to Western cultures, as other cultures encourage collective decision-making that involves the patient's community and family. In cultures that value beneficence, providers are obligated to encourage hope above all else. This is contrasted with those cultures that value nonmaleficence, in which providers protect patients from harm by not directly addressing seemingly negative outcomes such as death or end-of-life (Searight and Gafford 2007).

Conceptual Framework of Capacity

The ABA-APA Working Group on the Assessment of Capacity in Older Adults detailed a nine-part framework for conceptualizing capacity assessments (American Bar Association and American Psychological Association Assessment of Capacity in Older Adults Project Working Group 2008). The model builds off of the frameworks for guardianship as well as the framework for capacity assessment previously developed by Grisso (American Bar Association and American Psychological Association Assessment of Capacity in Older Adults Project Working Group 2008; Grisso 2003; Moye 2007). Components of the nine-part framework proposed by the ABA-APA work group includes the identification of: the relevant legal standards, functional abilities of capacity, relevant medical or psychiatric diagnoses contributing to incapacity, cognitive function, psychological and emotional factors, values and preferences, risks to the individual and of the

situation, ways of enhancing capacity, and a clinical judgment of capacity.

While a capacity assessment is a clinician's opinion about a person's ability to perform a specific task or make a specific decision, that task or decision has a specific legal standard. A clinical judgment regarding a person's capacity can then have a direct impact on that person's legal rights henceforth. Therefore, a familiarity with the legal standard is a requisite initial step in the approach to a capacity assessment. The expectation here is not that a provider becomes an expert in the legal standards surrounding the capacity in question, but more that the provider becomes familiar with the legal standard. This can be accomplished through a review of a state's statutory or case law or through a consultation with an attorney. Information gleaned from this review or consultation should be then used to guide the selection of the assessment battery, so as to ensure all aspects of the legal standard are met (American Bar Association and American Psychological Association Assessment of Capacity in Older Adults Project Working Group 2008). It should be noted that from the legal perspective, all persons are presumed to have capacity until proven otherwise.

The ABA-APA framework builds off of the previous work by Grisso (1986) to expand the concept of "function" to also include the identification and evaluation of the functional elements essential to the questioned capacity. Capacity assessments should include a tailored evaluation of the specific task or specific decision which can be accomplished through specific questions in a clinical interview as well as through direct assessment or observation of the person's functioning (American Bar Association and American Psychological Association Assessment of Capacity in Older Adults Project Working Group 2008). This portion of the capacity assessment will vary based upon to the type of decision-making capacity being assessed. For instance, if the assessment is one of financial decision-making, the provider should include a structured assessment of financial decision-making. If the assessment were one of testamentary capacity, the provider should include specific questions in the clinical interview designed to demonstrate a person's ability to

describe a will, to describe the nature and extent of one's assets, to name potential heirs, and to describe plans for distribution of one's wealth. This focus on functional abilities specific to the task or decision to be made is a defining feature of the capacity assessment.

The purpose of establishing or documenting a diagnosis in the capacity assessment is to identify a possible "causal factor" for potential incapacity (Grisso 2003). Older adults are vulnerable to many physical and psychiatric illnesses that may impact capacity including dementia, delirium, neurodegenerative disease (e.g., Parkinson's, Alzheimer's), stroke, and many more. Yet these conditions can have markedly different long-term outcomes, thus it is important to recognize the role of the prognosis of the condition in judgments of decision-making capacity. For instance, Alzheimer's disease is a progressive neurodegenerative disorder for which there is no cure. This is contrasted with delirium, which is a life-threatening medical condition in which a person's cognition can rapidly fluctuate, though with medical intervention can fully resolve. In both of these conditions, patients will have impaired decision-making ability. Yet in the case of delirium, patients are often able to fully recover decision-making abilities while those patients with Alzheimer's disease are not likely to regain their decision-making ability (American Bar Association and American Psychological Association Assessment of Capacity in Older Adults Project Working Group 2008). While a diagnosis can serve as a causal factor for the impaired decision-making, it can also serve as a prognostic indicator as to if capacity is likely to be regained. Yet a medical or psychiatric diagnosis by itself is insufficient to establish a patient's decision-making capacity as patients with impaired cognitive function due to a medical or psychiatric disorder may still retain the ability to make some decisions. Thus the focus should not be on the presence of the diagnosis but on the influence of the diagnosis on the person's decision-making.

Most states include a comment on a person's cognitive function as a necessary element in the determination of capacity. The causative role that many diagnoses have on decision-making is often

through their effect on cognitive functioning. Impaired cognitive functioning can result in impaired insight or impairment in the cognitive abilities necessary to perform a specific task or make a specific decision. This portion of the capacity assessment should include assessments designed to comment directly on the cognitive functions necessary to perform a specific task or specific decision, in addition to measures of overall cognitive function. For instance, assessments of financial capacity may include measures of written arithmetic whereas an assessment of driving capacity may include measures of visual attention and processing speed (American Bar Association and American Psychological Association Assessment of Capacity in Older Adults Project Working Group 2008). As with the determination of medical and psychiatric diagnoses, the purpose of the cognitive assessment is to characterize the level and nature of cognitive impairment and determine if (and how) the decision-making process is impacted by cognitive status.

Similar to the cognitive assessments, the purpose of the screening for symptoms of mental health disorders is to detect possible underlying factors that may impact a person's decision-making ability. Mental health disorders, like psychotic spectrum disorders and severe mood disorders, can impair a person's insight and ability to rationally weigh the risks and benefits of the proposed choices as well as the possible consequences. Many mental health disorders are amenable to intervention which presents with greater likelihood that the patient will regain decision-making ability (American Bar Association and American Psychological Association Assessment of Capacity in Older Adults Project Working Group 2008). It should be noted that many patients with clinically significant mental health symptoms are not captured by strict criteria-based diagnostic categories (Lyness et al. 2015), thus again the focus of these measures is not just diagnosis but to comment on the impact of the mental health symptoms on cognitive and functional abilities relevant to the questioned capacity.

As aforementioned, values are the beliefs, concerns, and experiences that directly inform one's decisions. The ABA-APA handbook

distinguishes values from preferences, as former refers to “preferred option of various choices that is informed by values.” Assessment of values and preferences is an essential component to a capacity assessment as one of the requisite functional abilities is the expression of a choice that is consistent with a person’s values. It should be noted that values and preferences can change over time thus a change in person’s values may not represent impaired decision-making capacity (American Bar Association and American Psychological Association Assessment of Capacity in Older Adults Project Working Group 2008). In addition to conveying capacity, knowledge of a patient’s values and preferences can assist in the development of effective treatment recommendations that are more likely to be accepted by the patient.

Some have argued that at its most basic, a capacity evaluation is a type of risk assessment (American Bar Association and American Psychological Association Assessment of Capacity in Older Adults Project Working Group 2008; Moye 2007; Ruchinskas 2005). The provider must consider all available data, including medical and psychiatric diagnoses, cognitive and functional impairment, and patient values and preferences, in the context of the risk of the situation. In addition to evaluating the patient in terms of the risk of the situation, the provider should also take account of social and environmental supports, as these may serve to mitigate or exacerbate the initial risk (American Bar Association and American Psychological Association Assessment of Capacity in Older Adults Project Working Group 2008; Moye 2007). For instance, the discharge of an older adult with limited mobility to independent living would carry more risk if that older adult lived in a two-level home and had no immediate family in the area to provide assistance. Those risks would be mitigated, however, if the older adult had the financial means to install a stairway lift and employ regular home health aides to assist him. Thus these risks were mitigated with effective interventions to enhance the older adult’s capacity. All recommended interventions should match the level of risk in the situation so to ensure the deployment of the least restrictive means necessary (American Bar Association and

American Psychological Association Assessment of Capacity in Older Adults Project Working Group 2008).

All capacity evaluations should include considerations of what can be done to maximize a patient’s functioning. As noted by Moye (2007), many of these recommendations are practical in nature and include things such as hearing or visual aids or medication management systems. Other interventions may include work with occupational or physical therapy as well as additional training or counseling. Efforts to maximize patient functioning represent opportunities for potential clinically impactful interventions (American Bar Association and American Psychological Association Assessment of Capacity in Older Adults Project Working Group 2008).

In the final component of the ABA-APA framework, the provider takes into consideration all of the data gathered through the capacity evaluation and provides a clinical opinion regarding the patients questioned capacity. This clinical opinion is oft expected to be presented in the form of a dichotomous conclusion (e.g., yes or no). There will be situations in which the determination of capacity will be clear based upon the available information such as when a patient is grossly impaired across multiple cognitive and functional domains or is unable to express a choice due to significant neurological impairment. Other decisions are more complex due to varying levels of impairment across multiple domains. In situations such as these, providers are encouraged to review the available data in the context of the patient’s values and preferences as well as any environmental supports or risks (American Bar Association and American Psychological Association Assessment of Capacity in Older Adults Project Working Group 2008).

Conclusion

The rapid global growth of older adults has compelled geropsychologists to gain the requisite knowledge and skills to address issues surrounding capacity. This topic is particularly relevant to geropsychologists as these professionals

understand the physical and mental changes that occur in late life and can often increase the risk of impaired capacity. Geropsychologists are also trained in the psychological, neurocognitive, and functional assessments that are included in the capacity assessment. Yet while geropsychologists have the clinical expertise, they are often less familiar with the legal standards required to determine capacity. The legal and health-care fields continue to evolve in their definitions of capacity as the focus has shifted towards one that recognizes capacity to be decision and domain specific as opposed to a global judgment of ability. Geropsychologists may find capacity evaluations to be a type of risk assessment that requires the balancing of the four moral health-care principles, which requires an understanding and appreciation of the role of culture on these principles. While there are no current “gold standards” for the assessment of capacity, there are conceptual frameworks as well as other assessment-specific tools available to assist those in evaluations such as these. Psychologists who work with older adults are encouraged to explore these frameworks and suggested assessments as they move towards achieving competency in assessment of decision-making capacity.

Synonyms

Confusion; Derangement; Irrationality; Hallucination

Delirium is characterized by an acute change in an individual's mental state, marked by fluctuating patterns of confusion and inattention. It is unfortunately encountered by nurses, family, and physicians, both in hospital and home-based care settings. Delirium can affect individuals of any age, though it is more frequently experienced by older individuals. It raises the risk of mortality, causes distress to both patients and caregivers, and increases health care expenditures. It is an acute condition that may present independently or in combination with other dementia syndromes; therefore, accurate diagnosis and timely treatment are imperative. In this entry, the authors discuss delirium in the general hospitalized patient, then subsequently focused on postoperative delirium for major orthopedic and cardiac surgeries that have the highest rates of delirium-affected individuals.

Delirium Defined

Delirium is an acute and temporary change in orientation and cognition. The Diagnostic and Statistical Manual of Mental Disorders (DSM-V; American Psychiatric Association and American Psychiatric Association, DSM-5 Task Force 2013, www.dsm5.org) provides a description of

delirium with subtypes. These include delirium due to an underlying medical condition (*delirium due to a medical condition*), medications (*substance-induced delirium, substance intoxication delirium*), or withdrawal from medications (*substance withdrawal delirium*). Delirium can also be multifactorial (*delirium due to multiple etiologies*) (see Table 1 for criteria and descriptor information; ICD-10 criteria are presented in Table 2). Delirium can be present at hospital admission and presurgically, although it is more often seen in postsurgically managed general medical units and most frequently in intensive care units (ICUs).

General Characteristics of Delirium

Delirium characteristics can vary by individual. Most common is fluctuating arousal with waxing and waning awareness of orientation. It is often accompanied by altered sleep-wake cycle and reversed night cycles. Hallucinations and delusions are common. Variability can be seen in activity levels; however, patients can present with hyperactive, hypoactive, or mixed hyper-hypo active cognitive and motor states. Hyperactive patients show increased psychomotor activity, such as rapid speech, irritability, and restlessness. These patients can be disruptive, time-consuming, and harmful to staff. They are therefore more readily identified and treated. Hypoactive patients, by contrast, typically show a calm appearance combined with inattention, decreased mobility, and have difficulty answering simple questions about orientation. Due to their calm appearance, these individuals are unfortunately less readily identified with delirium and may be inappropriately treated (Peritogiannis et al. 2015).

Significance of Delirium

Although a temporary condition, delirium is a medical and societal stressor from an economic and healthcare standpoint. Delirium occurs in at least 10–24% of the general patient population,

Delirium, Table 1 The following criteria are derived from the *Diagnostic and Statistical Manual of Mental Disorders*, 5th ed. All criteria (A-E) are required for diagnosis

DSM-V diagnostic criteria for delirium
(A) A disturbance in attention (i.e., reduced ability to direct, focus, sustain, and shift attention) and awareness (reduced orientation to the environment)
(B) An additional disturbance in cognition (e.g., memory deficit, disorientation, language, visuospatial ability, or perception)
(C) The disturbances in Criteria A and C are not better explained by another preexisting, established, or evolving neurocognitive disorder and do not occur in the context of a severely reduced level of arousal, such as a coma
(D) There is evidence from the history, physical examination, or laboratory findings that the disturbance is a direct physiological consequence of another medical condition, substance intoxication, or withdrawal (i.e., due to a drug of abuse or to a medication), or exposure to a toxin, or is due to multiple etiologies
Specify whether:
Substance intoxication delirium
Substance withdrawal delirium
Medication-induced delirium
Delirium due to another medical decision
Delirium due to multiple etiologies
Specify if:
<i>Acute:</i> Lasting a few hours or days
<i>Persistent:</i> Lasting weeks or months
Specify if:
<i>Hyperactive:</i> The individual has a hyperactive level of psychomotor activity that may be accompanied by mood lability, agitation, and/or refusal to cooperate with medical care
<i>Hypoactive:</i> The individual has a hypoactive level of psychomotor activity that may be accompanied by sluggishness and lethargy that approaches stupor
<i>Mixed level of activity:</i> The individual has a normal level of psychomotor activity even though attention and awareness are disturbed. Also includes individuals whose activity level rapidly fluctuates

with reports up to 50% of hospitalized older adults (over 65) (Inouye et al. 2014). Indirect costs of delirium stem from lost work and personal productivity by patients and caregivers and have been estimated to total more than \$164 billion in the USA alone (Inouye et al. 2014). Acute postoperative delirium has been shown to be an independent predictor of functional decline and morbidity after cardiac and orthopedic surgeries.

Delirium, Table 2 The following criteria are derived from the 2016 ICD-10 Procedure Coding System (ICD-10-PCS)

ICD-10 diagnostic criteria
(A) Clouding of consciousness, i.e., reduced clarity of awareness of the environment, with reduced ability to focus, sustain, or shift attention
(B) Disturbance of cognition, manifest by both:
(1) impairment of immediate recall and recent memory, with relatively intact remote memory; and
(2) disorientation in time, place, or person
(C) At least one of the following psychomotor disturbances:
(1) Rapid, unpredictable shifts from hypoactivity to hyperactivity
(2) Increased reaction time
(3) Increased or decreased flow of speech
(4) Enhanced startle reaction
(D) Disturbance of sleep or the sleep-wake cycle, manifest by at least one of the following:
(1) Insomnia, which in severe cases may involve total sleep loss, with or without daytime drowsiness, or reversal of the sleep-wake cycle
(2) Nocturnal worsening of symptoms
(3) Disturbing dreams and nightmares which may continue as hallucinations or illusions after awakening
(E) Rapid onset and fluctuations of the symptoms over the course of the day
(F) Objective evidence from history, physical and neurological examination, or laboratory tests of an underlying cerebral or systemic disease (other than psychoactive substance related) that can be presumed to be responsible for the clinical manifestations in A–D
Comments: Emotional disturbances such as depression, anxiety or fear, irritability, euphoria, apathy or wondering perplexity, disturbances of perception (illusions or hallucinations, often visual), and transient delusions are typical but are not specific indications for the diagnosis
Use the fourth character to indicate whether the delirium is superimposed on dementia or not: F05.0 Delirium, not superimposed on dementia; F05.1 Delirium, superimposed on dementia; F05.8 Other delirium; F05.9 Delirium, unspecified

Assessing Delirium

To assist with diagnosis, a number of investigators have collaborated to develop and validate rapid bedside approaches to diagnose patients at the bedside and ICU. The Confusion Assessment Method (CAM; Inouye et al. 1990) is the most well-known measure for assessing delirium. The CAM assesses four features: acute onset and

fluctuating course (feature 1), inattention (feature 2), disorganized thinking (feature 3), and altered level of consciousness (feature 4). Delirium diagnosis requires the presence of features 1 and 2 and either 3 and 4 (note that memory impairment is not included, for this is sometimes absent in mild delirium, whereas it is present in other conditions, such as dementia (Inouye et al. 1990)).

The Society of Critical Care Medicine has strongly recommended routine evaluation of delirium in ICU patients. For critically ill patients where delirium prevalence ranges from 11% to 87% (Aldemir et al. 2001; Ely et al. 2001a), the CAM-ICU (Ely et al. 2001b) was designed. It assesses the same four features of the original CAM, but relies more on nonverbal responses. For this exam, patients are observed to assess the presence of acute mental status change, inattention, disorganized thinking, and altered levels of consciousness. We encourage you to review some excellent video introductions to the CAM-ICU available via the Internet.

The CAM has been translated into 20 other languages including Chinese, Dutch, German, and Spanish, with the CAM-ICU having high validity relative to other delirium scales available in those languages. Overall, the CAM and CAM-ICU's simple algorithms allow them to be useful for rapid identification of delirium by both physicians and staff nurses. After training, both scales should take approximately 2 min to administer.

Aside from the CAM instruments, other frequently encountered screening tools include the Delirium Rating Scale-Revised-98 (DRS-R-98; Trzepacz et al. 2001), the Memorial Delirium Assessment Scale (MDAS; Breitbart et al. 1997), and the Nursing Delirium Screening Checklist (NuDESC; Gaudreau et al. 2005). The DRS is a 10-item scale, rated by a clinician with psychiatry training and is based on a patient's behavior over a 24-h period. The DRS was later revised and renamed the DRS-R-98. The DRS-R-98 includes a 16-item clinician-rated scale, including 13 items assessing delirium severity and three diagnostic items. The MDAS is a 10-item clinician-rated scale, based on DSM-IV criteria, which assesses disturbances in arousal and level of

consciousness, cognitive function, and psychomotor activity. The NuDESC is a measure used exclusively in surgical and recovery ward patients and can be administered by trained nursing staff. It consists of a 5-item scale assessing disorientation, inappropriate behavior and communication, hallucinations, and psychomotor retardation over a 24-h period. See Table 3.

Prevalence of Delirium Type and Considerations for Risk Factors in General Medical and Surgical Populations

The prevalence of delirium is reported highest before hospital discharge, this being often associated with respiratory infections, cellulites, and urinary tract/kidney infections. Central nervous system disorders have the second most frequently reported delirium codes with this particularly seen among those having craniotomy, CNS neoplasms, degenerative nervous system disorders, strokes/transient and other seizures/headaches, and other nervous system disorders (Lin et al. 2010).

Delirium due to a medical condition is the most common type of delirium, with drug-induced delirium being the second most frequently reported (Lin et al. 2010). Patients with drug-induced delirium, however, are typically younger than the other delirium groups and had the lowest proportion of comorbidities. Drug-induced delirium was also most common in patients who have lower extremity orthopedic surgery (relative to comparison groups of patients with pneumonia, urinary tract infection, congestive heart failure) (Lin et al. 2010). Dementia-related delirium, by contrast, is associated with high rates of admission from long-term facilities and older adults. This subtype typically has a higher mortality rate and greater frequency of atrial fibrillation, pneumonia, and urinary tract infections. General delirium risk factors include male sex type, increasing age, and cerebrovascular risk factors.

Structural brain disease traits are additional considerations for delirium risk. Although studies are of variable quality with regard to imaging methods, studies show that delirium patients

Delirium, Table 3 Common delirium screening tools

Tool ^a	Pro	Con	Sensitivity/ specificity ^b
CAM	Based on DSM criteria; best in ED, postoperative and mixed inpatient settings; high interrater reliability	Potential for false negatives in postop population	46–100%/63–100%
CAM-ICU	Brief assessment (<2 min); can be used in nonverbal pts	Be used in nonverbal pts in postop population	46–100%/63–100%
MDAS	Best in postop settings; designed to track changes in delirium	Tested in modest number pts, limited generalizability; may only be assessed by physician	64.1%/100%
DRS	More useful than DRS-R-98 in more impaired patients	May only be assessed by psychiatric physician; not useful with repeated admin	91–100%/84–92%
DRS-R-98	Can assess severity of delirium; distinguishes delirium from dementia	May only be assessed by a trained nurse	91–100%/84–92% and <75%/<75% (in older adults)
NuDESC	Best sensitivity and specificity of tools for postsurgical populations; brief assessment	May only be used by a trained nurse	85.7%/86.8%

have preexisting brain differences. Patients with delirium are reported to have preexisting larger ventricle sizes, basal ganglia or caudate lesions/lacunae, white matter abnormalities in the periventricular and deep regions of the brain, greater cortical and subcortical atrophy, and decreased regional and overall perfusion. An important caveat, however, is that almost all of these studies are confounded by age; delirium patients are significantly older in age than those without delirium. White matter abnormalities and atrophy increase with age for many individuals, particularly those with hypertension and hypercholesterolemia. See De Groot and Slooter (2014) for a more thorough review.

Functional MRI techniques may improve understanding of neural mechanisms for delirium. Choi and colleagues (2012) assessed the functional brain patterns of delirious subjects. They found that activity in the dorsolateral prefrontal cortex and posterior cingulate cortex were strongly correlated in patients during an episode of delirium, as compared with control subjects who demonstrated an inverse correlation between these regions. The authors also revealed that

functional connectivity between the intralaminar thalamic and caudate nuclei were reduced during a delirious episode, but this connectivity recovered to normal function after resolution of delirium (Choi et al. 2012).

These studies lend further support to the hypothesis that there are predisposing demographic, comorbidity, and brain vulnerability factors contributing to the development of delirium. Attention will now shift to specifically discuss unique risk and treatment applications associated with two major surgery types: orthopedic and cardiac surgery.

Reducing Postoperative Delirium: Anesthetic Considerations and Perioperative Variables

Postoperative delirium typically presents around 24 h after surgery and resolves in most patients by 48 h; however, in rare cases it can last for up to months or even a year or more. Different risk factors for orthopedic and cardiac surgery have been discussed in the literature and are therefore reviewed separately below.

Specific to Orthopedic Surgery

Although delirium can be noted in elective orthopedic surgery, it is more prominent and concerning among urgent orthopedic surgeries such as hip fracture. Patients who develop delirium after hip fracture surgery have higher rates of mortality, are more likely to be diagnosed with dementia or mild cognitive impairment, and/or require institutionalization. There is an increased need to identify ways to reduce delirium in these patients. Recent randomized controlled studies suggest that analgesia and pain management and depth of general anesthesia are important modifiable factors for delirium prevalence after hip fracture surgery. A Cochrane review (Parker et al. 2004) compared outcome differences in hip fracture patients versus regional anesthesia. From five randomized controlled trials meeting inclusion criteria, there were more patients with postoperative confusion in the general anesthesia groups relative to the regional anesthesia groups. The authors concluded that with hip fracture surgery, regional anesthesia relative to general anesthesia results in a twofold reduction of acute delirium. Zywiell and colleagues (2014) found mixed results (Zywiell et al. 2014), however. They identified that patients who receive general versus regional anesthesia during a hip replacement surgery experience delirium at a greater frequency, though after a few days postsurgery, the differences are no longer significant.

Identifying and treating delirium risk factors in patients *prior* to surgery may also be a venue for reducing postoperative delirium. Investigators have recently lead a quasi-experimental intervention study (Bjorkelund et al. 2010) where preoperative patients with hip fractures admitted to the hospital were either treated with a multifactorial intervention program ($n = 131$) or served as a control group ($n = 132$). The multifactorial intervention program included: (1) the use of supplemental oxygen; (2) intravenous iv fluid supplementation and extra nutrition; (3) increased monitoring of vital physiological parameters (oxygen saturation, systolic blood pressure maintained >90 – 100 mmHg, red blood cell transfusion should be considered if hemoglobin <100 g/l, avoid hypo/hyperthermia); (4) adequate

pain relief; (5) avoidance of delay in transfer logistics; (6) daily delirium screening; (7) avoidance of polypharmacia (sedatives/hypnotics with anticholinergic properties given in restriction); and (8) anesthesia recommendations (premedication with paracetamol, propofol and/or alfentanil iv on arrival to operating suite, spinal anesthesia with bupivacain, sedation with propofol) with systolic blood pressure maintained at $>2/3$ of baseline or >90 mmHG, red blood cell transfusion only when there is increased blood loss ($>.3$ l) or hemoglobin (<100 g/l), and postoperative analgesia with paracetamol as the first choice or in combination with an opioid. Findings showed less delirium in the intervention group relative to the control group, suggesting value of *multifactorial perioperative intervention approaches* rather than the use of one or two therapies alone.

Presurgical education may be an additional approach. One study (Krenk et al. 2012) showed that delirium did not occur for elective orthopedic surgery patients who were provided with more information about the anesthesia and surgical procedures, as well as prehabilitated by physiotherapists for appropriate exercise regimes commonly used after surgical intervention. The authors cite the need to engage patients in their own rehabilitation as well as consistent monitoring of cognitive changes. The study was limited, however, in that subjects were all cognitively well (Mini Mental State Exam >23) and may have experienced a protective factor in this regard.

Specific to Cardiac Surgery

Delirium after cardiac surgery has been reported for many years, but has recently been shown to be a strong independent predictor of mortality for up to 10 years postoperatively, even in younger individuals and in those without prior stroke. Coronary artery bypass graft or valve surgery is also associated with risk of functional decline at 1 month after discharge, with this outcome independent of comorbidity, baseline function, and cognition.

Operative risk factors include impaired left ventricular ejection fraction, time on cardiopulmonary bypass, high perioperative transfusion

requirement, and postoperative hypertension. Microemboli, common to all cardiac surgical procedures, has not, to date, been specifically associated with delirium although it continues to be considered a potential contributor when it occurs in combination with other risk factors such as hypoperfusion.

There may be specific modifiable risk factors for delirium after cardiopulmonary bypass (CPB). In a group of individuals receiving standardized surgery, anesthesia, and postoperative pain management protocols, and daily delirium evaluations, Burkhart and colleagues (2010) identified that delirium risk factors were: (1) the dose of fentanyl per kilogram of body weight administered during the operation, (2) the duration of mechanical ventilation, and (3) maximum value of C-reactive protein measured postoperatively (Burkhart et al. 2010). The authors pose that fentanyl, with questionable anticholinergic effects, may be a modifiable risk factor; alternatives such as remifentanyl or other opioids may be worth considering for intervention trials. Duration of mechanical ventilation requires sedation and therefore may be a consequence of the specific drugs used to maintain sedation. Sedation depth may also be worth considering. Postoperative rates of C-reactive protein suggest a systemic inflammatory response to surgery. This may indicate a relationship to endotoxin, a common consequence of coronary artery bypass grafting (CABG) and trauma-induced intraabdominal infections. Burkhart and colleague's (2010) C-reactive protein findings coupled with others findings that cortisol levels also correlate with postoperative delirium suggest that these areas need further investigation. Clearly, there is a specific need for intervention trials with potentially modifiable risk factors in cardiac patients.

Considerations for Anticholinergic Medications and Anesthesia

Anticholinergic drugs and/or interaction of these drugs with anesthetic agents is a probable factor for postoperative delirium. Anticholinergic drugs compete for acetylcholine receptor subtypes

(nicotinic and muscarinic). They impair memory performance by antagonizing the neurotransmitter acetylcholine and muscarinic receptors in the brain. High serum anticholinergic levels of anticholinergic drugs are associated with delirium and cognitive impairment. Unfortunately, these medications are commonly taken by older adults over the counter for sleep aids (any “*pm*” medication). Common anticholinergic medications include tricyclic antidepressants used to treat mood but also pain and sleep (i.e., amitriptyline), antihistamines, and antibiotics (e.g., cephalosporin, third generation). Anesthesiologists should identify patients on anticholinergic medications prior to surgery. One potential mechanism for anesthetic action is via the suppression of cholinergic cells (i.e., isoflurane and sevoflurane suppress acetylcholine release). Thus, there is potential for increased depletion of cholinergic activity. Randomized prospective studies are needed to identify the extent to which presurgery anticholinergic medications interact with anesthesia to increase vulnerability to delirium and even postoperative cognitive dysfunction. There have been attempts to prevent postoperative delirium with cholinesterase inhibitors (e.g., rivastigmine) in randomized treatment trials. Unfortunately, to date, these have been largely unsuccessful for both elective total joint replacement and cardiopulmonary bypass. Large intervention trials appear needed.

Considerations for Postsurgery Dementia Development or Progression

Threshold and Brain/Cognitive Reserve

The concept of a threshold and brain/cognitive reserve is often mentioned when attempting to explain why certain individuals may: (1) develop delirium or (2) proceed to dementia.

Martin Roth and colleagues (Roth 1971) first introduced the concept of a “threshold” in their postmortem Newcastle upon Tyne studies. These researchers observed patterns in senile plaque counts and measures of disease/dementia severity. For example, in Parkinson's disease, clinical Parkinsonism does not appear until 85% of the cells of the nigrostriatal system are depleted and

dopamine has declined in a similar proportion. A similar pattern has been reported in Alzheimer's disease with regard to neurofibrillary plaques and tangles.

Paul Satz contributed significantly to the concept of a threshold by formally providing some general properties for a threshold theory and reserve (Satz 1993). Satz outlines two postulates: A) how greater brain reserve (as measured by premorbid intellectual abilities, academic abilities, or current intelligence) serves as a protective factor to a lesion or pathology and B) how lesser brain reserve serves as a vulnerability factor to lesion or pathology. He also provides subpostulates discussing the effects of aggregate lesions, disease progression, and challenge. Satz' (1993) postulates apply to the topics of delirium.

Unfortunately, it is difficult to define and measure reserve and use the concept to predict risk for delirium. Some researchers propose that education is a surrogate marker for cognitive reserve. The concept of education is multifold, however. Education may signify more neuronal connections, but also it may simply mark better test taking abilities, better social networks, and healthcare. For these reasons, reserve has been extensively studied beyond that of education alone. According to Yacob Stern, Ph.D. at Columbia University, a leader on the topic of cognitive reserve, there are at least two forms of reserve. Reserve can be characterized: (1) as simply "brain reserve" (essentially brain structure) or (2) "as cognitive reserve" represented by neural reserve and neural compensation. Unfortunately, operationally defining both brain and cognitive reserve remains challenging and are topics worthy of longitudinal investigation. Familiarization with the topic of reserve subtypes, as well as discussions on reserve and postoperative disorders is encouraged.

Conclusion Statement

There is growing evidence that delirium can result in reduction of acute and long-term function for some individuals, especially older adults. Delirium can therefore be interpreted as representing an

insult to the brain. The development of interventions to prevent and treat delirium and postoperative cognitive dysfunction is essential with our ever-increasing older adult population.

Synonyms

Dementia and major neurocognitive disorder; Mild cognitive impairment and minor neurocognitive disorder

Definition

Dementia and neurocognitive disorder: In the latest edition of the Diagnostic and Statistical Manual Fifth Edition (DSM-5), the American Psychiatric Association panel subsumed the term “dementia” and its etiologies under the category “major neurocognitive disorder” (MND) or “minor neurocognitive disorder” (mND) based on disease severity (Ganguli et al. 2011; American Psychiatric Association 2013).

Introduction

The American Psychiatric Association retired the term “dementia” and introduced “major neurocognitive disorder” in the fifth edition of the Diagnostic and Statistical Manual (DSM-5) to emphasize the neurological origin of the degenerative disorders (i.e., presence of known structural or metabolic brain disease). Furthermore, authors proposed this amendment to differentiate neurodegenerative diagnoses from other illness with cognitive sequelae (such as psychiatric Axis I disorders), because a temporal relationship between psychiatric illness and cognitive deficits is an exclusion criterion for the diagnosis of dementia (Ganguli et al. 2011).

Recent advances especially in the field of genetics and neuroimaging modalities have generated a variety of potential biomarkers that may predict the presence of a neurodegenerative disease years before diagnosis or full manifestation of the clinical symptoms. Consequently, reformulation of diagnostic criteria for neurodegenerative disorders is underway. For example, in recognition of underlying disease biomarkers, the National Institute on Aging (NIA) and the Alzheimer’s Association have proposed new syndromic stages of Alzheimer’s disease (AD) including preclinical and prodromal stage of AD, which will be discussed in detail in this chapter (Jack et al. 2011).

This entry will include a review the general criteria for neurocognitive disorders (major and minor). The next section will discuss updates to research criteria based on biomarkers to delineate

between syndromic presentations (i.e., preclinical state, mild cognitive impairment [MCI], and dementia). Finally, a brief overview of etiology specific criteria for neurocognitive disorders is included. For detailed etiology (e.g., Alzheimer's disease) review, we encourage readers to refer to that entry in this encyclopedia (also cross-referenced with this entry).

Diagnostic Clinical Criteria

In the latest revision of the DSM (American Psychiatric Association 2013), “major neurocognitive disorder” (MND) replaced dementia while “mild neurocognitive disorder” (mND) was elevated from research criteria only to full clinical use. Etiologies related to the syndrome are included as specifiers for both MND and mND (e.g., due to Alzheimer's disease, Parkinson's disease, frontotemporal lobar degeneration, vascular disease, Lewy body disease, or traumatic brain injury). Delirium remains as a separate category under neurocognitive disorders (American Psychiatric Association 2013).

Minor Neurocognitive Disorder (mND)

The DSM-5 criteria (American Psychiatric Association 2013) are:

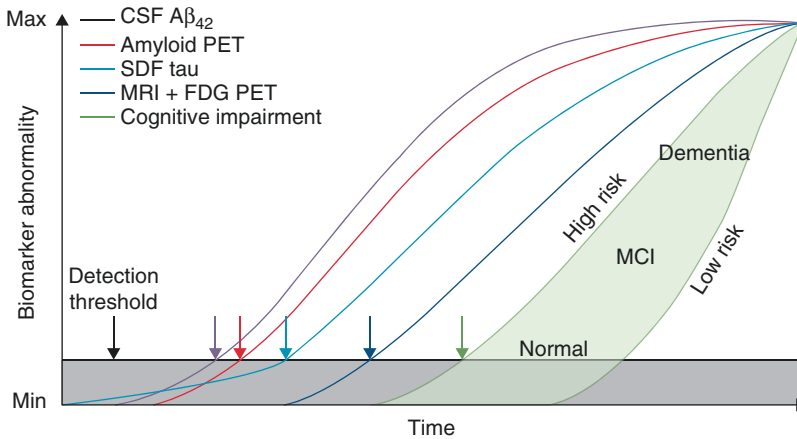

1. Evidence of *modest cognitive decline from a previous level of performance* in one or more cognitive domains (complex attention, executive ability, learning and memory, language, visual constructional-perceptual ability, or social cognition) based on both the criteria listed below.
 - (a) Report or concern for possible cognitive decline by patient, a knowledgeable informant, or by the clinician
 - (b) Quantifiable documentation of cognitive deficits, preferably with standard neuropsychological testing, typically 1.0–2.0 standard deviations (SD) below the mean (or 2.5th–16 percentile) based on a reference population (i.e., comparable with respect to age, gender, education, premorbid functioning, and cultural background)
2. The subtle but measurable cognitive deficit does not impede the individual's independence in instrumental activities of daily living (i.e., complex activities such as driving, medication and financial management, employment), but may require greater effort or compensatory strategies to maintain an independent level of functioning.
3. The cognitive deficits do not occur exclusively in the context of a delirium.
4. The cognitive deficits are not wholly or primarily attributable to another Axis I disorder (e.g., Major depressive disorder, schizophrenia).

Clearly, mND criteria comport with early suggestions for recognizing MCI (Smith et al. 1996; Petersen et al. 1999) but eliminates previously delineated subtypes: amnesic MCI-single domain (primary deficit in memory), amnesic MCI-multiple domains, nonamnesic MCI-single domain, and nonamnesic MCI-multiple domains based on the nature of the cognitive impairment (Petersen et al. 1999).

Major Neurocognitive Disorder (MND)

The DSM-5 criteria (American Psychiatric Association 2013) are:

1. Evidence of significant cognitive *decline from a previous level of performance* in one or more cognitive domains (complex attention, executive ability, learning and memory, language, visual constructional-perceptual ability, or social cognition) based on both the criteria listed below.
 - (a) Report or concern for significant cognitive decline by patient, a knowledgeable informant, or by the clinician
 - (b) Quantifiable documentation of cognitive deficits, preferably with standard neuropsychological testing, typically > 2.0 standard deviations (SD) below the mean (or below the 2.5th percentile) based on a reference population (i.e., comparable with respect to age, gender, education, premorbid functioning, and cultural background)
2. The documented cognitive impairments significantly interfere with the individual's ability to

Dementia and Neurocognitive Disorders, Fig. 1 Model integrating Alzheimer's disease biomarkers and immunohistology. $A\beta$ amyloid β . *FDG-PET* fluorodeoxyglucose Positron Emission Tomography, *CSF* Cerebrospinal Fluid, *MCI* mild cognitive impairment. The gray area denotes abnormal pathophysiological changes below the biomarker detection threshold (black line). In this model, tau pathology precedes other markers at a sub-threshold level. $A\beta$ deposition occurs independently and rises above the biomarker detection threshold (purple and

red arrows), which accelerates detection of tauopathy and CSF tau (light blue arrow). Later still, FDG PET and MRI (dark blue arrow) rise above the detection threshold. Finally, cognitive impairment becomes evident (green arrow) depending on the individual's risk profile (light green-filled area) (Reprinted from *The Lancet Neurology*, 12, Jack, Clifford R., et al. *Tracking pathophysiological processes in Alzheimer's disease: an updated hypothetical model of dynamic biomarkers*, 210(2013), with permission from Elsevier)

independently manage instrumental activities of daily living (ADLs) (i.e., complex activities such as driving, medication, and financial management).

3. The cognitive deficits do not occur exclusively in the context of a delirium.
4. The cognitive deficits are not wholly or primarily attributable to another Axis I disorder (e.g., Major depressive disorder, schizophrenia).

Research Criteria

The National Institute on Aging (NIA) and the Alzheimer's Association have spearheaded research criteria updates based on burgeoning information regarding utility of biomarkers in preclinical detection, tracking disease burden, and evaluating efficacy of treatment interventions in AD (Albert et al. 2011). While these updates have been made to AD research criteria, the pattern of differentiation between the syndromic presentations (preclinical, MCI, and dementia) will be common to most etiologies of dementia.

The following section outlines the criteria for these syndromes. Figure 1 is a model demonstrating the temporal pattern of involvement of biomarkers across clinical diagnoses (Jack et al. 2013).

Preclinical Stage

It is now possible to identify the presence of biomarkers of neurodegenerative disease years before clinical detection of symptoms or syndromes. Biomarkers for AD include genetic, molecular, neuroimaging modalities, and neurocognitive assessment (Knopman 2013; Fields et al. 2011; Smith and Bondi 2013). For AD, genetic markers include causative genetic mutations (Sherrington et al. 1995), as well as susceptibility genes such as apolipoprotein E (APOE) gene (Knopman 2013). Neuroimaging biomarkers include positron emission topography (PET) for amyloid detection and phosphorylated tau accumulation in the brain (Knopman et al. 2013), MRI for hippocampal volume loss, and accumulation of a -beta42 in the cerebrospinal fluid are typically used in AD (Jack et al. 2011). However, presence of neuroimaging biomarkers

is not definitive for future cognitive impairment as shown in a population based sample where over 50% of older adults demonstrated neurodegenerative findings on neuroimaging but demonstrated cognitive normality (Knopman et al. 2013).

Mild Cognitive Impairment

The NIA-Alzheimer's Association work group on MCI (Albert et al. 2011) proposed core criteria for MCI followed by characterization of biomarker data to identify level of certainty for presence of AD etiology. The core MCI features are comparable to mND diagnostic criteria and include:

1. Concern or report of change in level of cognitive function by patient, a knowledgeable informant, or a skilled clinician.
2. Presence of decline from estimated premorbid level of functioning in one or more cognitive domains including memory, executive function, attention, language, and visuospatial skills. If serial cognitive evaluations are present, there must be a progressive decline in scores.
3. Preservation of independence in functional abilities. Patients with MCI may struggle with complex activities such as managing finances and preparing a meal but are generally able to function independently with minimal aids or assistance.
4. Absence of dementia: Observed changes should not significantly impede social or occupational activities.

Dementia

Similar to MCI core symptoms, the NIA-Alzheimer's Association work group provided diagnostic guidelines for core dementia criteria (McKhann et al. 2011):

1. Interfere with the ability to function at work or at usual activities
2. Represent a decline from previous levels of functioning and performing
3. Are not explained by delirium or major psychiatric disorder
4. Quantifiable impairment in two or more cognitive domains

The guidelines elucidate on criteria for prominent cognitive and behavioral symptoms observed in dementia (minimum of two of the following (McKhann et al. 2011)):

- (a) Memory: Impairment in encoding and recall of recent information. Individuals may ask repetitive questions, frequently misplace belongings, forget appointments, or get lost on a familiar route.
- (b) Executive function: Impaired reasoning and difficulty completing complex tasks. Individuals may demonstrate poor decision-making, poor understanding of safety risks, and may be unable to manage finances or plan complex activities.
- (c) Visuospatial functioning: Individuals may have object agnosia, impaired face recognition, simultanagnosia and alexia, difficulty operating simple implements, or demonstrate difficulty finding objects despite good acuity.
- (d) Language (speaking, reading, and writing): Individuals may have word retrieval difficulty while speaking, speech may be hesitant, and writing may involve spelling or grammatical errors.
- (e) Changes in personality, behavior, or comportment – symptoms include: Individual demonstrates uncharacteristic mood fluctuations such as agitation, impaired motivation, initiative, apathy, loss of drive, social withdrawal, and decreased interest in previous activities, loss of empathy, compulsive or obsessive behaviors, and socially unacceptable behaviors.

Role of Neuropsychological Assessment

The strongest predictive power for progression to dementia is demonstrated by cognitive biomarkers (Fields et al. 2011). Neuropsychological assessments can provide measurable data regarding cognitive performance comparing the individual to a normative sample (ideally based on age, education, gender, and ethnicity) and accounting for confounding factors such as preexisting areas of cognitive weakness, preexisting mood disorder, and motivational factors. Neuropsychological evaluation can assist with diagnostic clarification

and to establish a baseline evaluation of cognitive function, should clinical features in the future warrant a reevaluation. These tests may be of greatest value in mild cognitive impairment or early dementia states as cognitive performance in most domains deteriorates due to eventual disease encroachment on neighboring neural structures and can be difficult to differentiate etiology at later stages of the disease.

Neurocognitive assessments may broadly use the heuristic “cortical” or “subcortical” to classify dementia syndromes based on typical pattern of cognitive impairment (Whitehouse 1986; Salmon and Filoteo 2007). A typical “cortical” dementia such as AD can be characterized by deficits in memory, language, and visuospatial and executive functioning. “Subcortical” dementias (vascular dementia or Parkinson’s disease) typically present with motor dysfunction in addition to reduced processing speed and prominent early deficits in executive function, visuosperceptual and constructional abilities. However, from a neuropathological perspective, these profiles are often mixed as patients with “cortical” dementia will often demonstrate abnormal neuropathology in “subcortical” regions, which speaks to the potential presence of neuropathological biomarkers before clinical symptom presentation as seen in Fig. 1. Neurocognitive performance in frontotemporal dementia and dementia due to Lewy body disease (LBD) may demonstrate a mixed cortical/subcortical pattern.

Etiologies

Alzheimer’s Disease

Majority of individuals diagnosed with dementia will demonstrate etiology consistent with AD. Neuropathology reveals neuronal loss associated with presence of neuritic plaques (deposition of amyloid) and neurofibrillary tangles (accumulation of tau abnormalities) (McKhann et al. 2011).

MCI or mND due to AD (Research Criteria)

The individual meets criteria for MCI or minor neurocognitive disorder as outlined previously

(Ganguli et al. 2011; American Psychiatric Association 2013). A majority of patients with MCI due to AD demonstrate prominent impairment in episodic memory (i.e., amnesic MCI), but other patterns of cognitive impairment can also progress to AD over time (e.g., multidomain MCI, executive dysfunction/nonamnesic MCI, or visual spatial impairments in the posterior cortical atrophy variant of AD). Presence of a positive topographic (e.g., MRI evidence of medial temporal atrophy, or FDG PET evidence of age-adjusted temporoparietal hypometabolism) or molecular neuropathology of AD (e.g., lower CSF A β -42 and raised CSF tau measures) when available can further characterize the pattern of MCI (Albert et al. 2011). To further classify patients based on level of certainty of etiology, the following research criteria for AD are proposed (Albert et al. 2011):

1. MCI of a neurodegenerative etiology: Low confidence of AD etiology
 - (a) Core features of MCI are present.
 - (b) Negative or ambiguous biomarker evidence (topographic or molecular biomarkers).
2. MCI of the Alzheimer type: Intermediate confidence of AD etiology
 - (a) Core features of MCI are present.
 - (b) Presence of one or more topographic biomarkers (MRI evidence of medial temporal atrophy or FDG PET pattern of hypometabolism in the temporoparietal region).
 - (c) Absence of molecular biomarker information.
3. Prodromal Alzheimer’s dementia: High confidence of AD etiology
 - (a) Core features of MCI are present.
 - (b) Presence of molecular neuropathology of AD (e.g., lower CSF A β -42 and raised CSF tau measures).
 - (c) Further increased certainty with presence of a topographic biomarker. However, absence or equivocal findings are still consistent with the highest level of certainty that the individual will progress to AD dementia over time.

Dementia due to AD (or MND Due to AD)

The most common syndromic profile of AD dementia is an amnesic presentation. The deficits should include impairment in learning and recall of recently learned information in addition to significant impairments in other cognitive domains as outlined in the dementia criteria described above. McKhann and colleagues (2011) also proposed levels of certainty in AD diagnosis characterized by neuropathological biomarkers, primarily used in research settings (McKhann et al. 2011).

1. Probable AD dementia:

Meets clinical and cognitive criteria for dementia given above with primary amnesic presentation. There is no evidence of alternative diagnoses, specifically, no significant cerebrovascular disease. In these individuals, presence of any *one* of the three features increases certainty of AD:

(a) *Documented decline*: Subsequent evaluations demonstrate progressive cognitive decline based on a knowledgeable informant or cognitive testing (brief mental status screens or neuropsychological testing).

(b) *Biomarker positive*: Has one or more of the following supporting biomarkers.

(i) Low cerebrospinal fluid A β 42, elevated cerebrospinal fluid tau or phospho tau

(ii) Positive amyloid PET imaging

(iii) Decreased FDG uptake on PET in temporoparietal cortex

(iv) Disproportionate atrophy on structural MR in medial temporal lobe (especially hippocampus), basal and lateral temporal lobe, and medial parietal isocortex

(c) *Mutation carrier*: Meets clinical and cognitive criteria for AD dementia and has a proven AD autosomal dominant genetic mutation (PSEN1, PSEN2, and APP).

2. Possible AD dementia.

(a) *Atypical course*: Evidence for progressive decline is lacking or uncertain but meets other clinical and cognitive criteria for AD dementia

(b) *Biomarkers obtained and negative*: Meets clinical and cognitive criteria for AD dementia but biomarkers (CSF, structural or functional brain imaging) do not support the diagnosis

(c) *Mixed presentation*: Meets clinical and cognitive criteria for AD dementia but there is evidence of concomitant cerebrovascular disease; this would mean that there is more than one lacunar infarct; or a single large infarct; or extensive and severe white matter hyperintensity changes; or evidence for some features of dementia with Lewy bodies (DLB) that do not achieve a level of a diagnosis of probable DLB.

3. Not AD Dementia

(a) Does not meet clinical criteria for AD dementia.

(b) Has sufficient evidence for an alternative diagnosis such as HIV, Huntington's disease, or others that rarely, if ever, overlap with AD.

4. *Pathologically proven AD dementia*. Meets clinical and cognitive criteria for probable AD dementia during life AND is proven AD by pathological examination.

Vascular Dementia

In 2011, the American Heart Association and American Stroke Association workgroup jointly published consensus definitions and recommendations for the vascular contributions to mild cognitive impairment and dementia (Gorelick et al. 2011). Vascular pathology includes ischemic and/or hemorrhagic cardiovascular disease (CVD), other cerebrovascular insults (subclinical brain infarction [SBI]), multiple small vessel disease, or cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL).

Vascular MCI

1. Probable VaMCI:

(a) Meets core MCI criteria (Albert et al. 2011).

(b) Presence of clear temporal relationship between a vascular event (e.g., clinical stroke) and onset of cognitive deficits.

- (c) Onset of cognitive deficits or relationship in the severity and pattern of cognitive impairment and the presence of diffuse, subcortical cerebrovascular disease pathology (e.g., as in CADASIL).
 - (d) No history of gradually progressive cognitive deficits before or after the stroke that suggests the presence of a nonvascular neurodegenerative disorder.
2. Possible VaMCI:
- (a) Meets core MCI criteria (Albert et al. 2011).
 - (b) Presence of cognitive impairment and imaging evidence of cerebrovascular disease.
 - (c) *No* clear relationship (temporal, cognitive pattern or severity) between the demonstrated vascular disease (e.g., silent infarcts, subcortical small-vessel disease) and onset of cognitive deficits.
 - (d) There is insufficient information for the diagnosis of VaMCI (e.g., clinical symptoms suggest the presence of vascular disease, but no CT/MRI studies are available).
 - (e) Severity of aphasia precludes proper cognitive assessment. However, patients can be classified as probable VaMCI with documented normal cognitive function (prior cognitive evaluations) before the vascular event that resulted in aphasia.
 - (f) There is evidence of other neurodegenerative diseases or conditions in addition to cerebrovascular disease that may affect cognition, such as:
 - (i) A history of other neurodegenerative disorders (e.g., Parkinson disease, progressive supranuclear palsy, dementia with Lewy bodies).
 - (ii) The presence of Alzheimer's disease pathology is confirmed by biomarkers (e.g., PET, CSF, amyloid ligands) or genetic studies (e.g., PS1 mutation).
 - (iii) A history of active cancer or psychiatric or metabolic disorders that may affect cognitive function.
3. Unstable VaMCI:
- Subjects with the diagnosis of probable or possible VaMCI whose symptoms revert to

normal should be classified as having “unstable VaMCI.”

Vascular Dementia (VaD)

Individuals meet criteria for core features of dementia (decline in cognitive function and deficit in two cognitive domains) (McKhann et al. 2011) with sufficient severity to affect a person's ADLs. In addition, the impairments in ADLs are independent of the motor/sensory sequelae of a vascular event (Gorelick et al. 2011). Criteria for probable and possible VaD are similar to those stated for VaMCI, but these individuals demonstrate significant impairment in activities of daily living to meet criteria for dementia (vs. MCI criteria).

Lewy Body Disease (LBD)

Lewy bodies are intraneuronal inclusions primarily made of alpha-synuclein (McKeith et al. 2005). High concentration of inclusions in substantia nigra are associated with Parkinsonism (e.g., idiopathic Parkinson's disease), where subsequent onset of dementia is termed Parkinson's disease dementia (PDD). On the other hand, presence of inclusions in the cortex can lead to Lewy body disease (LBD), which can refer to any syndromic presentation of Lewy body (preclinical, MCI, and dementia). Dementia with Lewy Body (DLB) refers solely to the dementia syndrome due to LBD.

Mild Cognitive Impairment of LBD

Presence of REM Sleep Behavior disorder (RBD), which was included in the last revision of DLB criteria (McKeith et al. 2005), has demonstrated 52.4% increased 12-year risk of developing DLB (Postuma et al. 2009) and is thought to be associated with presence of synucleinopathy (McKeith et al. 2005). Therefore, presence of RBD and cognitive decline can be a type of MCI due to LBD and may include other cardinal symptoms such as Parkinsonism or visual hallucinations. The cognitive profile of MCI with LBD shows prominent visuospatial and/or attention deficits, nonamnestic profile.

Dementia with Lewy Body Disease (DLB)

International diagnostic criteria (McKeith et al. 2005) include:

1. Central feature (for diagnosis of possible or probable DLB): Presence of dementia (i.e., progressive cognitive decline which significantly interferes with daily functioning)
 - (a) Prominent or persistent memory impairment may not necessarily occur in the early stages but is usually evident with progression.
 - (b) Deficits on tests of attention, executive function, and visuospatial ability may be especially prominent.
2. Core features (Probable DLB: 2 features, Possible DLB: 1 core feature)
 - (a) Fluctuating cognition with pronounced variation in attention and alertness
 - (b) Recurrent visual hallucinations that are typically well formed and detailed
 - (c) Spontaneous features of Parkinsonism
3. Suggestive features (Probable DLB: at least 1 suggestive feature and at least 1 core feature while possible DLB includes: at least 1 suggestive feature in the absence of core features)
 - (a) REM sleep behavior disorder
 - (b) Severe neuroleptic sensitivity
 - (c) Low dopamine transporter uptake in the basal ganglia demonstrated by SPECT or PET imaging
4. Supportive features (commonly present but not proven to have diagnostic specificity)
 - (a) Repeated falls and syncope
 - (b) Transient, unexplained loss of consciousness
 - (c) Severe autonomic dysfunction, e.g., orthostatic hypotension, urinary incontinence
 - (d) Hallucinations in other modalities
 - (e) Systematized delusions
 - (f) Depression
 - (g) Relative preservation of medial temporal lobe structures on CT/MRI scan
 - (h) Generalized low uptake on SPECT/PET perfusion scan with reduced occipital activity
 - (i) Abnormal (low uptake) MIBD myocardial scintigraphy
 - (j) Prominent slow wave activity on EEG with temporal lobe transient sharp waves
5. A diagnosis of DLB is less likely:
 - (a) With evidence of cerebrovascular disease (focal neurologic signs or on brain imaging)
 - (b) In the presence of any other physical illness or brain disorder sufficient to account in part or in total for the clinical picture
 - (c) If the parkinsonism only appears for the first time at a stage of severe dementia
6. Temporal sequence of symptoms:

DLB should be diagnosed when dementia occurs before or concurrently with parkinsonism (if it is present). The term Parkinson disease dementia (PDD) should be used to describe dementia that occurs in the context of well-established Parkinson disease. In a clinical practice setting, the term that is most appropriate to the clinical situation should be used and generic terms such as LB disease are often helpful.

Frontotemporal Lobar Degeneration

Frontotemporal lobar degeneration (FTLD) is a heterogeneous collection of diagnoses (Pick's disease or Primary Progressive Aphasia) and syndromes (FTD with motor neuron disease, corticobasal degeneration), and etiologies (e.g., tauopathies versus TDP-43 proteinopathies) (Smith and Bondi 2013; Josephs 2008).

Frontotemporal dementia (FTD) refers to the dementia phase of FTLD. Currently, the three main recognized phenotypes of FTD are: behavioral variant-FTD (bvFTD), semantic dementia (SD), and primary progressive aphasia (PPA). Furthermore, PPA can be subclassified into three variants: logopenic (lvPPA), semantic (svPPA), and agrammatic (agPPA) or nonfluent progressive aphasia (PNFA) (Gorno-Tempini et al. 2011). Pathology for semantic and agrammatic variants of PPA are largely consistent with tauopathies and TDP-43 suggestive of FTLD spectrum disorders, while the lvPPA variant is strongly associated with AD pathology (Josephs 2008). The diagnosis of FTD is challenging due to the complexity and heterogeneity in FTLD. Individuals may be misdiagnosed as psychiatric disorder or AD early in the disease course.

Preclinical stage of FTD involves being a carrier of genetic mutations associated with FTD such as MAPT, GRN, and C9ORF72 genes (Rohrer et al. 2013). The behavioral variant FTD presents with impairments in "social cognition"

including behavioral disinhibition, apathy, loss of empathy, perseverative or compulsive behavior, and hyperorality or dietary changes early in the disease process (Piguet et al. 2011). Other variants of FTD demonstrate predominant language or speech deficits. Core features of semantic PPA include impaired naming and single-word comprehension. Logopenic variant of PPA is characterized by hesitant speech (impaired single-word retrieval in speech) and impaired repetition of complex sentences. Core features of the agrammatic variant of PPA are agrammatism in speech or written output and reduced comprehension (Gorno-Tempini et al. 2011).

Conclusion

Recent advancements in biomarkers in varied scientific fields including molecular genetics, neuroimaging, behavioral neurology, and neuropsychology have accelerated research and shifted nomenclature in neurodegenerative disease. Identification of these biomarkers has led to a clear articulation of the distinction between syndromic phases of neurodegenerative disease across most dementia etiology (preclinical or asymptomatic phase, mild cognitive impairment, and dementia). It is now possible to have biomarkers of neurodegenerative disease without being (and possibly never becoming) symptomatic. These changes will be instrumental in future research focused on prevention, early detection, or delayed progression to dementia (Smith and Bondi 2013).

Cognition Thinking skills or abilities that include attention, processing speed, working memory, language, visuospatial skills, language, and executive functioning

Introduction

As an age group, older adults have a smaller prevalence rate for depression compared to middle-aged adults that continues to decrease with advancing age (e.g., Byers et al. 2010). Although the prevalence of depression is lower with older age, the effects of depression in the daily life of patients may be greater with advancing age due to other factors that make older adults a more vulnerable population (e.g., decrease in physical health, cognitive changes due to normal aging, comorbidity with other health/mental health disorders). In particular, cognitive declines due to age-related changes in the brain may compound the effects of depression on the daily functioning of older adults.

A review of the rate of comorbid depression and cognitive impairment in older adults estimated it to double every 5 years after the age of 70, with over 25% of community dwelling 85-year olds living with comorbid MDD and cognitive impairment (Ellen and David 2010). Lee et al. (2007) noted that a high number of depressed older adults present with “mild cognitive impairment,” defined in the literature as the stage between normal aging and dementia. Moreover, these cognitive impairments that accompany an acute depressive episode continue long after the remission of depressive symptoms (Ellen and David 2010; Lee et al. 2007). Furthermore, in a recent review and meta-analysis by Diniz et al. (2013), they determined that late-life (geriatric) depression is in fact associated with a higher risk of dementia, including vascular and Alzheimer's disease.

This encyclopedia entry will first review the neurobiological effects of depression in older adults. Then it will describe the effects of

Depression and Cognition

Synonyms

Mood disorder; Neuropsychology

Depression A psychiatric disorder that includes symptoms of sad mood, hopelessness, poor sleep and appetite, guilt or worthlessness, low energy, and severe suicidal thoughts

depression on global cognitive functioning as well as specific cognitive domains including attention and working memory, processing speed, spatial skills, language, memory, and executive functioning. Afterward, the special considerations of age moderating the impact of depression on cognition, dementia/pseudodementia, and the effects of antidepressants on cognition will be covered.

Neurobiology of Depression in Older Adults

The impact of depression on cognition in older adults and in other age groups has been hypothesized to be mediated by the neurobiological effects of depression in the brain. In fact, there are several different hypotheses about how this mediation occurs. For instance, there is evidence that older adults with depression have a higher prevalence risk for cardiovascular disease and dementia. There is a “vascular depression hypothesis” (e.g., Sneed and Culang-Reinlieb 2011) that theorizes that heart disease may cause, be a result of, or prolong depression in older adults. Furthermore, this link has also been connected to brain-related changes. For instance, MRI studies have found significant relations between ischemic lesions in the brain and depression severity or diagnosis (Sneed and Culang-Reinlieb 2011). Specifically, for late-life depression, the vascular depression hypothesis is specific regarding the location of deep white matter hyperintensities (DWMH) within frontostriatal circuits that are involved in executive functioning (Sneed and Culang-Reinlieb 2011). In the update by Sneed and Culang-Reinlieb (2011), the authors reported other MRI studies that have found DWMH, reduced volume in frontal and sub-cortical areas, neuronal abnormalities within the prefrontal cortex, and reduced neuronal density in the dorsolateral and ventromedial areas of the caudate nucleus. Sneed and Culang-Reinlieb concluded that neuronal abnormalities in some LLD are present in the frontal and striatal brain regions, which is consistent with the vascular depression hypothesis.

In a review by Byers and Yaffe (2011), they reported several other neurobiological factors related to how depression can impair cognition

through changes in the brain in older adults. These factors include increased levels of cortisol and hippocampal atrophy, increased deposition of β -amyloid plaques, inflammatory changes, and deficits of nerve growth factors. In relation to greater cortisol, higher levels of depression would cause the HPA axis to increase glucocorticoid production that would damage the hippocampus and result in a downregulation of glucocorticoid receptors ultimately resulting in a vicious cycle leading to impairments in cognition. As for beta-amyloid relationships, Byers and Yaffe hypothesized that depression may increase β -amyloid production due to a stress response to depression resulting increase of cortisol. Although the research findings are mixed, they reported some evidence that depression with a high ratio of plasma β -amyloid peptide 40 (A β 40) to A β 42 has been associated with memory, visuospatial abilities, and executive function deficits. As for the inflammation hypothesis, Byers and Yaffe stated that depression is associated with increased levels of cytokines that can lead to a decrease in inflammatory and immunosuppressant regulation, resulting in inflammation of the central nervous system that would ultimately result in cognitive impairment and an increase risk of dementia. The increase in cytokines may also interfere with serotonin metabolism that can lead to decrease in synaptic plasticity and hippocampal neurogenesis. Lastly, they mentioned problems with nerve growth factors, specifically, such as brain-derived neurotrophic factor (BDNF). They stated that impairments in BDNF functioning have been found in animal and human models of depression that have been linked to declines in cognitive functioning.

In all, there seems to be multiple pathways of how neurobiological changes due to depression can then impact cognitive functioning and increase the risk of cognitive disorders, including dementia. More research is needed in this area to determine which pathways are most related to cognitive decline in geriatric depression.

Depression on Cognition in Older Adults

Mental Status

Mental status is also commonly referred to as global cognitive functioning as is typically

measured using the mini mental status exam. Older adults with depression have been found to have lower MMSE scores than healthy older adults (Pantzar et al. 2014). But this may also be related to the depressed group being older (healthy control age mean = 72.6 years, mild depression mean = 78.6 years, and moderate-severe depression mean = 75.9 years) and having less years of education (healthy control education mean = 12.1 years, mild depression mean = 10.7 years, and moderate-severe depression mean = 10.5 years). However, in a study by Rapp et al (2005), they also found significantly lower MMSE scores in the older adults with recurrent or late-onset depression versus those with no history of or current depression. These diagnostic groups did not significantly differ in age, years of education, nor gender.

In a 13-year longitudinal study, depression at baseline predicted decline in general cognitive functioning using the MMSE even after controlling for covariates that include age, sex, and years of education (van den Kommer et al. 2013). Using the Cognitive Abilities Screening Instrument (CASI) as a measure of global cognition, greater depression severity is related to poorer cognitive performance even after controlling for age and education in elderly Chinese males (Tzang et al. 2015).

Thus, research indicates substantial evidence that global cognitive functioning is impaired in older adults with depression.

Attention and Working Memory

Simple attention can be defined as the limited capacity to passively hold information in the mind such as repeating a list of numbers in the same order spoken as in Digit Span Forward from the Wechsler Adult Intelligence Scale. For this task, no effects of depression on attention were found in American (Pantzar et al. 2014) and Chinese older adult samples with depression (Tzang et al. 2015).

Working memory is related to general attention but includes active (versus passive) manipulation specifically reversing the order of digits, such as in Digit Span Backward. In Digit Span Backward, no effects of depression were found in American (Pantzar et al. 2014) and Chinese older adult

samples (Tzang et al. 2015). In another study that used the N-back task as a measure of working memory, the depression group performed worse than healthy older adults (Nebes et al. 2000). This deficit was also seen in older adults whose depression remitted compared to older adults without any history of depression (Nebes et al. 2000).

Processing Speed

Processing speed is broadly defined as the rate at which an individual can process incoming information in order to carry out a task (e.g., Nebes et al. 2000). While normal aging has been known to slow down the speed of information processing for a majority of older adults (Salthouse 1996), this cognitive domain is significantly more impaired in older adults with depression (Dybedal et al. 2013; Ellen and David 2010; Pantzar et al. 2014) compared to healthy older adults. Using the trail-making task, Rapp et al. (2005) found no significant processing speed differences in the easier task of Trail A but did find differences in diagnostic groups on a harder task of Trail B, where older adults with no history or no current depression were faster than older adults with recurrent depression and slowest with older adults with late-onset geriatric major depression (when the age of onset for a first episode of depression occurs is 65 years old or older). Another study also concluded slowed speed of information processing persists even after the clinical symptoms of depression remit in older adults (Thomas and O'Brien 2008). Butters et al. (2004) and Dybedal et al. (2013) also determined that late-life depression is associated with a slower speed of information processing. In fact, Sheline et al. (2006) concluded that processing speed has emerged as the most salient cognitive impairment in older adults diagnosed with depression.

Longitudinal studies have also found associations between depression and slower processing speed in older adults. For instance, a 9-year longitudinal study examined the impact of depression on cognitive functioning in older women (Rosenberg et al. 2010) found that baseline depression ratings were strongly associated with impairments on measures of psychomotor speed. Another longitudinal study examining a large

cohort of older adults found that the level of depression at baseline predicted the rate of decline in speed of information processing, such that more severe depression led to slower speed consistently during the 13-year follow-up period (van den Kommer et al. 2013). These results remained even after controlling for age, sex, and education. Notably, the slower processing speed at baseline also predicted worsening of depression severity over time.

Salthouse has theorized that the effects of declines in cognitive functioning such as memory and executive functioning are mediated by slowed processing speed in older adults (Salthouse 1996). This also appears to be true in older adults with depression. For instance, Nebes and colleagues (2000) conducted hierarchical regression analyses that depression explained a significant amount of neuropsychological variance on global cognition, visuospatial construction, and verbal and visual memory. However, when processing resources (working memory as measured by then-back task and processing speed as measured by digit symbol substitution test) were removed first, depression no longer accounted for a significant amount of neuropsychological performance. Butters et al. (2004) also determined that late-life depression is associated with a slower speed of information processing, which then impacts all other cognitive domains including memory, language, visuospatial skills, and executive functioning. In addition, Sheline et al (2006) found that processing speed mediated the impact of other factors including age, education, race, depression severity, and vascular risk factors on working memory, episodic memory, language processing, and executive functioning (Sheline et al. 2006). However, in a relatively more recent 4-year longitudinal study, Köhler et al. (2010) found that although processing speed partially mediated some of the deficits in their depressed older adult participants, it did not adequately account for the differences between them and the normal control group participants.

Visuospatial Ability

In general, there are only a few studies that examined spatial ability in geriatric depression. Using

simple drawings and block design, Butters et al. (2004) found significant differences between older adults with late-life depression and healthy older controls. Nebes and colleagues (2000) found depression group differences (recurrent/current depression, remission from depression, and no history of depression) on a block design task. Notably, when controlling for working memory or processing speed, the effects of depression on the visual-construction task were no longer significant. In a timed, visual pattern-matching task, there was no difference in correct responses between older adults with depression and those without depression, but those with depression had overall slower reaction time compared to the controls (Hofman et al. 2000). Incidentally, when controlled for MMSE scores, the older adults with depression had similar reaction times on this task as those with dementia. In a mental rotation task, no differences were found between older adults with depression and were not on antidepressants compared to healthy older adults (Pantzar et al. 2014).

In sum, these studies indicate limited evidence of the association of depression with impairments in visuospatial and visuo-construction skills.

Language

As in visuospatial ability, relatively less research has been conducted in examining the relation of depression and language, compared to other cognitive domains in older adults. Dybedal and colleagues (2013) found that after controlling for age, there were no differences between the older adults with versus those without depression on animal or letter fluency. Similarly, Butters et al. (2004) found impaired language performance of older adults with late-life depression compared to healthy older adults for a task of verbally naming pictures but no differences on letter or animal fluency. Furthermore (Rapp et al. 2005), no diagnostic group differences were found between older adults with recurrent depression, late-onset depression, remitted depression, and no history of depression. In conclusion, the limited research in this cognitive domain indicates that there is generally little to no relationship between depression and language ability.

Learning and Memory

Memory has been one of the most studied cognitive domains for depression in older adults as well as other age groups. Many studies have focused on verbal memory and most commonly used word lists or stories to measure learning, short- and long-term recall, and recognition. In older adults, many studies have found poorer memory performance in depressed groups versus healthy controls (Butters et al. 2004; Pantzar et al. 2014). For instance, Rapp et al. (2005) used a 10-item list learning task and found that older adults with no history of depression and no current depression performed significantly better on learning, delayed recall, and recognition compared to older adults with recurrent depression and those with late-onset depression.

Studies have also found that poorer verbal memory performance is related to increased severity levels of depression. A relatively recent study (Mesholam-Gately et al. 2012) examined learning and memory performance in older adults with two severity types of depression using the California Verbal Learning Test. The study compared older adults with minor depression (defined as “subsyndromal depression that meets duration criteria but not symptom count criteria for Major Depressive Episode”) (Mesholam-Gately et al. 2012, p. 197), to those meeting criteria for major depressive disorder, and healthy control participants. The findings indicated individuals with major depressive disorder performed significantly worse than older individuals with minor depressive symptomatology, who in turn performed comparably to normal control participants. Similarly, a population-based study found that only older adults with moderate to severe levels of depressive symptomatology had verbal memory impairments compared to healthy controls (Pantzar et al. 2014). However, no differences were found between the older adults with mild depression from the healthy controls.

Longitudinal studies have also indicated a predictive relationship between depression and verbal memory. For instance, in a 9-year longitudinal study examining the impact of depression on cognitive functioning in older women, Rosenberg et al. (2010) found that baseline depression ratings

were strongly associated with greater verbal memory declines in a list learning task, over time.

However, not all studies have reported significant results. For example, Butters et al. (2004) found no group differences with older adults with late-life depression compared to healthy older adults on verbal memory performance for story and list learning tasks. Consistent with this, Dybedal et al. (2013) conducted a more recent study that also found no verbal memory differences on a list learning task between those with late-life depression and healthy older adults after controlling for age.

In comparison to verbal memory, there are relatively fewer studies that examined the relation between depression and spatial memory in older adults, compared to verbal memory. Burt et al. (2000) found that within a group of patients diagnosed with major depressive disorder, patients older than 60 years showed significantly greater impairments on a delayed memory task of visuospatial construction and organization (Rey complex figure test) compared to younger patients. Additionally, depression severity was significantly associated with poor delayed recognition. In contrast, Dybedal et al. (2013) found no visual memory differences between those with late-life depression and healthy older adults after controlling for age.

In sum, while there are substantial evidences that depression and depression severity impair verbal memory in older adults, the findings are not always consistent. Conflicting findings can be due to differences in sample size, medication, types of memory task, and use of covariates in the data analyses. In visual memory, the research is relatively sparse and indicates further need of more research in this area.

Executive Functioning

Executive functioning is a broad term used to refer to higher-order cognitive skills involved in carrying out goal-directed behavior. The skills involved in executive, goal-directed behavior include, but are not limited to, identifying future goals, developing a plan, reasoning, solving complex problems, choosing among various alternatives, and inhibiting irrelevant responses. Many studies have found executive function to be one of

the most profoundly impacted cognitive domains in depressed older adults (Lockwood et al. 2002; Pantzar et al. 2014; Rapp et al. 2005).

There are many studies that have found significant relationships between depression and poorer executive functioning in older adults. In particular, the performance of older adults with depression on executive measures revealed impairments in response to initiation and inhibition (e.g., Dybedal et al. 2013), active switching (e.g., Butters et al. 2004; Dybedal et al. 2013; Pantzar et al. 2014), and problem solving using error feedback (Lockwood et al. 2002). Longitudinal studies have also shown declines in executive functioning in geriatric depression such as in a 9-year longitudinal study that examined the impact of depression on cognitive functioning in older women. Rosenberg et al. (2010) found that, in terms of subtypes of depression, both early and late onset of depression in the elderly, has also been linked to executive functioning deficits (e.g., Butters et al. 2004). However, the decline in executive functioning has been found to be greater for older adults with late-onset than the early-onset cohort (Herrmann et al. 2007).

Notably, antidepressant treatment and remission studies have also found that executive dysfunction can still occur in older adults. Dybedal et al. (2013) found that older adults with late-onset depression were still significantly impaired executive function compared to healthy older adults even after controlling for processing speed. Similarly, Elderkin-Thompson et al. (2007) found that older adults continued to show residual deficits in executive functioning even after successful treatment of depression. Interestingly, even when the depression is in full remission, Thomas and O'Brien (2008) found declines in executive functioning in older adults.

In all, there is substantial evidence that depression impairs executive functioning in older adults and may continue to persist despite the use of antidepressants.

Special Considerations: Pseudodementia Versus Depression

Understanding the cognitive sequelae of geriatric depression is especially challenging because of

the age-related changes in the brain that may contribute to cognitive deficits or to the etiology of the depression itself. Moreover, many of the affective, behavioral, and cognitive issues among the elderly are often the result of an interaction between multiple psychiatric, neurological, and medical conditions (Ellen and David 2010).

A critical clinical question is whether cognitive deficits associated with depression resolve following remission of the depressive episode. A growing body of evidence suggests the presence of a syndrome of cognitive impairment that is reversible after the successful treatment of depression in older adults. This syndrome, popularly termed "pseudodementia" or "reversible dementia," can masquerade as dementia and, as such, is an important consideration in the differential diagnosis of dementia in the aging population (Ellen and David 2010). It is estimated that 18–57% older adults with depression present with a reversible syndrome of dementia that resolves upon alleviation of depressive symptoms (Alexopoulos and Meyers 1993). However, it is extremely challenging to reliably differentiate between geriatric depression and reversible or irreversible dementia.

This issue becomes more complicated because cognitive impairments that can result from dementia can manifest with depressive symptoms as well (Kang et al. 2014). Some researchers have suggested that depressive pseudodementia may be a transient state that eventually progresses to dementia. For example, a recent review suggested that late-life depression is a strong predictor for the progression of reversible dementia to an irreversible one (Kang et al. 2014). This is also consistent with the meta-analysis of 23 studies conducted by Diniz and colleagues (2013), which found that geriatric depression was significantly associated with higher risk of all-cause dementia, including vascular and Alzheimer's disease.

Thus, the question of pseudodementia and depression remains unclear. While some researchers have concluded that depression can mimic dementia, others state that it can also be a risk factor for dementia in late life and that depression is likely an early manifestation of dementia

rather than a risk factor for the neurodegenerative disease Panza et al. (2010).

Age Moderating the Impact of Depression on Cognition

In the adult depression literature, researchers have reported greater relationships between depression and cognitive impairment in the older adult groups compared to the younger adult age groups. Sparse research indicates some evidence that this pattern also exists in the old age group. For instance, Pantzar et al. (2014) found that the effect size of depression on cognitive performance in depressed sample was greater for old-old age group (85 years and older) than young-old age group (60–84 years old).

Although there are several hypotheses of how depression causes neurobiological changes that can result on cognitive decline, there is sparse data of how chronicity of the depression affects the brain and cognitive performance in older adults. Perhaps part of that problem is because chronicity is so intimately related to age and age is a significant factor of the relation between depression and cognition, especially in old age.

Effects of Antidepressants on Cognition in Geriatric Depression

In general, typical pharmacological intervention for depression includes the use of tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors (MAOIs). Additionally, newer classes of antidepressant drugs including selective serotonin reuptake inhibitors (SSRIs), serotonin-norepinephrine reuptake inhibitors (SNRIs), and medications acting on noradrenergic and dopaminergic neurotransmission [e.g., bupropion (Wellbutrin)] are increasingly being used for treatment. However, when treating late-life depression, it is important to pay special attention to aging considerations for this patient population. There is evidence to suggest that age-associated changes can alter the pharmacodynamics and pharmacokinetics of drugs and dictate the type of medication and dosage that will be safe and effective for the elderly.

Researchers generally agree that the newer antidepressants including SSRIs and SNRIs have

been shown to be relatively safer for older adults (e.g., Culang et al. 2009). Some researchers postulate that the use of antidepressants in elderly patients can improve memory and other cognitive domains through their effects on improving the depressive symptoms and by the pharmacodynamic effects that are mediated by neurophysiological changes in the brain (Bali et al. 2016). For instance, Doraiswamy and colleagues (2003) pooled data from two double-blind 12-week studies that included 444 older adults with depression comparing sertraline, fluoxetine, and nortriptyline. They found that there was an improvement for short-term memory and psychomotor speed for those patients whose depression improved (responders) and had lower anticholinergic side effects. In order of the highest correlations between depression improvement and cognitive improve, it was sertraline, then nortriptyline, and then fluoxetine.

In contrast, other studies have shown that cognitive deficit either persists or still ensues after successful treatment for depression. For instance, Nebes et al. (2003) conducted a randomized double-blind design examining the effects of an SSRI (paroxetine) or a tricyclic antidepressant (nortriptyline) on cognition in older patients with depression. They found that after 12 weeks of treatment, their cognitive functioning did not improve more than the control group, suggesting that the impairment in cognition due to depression still persists despite response to antidepressants. Culang et al. (2009) conducted an 8-week, double-blind, placebo-controlled study that examined the effects of SSRI, specifically, citalopram, on neuropsychological functioning on older adults with late-life depression. They found that those who did not respond to the citalopram (depression symptoms did not improve), declines were found on verbal learning and memory and in psychomotor speed. For those who did respond to the medication, they improved in visuospatial functioning compared to nonresponders but not better than those in the placebo group.

In a recent longitudinal study by Saczynski and colleagues (2015), over 3000 adults from the National Health and Retirement Study (mean age 72) were followed for 6 years on their use of

antidepressants, depression symptoms, and cognition, as measured by a battery of cognitive test that included memory, working memory, and naming. The researchers found that those taking the antidepressants declined on cognitive tasks at the same rate as those who were not on antidepressants after controlling for baseline cognition, age, and duration of antidepressant use.

In sum, there is little evidence that antidepressant usage can improve cognitive functioning even if they improve depression severity in older adults. There is evidence that the cognitive impairments due to depression persist whether or not the older adults respond to the medications. Furthermore, there is evidence that the use of these medications will not decrease the rate of cognitive decline over time in geriatric depression.

Conclusions

Some cognitive domains seem to be not or minimally affected by depression in older age such as attention and working memory, visuospatial skills, and language, while other cognitive domains seem to be consistently and negatively impaired by depression and/or depression severity such as processing speed, memory, and executive functioning. Mediating factor of processing speed (with but sometimes without working memory) seems to be the way depression affects higher-order or more complex cognitive functioning such as memory and executive functioning. In addition, age and medication seem to also moderate the effects of depression on some of the cognitive domains. All these studies point to a relationship between depression and cognitive functioning; however, there are diverging hypotheses about whether depression causes cognitive declines or if the relationship is bidirectional.

Definition

The term depression can have different meanings. It can be regarded as a “symptom” (low mood), a

“syndrome” (a set of symptoms with various definitions), or as a medically defined diagnosis according to a classification system. Depressive symptoms can be viewed dimensionally, from more or less normal reactions to pathologically severe depressive symptoms. The symptoms occur on a continuum of severity from mild reactions to complete disablement. The classification systems have traditionally viewed depressive symptoms and depression categorically (Baldwin 2014).

There is no defined biomarker for depression; the diagnosis is based on a clinical interview, observation, and supplemental information from relatives and caregivers. A diagnosis of depression is made according to two main classification systems: the American Psychiatric Association’s Diagnostic and Statistical Manual, Fifth Edition (DSM-5), or the International Classification of Diseases, Tenth Revision (ICD-10). To fulfill the criteria for a diagnosis of a depressive episode in ICD-10, four depressive symptoms must be present. To fulfill the criteria for a major depressive disorder (MDD) in DSM-5, at least five depressive symptoms must be present. In both systems, the symptoms have to be present for at least 2 weeks, causing clinically important impairment in daily life function, and one (DSM-5) or two (ICD-10) of the symptoms should be among the core symptoms, which are depressed mood, loss of interest or pleasure (DSM-5 and ICD-10), or decreased energy (ICD-10). DSM-5 and ICD-10 comprise similar criteria but may differ in the identification of people fulfilling the criteria for depression (Table 1).

A substantial proportion of older persons can have clinically important depressive symptoms but not fulfill the DSM-5 or ICD-10 diagnostic criteria for depression. Only DSM-5 includes specific criteria for depressive episodes with insufficient symptoms, also termed minor depressive disorder or subsyndromal or subthreshold depression. Subthreshold depressive symptoms persisting for more than 2 years may be diagnosed as dysthymia in both classification systems. In DSM-5, persistent depressive disorder also includes persistent MDD. Finally, the DSM-5

Depression in Later Life, Table 1 Diagnostic criteria of depression according to DSM-5 and ICD-10 (abbreviated)

	DSM-5	ICD-10
Core symptoms	Depressed mood	Depressed mood
	Loss of interest or pleasure	Loss of interest or pleasure
		Decreased energy or increased fatigability
Other symptoms	Weight loss or weight gain, increased or decreased appetite	Decreased or increased appetite with corresponding weight gain
	Insomnia or hypersomnia	Sleep disturbance of any type
	Psychomotor agitation or retardation	Psychomotor agitation or retardation
	Fatigue or loss of energy	Loss of confidence and self-esteem
	Feelings of worthlessness or excessive or inappropriate guilt	Unreasonable feelings of self-reproach or excessive and inappropriate guilt
	Diminished ability to think or concentrate or indecisiveness	Diminished ability to think or concentrate
	Recurrent thoughts of death, suicidal ideation, attempt, or plan	Recurrent thoughts of death or suicide or suicidal behavior

DSM-5 Diagnostic and Statistic Manual, Fifth Edition
ICD-10 International Classification of Diseases, Tenth Revision

and ICD-10 have specific criteria for bipolar depressive disorder, including different kinds of mania as part of the depressive disorder. It is important to keep in mind that DSM-5 and ICD-10 have been developed mainly in younger populations without cognitive impairment or substantial physical disease, and it has been argued that this makes the classification systems less valid in older people, particularly in the presence of cognitive impairment.

Depression in later life (DLL), also termed late-life depression or geriatric depression, is traditionally defined as depression occurring in

persons older than 65 years, but other age cutoffs have been suggested, such as 60 years and even 55 years. Conversely, it has been suggested that the DLL should use a higher age cutoff than 65, because older people now experience better health and everyday function than they did in earlier times. Older persons can have DLL as part of a previously established mood disorder, or the depression can arise for the first time in late life. DLL is sometimes subdivided according to the age of the first lifetime depressive episode. Studies have used different age cutoffs (e.g., 50, 60, or 65 years) to distinguish between depression beginning in early life (early-onset depression [EOD]) and depression with the first manifestation in later life (late-onset depression [LOD]).

There is a complicated interplay between DLL and dementia. Some important issues are summarized in Table 2.

Epidemiology

Depressive disorders are debilitating health problems and important causes of death for adults. Depression among adults across the life span is projected to be the leading cause of disability in middle and higher income countries by 2030. As the population of those aged 65 and over grows, DLL will become a major health problem worldwide. The prevalence estimates of DLL vary according to which diagnostic criteria have been applied, but overall the prevalence rates do not seem to be higher in older persons than they are in younger age groups. However, in subgroups of older persons, the prevalence rates are considerably higher. As in younger age groups, women are more likely to experience depression than men. Compared to the younger group of old adults, depression seems to be more common among the oldest old, often defined as 85+, as most studies find an increasing prevalence of depression with a higher age. However, the association between depression and increasing age seems to disappear when adjusting for physical disease and increased disability in older age. In

Depression in Later Life, Table 2 Depression and dementia

Depression increases the risk of dementia	There is an association between early-life depression and risk for dementia. It is less clear whether DLL is an independent risk factor for dementia
Depression and dementia share biological pathways	Vascular disease, hippocampal atrophy, pro-inflammatory states, decreased neurotrophic factors are potential biological mechanisms linking depression and dementia
Depression as a prodromal feature of dementia	Patients with depression and substantial cognitive impairment are at an increase risk for developing dementia
People with dementia are at a higher risk of having depression	Almost one in four individuals with dementia experience significant depressive symptoms. Depression is more common in vascular dementia or dementia with Lewy bodies than in Alzheimer's disease
Symptoms of dementia and depression overlap	Diminished interest in activities that were once enjoyed, sleep changes, psychomotor changes, and problems concentrating are common symptoms in both depression and dementia
Symptoms of depression can present different in older adults with versus without dementia	Aphasia in dementia can impede reporting of subjective depressive feelings. Thus, provisional diagnostic criteria for depression in dementia have been suggested, which include observable symptoms such as withdrawal, irritability, and agitation
Treatment of depression with antidepressants is less effective in patients with dementia	The efficacy of antidepressants for treating depression in dementia is uncertain suggesting different biological pathways in depression in patients with dementia

community-based samples, the point prevalence of MDD in older people has been reported to be between 1 and 6%, but rates for subthreshold depression seem to be two to three times higher (Meeks et al. 2011). Higher prevalence rates of depression are found among old individuals in institutions, such as residential care or nursing home care facilities. Depression is also more prevalent in individuals with somatic disease, particularly brain disorders. Depression may occur in up to half of those who suffer from Parkinson's disease or in those who have had a stroke. The prevalence estimates of depression in dementia are high but vary widely, reflecting the difficulty in defining and diagnosing depression in the context of dementia. To improve the diagnosis of depression in dementia, provisional diagnostic criteria for depression have been suggested, but their validity remains uncertain. Overall, depressive episodes in later life are more likely to be a recurrence rather than a first-time episode.

Etiology

Several biological, psychological, and social factors can interact and thus contribute to the development of depression. A biopsychosocial model of etiology seems to be particularly appropriate to DLL, highlighting that the causes of DLL are multiple and range across all three domains (Blazer 2003). It is useful to consider both predisposing and precipitating factors when putative causes of depression in an individual are assessed. There is still limited knowledge about why some older adults develop depression and others do not, even though they seem to be affected by the same set of risk factors.

Biological Factors

DLL regularly arises in the context of medical illness. There are several well-established physical risk factors like ischemic heart disease, chronic obstructive pulmonary disease, diabetes, malignancy, chronic pain, and organic brain diseases.

In addition, the use of drugs may play a central role in the development of depression in older adults. The role of alcohol is especially important

to consider in the etiology of DLL given that the rates of alcohol consumption have risen among older adults, and it is well established that alcohol use is linked to lower mood and depression. Older individuals also use more medication more often than younger individuals, and it has been suggested that polypharmacy may be associated with the risk of depression. However, empirical evidence is not consistent, and the results are difficult to interpret because the condition for which the medication is taken often confers an increased risk of depression. Finally, substance dependence can also be a factor in the etiology of DLL and can be easily missed if not assessed in an older patient.

Brain Anatomy

Research indicates that certain areas or circuits of the brain are relevant to the etiology of DLL (Naismith et al. 2012). These areas include the dorsolateral prefrontal cortex, orbitofrontal cortex, anterior cingulate cortex, subcortical white matter, basal ganglia (especially striatum), and the hippocampus. Dysfunction in frontal-subcortical neural networks involving these areas seems to be associated with the onset and prognosis of DLL.

Neurotransmitter Dysfunction

The monoamines, namely, serotonin, noradrenaline, and dopamine, are important modulating neurotransmitters for mood and behavior. Dysfunction in serotonergic and noradrenergic neurotransmission and, to a lesser extent, dopaminergic transmission has been demonstrated in DLL (Thomas 2013). An association between abnormalities in these neurotransmitters and depression is also supported by the fact that antidepressant medication targeting serotonin and noradrenaline function improves depressive symptoms. Dysfunction in other neurotransmitters associated with the occurrence of depression includes gamma-aminobutyric acid (GABA) and glutamate. All of these neurotransmitters have widespread projections to the prefrontal cortex. Even though dysfunction of monoaminergic transmission is shown in DLL, it is not completely clear how aging affects the neurotransmitters.

Some evidence suggests, however, that the age-related changes of the neurotransmitters can make older persons more vulnerable to mood disorders.

Genetics

Hereditary factors could predispose some older persons to depression. There has been great interest in genetic susceptibility across the life cycle, but specific genetic markers for DLL have not been identified. Heritability appears to be related to multiple loci of the genetic material (DNA) with small effects rather than few loci with large effects. Genetic factors have been found to have a greater impact in DLL with EOD. Recent genetic research has focused on the serotonin transporter (5HTTLPR) gene, apolipoprotein E (ApoE) gene, brain-derived neurotrophic factor (BDNF) gene, and 5-methylenetetrahydrofolate reductase (MTHFR) gene and has found that these genes may be involved in the development and treatment response of DLL (Naismith et al. 2012).

Immune System

Scientific knowledge regarding the interplay among the nervous, endocrine, and immune system has expanded immensely in recent years. It is suggested that these systems should be regarded as a single network that gives rise to the new discipline of psychoneuroimmunology (Thomas 2013). Research has shown that aging can lead to an increased peripheral immune response, impaired communication between the immune system in the central nervous system (CNS) and peripheral nervous system (PNS), and a shift toward a pro-inflammatory state of the immune system in the CNS. Raised levels of pro-inflammatory cytokines, such as IL-1 β , IL-6, and TNF- α , have been reported in studies of DLL. It is probable that aging and comorbid diseases may alter neuroinflammation and predispose individuals to DLL (Alexopoulos and Morimoto 2011).

Dysregulation of the HPA (hypothalamic-pituitary-adrenal) axis has been suggested as a cause of depression in older and younger adults. The associated high glucocorticoid levels may have a toxic effect on the brain, particularly the hippocampus. This has been forwarded as an

explanation for the increased risk of dementia in people with depression, although findings linking high glucocorticoid levels with hippocampus atrophy are conflicting.

Vascular Disease

There is a well-established bidirectional association between vascular disease and depression. This includes coronary heart disease as well as cerebrovascular disease (i.e., stroke). The white matter of the brain is composed mainly by myelinated nerve fibers. Lesions to the white matter identified on MRI, or white matter hyperintensities (WMH), have been studied extensively in relation to depression. It is presumed that WMH are caused by chronic hypoperfusion of the white matter and the disruption of the blood–brain barrier. WMH are related to vascular risk factors, the risk of depressive episodes, poorer remission, and cognitive impairment. The strong relationship between cerebrovascular disease and depression has led to the “vascular depression” hypothesis, which postulates that cerebrovascular disease can predispose, precipitate, and perpetuate depressive syndromes in later life by damaging frontal-subcortical circuits (Alexopoulos 2005). However, the concept of a vascular depression has received some criticism and it has proved difficult to reliably identify such a subgroup. Nevertheless, vascular disease is likely to be an important factor in about 50% of people with DLL (Thomas 2013).

Psychosocial Factors and Personality

It is a common view that psychosocial factors are most important in mild to moderate depression, whereas biological factors play a greater role in severe depression. The scientific evidence for this view is rather limited, and the evaluation of possible psychosocial etiological factors should be part of the assessment regardless of the severity of depression.

Several psychological factors are associated with depression. Relatively little research on the association between personality and depression has been done, and the interpretation of the results is difficult. Most studies are cross-sectional or retrospective, and the recall of earlier personality

traits may be influenced by the present situation. It is also difficult to establish what came first, the depressive disease or the presumed personality trait. Furthermore, it is complicated to disentangle the contribution of the personality traits from the social situation of the person as risk factors for depression.

There is some evidence that a high level of neuroticism is linked to DLL. Neuroticism is a personality trait characterized by worry, fear, anxiety, guilt, and moodiness. People with a high level of neuroticism can be sensitive to life stressors and may interpret minor situations as threatening or hopelessly difficult. It has been suggested that older persons with depressive syndromes can display cognitive distortions, where they generally overrate their own mistakes and exaggerate negative outcomes of life events and where loss and defeat are core themes.

High levels of mastery of one's environment and self-efficacy have been shown to provide protection against DLL. A higher sense of control, an internal locus of control, and more active strategies have been found to be associated with fewer depressive symptoms (Bjorklof et al. 2013).

Learned helplessness is the idea that individuals behave according to the expectation that acting in continually stressful situations has no meaning. Older adults frequently encounter circumstances such as chronic physical illness and disability that may lead to learned helplessness, and this notion has been linked to the occurrence of DLL (Aziz and Steffens 2013).

Life Events

Stressful life events can be seen as an integral part of becoming old, but some types of stressful life events, such as divorce or criminality, are less common in old age. It could also be argued that stressful life events are more often expected in late life, making it easier to deal with them.

As a person grows older, he or she will inevitably deal with different types of loss. For example, these losses include loss of position in society, loss of a job, loss of financial and functional independence, and loss of a social network and loved ones. These losses may produce grief that develops into depression.

Social support may act as a buffer to stressful life events, and it is documented that impaired social support is related to DLL. However, it is important to bear in mind that the majority of people who experience significant losses in old age do not develop depression. Hence, the meaning of loss has to be interpreted in the context of the person's mastery style, social situation, and other predisposing factors (Aziz and Steffens 2013).

Clinical Picture

Several studies have shown that clinicians at various levels fail to recognize depression in older persons. There may be a tendency to attribute depressive symptoms to the normal aging process. This may also explain the reluctance of some old people to view their symptoms as signs of depression. It is important to stress the fact that depressive symptoms are not a consequence of normal aging. The most plausible reason for the low detection levels of depression is probably the rather complicated interplay between normal age-related changes, symptoms of somatic disorders and depressive symptoms. This may cause clinicians to miss the diagnosis or also hinder insight by the person with depressive symptoms.

The ICD-10 criteria for depressive episode and DSM-5 criteria for MDD are identical for both younger and older patients (Table 1). The core symptoms of depression are depressed mood, loss of interest or pleasure, and decreased energy (the latter only in ICD-10). Additional symptoms defined in the diagnostic criteria are loss of confidence, an excessive feeling of guilt or worthlessness, difficulty concentrating, change in psychomotor activity, disturbance of sleep, change in appetite with corresponding weight change, and suicidality.

The clinical presentation of depression in old people differs from what is seen in younger age groups. The aging process, cognitive impairment, reduced physical health, polypharmacy, and disability can contribute to a more heterogeneous presentation of a depression syndrome in older individuals. Older adults may be less likely to

describe their suffering in ways that match up to common depressive symptoms. For instance, older persons with frank depression rarely describe experiencing feelings of sadness. This has led to the term “depression without sadness.” More recent research, however, has challenged the view that there is a specific phenotype in depression among old people, suggesting that the key symptoms of depression are the same, irrespective of age (Thomas 2013).

However, it seems that some symptoms are more prominent in DLL, with cognitive impairment being the most important. Various expressions have been used to describe cognitive impairment in depression, with pseudodementia being the most common. Pseudodementia refers to depression that is misdiagnosed as dementia due to marked symptoms of cognitive impairment. This term has fallen out of use, however, given the persistent nature of cognitive deficits in depression, even after the depression has been successfully treated and recent evidence suggesting that depression is a risk factor for dementia (Butters et al. 2008). The characteristic pattern of cognitive impairment in depression includes impaired attention and executive and amnesic impairment, whereas apraxia, visuospatial impairment, and aphasia may indicate that the cognitive impairment stems from a comorbid dementia disorder. People with a substantial cognitive impairment as part of their depressive episode should be followed-up closely, even if the cognitive impairment is reversed after the treatment of depression, because the risk of developing dementia in the following year is higher in this group.

Other patterns of the symptom profile in DLL are somatization or hypochondriasis, psychomotor retardation, anxiety, and agitation. It should be noted that some of these symptoms are also common in other diseases that frequently occur in old age, such as chronic obstructive pulmonary disease and coronary heart disease.

Psychotic symptoms seem to be more common in DLL compared to depression in younger adults.

There is evidence that for many patients with dementia, the depression syndrome may differ

from the diagnostic criteria in the ICD-10 and the DSM-5. Thus, provisional criteria for depression in patients with Alzheimer’s disease have been suggested. These criteria require fewer symptoms for a diagnosis of depression and the symptoms do not have to be present nearly every day. In addition to the depressive symptoms described in ICD-10 and DSM-5, the criteria for depression in Alzheimer’s disease also include social withdrawal or isolation and irritability (Olin et al. 2002).

Assessment of Depression

In addition to a thorough disease history that considers biological and psychosocial risk factors, the use of a structured assessment scale for depression is recommended. A few scales have been developed for use in old people, such as the Geriatric Depression Scale (GDS) and the Cornell Scale for Depression in Dementia (CSDD); the latter is also used in people without dementia. Other well-known scales, such as the Montgomery-Åsberg Depression Rating Scale (MADRS), the Hamilton Depression Rating Scale (HAM-D), the Beck Depression Inventory (BDI), the Patient Health Questionnaire (PHQ), and the Hospital Anxiety and Depression Rating Scale (HADS), are frequently used, and the psychometric properties of most of these scales are found to be acceptable in the assessment of DLL. Reporting depressive symptoms may be hampered by cognitive impairment and the assessment may have to include a proxy-based assessment, such as the CSDD. Given the large proportion of people with DLL who experience impaired cognition, a structured assessment of cognition should be included in the diagnostic process, whether or not a dementia disorder is suspected.

Suicidality

The suicide rates in older adults, particularly in men, have risen. Older men have few suicide attempts per completed suicide, i.e., they choose more lethal methods. An assessment of suicidality should be part of all assessments of DLL. As with any patient population, the older patient must be approached sensitively. Nevertheless, an explicit and specific exploration of suicidal thoughts

should be carried out during the assessment. Older men who commit suicide often seek medical help prior to the attempt, but symptoms of depression or suicidal thoughts are rarely mentioned. Practitioners need to be aware of this and have suicidality in mind when older men seek advice about other conditions, particularly issues concerning pain management. Established risk factors for suicide among old people are bereavement, social isolation, earlier attempts, chronic painful illness, disability or the threat of increasing disability, drug or alcohol use, and sleep problems (Manthorpe and Iliffe 2010). Despite the concern about the high rate of suicide among old people, this issue has received little attention, particularly when compared to the attention toward suicidality in younger people. Practice guidance on how to reduce the risk is lacking, and intervention studies are scarce.

LOD and EOD

Some researchers suggest etiological and clinical differences between EOD and LOD. EOD is associated more with a family history of depression, personality dysfunction, and severe disorders. EOD is regarded as a risk factor for the later development of dementia. LOD is associated more with WMH on MRI, prominent cognitive impairment, and it relates more to systemic vascular risk and neurodegenerative disorders. There is a debate as to whether the symptom profile of depressive symptoms defined in the classification systems is different in EOD and LOD patients.

Bipolar Disorders in the Late Life

The number of people seeking care for bipolar disorders is increasing. Bipolar disorders can develop early, i.e., onset before 50 years of age, or can arise with a late onset, i.e., after 50 (different cutoffs between 50 and 65 have been used). Bipolar disorders in late life include both early and late onset. Due to the complexity and heterogeneity in the classification of the disease, prevalence rates vary. Among older patients with bipolar disorder, most have their first episode of mania or depression early in life; in the minority, a bipolar

disorder may present itself for the first time in old age. In that case, the diagnostic process may be challenging due to the extensive medical comorbidity. Medical comorbidity in bipolar illness is associated with a more disabling course of the illness and a higher risk of suicide (Sajatovic and Chen 2011). Psychiatric comorbidity, such as anxiety disorders or substance use disorders, is often less common among older people than younger people with bipolar disorder. Patients with a late onset of bipolar disease tend to have less history of mood disorders in their family. About half of all older patients with bipolar disorder have depression as their first mood episode.

Treatment

Before starting treatment, a careful assessment focusing on the biopsychosocial aspects of DLL is needed. The assessment should not be restricted to counting symptoms in order to establish a diagnosis; the meaning or the impact of the depressive symptoms to the individual person needs to be taken into account. Functional limitations and disability, disease history, and the duration of symptoms are key issues to keep in mind when weighing the benefits of treatment against risks. Earlier treatment experiences and preferences of the patient should be taken into account. A careful explanation of the treatment plan involving the patient – and if appropriate a family caregiver – is mandatory for treatment success, as low treatment adherence has been reported among old people.

A stepped care approach, identifying the least restrictive and least costly intervention that will be effective for a person's presenting problems, is recommended (NICE 2010). People with sub-threshold depression without a significant impact on everyday life should be offered supportive and psychosocial interventions, but they should normally not be offered medical treatment. In milder forms of depression or persistent subthreshold depression, more intensive psychotherapeutic approaches are advocated. Drug treatment should still not be a first-line treatment option, but should be considered if other alternatives fail to produce

substantial improvement. In moderate or severe depression, drug treatment should be offered, often in combination with intensive psychotherapeutic treatment.

In the treatment of depression, it is important to aim for remission (i.e., patients do not meet the diagnostic criteria for depression or they have no more than minimal depressive symptoms according to a depression assessment scale) and not merely for response (i.e., significant symptom reduction), because residual symptoms after treatment are strongly associated with a risk for relapse. Once in remission, a plan for the continuation of treatment should be established. There is reason to believe that maintenance therapy should be offered more liberally in DLL than in younger age groups, due to a greater risk of relapse.

Psychosocial Interventions

Older patients with minor or mild depression can benefit from participating in various types of social activities to prevent isolation and loneliness, e.g., befriending services and attending day centers and local community events. Physical exercise includes bodily activity that enhances overall health and wellness. There is evidence that structured exercise programs can help older patients with milder depressive syndromes. Different kinds of exercises can be beneficial, but results are most consistent from aerobic exercise. However, there are also studies that have failed to find a positive effect of physical exercise in DLL.

Psychotherapy

Research indicates that psychotherapy can be an effective treatment for DLL even though the quality of studies is relatively low (Wilson et al. 2008). There is a variety of therapies that may be applied, such as supportive therapy, life-review therapy, cognitive-behavioral therapy (CBT), interpersonal therapy (IPT), and problem-solving therapy (PST). Psychotherapy can be offered to individuals (in- or outpatients), couples, families, and as group therapy. Supportive treatment and adding structure to the day can be effective in patients with minor depression syndromes. CBT focuses on here-and-now situations as well as the link between negative thought patterns and mood and

behavior and is often structured in sessions and length. CBT is widely studied and applied in DLL with mild to moderate severity. IPT is also based on here-and-now situations, but emphasizes interpersonal relationships. PST is based on CBT principles, but is a more focused treatment approach. PST aims to teach patients to better define their problems and goal, and the strategies to cope with the problems, carry out the strategies, and then evaluate them. PST has shown strong results for depressed patients with executive dysfunctions. As a result, it has been suggested as a key treatment approach in “vascular depression,” where it has been implicated that the dysfunction of frontostriatal circuits gives rise to executive impairment (Espinoza et al. 2014).

Psychotherapy, in combination with medical treatment, may be more efficacious than any of the two modalities alone in the treatment of DLL, both in the acute phase and as maintenance therapy.

Medication

A number of issues need consideration when prescribing antidepressive medication to older adults. As noted earlier, polypharmacy is common in older individuals. Medication with negligible side effects in healthy young people may cause serious side effects in older adults who take many prescribed drugs, especially when several of those drugs could have direct effects on the brain. An example is the rather weak anticholinergic effect of a drug like paroxetine; in combination with other drugs with weak anticholinergic effects, it may cause confusion or delirium in susceptible individuals. Pharmacokinetic changes, such as increased distribution volume, reduced hepatic metabolism, and reduced glomerular filtration rates, may lead to higher plasma and brain levels of the drug. However, there is great variation among older adults in these changes. The slogan “start low, go slow” that was often voiced in old-age psychiatry may be appropriate, but should not prevent older patients from being treated with adequate doses. When evaluating dosing regimens, the polymorphisms of key enzymes of the cytochrome P450 system involved in the metabolism of several psychopharmacological

substances should be taken into account. A considerable proportion of individuals can have polymorphisms that may cause great variation in the plasma level of a medication. In cases of unusual side effects at low doses or treatment resistance, an analysis of P450 enzymes may be indicated.

Most studies regarding drug treatments for depression have been done in samples with MD-D. Hence, the results cannot readily be extrapolated to people with mild depression or subthreshold depression. The effect of antidepressants in treating DLL is well documented (Nelson et al. 2008). However, there is great variability among studies. The older tricyclic antidepressants (TCAs) have a comparable effect to the new ones but a higher prevalence of side effects – particularly anticholinergic and antiadrenergic effects – that have made them less useful in treating DLL.

Contrary to the positive treatment effect in older adults without substantial cognitive impairment, most of the studies concerning the use of antidepressive treatment in patients with dementia have failed to show an effect (Nelson and Devanand 2011). This may be because of an inability to define homogenous patient groups with depression and dementia. Symptoms of depression and dementia partially overlap and cognitive impairment may prevent any verbalization of the depressive symptoms. Furthermore, people with dementia may be more susceptible to adverse events. Taken together, there is not enough evidence to suggest antidepressive therapy as a first-line treatment in people with dementia except in specific cases, such as very severe depressive symptoms or a history of earlier episodes that have responded to treatment.

There are a large number of antidepressive drugs to choose from, but selective serotonin reuptake inhibitors (SSRIs) are the first choice in most instances, in line with most clinical guidelines. These drugs are generally well tolerated and they have a predictable interaction profile. Nonetheless, recent studies indicate that SSRIs may also be associated with serious adverse outcomes, such as increased QT interval, falls, and hyponatremia. SSRIs may be combined with

other antidepressants; combining SSRIs with mirtazapine or mianserin can be particularly useful for patients with sleeping problems and low appetite. Serotonin and noradrenaline reuptake inhibitors (SNRIs) have adverse event profiles similar to SSRIs and are a useful second-line treatment option because of their somewhat broader receptor profile. Because older adults with depression constitute a heterogeneous group, the prescription of antidepressive medication should be individualized based on the side effect profile of the drug, previous medication history, somatic diseases, and the use of other drugs.

Monotherapy is preferred, but in cases of treatment resistance, augmentation therapy with other drugs may be tried. The best evidence is for augmentation with lithium, used for bipolar disorder (Cooper et al. 2011). However, lithium serum levels have a very narrow therapeutic window and require careful observation in order to avoid potentially serious adverse events.

Electroconvulsive and Neuromodulation Therapies

Electroconvulsive therapy (ECT) is well tolerated and efficacious in treating DLL (Riva-Posse et al. 2013). It should be an option in people with severe depression when other treatment alternatives have failed. In many countries, ECT is reserved for severe depression with psychosis, suicide risk, or life-threatening refusal of food or fluids. Concerns about using ECT in DLL have been raised, especially the fear of precipitating delirium or memory impairment. Recent studies demonstrate a faster remission in patients treated with ECT than patients treated with antidepressants, without extra side effects. This suggests that the indication for ECT could be broader. The high relapse rate after ECT is a therapeutic challenge; maintenance therapy may be indicated. Other stimulation therapies, such as transcranial magnetic stimulation, vagal stimulation, or deep brain stimulation, have been tried out in selected patient groups, but these alternatives are not easily accessible and there is limited evidence to date to justify their use in clinical practice.

Prognosis

DLL is associated with a number of negative outcomes, such as disability, cognitive impairment, poorer outcomes of physical disorders, and an increased risk of mortality. Remission rates of DLL after treatment are not different from those in younger age groups; however, relapse rates are higher (Mitchell and Subramaniam 2005). The risk of relapse is highest for the first 6 months. Hence, it is important to continue treatment for at least 6–9 months. Even after the first depressive episode in old age, the relapse rate is high after the treatment has been discontinued. This has led many to recommend lifelong maintenance treatment even if the first depressive episode has a later onset, particularly if it was an episode of great severity. This recommendation has to be weighed against risks associated with polypharmacy, side effects, and other risk factors for relapse, such as cerebrovascular pathology, other physical diseases, and cognitive impairment.

Conclusion

DLL is a disease with vast consequences for affected individuals and society as a whole. The symptoms are well characterized and there is a huge knowledge base around epidemiology, etiology, and treatment. However, a substantial part of the knowledge relates to younger age groups, which has been extrapolated to DLL. There is reason to believe that there are important etiological and clinical issues that apply to DLL, which differ from what we see in younger age groups. Yet, there is probably greater diversity among older versus younger age groups. This calls for a careful assessment and consideration of biological and psychosocial issues common with advancing age. Particular attention should be paid to comorbid physical diseases, cognitive impairment, and distressing life events. The increased vulnerability of some older adults to depression in itself and treatment side effects, the uncertain efficacy of treatment in subgroups, and the high relapse rate in DLL call for close follow-up. Lastly, the high

risk of suicide, particularly in older men, warrants special attention among all health workers providing care for older individuals.

Synonyms

Age-related disease; Age-related impairment; Chronic disease; Functional change and loss; Impairment

Definition

Disability is a broad term that has multiple definitions. The World Health Organization (World Health Organization 2012) defines disability as encompassing:

1. Impairments: a problem or problems with bodily structure or function
2. Activity limitations: a problem or problems experienced by an individual when attempting to carry out an action or task
3. Participation limitations: a problem or problems in dealing with life situation (e.g., social, vocational)

The term disability, however, is not limited to health conditions. In fact, the International Classification of Functioning, Disability, and Health views *disability* as an umbrella term (World Health Organization 2012). In their definition, disability is the interaction between environmental and personal factors (e.g., stigmatization, access to healthcare, social support) and a health condition (e.g., schizophrenia, cardiovascular disease). This means that experiencing a disability is really the combination of *both* some health

condition and how you are treated and/or limited as a result of it (World Health Organization 2012).

Disability is not an inevitable part of aging, but the odds of experiencing a disability or living with a disability increase with age. As this entry will show, many age-related changes are associated with disability (e.g., age-related eye degeneration resulting in cataracts leading to visual disability) (Hoyer and Roodin 2009).

The Nature and Causes of Disability for Older People

As of 2010, approximately a billion people (around 15% of the world's population) were estimated to live with some form of disability. Among these, 2–4% were estimated to have severe disability that dramatically impaired functioning (e.g., quadriplegia, blindness). Rates of disability (i.e., experiencing difficulty in performing activities), and severe disability (i.e., being prevented from performing activities), increase with age (World Health Organization 2011). We can use the USA as an example here. In the USA, fewer than one in five people aged under 65 report a disability (2010 US Census data) (Brault and United States. Bureau of the Census 2012). This increases to about 50% in adults aged 65 years and over. In this age bracket, one in two will report a disability. Over a third will live with a severe disability. For people in their 80s, rates of disability are close to 75% and severe disability 60% (Brault and United States. Bureau of the Census 2012).

The way that disability is assessed and recorded, however, differs country to country. This means that it is hard to accurately estimate how many people are disabled, let alone how many older people are disabled. According to best estimates, however, approximately 30% of adults aged 60 years and over in higher-income countries have a disability, and approximately 45% of adults over 65 in lower-income countries live with a disability. For example, the rates of

disability are substantially higher in African and Southeast Asian nations than they are in the Americas or Europe (World Health Organization 2012). International differences notwithstanding, with an expanding older population, globally, there are more people living with disability today than there have been in the past.

In general, part of the reason that we are living longer is because we are better at preventing and treating communicable disease. Communicable diseases are those that can be spread between people or between people and animals. Vast reductions in infectious and parasitic disease have resulted from effective and available immunization, attempts to manage poverty, and improvements in diets and infrastructure. Thus, at present, in developed or high-income countries, the leading causes of disability (as well as disease and death) are noncommunicable (e.g., arthritis, cancer, mental health disorders). The same is true of middle-income countries – it is only in developing countries that the leading cause of disease and death remains communicable disease (alongside maternal, perinatal, and nutritional conditions). It is estimated that by 2030 this will change – noncommunicable disease will be the leading cause of disability, disease, and death worldwide (World Health Organization 2011).

To some extent, this represents a challenge to the way that disability is traditionally conceptualized. When we think about disability in aging, we often draw on standard stereotypes – imagining someone in a wheelchair or someone who is vision impaired. The reality is that disability is varied, not only in its nature, but also in the extent to which it affects or limits people.

The most common disability-related health conditions in Australia and Canada are arthritis, back problems, and hearing problems (World Health Organization 2011, 2012; Australian Bureau of Statistics 2012). Others include heart disease, hypertension, asthma, diabetes, stroke, depression, dementia, speech disorders, and vision disorders. In the USA, rheumatism and heart problems represent the most common causes

of disability among adults 65 or older (World Health Organization 2011; Centers for Disease Control Prevention 2009). As of 2011, the most common health conditions in developing countries were heart disease, stroke, cancers (breast, prostate, and lung), sensory problems (cataracts and glaucoma), hearing loss, and musculoskeletal impairment (osteoarthritis and osteoporosis) (World Health Organization 2011).

Older people with disability can either enter old age with a preexisting disability or develop a disability in later life (either due to age-related factors or other factors such as communicable disease or accident). As highlighted above, however, rates of disability increase with age, in part due to biological change. For example, as we age, visual deterioration is common. This includes declines in accommodation (the ability of the lens to focus), contrast sensitivity, and sensitivities to glare (Hoyer and Roodin 2009). Changes in the eye give rise to visual pathologies. Approximately 70% of adults aged 80 or over have cataracts, with 20% and 7% of the same age group experiencing age-related maculopathy and glaucoma, respectively (Resnikoff et al. 2004). Similarly, with age comes a predictable breakdown of cells in the inner ear (albeit at different rates for different people). This can result in hearing impairment, with approximately 35% of men and 22% of women aged 70–74 experiencing such impairment, and this rises to 58% of men and 49% of women at 85 years or older (Mathers et al. 2000). Taste, smell, and touch sensitivities also decline. In the case of touch, this can be particularly problematic – as insensitivity to touch and pain can lead to accidents and subsequent disability (Hoyer and Roodin 2009). Finally, loss of bone density and muscle mass, circulation, and respiration are also part of the normal aging process (Deschenes 2004). As this highlights, many factors contribute to disability and all can hinder effective participation in many activities of daily living (Hoyer and Roodin 2009).

Factors Exacerbating Disability

While age increases the risk of developing diseases and disabilities, the cumulative effects of

adverse lifestyle or environment can expedite disability in later life (World Health Organization 2011, 2012). One of the most consistent predictors of disability is socioeconomic disadvantage. Poor nutrition, and inability to access healthcare, increases the risk of developing a disability (World Health Organization 2012). At the international level, rates of disability in the USA are high when compared to other developed countries. The reason for this is largely assumed to be ready and equal access to healthcare provided by governing bodies. Similarly, healthcare is often difficult to access in low-income countries. Just as there are higher rates of disability within low-income countries than within high-income countries, so too are there higher rates of disability in people of low socioeconomic status (SES). Poverty has a cumulative effect, and this becomes more evident in later life. Further, poverty is more evident among the elderly (World Health Organization 2011). Those born into poverty are more likely to develop a disability – and if they survive into old age, carry it with them. The prognosis and quality of life for those with a disability who experience poverty are worse than for those with a disability who do not experience poverty. Thus, there appears to be a cycle of disability – where poverty breeds disability and also exacerbates it. Gender also interacts with poverty. As women live longer than men, on average they are more likely to experience poverty in old age (Hoyer and Roodin 2009).

The Impact of Disability on Older Adults

The most obvious impact of disability on older adults is in the realm of self-care. Physical disability in older adults can prevent them from being able to independently move in and out of bed, leave the house, and engage in house maintenance (Brault and United States. Bureau of the Census 2012). In fact, as of 2010, at least one in ten American adults aged 65 or older reported needing assistance in leaving the house, with a similar proportion reporting needing assistance with housework (Brault and United States. Bureau of the Census 2012). When we consider the fact that

many people with disabilities require doctor or hospital visits, as well as pharmacy medication, any disability that prevents them from leaving the house would exacerbate challenges associated with disability management should they not have access to assistance.

Disability can impact on basic activities of self-care or *activities of daily living*. These include the ability to bathe, dress, and toilet independently. *Instrumental activities of daily living* – like paying bills, shopping and food preparation, and taking medications appropriately – require some degree of planning and intellectual engagement (Cavanaugh and Blanchard-Fields 2014). In the USA, of Medicare enrollees 65 years or older, approximately 41% needed some assistance with these activities. Twelve percent of adults aged 65 years or older needed help with instrumental activities only, with the remaining 29% also requiring assistance with at least one activity of daily living (Cavanaugh and Blanchard-Fields 2014). The most common problems include difficulties in walking, bathing, dressing, using the toilet, getting in and out of bed, and eating (Cavanaugh and Blanchard-Fields 2014). Impairments in these areas increase with age. In the case of walking, approximately 15% of adults aged 65–74 years are having difficulty in doing so, compared to almost 50% of adults aged 85 years and older. Around 20% of adults aged 65 or over require either the use of a walking aid (e.g., cane, walker, crutches) or wheelchair for mobility (Centers for Disease Control Prevention 2009). Importantly, when an older person becomes restricted in some capacity, their decline is more rapid and recovery protracted, thus increasing the likelihood of additional disability that further limits their ability to live independently (World Health Organization 2011; Hultsch et al. 1999)

Chronic disabilities are a robust predictor of falls in the elderly (as can be assumed with over 50% of adults 85 and older reporting difficulties walking). Further, in the USA, accidental injury is the fifth leading cause of death in older adults after cardiovascular disease, cancer, stroke, and pulmonary disease (Rubenstein 2006). Falls themselves account for approximately 60% of these deaths. As a consequence, data in the USA reveals that

falls are the most common causal factor of restrictions of activities of daily living (Rubenstein 2006). The more chronic health conditions an elderly person reports, the more likely they are to fall and fall recurrently (Tinetti et al. 1986). Thus, we can see that disability in and of itself puts people at the risk of future disability (World Health Organization and Ageing Life Course Unit 2008).

Participation in Society

Disability in the elderly often puts limits on their ability to live happy, fulfilled lives. This is not just because of problems associated with activities of daily living (e.g., walking, getting dressed); rather, impairments can also impose barriers to social and vocational interactions. For example, difficulties in vision can prevent older adults from driving (Hoyer and Roodin 2009). Mobility difficulties can prevent catching public transport, as can the availability or affordability of public transport (Gilhooly et al. 2002). Thus, disability can lead older adults to withdraw from social activities or cease attending gatherings or going on outings.

Physical and/or cognitive disability may also prevent older adults from engaging in work-related activities. There are a number of reasons for this. Firstly, physical disability may prevent someone from performing a job that they previously held (e.g., problems with walking may prevent a farmer from farming). However, potent misconceptions about the disabled elderly (including those held by the elderly themselves) can also prevent older adults with disabilities who desire employment from seeking and attaining it (World Health Organization 2012). For example, older adults with a disability are often excluded from disability services that aim to provide rights and opportunities to those living with a disability (Jönson and Larsson 2009). In Sweden, for example, a system of long-term support (personal assistance) has been introduced for those living with a disability who are *under the age of 65* (Jönson and Larsson 2009). Researchers argue that ageism affects disability here – whereby many conflate disability and aging (i.e., assume that disability is a normal and natural part of aging) (Jönson and Larsson 2009). Thus, older adults with a disability

often are not able to take advantage of programs designed to support them in pursuing paid work, among other things.

As prefaced above, older adults with disabilities are likely to face discrimination. Some researchers have argued that the recent focus on “positive,” “successful,” or “healthy” aging has meant that older adults with a disability are stereotyped as people who age “badly” or “unsuccessfully” (Minkler 1990). When looking at specific prejudices, mental disabilities are stigmatized, and physical disabilities are often assumed to extend to cognitive impairment. Those with dementia are sometimes seen as “less than human” and consequently are not afforded time and companionship.

Whether through physical barriers, or social exclusion, isolation can have a severe negative impact on older adults with a disability. A primary predictor of longevity is the strength and quality of our social relationships (often marriages (Tucker et al. 1996)). Older adults with strong social networks thrive – especially when they enjoy close and meaningful relationships (Hoyer and Roodin 2009). When disability limits this, either through preventing socializing or through increased incidents of discrimination, older adults with disability are likely to experience declines in health and quality of life.

Societal Impact and Management of Disability in Aging

Given the rising number of people with a disability, there is a considerable burden experienced globally – both in terms of health and finances. Financial costs are borne by the disabled themselves, governments, and individual carers (and families). One report estimated that, in the period between 2006 and 2015, the financial cost of heart disease, stroke, and diabetes in 23 low- and middle-income countries approached \$US100 billion (World Health Organization 2011). In 2009, the cost associated with new cancer cases in the USA was estimated at \$US286 billion. The worldwide cost of dementia in 2010 was estimated to exceed \$US600 billion (World Health Organization 2011). Note that this figure includes

nonprofessional care provided by family members. In fact, the majority of older adults with a disability do not live in aged care facilities. In Australia, one in ten people reports being a carer for a person with a disability (Australian Bureau of Statistics 2012). The majority of carers are female (70% of primary carers), and of carers themselves, approximately a third have a disability. Labor force participation is lower for carers, who often spend more than 40 h a week in their caretaking roles (Australian Bureau of Statistics 2012).

The cost of caring for older adults is not just financial; it is also emotional. Carers are typically overworked and often unpaid. They face substantive stress, especially because their role often involves negotiating and managing the current impairment and the future consequences of the impairment (palliative care and death), which is often not recognized publically (Hoyer and Roodin 2009).

The costs detailed above, both to societies and individuals, highlight the importance of looking at disability in older adulthood at national, and global, levels. When it comes to disability, generally, the World Health Organization recommends that multiple environmental changes should be implemented to improve the lives of those with disabilities (World Health Organization 2011, 2012). For example, it is recommended that policies concerning accessibility of education and healthcare be designed with specific reference to meeting the needs of disabled people. Funding and the provision of services for those with disability need to be increased. At a very basic level, built environments should be designed to be accessible to all. Negative attitudes and poor standards of care need to be combated. In each case, it is recommended that extensive consultation with people with disabilities is undertaken and that any programs instituted are rigorously documented and evaluated (World Health Organization 2012).

When it comes to programs specifically designed to help older adults with disabilities, multiple successful examples can be found. For example, in Japan, free social exercise classes are made readily available to older adults living in large cities (Hoyer and Roodin 2009). Indeed,

exercise programs in the USA have been shown to reduce disability and pain for older adults with knee osteoarthritis (Ettinger et al. 1997). Community-based programs in the USA aimed at preventing disability in older adults, as well as promoting disease self-management, have been shown to reduce functional decline and length of hospital stays (Wagner et al. 1998).

On an individual level, managing disability in older adulthood – much like disability itself – is complex. Several factors have been identified, however, that reliably delay the onset of disability. Most importantly, exercise is a factor that has been shown to increase both physical health and mental health and is effective in delaying the onset of dementia (Cotman and Berchtold 2002) and preventing physical disability (see above). Cognitive stimulation is also important. Older adults who remain in the workforce until later in life display better cognitive integrity than those who retire early, and it is likely that cognitive challenge is protective (World Health Organization 2011). Finally, a strong social network is vital. Older adults do not necessarily benefit from having a large social group. Rather, they are most healthy when they report close, developed, and deep friendships (Hoyer and Roodin 2009). A reduction in smoking, drinking, and drug taking also reduces the chance of disability (Hoyer and Roodin 2009; Cavanaugh and Blanchard-Fields 2014).

Conclusion

Disability is multifaceted. The current statistics on rates of disability vary country to country, in large part due to differences in definition and measurement. Despite this, it is clear that disability increases with age. This is largely due to biological changes that are associated with aging, such as reduction in bone and muscle density. Much of this, at present, is unchangeable – we cannot stave off the process of aging. What is malleable, however, is how we treat and support older adults with a disability, and how we prepare for old age ourselves. At present, the bulk of the caring for older adults with a disability is undertaken by partners

and relatives – who are often unpaid and under-resourced. Further, older adults with a disability attract substantive discrimination. They are often treated as if they are childlike or impaired beyond their disability. Increases in support to caregivers, better government and aged care services, as well as improvements in attitudes toward older adults with a disability would lead to improved quality of care and life for older adults with a disability (as well as their caregivers). Finally, while avoiding disability in later life is probably unrealistic, it can be delayed and managed more positively. Specifically, regular exercise and social interactions have both been shown to be protective, as has income equality. Some changes can be made at a personal level, such as adherence to an exercise program. Others will need to be tackled at a societal level. Income inequality, for example, is to a large degree a product of public expenditure, taxation, laws, as well as government provision of healthcare and education. With an aging population, it is clear that changes must be considered, if we are to reduce the global burden of disability.

Distance-to-Death Research in Geropsychology

Oliver K. Schilling
 Department of Psychological Ageing Research,
 Institute of Psychology, Ruprecht-Karls-
 Universität, Heidelberg, Germany

Synonyms

Distance-to-death and time-to-death; Terminal changes and time-to-death-related changes; Terminal decline and terminal drop; Time-to-death-related trajectory and time-to-death-related growth curves

Definition

In the broadest sense, distance-to-death research in geropsychology includes all kinds of examinations of associations between facets of psychological functioning and time-to-death. In a narrower sense, however, the term refers to the study of terminal changes in psychological functioning, that is, intraindividual changes that occur time-to-death related at the end of the individual's lifespan. Up to the present, geropsychological distance-to-death research for the most part consists of studies of terminal decline and terminal drop in cognitive functioning and subjective well-being.

Distance-to-Death Research in Geropsychology

Across the past decades, research in geropsychology increasingly considered distance-to-death as indicator of psychological changes that unfold at the end of the human lifespan. That is, this research is based on the rationale that crucial changes in psychological functioning may occur in late life as individuals approach their death, meaning that the occurrence of these changes is closely related to biological processes of deterioration that precede and will finally precipitate the death of the individual. Historically, this approach was initiated in the field of geropsychological research on cognitive functioning early in 1960s by Robert Kleemeier, who presented evidence of an association between late-life declines in intellectual function and mortality, suggesting *the existence of a factor, which might be called terminal drop or decline, which adversely affects intellectual performance and is related to impending death of the aged person* (Kleemeier 1962, p. 293). Such terminal change might unfold late in people's life over some time period before death, hence timely associated with distance-to-death, rather than with calendar age (i.e., distance-to-birth). To put this reasoning simply, if humans are not hit by lethal developments that unfold short termed (such as accidents or severe acute illnesses), crucial changes driven by end-of-life degradations may not occur "normatively" in terms of age related, but "terminally" in terms of time-to-death related.

Thus, in the broadest sense, geropsychological distance-to-death research includes all kinds of empirical studies that examine associations between psychological functioning and time-to-death. In a narrower sense, however, the key objectives of such research refer to terminal change. This distance-to-death research was largely driven by the concepts of *terminal decline* and *terminal drop*. The latter term has been used to differentiate time-to-death-related processes

that unfold rapidly and accelerated aggravation or loss of functionality prior to death (i.e., "drop") from processes that run in a more steady and less accelerated way (i.e., "decline"). This distinction has been grounded on theoretical considerations regarding the causal processes driving the terminal changes in psychological functioning: *Terminal decline reflects a gradual accumulation of underlying biological and environmental causes, whereas terminal drop implicates a threshold model with an acute precipitating mechanism* (Bäckman and MacDonald 2006, p. 227). However, both terms are often used interchangeably in distance-to-death research, supposedly because clear-cut empirical criteria to distinguish terminal decline from terminal drop in observations of time-to-death-related changes are hard to establish. That is, any notion of changes that occur uniquely time-to-death-related at the end of individuals' lifespans implies some kind of acceleration, in that these changes occur after the onset of the terminal process, adding to ongoing normative age-graded (or otherwise time-graded) changes or stability. Therefore, the remainder of this chapter will not follow a strict distinction between slow-running and fast-running terminal changes, but rather deal with terminal change in general, including both dynamics of terminal decline and terminal drop.

Doing so, this chapter will mainly focus on conceptual and theoretical aspects of distance-to-death research. Thus, only a brief overview on empirical findings on terminal change will be given first. Second, methodological concepts that are key constituents of distance-to-death research will be outlined. Third, the relevance and potentials of distance-to-death research will be considered: Which insight about late-life development *does* – or *could* – distance-to-death research provide to geropsychology?

Empirical Evidence: Terminal Decline in Cognition and Subjective Well-Being

Starting with Kleemeier's investigation, gerontologists' interest in phenomena of terminal decline

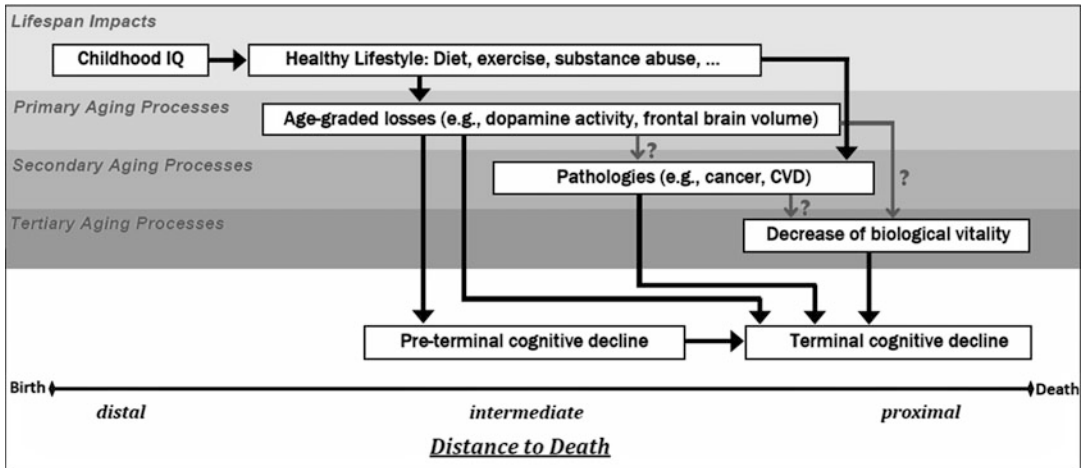

has long been focused on cognitive functioning (e.g., Kleemeier 1962; Riegel and Riegel 1972; Siegler 1975; White and Cunningham 1988). This “early” research revealed manifold and strong evidence that (a) levels of cognitive function predicted subsequent survival (for review Small and Bäckman 1999) and (b) intraindividual declines of cognitive performance were associated with distance-to-death (for review, see Bosworth and Siegler 2002). Overall, these findings suggested that terminal change accounts for a substantial portion of the differences in cognitive performance among older individuals, leading to questions on the nature of the phenomenon, particularly concerning the causal processes underlying terminal change and the pervasiveness of such distance-to-death-related changes across different – including also “non-cognitive” – facets of psychological functioning. With the terminal decline paradigm well established in aging research, more recent investigations in the broadest sense dealt with these questions.

The further progress of distance-to-death research up to the present may be summarized with respect to two predominant topics, namely, (a) increasing evidence of distance-to-death-related changes not only in cognitive functioning but also in indicators of subjective well-being (SWB) and (b) the provision of more and in-depth insights about the course and predictors of terminal decline. Up to the present, a large body of research provides massive evidence of terminal decline in cognitive functioning, unfolding in a dedifferentiated manner across various cognitive abilities (Wilson et al. 2012). Moreover, broadening the distance-to-death perspective beyond the focus on cognitive functioning, SWB emerged as important field of terminal changes in recent years. An increasing body of studies provided evidence of changes in SWB associated with time-to-death – showing patterns of terminal decline of cognitive (i.e., life satisfaction) and affective components of SWB (e.g., Gerstorf et al. 2008a, b, 2010; Palgi et al. 2010; Schilling et al. 2013; Vogel et al. 2013; Windsor et al. 2015).

Given its historical “forerun,” in particular cognitive distance-to-death research revealed

manifold hints toward proximal and distal influences across the lifespan that might impact on the onset and speed of terminal declines (for review, see Bäckman and MacDonald 2006; for more recent findings, see, e.g., Gerstorf and Ram 2013; Muniz-Terrera et al. 2013; Cadar et al. 2015). Overall, terminal decline in cognitive functioning appears as developmental dynamic not fully mediated by specific diseases, but a phenomenon determined by multiple impacts, including some “core” of time-to-death-related change that still could not be attributed to particular causes and might be understood in terms of a “deterioration of global biological vitality” (Bäckman and MacDonald 2006, p. 225). Figure 1 summarizes proximal and distal impacts of terminal cognitive decline, adapted from Bäckman and MacDonald’s (2006) respective summary (leaving out predictive pathways from genes and early environment to childhood IQ and also direct links from childhood IQ and normative age-graded influences to death that were part of their figure). The original figure has been modified by adding potential causal pathways among impacts, which Bäckman and MacDonald did not include in their model, but may be considered at least hypothetically.

Thus, keeping this chapter’s conceptual focus, empirical distance-to-death research up to the present might briefly be characterized as a process moving from mere evidence of terminal change in psychological functioning toward an understanding of these terminal changes as driven by proximal and distal impacts across the individual’s lifespan. This course of the investigation of the phenomenon – from disclosure to causes – seems also implied in Gerstorf and Ram’s (2013, see also for more review of empirical findings) suggestion to organize objectives for future research on terminal decline according to five basic rationales (Baltes and Nesselroade 1979), namely, (a) identification and description of terminal changes and (b) the interindividual differences in terminal changes, (c) analysis of interrelationships between terminal change in different attributes or multiple aspects of functioning, and (d) identification of the causes of terminal change and (e) of the interindividual differences in

Distance-to-Death Research in Geropsychology, Fig. 1 Distal and proximal impacts on terminal cognitive decline (Note. Modified figure adapted from Bäckman and

MacDonald, *European Psychologist* 2006, 11(3), p. 229. *Black arrows* denote impacts considered originally by Bäckman and MacDonald)

terminal change. It could be expected, hence, that ongoing and future distance-to-death research will increasingly focus on the causes of terminal change in psychological functioning.

However, crucial to such understanding of causes, research on terminal decline in cognitive functioning suggests that psychological changes preceding one's death are driven by impacts which do not all unfold distance-to-death-related, but differentially timed within the individual's life course. The "classic" distinction of primary, secondary, and tertiary aging processes – also added in Fig. 1 to the model adapted from Bäckman and MacDonald (2006) – has been suggested as conceptual framework to disentangle this temporal overlay and interplay of the driving forces of late-life changes (Ram et al. 2010): Primary aging denotes processes that are intrinsic to aging (i.e., unfolding regularly and irreversibly within individuals at certain ages), whereas secondary aging refers to pathological changes that do not occur age-graded and may be preventable or reversible (Busse 1969), and tertiary aging denotes biological degradations that unfold under impending death (Birren and Cunningham 1985). Thus, processes that unfold normatively age-related, or nonnormatively across some limited time period in one's life, or uniquely distance-to-death-related might impact on terminal

changes in the psychological functioning observed at the end of the lifespan. However, key to distance-to-death research, this rationale implies that *unique* statistical association of intraindividual change with time-to-death (controlling for age- and pathology-related time metrics, such as time since diagnosis) means strong evidence for the effectivity of tertiary aging processes.

Methodological Concepts of Distance-to-Death Research

Time-to-Death as Predictor of Change in Psychological Functioning

Across the past decades, distance-to-death research gained tremendous inspiration from appearance of longitudinal growth curve methodologies (e.g., Curran et al. 2010). Growth curve modeling of time-to-death-related trajectories – mostly done by means of longitudinal mixed/multilevel models employing time-to-death as within-subject predictor (e.g., Vogel et al. 2013; Sliwinski et al. 2003) – is a suitable and effective tool to analyze the association between intraindividual changes and time-to-death, meaning evidence for terminal *change* in a strict sense. Since the 1990s, studies of terminal change increasingly used longitudinal data

to model time-to-death-related trajectories of the variable under study.

By means of time-to-death-related growth curve modeling, fundamental objectives concerning terminal change can be addressed. For instance, the abovementioned objectives suggested by Gerstorf and Ram (2013) can be linked to model parameters of a time-to-death-related growth curve model (e.g., terminal change may be identified in terms of the fixed level and slope effects and described by the “curvature” of a growth curve model, whereas interindividual differences in terminal change are mirrored statistically in the random level and slope variances) or could easily be operationalized by more elaborate growth curve model specifications (e.g., latent dual growth curve models may be used to analyze interrelationships between terminal declines in different attributes and potential causes of terminal change might be included as predictors of time-to-death-related slopes; McArdle 2009).

By now, the longitudinal growth curve modeling approach has become key to the analysis of terminal change and therefore is essential for geropsychological distance-to-death research. However, a methodological drawback often present in these analyses of terminal change should also be noted: In the typical scenario of distance-to-death research, using data from longitudinal samples to model time-to-death-related trajectories, only those participants can be included that had deceased (and those time of death had been recorded) when the analysis is conducted. Thus, the participants still alive at the last mortality follow-up are excluded from these analyses. This practice could lead to considerable selectivity of the subsample used for analysis, as participants from early birth cohorts that survived to very old age are excluded and/or only these from the younger birth cohorts that died already at rather young ages are included. Concerning, for instance, that the terminal processes of the long-living could differ systematically from those that die at rather early ages, such selectivity could lead to biased evidence of terminal change.

Trajectories of Terminal Change

Piecewise growth curve models (also referred to as multiphase models, change point models, or

transition point models, e.g., Cudeck and Harring 2007) have become a particularly relevant tool to model time-to-death-related trajectories: As an implication of the concept of terminal change, trajectories of psychological functioning in late life might typically be shaped such that they mirror some kind of transition from a phase of preterminal change – which might show only minor change or change unfolding normatively age graded – into the phase of increased terminal change prior to death. That is, the typical end-of-life growth curves might appear as compound of two pieces, namely, the preterminal trajectory showing relatively low rates of change and the terminal trajectory showing higher, accelerated change. For illustration, Fig. 2 shows different widely used distance-to-death-related trajectory functions, including a piecewise growth curve, fitted to the hypothetical values observed from one individual at varying temporal distance-to-death. Piecewise growth curve models hence are the statistical “translation” of this implicit characteristic of distance-to-death-related processes and have been used in many studies of terminal changes (e.g., Gerstorf et al. 2008a, b, 2010; Vogel et al. 2013; Wilson et al. 2003; Sliwinski et al. 2006).

An alternative to modeling piecewise trajectories are growth curve models employing a nonlinear growth function that also may reflect the transition from a preterminal phase of moderate changes into a terminal phase of accelerated change – for instance, curvilinear (quadratic) trajectories showing accelerating trends toward the end of life, or exponential growth functions that could follow a pattern of high stability across a period more distant from death, turning into rapid change as death comes close. These nonlinear functions may be more realistic in that they do assume a continuous transition from preterminal to terminal change, instead of a sudden onset of the terminal phase at a single point in time. However, it is this “coarseness” of the piecewise growth curve model that makes it attractive for research on terminal change: Fitting a series of measures obtained at decreasing distance-to-death to a piecewise trajectory with a distinct change point includes an estimation of the onset and

Distance-to-Death Research in Geropsychology, Fig. 2 Illustration of widely used time-to-death-related growth curve functions

duration of the terminal process. That is, even if one does not assume that terminal change will start suddenly within a short temporal range (say, a day or a week), an estimate of the change point in time provides valuable evidence of the timing of the terminal phase, indicating at about which time-to-death the terminal processes began to evoke perceptible and observable changes in the study variable. For example, for the individual depicted in Fig. 2, the onset of the terminal phase would be estimated at about 3.2 years before death.

Moreover, comparing the growth curves depicted in Fig. 2 it should also be evident that

the choice of a growth function is relevant with respect to the distinction of terminal drop versus terminal decline. Piecewise or exponential growth functions are better suited than the polynomial functions (linear or quadratic) to fit a terminal drop pattern of sharp and steep decrease within a shorter time period before death.

Psychological Functioning as Predictor of Time to Death

In contrast to the longitudinal approaches that employ time-to-death as predictor of psychological functioning, time-to-death is also a widely used outcome variable mainly in epidemiological

research. These studies apply event history analyses to predict time-to-death (Yamaguchi 1991), for instance, using cognitive abilities measured in a sample as predictor of survival. Thus, this approach could be classified as cross-sectional, in that it models the statistical association between time-to-death and the interindividual differences in the predictor at a given point in time (e.g., White and Cunningham 1988; Smits et al. 1999). Cross-sectional survival analytic findings of time-to-death-related variability in a variable under study might be taken as indirect evidence of time-to-death-related *changes* that could have caused these differences. However, these analyses do not provide clear-cut evidence of terminal changes, leaving it unexplored whether and when intraindividual changes did generate the interindividual differences that are analyzed. For example, interindividual differences in cognitive abilities that predict survival might have persisted stably since early phases of the lifespan (Deary et al. 2004).

While it presents a weakness of the cross-sectional approach to distance-to-death research that survival analytic findings cannot provide evidence of terminal *change* in a strict sense, it should also be noted that this procedure is not affected by the potential selectivity problems due to the exclusion of study survivors (which may affect longitudinal analysis of terminal change, as explained above). In cross-sectional event history analyses, time-to-death can be treated as right-centered variable. That means that participants that have not deceased until the last mortality follow-up are included in these analyses, with their time-to-death considered as unknown but above the maximum value observed in the sample.

Distance-to-Death Research in Geropsychology: What Is It Good For?

Terminal Versus Age-Graded Changes in Late life?

In very general terms, gerontological research deals with changes in biological, psychological, and social functioning that unfold with some

regularity as humans approach and traverse the old age period of life. Therefore, analyses of age-related change had always played the important role to provide gerontologists with basic knowledge of such regularity, in terms of normative changes which are to be expected at certain ages, as well as the interindividual variability of such changes, pointing at the plasticity of aging processes. A great deal of research interest in psychological development in late life has focused on the losses and hardships that accumulate in old age, considering in particular how psychological functioning – such as cognitive performance, subjective well-being, etc. – gets affected by fundamental biological degradations that must occur in old age at least among those that prevented acute lethal diseases and other causes of premature death. With regard to this question, the analysis of age-related changes in psychological outcomes could be understood as an application of chronological age as indicator of such accumulation of loss: The older, the worse the physical health and other “objective” living conditions; hence, age may predict decline in psychological functioning. However, distance-from-birth may not be the optimal predictor of old age development driven by the biological degradations and the losses that tend to accumulate toward the end of the human lifespan. Taking into account that the occurrence, onset, and speed of such late-life aggravations are to some extent driven by nonnormative developmental influences, which may or may not affect individuals’ development more or less strongly at different times of their life course, a great deal of late-life development may come in old age, but not strictly age-graded (Baltes and Nesselroade 1979). Thus, chronological age might be unreliable indicator of impacts that promote changes in psychological functioning in old age.

In contrast, distance-to-death may do a better job in indexing the accumulation of crucial biological degradations (and other kind of loss) late in an individual’s life, considering that this accumulation itself marks the process that will end up in the individual’s death. That is, the health status of a 75-year-old who will not survive until age 80 could be expected worse compared to another

75-year-old who will live another 20 years, but might rather resemble the health status of a 90-year-old who will die before age 95. Following this reasoning, a focus on distance-to-death-related changes seems promising to add to the traditional age-related perspective in research on psychological late-life development in threefold respects, namely, (a) enabling the disclosure of non-age-graded developmental late-life dynamics, (b) promoting insights in the nature of processes that drive psychological late-life development, and (c) advancing geropsychological reasoning with paradigms of terminal phase of life and psychological terminality.

Disclosure of Non-age-graded Late-life Developments

The distance-to-death perspective can provide some “instrumental” value for the empirical detection of change dynamics unfolding at the end of the human lifespan. That is, using time-to-death as a metric of time-graded changes in psychological variables under study could reveal changes that occur frequently and with some regularity in late life, which otherwise, grading change to age or calendar time of measurement, would not be detected.

Such added value gained from shifting the focus from an age-related to a distance-to-death-related perspective became apparent in recent years from studies that examined longitudinal changes in subjective well-being (SWB) using both time metrics, chronological age, and time-to-death (Gerstorff et al. 2008a, b, 2010; Palgi et al. 2010; Schilling et al. 2013; Vogel et al. 2013; Windsor et al. 2015). These studies reported changes in SWB associated with time-to-death – showing patterns of terminal decline of life satisfaction and affective components of SWB – but weaker (or no such) associations with age. This evidence of time-to-death-related decline is inconsistent with the notion of a “stability-despite-loss paradox” of SWB in old age (e.g., Kunzmann et al. 2000): Age-graded longitudinal SWB trajectories or cross-sectional age-SWB associations showed no age-related decline – or even some age-related improvement – in many studies, suggesting that SWB in general is maintained largely stable

across large parts of the old age period (noticing, however, reports of accelerated age-graded declines in the oldest-old ages; e.g., Pinguart 2001; Schilling 2005). Such apparent stability has been taken as evidence of old people’s overall high resilience toward the losses they are confronted with in late life (e.g., Kunzmann et al. 2000; Charles and Carstensen 2009). However, rather than “paradoxical” stability of SWB, the absence of age-related decline might mirror effects of differential survival, in that those who suffer from severe health losses that could aggravate their SWB will soon die or otherwise be prevented from study participation. Evidence of time-to-death-related decline in SWB supports this latter interpretation. Thus, shifting the focus from age-graded to time-to-death-graded changes in SWB was “instrumental” in drawing a more clear-cut picture of SWB development toward the end of the human lifespan, disclosing late-life change dynamics that imply a correction of a widespread notion of stability built on the age-related perspective.

Insights in Processes Driving Psychological Late-life Development

Disentangling time-to-death-related changes from age-graded developments (or other intraindividual changes that unfold neither age- nor time-to-death-graded), could be essential to deepen the insights in the driving forces that impact on late-life psychological functioning. Usually, the time metric used to index changes in developmental studies is not considered a causal variable, but a proxy variable representing a set of processes covarying with the index time, considered causally linked with the change in the developmental variable under study. Interest in distance-to-death-related changes in psychological functioning follows an inherent rationale that these changes are driven by (or might even drive reciprocally) those “fatal” processes that will end in the loss of the individual’s biological capability needed to survive. Thus, psychological changes that unfold in association with distance-to-death are usually considered as linked with tertiary aging processes, denoting the biological degradations that unfold under impending death (Ram et al. 2010; Birren and Cunningham 1985).

Disentangling time-to-death-related change in a given psychological study variable from changes that unfold age-related and or related with the duration of some pathological conditions provides insight in the nature of the developmental process, telling the researcher whether the respective psychological changes are driven by terminal degradations or could be considered as consequence of biological aging in a strict sense or of the individual's particular pathological conditions (Ram et al. 2010; Sliwinski et al. 2003).

However, stressing such conceptual relevance of the distance-to-death perspective, some principal limitation of every time metric used to grade developmental changes should also be kept in mind. Regarding the study of age-related change, Wohlwill stated that *age is at best a shorthand for the set of variables acting over time, most typically identified with experiential events or conditions, which are in a direct functional relationship with observed developmental changes in behavior; at worst it is merely a cloak for our ignorance in this regard* (Wohlwill 1970, p. 50). This rather critical view might also apply to the use of time-to-death as time metric in developmental studies. That is, evidence of time-to-death-related psychological changes – such as terminal decline in cognitive performance or affective well-being – points at tertiary aging processes underlying such change, but of course it does not include an identification and confirmation of the particular causal impacts that drive this terminal change. Thus, in the quest for an in-depth understanding of late-life psychological development, evidence of time-to-death-related change does not mark the final destination, but rather a stopover, directing further scientific inquiry toward the specification of and the causal interplay between particular variables involved in the underlying process of tertiary aging.

Moreover, the clear-cut distinction of changes uniquely related with the timing of primary, secondary, and tertiary aging processes – by means of statistical modeling with given longitudinal data – might be an ideal hardly met. In particular, primary, secondary, and tertiary aging processes may not only co-occur and overlap but also interact in determining the course of individual

developmental trajectories. Obviously, mortality and pathology risks increase with age, and “secondary” pathology processes might also increase mortality risks. That is, the onset of tertiary aging processes cannot be considered independently from the onset and course of secondary aging processes, and both might depend on the course of the primary aging (considering plasticity of aging in terms of interindividual differences in the severity of age-graded changes). Thus, an interplay, rather than mere co-occurrence, of primary, secondary, and tertiary aging processes should be considered (for illustration see again Fig. 1).

Concerning statistical analyses that employ specific time metrics as proxy variables representing the impacts of these different processes, this consideration should take into account the “uniqueness” of the separation of time-to-death, age, or other time metrics’ effects on the developmental outcome variable studied: Most of the findings on terminal decline in cognitive performance or SWB published over the past decades rested upon some kind of longitudinal analysis of intraindividual differences in the outcome predicted by time-to-death and/or chronological age (commonly done by running multilevel or latent growth models). Typically these studies focused on evidence of unique time-to-death-related change that may not be accounted for by normative age-graded development, by either comparing separate models of age- versus time-to-death-related change in terms of model fit or intraindividual variance accounted for (e.g., Gerstorf et al. 2008a, b, 2010; Windsor et al. 2015), or by employing both time metrics simultaneously in one model in order to estimate their “unique” effects mutually controlled for the other time metric (e.g., Vogel et al. 2013; Sliwinski et al. 2003). If primary, secondary, and tertiary aging processes *interact* to some degree in causing the interindividual changes in the psychological outcomes studied, the estimates of time-to-death-related variability obtained with these statistical designs would not be perfectly “freed” from primary age-graded or secondary pathological processes. The potential interplay between such differentially time-graded processes might

be modeled statistically by inclusion of respective interaction effects between different time metrics in growth models (see, e.g., the statistical strategy proposed by Ram et al. 2010).

However, regarding the conceptual meaning of the statistical effects, the crucial point is that time-to-death-effects found in empirical data do not strictly correspond with tertiary aging processes and hence do not strictly discriminate the impacts of terminal degradations on late-life development from those of normative aging and “nonterminal” pathology. Thus, again, evidence of time-to-death-related psychological changes marks an important stopover on the pathway to an in-depth understanding of end-of-life development, pointing at terminal degradations of the human system that affect psychological functioning, but proceeding further on this pathway will need a specification and confirmation of the processes “proxied” by the time-to-death metric.

Considering Paradigms of Terminal Phase and Psychological Terminality

In view of the so far massive evidence of intense changes in many domains of human functioning that co-occur and accelerate over individuals’ final years of life, the distance-to-death perspective in the study of late-life development may be driven further theoretically, considering psychological terminality and the terminal phase of the human lifespan as theoretical paradigms that might inspire and enrich future research on late-life development.

As a basic conclusion drawn from the large body of distance-to-death research, individuals approaching their end of life frequently undergo changes in psychological functioning along with physical health degradations, which did not unfold in some continuous manner across the adult lifespan, but occur specifically over some limited time period preceding the end, at whatever age it occurs. Therefore, the aging person’s “final years” might be considered distinct from previous life phases: An individual might pass on to the terminal phase of life when the accumulation of losses caused by primary and secondary aging processes sum up to a critical mass, triggering dynamics of physical and psychological change

specifically related with impending death. The co-occurrence and interaction of these particular dynamics might activate causal linkages which are not effective at “earlier” stages of the human life course, but particularly involved in the degradation of the human system in the approach of death.

For instance, research on nutritional health effects in very old subpopulations indicated a “risk factor paradox,” in that mortality risks implied by the nutritional status in the general adult and young-old population were reversed (e.g., obesity seems protective against mortality and decline of physical function; Kaiser et al. 2010), also adding to other findings of so-called reverse epidemiology (Kalantar-Zadeh et al. 2005). Though “nonpsychological” and not taken from distance-to-death research, this denotes an exemplary case of specific causalities – different from those found in the healthy general population – that emerge under conditions of aggravated physical health and biological degradations. Similarly, the severe physical and functional loss conditions typically met in the terminal phase of life might interact in triggering consequences that will reveal causal dynamics not only quantitatively more intense, but qualitatively different from those driving preterminal development. Therefore, the terminal phase of life might be viewed conceptually as a period of unique meaning, to be distinguished from age-graded segmentations of the lifespan such as the “third” and “fourth” ages.

Furthermore, a crucial aspect which could hold particular importance for psychological functioning in this terminal phase is the individual’s subjective perception of distance-to-death-related accumulations and accelerations of degradative changes. These might generate a sense of impending death, provoking behavioral and affective responses which could be understood in terms of psychological terminality. The self-regulatory reactions of individuals who “feel it coming” may at least to some extent be directed toward the impending death, serving to facilitate the unavoidable process of dying. Thus, criteria of successful preterminal adaptation – such as maintenance or restoration of goal achievement and primary

control capacities (Heckhausen et al. 2010), protection or optimization of positive SWB outcomes, and so forth – might no longer be sufficient to understand end-of-life self-regulation. Reasoning in such a way about psychological terminality could inspire research on late-life development, at least by creating “paradoxical” views of adaptive changes, conflicting with the motivational constructs assumed as driving forces of adaptation across the lifespan. For instance, it might be asked whether terminal declines of hedonic well-being could be adaptive in supporting the self-regulation of impending death, in that individuals may easier disengage from life when it has become less hedonically rewarding. Similarly, one might even consider some cognitive declines adaptive in the terminal phase of life: For instance, reduced memory function might help to prevent too intense cognitive processing of the loss of life, which otherwise might cause feelings of regret and despair.

The arguments for such uniqueness of the terminal phase of life and psychological terminality unfolding within are quite speculative at this stage of distance-to-death research, as empirical research findings relevant to the particular matter of such uniqueness are barely present in the gerontological publication arena. Thus, these theoretical propositions should be understood as prospective paradigms for the further proceeding of distance-to-death research (noticing also theoretical work that provided at least implicitly some ideas of psychological terminality, such as Joan Erikson’s addition of a ninth stage of development to the Eriksonian psychosocial theory of lifespan development, (Erikson 1997); and the thanatopsychological premise that knowing about their death impacts on human’s attitudes and behavior, (Kastenbaum 2000)). That is, with substantial evidence of time-to-death-related changes in key domains of psychological functioning established, future research might move toward distance-to-death-related changes of structural relationships and dynamic interactions, involving these psychological domains. For instance, key questions that are still hard to answer include: How do people cope with health experiences signaling impending death – do they adapt to the

health aggravations in the terminal phase of life differently than to health problems experienced earlier in a “nonterminal” life situation? Which role do fears of death and dying play for such adaptation in the approach of life’s end?

Conclusions

Up to the present, distance-to-death research in geropsychology has developed over a period of more than five decades, revealing a body of solid evidence on terminal decline of cognitive functioning and, more recently, in SWB. Altogether, this research suggests that the end of life typically comes with intense and accelerated intraindividual changes of psychological functioning, which reflect the degradation of the biological and psychological systems that drive these changes. In such a way, the terminal phase of life appears as some kind of mirror image of the initial phase of life, in that rapid changes unfold at both ends of the lifespan, driven by causal mechanisms related with the respective endpoint – maturational processes unfolding after birth and terminal processes promoting the degradation of the organism.

However, distance-to-death research at present also appears as a still emerging field of geropsychological inquiry, far from any state of completion. The manifold findings of terminal changes reported so far inspire further questions concerning the interrelationships between time-to-death-related changes in different psychological domains and on the nature and specification of the underlying processes. Also, the generality of the terminal change phenomenon has yet to be explored (Gerstorf et al. 2013): Which other domains of psychological functioning – in addition to cognitive abilities and well-being – undergo time-to-death-related changes? Finally, in view of the co-occurrence and interplay of terminal changes in different psychological attributes, considering the terminal phase of life as a distinctive developmental segment of the human lifespan might be a paradigm advancing research on late-life development. In the terminal phase, the accumulation and acceleration of biological degradations preceding an individual’s death might

make special adaptive demands, not faced so far in previous developmental phases. Distance-to-death-related changes of psychological functioning might then be better understood in regard of their terminality, driven by these demands.

Dual Sensory Loss

Chyrisse Heine

College of Science Health and Engineering,
Department of Community and Clinical Allied
Health, School of Allied Health, La Trobe
University, Melbourne, VIC, Australia

Synonyms

Combined sensory loss; Deafblind; Dual sensory impaired; Dual sensory impairment; Vision and hearing loss

Definition

Dual sensory loss (DSL) is the acquired loss, in various degrees of severity of both vision and hearing acuity, associated with aging and prevalent in older adults.

Dual sensory loss (DSL) is the acquired, combined loss of vision and hearing prevalent in older adults. As adults get older, they often also experience changes in their sensory acuity as well. In particular, significant eye and ear changes occur. Commonly, the sclera of the eye changes in color, the number of mucous cells in the conjunctiva may decrease, the retro-orbital fat atrophies causing the eye socket to recede, eyelid tissue becomes lax and the levator muscle weakens causing the eyelid to droop, deposits of calcium and cholesterol salts often appear, retinal changes take place, and the pupil weakens and changes size (Nigam and Knight 2008). Visual conditions such as cataract, diabetic retinopathy, retinitis pigmentosa, glaucoma, and macular degeneration are common in older adults often leading to devastating visual difficulties (including low vision or legal blindness). The degree of impairment arising from the visual difficulty varies. Early cataract changes often only affect glare, while in more advanced stages, cataracts cause blurred vision and impaired contrast sensitivity and in severe cases blindness may occur, although cataract surgery

often restores functional vision. Diabetic retinopathy usually affects both eyes and results in blurred, distorted vision of the central visual field although laser surgery is sometimes successful in restoring functional vision. Glaucoma results in loss of the visual field and if controlled, sight loss may be minimal. If uncontrolled, impaired vision or blindness often results. Finally, age-related macular degeneration is the progressive loss of reading vision and sharp distance vision. This retinal disorder usually occurs bilaterally and affects the central part of the visual field frequently leaving peripheral vision unaffected. According to the WHO ICD-10 ([World Health Organization](#)), the severity of visual impairment ranges from moderate visual impairment (distance visual acuity worse than 6/18 and equal or better than 6/60), to severe visual impairment (distance visual acuity worse than 6/60 and equal or better than 3/60), to blindness (distance visual acuity worse than 3/60 to no light perception).

Age-related visual loss frequently results in light sensitivity and reduced tolerance for glare. Central or peripheral field losses cause a multitude of problems ranging from intolerance to variations in luminance to dependence on high levels of luminance, reduced contrast sensitivity, the inability to see fine detail of large low contrast objects, difficulty visualizing distant objects, discriminating detail, adapting to darkness, and distinguishing between colors. Additional visual difficulties include the reading of print even when using visual aids (e.g., reading legal documents, notices, magazines, or recipe books) and restricted mobility which frequently interferes with a person's ability to move around safely in the environment. These difficulties are disabling having severe psychosocial ramifications, such as decreased ability to participate in activities of daily living (ADLs) and independent activities of daily living (IADLs) independently, depression, and decreased social interaction.

Likewise, ear changes associated with the aging process occur and include: changes to the external pinna (such as enlargement), loss of elasticity of the external auditory canal, thinning and stiffening of the eardrum, calcification of the ossicles, atrophy of the muscles of the middle ear,

atrophy and diminishing cochlea hair cells, and vestibular and neural changes (Nigam and Knight 2008). Ear conditions that are prevalent in older people are cerumen (earwax) accumulation, conductive hearing loss (e.g., due to middle ear ossification), sensorineural hearing loss (e.g., due to presbycusis, noise-induced hearing loss, or multiple sclerosis). Central auditory processing disorder (CAPD) may occur due to neural changes in the central auditory nervous system. Hearing loss is usually defined according to the corresponding decibel loss consisting of mild, moderate, moderate-severe, severe, or profound hearing loss categories. These acquired hearing disorders are often slow to deteriorate and difficult to identify early due to the subtle changes that develop gradually. The hearing loss is typically more severe in the high frequencies affecting the perception of sounds (such as f, th, sh, and s speech sounds) and speech reception or understanding (particularly in poor listening situations or when there is high background noise or reverberation), difficulty with speech discrimination and the processing of auditory information.

Any combination of vision and hearing loss (even when a mild loss occurs in both vision and hearing) is termed DSL. The impact of DSL is devastating for older people, having significant implications for their health care. These prevalent conditions (vision and hearing loss) need to be recognized and considered by clinicians, researchers, and policy makers, particularly since the prevalence of these conditions is expected to rise in future years.

Prevalence

In line with global population aging, there will be an increased number of older adults with vision and hearing loss. According to the WHO (2012a), amongst the 285 million people worldwide who are visually impaired, in the 50 year and over age group, 65% are visually impaired and 82% are blind. Similarly, of the 328 million adults with disabling hearing loss worldwide, approximately one-third is aged 65 years and over (World Health Organization 2012b).

Since the prevalence of vision loss and hearing loss is high in the older adult population, it is a rightful assumption that the prevalence of the combined sensory loss (DSL) would be high in this segment of the population and worthy of further investigation and discussion. Research in the prevalence of DSL, however, reflects a relatively small body of work in comparison to other chronic conditions affecting older adults such as diabetes or dementia. Estimates of the prevalence of DSL vary greatly in the literature. This is primarily due to the different methodological approaches used to investigate DSL and the specific population investigated in studies of DSL. The following are two examples of studies that illustrate the disparity in prevalence estimates: Caban et al. (2005) found that the prevalence of DSL in their sample of 1110 community residing people in the USA was 7.3% in those participants aged 69–79 years and 16.6% for those aged 80 years and over. Schneider et al. (2012), however, obtained considerably different results in their longitudinal study of 2015 adults living in the Blue Mountains in Australia. Participants were aged 55 years and older at baseline. Results suggested that the prevalence of DSL (termed DSI in this study) was 6% at baseline, increasing from 0% for ages <60 years to 26.8% for participants aged 80 years and over.

The type of cohort included in studies of DSL also produces different prevalence rates. While Smith et al. (2008) concluded that DSL ranged from 5.0% to 7.4% in the older adult veteran cohort, increasing to 20% in veterans aged 85 years and over, Cacchione et al. (2003) found that 52.6% of their sample of older adults living in rural long-term care facilities were visually impaired; 44.1% were hearing impaired; 24.6% were dually impaired (had DSL); and 23.4% had no sensory impairment.

Gender is also an important factor that influences the prevalence of DSL. The literature shows that moderate and severe vision impairment and blindness have a higher prevalence rate in women than men (West et al. 1997). However, men are at a higher risk for developing hearing loss due to their increased participation in the military (noise exposure) or having worked in noisy occupations during their lifetime. Physically, hearing loss is

associated with different phenomena in men compared to women. In men, hearing loss is associated with high triglyceride levels, high resting heart rate, and a history of smoking, while hearing loss in women is associated with high body mass index, high resting heart rate, fast pulse wave velocity, and low Ankle-Arm Index (Helzner et al. 2011).

A variety of vision and hearing measurement methods (such as self-report, standardized measures or observation) have been used to investigate DSL (Heine and Browning 2015). This use of different measures as well as the above-mentioned factors has made the comparison of studies difficult.

Consequences of DSL

DSL affects older adult's everyday lives, functioning and participation in activities, and has implications for their health and psychosocial well-being. In particular, difficulty with communication is frequently observed (Heine and Browning 2002). Many older adults with severe visual loss cannot see their communication partner's face clearly and therefore cannot lip-read or perceive cues such as gesture, facial expression, and body posture and thus need to rely heavily on the auditory modality for adequate speech reception (Heine et al. 2002). For people with DSL, auditory acuity is reduced and even if hearing loss is mild, the auditory modality cannot compensate for diminished visual acuity. Communication difficulties such as reduced conversational fluency, adequate reception of a verbal message, and difficulty with identification of verbal and nonverbal cues result in communication misunderstandings or breakdowns (Heine and Browning 2002). In turn, conversational difficulty interferes with performance and confidence in social-communication situations often resulting in diminished psychosocial functioning.

Many older adults with DSL are at risk for developing a multitude of difficulties, including depression and decreased well-being. Kiely et al. (2013) investigated the association between DSL and mental health in 1611 adults aged

65–103 years. They found an association exists between depressive symptoms and DSL that was attributed to adults with DSL experiencing difficulty with completing ADLs and having limited social engagement. In line with these findings, Crews and Campbell (2004) also found that older adults with DSL had difficulty with everyday competence, experienced poorer health, and had decreased social roles.

The consequences of DSL are extensive as was evident in a study by Wallhagen and colleagues (2001) who investigated the relationship between DSL and several comorbidities in 2442 adults aged 50–102 years. These authors concluded that DSL had a strong impact on physical and social functional status.

Clinical Assessment

To date, there is no consensus regarding the identification and assessment of DSL for either research or clinical purposes. While self-report, questionnaires, and tests such as the Snellen eye test (for vision) and pure-tone air audiometry for hearing have been commonly used in research studies (Heine and Browning 2015), little literature exists regarding the identification of both disorders in one clinical setting. Service providers almost always identify vision and hearing disorders within separate contexts. That is, the vision specialists (such as the optometrist and ophthalmologist) assess vision and evaluate the client's perceptions about their visual loss, while audiologists assess hearing and appraise the client's perceptions about their hearing loss. The identification of DSL clinically is therefore reliant on a collaborative approach between professionals, which assumes that additional education concerning DSL has been provided to all team members working with older adults. For example, the audiologist needs to take into account a client's visual difficulties (such as "blurry" vision) and conducts the audiological consultation by considering the necessary accommodations that are required. These might include: reducing the distance between conversationalists, accounting for mobility needs, and adjusting the room

lighting (e.g., by reducing the glare). Likewise, it is essential for the vision specialist to accommodate a client's hearing difficulties by reducing the distance between conversationalists and using effective communication strategies such as speaking slower, clearer, and louder and repeating or expanding utterances for clarification purposes. The lack of DSL clinical guidelines and professional education programs educating visual specialists about hearing loss and audiologists about vision loss are significant barriers to the early identification of DSL and is thus an area for further investigation.

Management of DSL

This interdisciplinary area of practice requires the collaboration of a number of medical and allied health professionals including general physicians, ophthalmologists, otolaryngologists, vision specialists (such as optometrists), audiologists and speech-language pathologists (SLPs). Following diagnosis, the vision specialist and audiologist counsel and advise clients about their sensory acuity and provide rehabilitation or management strategies, especially fitting the necessary devices (such as magnifiers to enlarge print for visual enhancement and hearing aids and assistive listening devices for amplification). The SLP is often included as a team member in the rehabilitation program and is in an ideal professional position to provide clients with DSL strategies and practice to improve their communication. Heine et al. (2002) conducted a cross-sectional study at a day center for visually impaired people investigating the communication, situational difficulties and conversational needs of older adults with sensory loss, and their communication partners. Results suggested that older adults with DSL experienced a range of functional vision and hearing and communication difficulties and would benefit from specifically devised training programs.

The management plan for those with DSL needs to take into account the client's unique sensory status, competencies, and barriers. Again, the vision specialist, audiologist, and SLP need to be educated in the area of DSL and its

management in order to delineate and implement an adequate rehabilitation program. For example, as part of the rehabilitation program, when fitting a hearing aid for a client who has DSL, the audiologist needs to consider the client's visual difficulties and possible inability to manipulate small objects such as the battery of a hearing aid or read written instructions. In these instances, visual accommodations such as the use of a magnifier or enlarged font size may be warranted and from an audiological viewpoint a magnetic-tipped device for battery removal may be useful. From a technological perspective, it is imperative that the audiologist considers that a client who has DSL has different audiological needs to a client who has a hearing loss. Simon and Levitt (2007) discussed numerous audiological issues in relationship to DSL including specific recommendations for amplification fittings. These authors proposed that hearing aid fittings should be adjusted for people with DSL (e.g., consider the use of directional microphones) to improve their sound localization and binaural processing which are of primary importance for speech perception and spatial orientation.

Visual and hearing devices are one aspect of the rehabilitation process. Other relevant clinical target areas include speech perception training, communication programs for clients and carers (Heine et al. 2002), and the provision of informational counseling and psychosocial support (Brennan and Bally 2007). Tye-Murray (2009) has been instrumental in researching audiovisual speech perception in people with vision and/or hearing loss. Outcomes of their research suggest that audiovisual speech perception is related to auditory and visual word neighborhoods (context) and multisensory integration. Thus for people with DSL, practice drills including these concepts should be included in the intervention program.

Over the past two decades, communication training has gained popularity as a valuable rehabilitation method for people with DSL. In accordance with a client-centered approach, the person with DSL and if possible, their frequent communication partner/s (family or carer) participate in a communication training program to address the

environmental, situational, and conversational needs of the person with DSL (Heine et al. 2002). In these training programs, the clients and carers practice effective listening skills, situational management (such as being proactive and preselecting a quiet listening environment for a conversation; reducing glare or background noise), and the use and implementation of communication strategies (such as identification of conversational breakdown and the use of communication repair strategies). Communication training programs can enhance conversations, minimize communication breakdown, and increase social confidence thereby improving the social interaction, quality of life, and well-being of older adults with DSL.

A complimentary unique model of intervention is the biopsychosocial model discussed by Brennan and Bally (2007). This model focuses on the coping and adaptation strategies that older adults with DSL can use to improve their functioning, independence, and well-being. Counseling and assertiveness training are beneficial especially since many older adults with DSL often feel vulnerable and have decreased self-esteem and confidence. This emotional reaction in turn often leads to social isolation, depression, and decreased feelings of well-being.

Although DSL is a new field of research and clinical practice, the diverse management programs show promising progress.

Future Directions

Between 2000 and 2050, the number of people aged 80 years and over in major areas worldwide will more than quadruple (United Nations, Department of Economic and Social Affairs, Population Division 2004). With increasing longevity, and the increase in the size of the older adult population, the prevalence of DSL will increase dramatically.

While DSL in this segment of the population is still under-researched, gains have been made in the recognition of DSL as a clinical entity that is currently being researched more widely. Prevalence studies are more common although they

still reflect disparate findings. Interventions such as enhancing signal processing by modifying the dimensions of hearing aids, (Simon and Levitt 2007) multisensory integration (Tye-Murray 2009), communication strategy usage, and psychosocial adaptations continue to be researched and discussed in the literature. Further research is, however, necessary to increase professional and community awareness, knowledge and understanding of this group's communication and psychosocial needs. In order to achieve an exceptional professional service for older adults with DSL, including methods of early identification of DSL and the use of effective visual and auditory rehabilitation strategies, a richer discussion among researchers and professionals is required. The adoption of an interdisciplinary perspective is imperative, and the development of clinical guidelines to support this collaboration is an essential step in informing clinical practice.

For older adults with DSL, the future looks promising as research continues. Promoting the topic of DSL provides this area with the important recognition it deserves, especially since outcomes of research and clinical studies can contribute to these adults' well-being and improved quality of life.

Dynamic Analyses to Optimise Ageing (DYNOPTA)

Kim M. Kiely, Richard A. Burns and Kaarin J. Anstey
Centre for Research on Ageing Health and Wellbeing, Research School of Population Health, The Australian National University, Canberra, ACT, Australia

Definition

The Dynamic Analyses to Optimise Ageing (DYNOPTA) project has harmonized and pooled nine epidemiological studies of human aging to examine pathways to compressing morbidity and optimizing healthy aging in the Australian population. Research using the DYNOPTA dataset has focused on four main outcomes that contribute to disease and disability burden among older adults: cognitive function, sensory function, mental health, and mobility or activity limitations.

Project Background and Aims

DYNOPTA is a cross-institutional and multidisciplinary project that has harmonized and pooled

nine independently designed longitudinal studies of aging, creating a large nationally representative dataset of older adults in Australia. Aggregating data from a number of cohort studies has the advantages of enhancing population coverage (reducing coverage error), increasing sample size of underrepresented groups (such as the oldest old or those with rare medical conditions), facilitating instantaneous replication across studies, allowing cross-population comparisons, and investigating the impact of study idiosyncrasies on research findings. The broad aims of the DYNOPTA project are to identify effective pathways to compress morbidity and optimize aging (Anstey et al. 2010a, 2011a).

The DYNOPTA dataset is rich including the theme areas of cognitive functioning, sensory-motor functioning, mental health, mobility, and functional independence. The pooled dataset also includes background variables that cover sociodemographics, health, lifestyle, medical conditions, carers, and mortality. Within the DYNOPTA dataset, there are over 400 harmonized variables, which, when combined with individual observations, results in excess of 18 million data points. DYNOPTA therefore provides some of the most comprehensive available evidence on the health and well-being of older Australians between the years 1990 and 2006.

Contributing Studies and Sample Composition

The target population for the pooled DYNOPTA dataset is defined as all Australians born prior to December 1955, resulting in a baseline age range of 45–103. However, the target populations for the individual studies vary by geography and demography. There are study design differences in sample frame, random sampling procedures (simple, stratified, and clustered), data collection procedures (clinical interview, postal, telephone and self-completion questionnaire), baseline year (ranging from 1990 to 2001), age range, sample size, time intervals, and the number of follow-up waves. It is therefore important that analyses account for study design effects either through weighting and/or

Dynamic Analyses to Optimise Ageing (DYNOPTA), Table 1 Nine studies contributing to the DYNOPTA dataset

Study	Location	N	Baseline age range	Waves	Period
Australian Diabetes, Obesity and Lifestyle (AusDiab) study	National	7,296	45–95	2	1999–2005
Australian Longitudinal Study on Women's Health (ALSWH)					
Middle-aged cohort	National	13,706	45–51	4	1996–2005
Older-aged cohort	National	12,431	68–76	4	1996–2005
Household, Income and Labour Dynamics in Australia survey (HILDA)	National	6,164	45–90+	5	2001–2006
Australian Longitudinal Study of Ageing (ALSA)	Adelaide	2,087	65–103	7	1992–2004
Blue Mountains Eye Study (BMES)	Blue Mountains	3,654	45–100	3	1992–2004
Canberra Longitudinal Study (CLS)	Canberra, Queanbeyan	1,134	70–103	4	1990–2002
Melbourne Longitudinal Study on Healthy Ageing (MELSHA)	Melbourne	1,000	65–94	11	1994–2006
Personality and Total Health (PATH) Through Life	Canberra, Queanbeyan	2,550	60–66	2	2001–2006
Sydney Older Persons Study (SOPS)	Sydney	630	75–97	5	1991–2003

modeling adjustments. The contributing studies include three nationally representative panel surveys and six regional studies that were representative of the local community (see Table 1). The national surveys contribute 65% of participants.

The full DYNOPTA dataset is large and complex, consisting of 50,652 participants who were followed longitudinally, on up to 11 measurement occasions over a 15-year period. Over all studies, there was an average of 4.4 measurement occasions over a period of 9.4 years ($SD = 2.9$) and on average sample members participated in 3.1 measurement occasions. The mean age at baseline was 61.7 years ($SD = 12.4$, range = 45–103), and 77% of the sample were women, reflecting the inclusion of the all-female cohorts from the ALSWH and women's greater longevity (excluding participants from the ALSWH, 53% were woman). Study participants were generally community living, but five studies did include adults who resided in institutions such as nursing homes. Further information about each of the contributing studies, full description of the sample, and project background can be found in a cohort profile published in the International Journal of Epidemiology (Anstey et al. 2010a) and a

summary of policy-relevant findings in the Australasian Journal on Ageing (Anstey et al. 2011a).

Variable Harmonization

Variable harmonization is the rescaling of functionally equivalent measurement instruments onto a common metric. While this process may result in coarse-grained data (information loss), it has the advantage of providing a framework for the direct comparison of data obtained from independently sampled populations. Within DYNOPTA, variables were primarily harmonized retrospectively using the *by fiat* method, which involves identifying common variables and, when necessary, recoding response categories onto the same scale where the possibility of disputing the recode is deemed trivial by a panel of experts. Modeling-based approaches were used to standardize mental health variables such as depression symptoms. Table 2 shows a selection of variables harmonized in each of the content domains. Where possible, variables were harmonized to conform to Australian national standards. Some measures were not collected by all contributing studies, resulting in

Dynamic Analyses to Optimise Ageing (DYNOPTA), Table 2 Selection of harmonized variables for each domain

Domain	Example measures
Cognitive function	Mini-Mental State Examination (MMSE)
Sensory function	Visual acuity, pure-tone audiometry, self-reported vision and hearing difficulties, hearing aid use, dual sensory loss
Mental health	SF-36, probable depression, psychological distress
Mobility and disability	Activities of daily living, driving
Mortality	Date of death
General health and medical conditions	Diabetes, hypertension, cardiovascular disease, stroke, arthritis, BMI, self-rated health
Sociodemographics	Age, sex, partner status, education, career occupation, labor force status, domicile
Health behaviors	Alcohol consumption, smoking status, physical activity

study censoring. For example, the Mini-Mental State Examination (MMSE) was only collected by the six regional studies. Mortality data were obtained by linkage with the Australian National Death Index. Weights have been calculated to account for design differences in sampling, selection, and response rates. Weighted estimates are intended to reflect the Australian estimated resident population in 1996.

Profiling the General Health and Population Norms for Older Adults

One of the main contributions of the DYNOPTA project has been the estimation of population prevalence, national trends in behavioral patterns, and calculation of normative data for older adults. Population estimates derived from single studies are often restricted to reporting norms for broad age ranges (e.g., 75+) or may even exclude adults aged older than 85 due to lack of recruitment (Anstey et al. 2010b; Burns et al. 2013a). Of particular importance, data pooling in DYNOPTA has increased the number of participants aged over 80, allowing for more robust and reliable

norms of those in older age. For example, population prevalence has been estimated for chronic disease and medical conditions (Bielak et al. 2012), probable dementia (Anstey et al. 2010b), hearing loss (Kiely et al. 2012a), depressive symptoms (Burns et al. 2012a), self-rated health (Anstey et al. 2007), and driving trends (Ross et al. 2009) in older Australians. Normative data that is representative of the older adult population has been generated for common neuropsychological tests and assessment scales including the National Adult Reading Test (NART) (Kiely et al. 2011) and SF-36 (Bartsch et al. 2011). Population level norms have also been published for health behaviors such as smoking and alcohol consumption (Burns et al. 2013a) and engagement in physical activity (Sims et al. 2014). Burns and colleagues (Burns et al. 2013a) examined period effects by comparing patterns of alcohol and smoking consumption during the years between 1990–1994 and 1996–2002. They reported a decline in the proportion of adults who consumed alcohol at high risk levels or currently smoked tobacco over this period.

By mapping the demographic profile of a number of longitudinal cohort studies, DYNOPTA researchers have been able to reveal public health knowledge gaps by identifying subpopulations with low participation rates. In particular, they have documented the poor representation of Indigenous Australians in longitudinal studies of aging (Anstey et al. 2011b).

Cognitive Function

There are no existing prevalence data for dementia based on clinical diagnoses in Australia, and other national surveys have limited numbers of participants in ages 75 years and older. To address this, DYNOPTA has provided the most recent national prevalence estimates of cognitive impairment (probable dementia) (Anstey et al. 2010b). Cognitive impairment was defined by an MMSE score of 23 or less. A cut point of 23 on the MMSE was reported to have a specificity of 0.96 and 0.91 and sensitivity of 0.75 and 0.60 for dementia diagnoses in the Canberra Longitudinal Study (CLS) and

Sydney Older Persons Study (SOPS), respectively. Cognitive impairment was estimated to occur in 15.8% (95% CI: 14.0–17.7) of adults aged 75 years and older, increasing to 41.4% (95% CI: 31.3–50.8) of adults aged 90 years and older. These estimates were highly consistent with results from meta-analyses of European studies. There were no significant sex differences in the prevalence of cognitive impairment, although higher education was associated with higher MMSE scores.

Healthy life expectancy research on cognition had previously focused on social inequalities in cognitive impairment-free life expectancies, by demonstrating differentials in years lived with cognitive impairment by level of educational attainment. DYNOPTA data has been used to extend this literature by investigating the effects of modifiable risk factors for dementia. Multistate models were used to estimate the impact of obesity, smoking, and sedentary behavior on cognitive impairment-free life expectancies (Anstey et al. 2014). Smoking was associated with the largest reductions in total life expectancy and years lived without cognitive impairment for men and women, regardless of their education level. However, with the exception of obesity in men, all risk factors were also associated with fewer years lived with cognitive impairment. The key conclusion from this analysis was that although healthy lifestyle behaviors delayed the onset of cognitive impairment, they did not necessarily prevent it. Crucially, as age is the strongest risk factor for dementia, and dementia risk reduction also increases longevity, risk reduction strategies may result in more years lived with cognitive impairment at a population level. This finding has important implications for statistical modeling of the impacts of dementia risk reduction and projections of future dementia prevalence.

Sensory Function

The DYNOPTA dataset includes measures of self-rated vision and hearing loss as well as clinically assessed measures of visual acuity and pure-tone

audiometry. To date, most DYNOPTA studies of sensory function have focused on age-related hearing loss. Notably, over 70% of adults aged 80 years and older were estimated to have at least a mild degree of hearing impairment as defined by a pure-tone average of speech frequencies (0.5–4 kHz) greater than 25 dB in the better ear (Kiely et al. 2012a). An evaluation of the utility of self-reported hearing loss in comparison to hearing loss defined by pure-tone audiometry demonstrated that the prevalence of hearing loss based on self-report data was likely to be overestimated for adults younger than 75, but underestimated for older age cohorts (Kiely et al. 2012a).

Another significant study modeled longitudinal trajectories of audiometric hearing thresholds in 3,526 adults. Importantly, these analyses examined an extensive range of risk factors for hearing loss not elsewhere investigated, including sociodemographics, noise exposure, medical conditions, and cognitive impairment. It was found that age, cognitive impairment, and hypertension were associated with faster rates of decline in hearing thresholds. However, many other factors commonly associated with differences in hearing levels did not predict rates of decline in hearing thresholds (Kiely et al. 2012b). A currently active stream of research on sensory functioning involves calculating sensory impairment-free life expectancies. These analyses demonstrate that in addition to being highly prevalent, hearing and vision impairment can affect older adults for substantial periods of their remaining life.

Mental Health

The burden of psychological distress of older adults, particularly those living in the community, is unclear; some findings purport an increase in depression risk with increasing age; others suggest a decline in depression risk. However, many of these findings are confounded by increasing heterogeneity with age and small sample sizes. This is particularly the case for older men with some suggestion that men are at greater risk of reporting depression in late life. Analyses with DYNOPTA indicate a pattern of increasing

depression risk in men although this failed to reach a level of statistical significance (Burns et al. 2012a, 2013b). More robust evidence was found for increasing levels of depressive symptomatology among older men (Burns et al. 2013b); this appears to mirror rates of suicide in older Australian men. Gender differences in mental health in late life have also been reported when examining terminal mental health decline. That is, in both men and women, there is evidence that depressive symptoms increase substantially in the years preceding death. Findings from DYNOPTA indicate this association is more strongly pronounced in men and that most of the effect in women can be accounted for by comorbid physical health states (Burns et al. 2013c).

With increasing interest in dimensions of positive mental health and well-being, DYNOPTA has provided substantial evidence of the need to examine dimensions of psychological health and well-being that are not necessarily captured in clinically relevant dimensions of psychological distress. For example, in contrast to measures of psychological distress, vitality – a sense of vigor, energy, and engagement – has been implicated as a stronger predictor of self-rated health (Burns et al. 2014a), falls (Burns et al. 2012b), and mortality (Burns et al. 2014b, c).

Another study examined age differences in high- and low-arousal positive and negative affect. Lower levels of negative affect and higher levels of low-arousal positive affect were reported by older adults relative to those in midlife (Windsor et al. 2013). Interestingly, physical function suppressed the association of older age with reduced high-arousal positive affect and lower negative affect. In other words, age differences in affect were amplified after additionally accounting for covariation with physical function. These findings were interpreted as being consistent with the notion that older adults tend to restrain high-arousal emotions in order to avoid uncomfortable levels of physiological arousal and provided further evidence that age differences in the expression of negative and positive affect are underpinned by lower levels of physical functioning among older adults.

Driving

DYNOPTA has been used to provide national trends in driving rates and predictors of self-reported driving and to investigate the proportion of older drivers with low levels of cognitive and/or sensory functioning (Ross et al. 2009). In this study it was reported that 46% of adults over the age of 65 were nondrivers. The proportion of nondrivers was greater for women and for older age groups, such that for those aged 85 years and older, 37% of men and 5% of women reported that they were current drivers. Discontinued driving was more likely to be reported by participants who were women, older, not married, had careers in lower-skilled occupations, were living with impaired levels of visual acuity, and had poorer health. Although people with suspected cognitive impairment (MMSE < 23), and visual impairment (visual acuity > 0.3 logMAR) did generally reduce or cease driving, there remained substantial numbers of men who continued driving with cognitive or visual impairments.

By combining data from a number of state jurisdictions across Australia, Ross and colleagues were able to evaluate the implications of differing licensure policies for older adult driving rates (Ross et al. 2011). They compared differentials in driving rates between state jurisdictions with and without mandatory age-based license testing. It was reported that mandatory age-based testing for renewal of driving licenses was associated with lower rates of driving, but was not effective in reducing the proportion of older drivers who had either a visual or cognitive impairment.

In summary, the pooling of existing datasets to create DYNOPTA has produced the largest dataset on aging in Australia. This resource has enabled both population-based research of a descriptive nature and developmental research on trajectories, trends, and patterns of characteristics at ages for which Australia previously lacked large datasets. The process of developing the pooled dataset has demonstrated the feasibility and utility of this approach.

Early and Unplanned Retirement

Gwenith G. Fisher¹, Amanda Sonnega² and Dorey S. Chaffee¹

¹Department of Psychology, Colorado State University, Fort Collins, CO, USA

²Health and Retirement Study, Survey Research Center, Institute for Social Research, University of Michigan, Ann Arbor, MI, USA

norms. Unplanned retirement refers to a retirement process or decision that was not anticipated. Because retirement has been increasingly conceptualized as a process rather than a discrete event, it has become more challenging to conceptualize early and unplanned retirement. Early and unplanned retirement combines the timing of retirement as well as the extent to which the process of retirement was anticipated.

Synonyms

Early retirement age

Definition

Early retirement refers to the timing of leaving the labor force, but the notion of early is relative, and therefore, there is not one single definition of what constitutes early retirement. One definition of early retirement is economically driven (e.g., earliest age of eligibility for pension plan benefits). The exact age that defines early retirement varies across countries due to differences in public policies. In the United States, early retirement is currently considered prior to age 62, because age 62 is the earliest age of eligibility for Social Security benefits. The second definition is early relative to one's own expectations regarding the timing of retirement. The third definition is based on societal, cultural, or institutional

Introduction

Given the rapid aging of the large baby boom generation and global aging generally, understanding the retirement transition and its impact on retirement well-being is more important than ever. A key factor in this transition is whether retirement is planned or unplanned. Another important distinction is whether retirement occurs at an early age or a normal retirement age. What constitutes "early" retirement is relative. This entry addresses issues around early and/or unplanned retirement. The study of early and unplanned retirement has implications for determining when and how workers may depart from the workforce, as well as for understanding consequences, including adjustment and well-being postretirement.

A great deal of research in the 1980s and 1990s focused on retirement timing and particularly decisions to retire early (e.g., Feldman 1994) because studies of labor force participation clearly

documented a trend toward increasingly younger average age at retirement. For a variety of reasons, that trend now appears to have reversed, yet a significant proportion of workers in their late 50s and early 60s continue to leave the labor force, both voluntarily and involuntarily. Therefore, understanding the antecedents and consequences of early and unplanned retirements remains an important research and policy focus. A variety of antecedents to retirement have received research attention, including characteristics of workers (e.g., health status, sociodemographics, preferences), characteristics of their families (e.g., spouse's health status and other caregiving needs), and characteristics of the work environment. Each of these is described below (see "[Antecedents](#)"). Other researches direct attention to the consequences of early and unplanned retirement such as impacts on mental and physical health, family, and financial well-being (see "[Consequences](#)"). Lastly, a growing literature addresses the variety of paths workers are now taking as they exit the labor force. The traditional model of moving from full-time employment to full and permanent retirement is growing less common. Retirement is seen as a process rather than an abrupt transition (Shultz and Wang 2011). Implications for this trend on early and unplanned retirement are discussed (see "[Bridge Employment](#)").

Background

The concept of early retirement is relatively new historically. As far back as 1850, approximately 75% of men age 65 or older were in the US labor force (Zickar 2013). When the US Social Security program was introduced in 1933, approximately 58% of men were still working at age 65 (Costa 1998). Combined with Social Security and other pension incentives, most American workers began retiring when they could afford to do so.

Retirement timing is driven to a large extent by economic circumstances. This includes government- as well as employer-provided pensions. For example, two notable peaks in retirement at ages 62 and 65 in the United States (the

ages of early eligibility and full Social Security retirement benefits) are evident (Gustman and Steinmeier 2005). This provides evidence that pension eligibility is a powerful retirement incentive. Although the early retirement age in the United States currently remains at 62, the age of eligibility for higher monthly benefits has increased from 65 to older ages determined by birth date, with additional incentives to delay retirement benefit claims to age 70. In addition, the financial penalty for continued work while receiving Social Security benefits has decreased (Gruber and Wise 1998). Many other countries (e.g., Germany, Italy) have recently modified public policies to increase the age of eligibility for government pensions, thereby modifying the age that constitutes early retirement (Gruber and Wise 2007). In terms of private pensions, the shift from defined benefit plans to defined contribution plans beginning in the 1990s has provided stronger incentives to continue working (i.e., disincentives for early retirement).

Other changes in public policy have changed the retirement landscape as well. For example, the US Age Discrimination in Employment Act (ADEA) was passed in 1967 to protect workers age 40 and older from discriminatory employment practices. In 1986 it was amended to eliminate mandatory retirement ages for all but a few occupations (e.g., those involving public safety, including airplane pilots and federal law enforcement).

Even though policy has moved toward a focus on extending working lives, a considerable number of workers depart the labor force early for a variety of reasons. Thirty percent of retirees indicate that their retirement was forced (Szinovacz and Davey 2005). Others choose to leave the workforce at relatively young ages despite substantial work capacity. Here a range of factors that influence both voluntary and involuntary early work force departure have been described.

Theory

Psychologists studying retirement trends have sought to provide theoretical grounding. Multiple

theories have been offered in the psychological literature to facilitate understanding of retirement behavior and retirement decisions. Theories relevant to early and unplanned retirement include continuity theory (Atchley 1999), role theory (Kahn et al. 1964), the life course perspective (Elder 1994), and the push/pull model of retirement (Shultz et al. 1998; Barnes-Farrell 2003).

Continuity theory indicates that maintaining continuity or stability is related to positive outcomes. This theory would suggest a negative relationship between early and unplanned retirement and outcomes because by its very nature early and unplanned retirement may disrupt or significantly modify one's life.

Role theory proposes that life is comprised of multiple sets of roles or expectations, such as work, family, and community (Kahn et al. 1964). Early and unplanned retirement involves a change in roles in which an individual who worked must now adjust to retirement, perhaps having more of an opportunity to develop nonwork roles. Unplanned retirement in particular likely involves a more abrupt role change, particularly as work may provide an individual with a source of identity with a work role, and one must adjust to no longer working.

Related to role theory, the push/pull model of retirement indicates that some workers will retire because they are pushed out of the work role, whereas others will be pulled toward retirement for nonwork reasons. Unplanned and early retirement may result from push factors (e.g., declines in worker health, organizational incentives for early retirement) or pull factors (e.g., caring for a spouse, receiving a financial windfall, or desiring leisure more than work). Barnes-Farrell (2003) described four factors related to the retirement decision process beyond health and wealth: job attitudes, job conditions, organizational climate, and societal pressures. Negative job attitudes (e.g., low job satisfaction), poor job conditions, a negative or unsupportive organizational climate, and societal pressures (e.g., norms regarding retirement age or retirement timing) may lead to early retirement.

Recently, Kanfer et al. (2012) proposed an organizing framework for understanding work

motivation among older adults. They developed a person-centered approach, explaining goals for individuals at work, to work, and to retire. These goals take into account multiple reasons for working or retiring, including financial, social, personal, and generative, as well as fluctuations in motivation to work and motivation to retire.

Antecedents

While not an exhaustive review, this section highlights major findings from research exploring reasons for, or antecedents to, early and unplanned retirement. Although each of these reasons is described separately, reasons for retiring early interact in important ways. Many of the studies mentioned investigate several retirement antecedents simultaneously.

Health

One of the most widely studied potential reasons for early workforce departure is poor health. Much of what is known about the impact of health on retirement decisions in the United States comes from studies using rich information from the Health and Retirement Study (HRS) (see the chapter “► [Health and Retirement Study, A Longitudinal Data Resource for Psychologists](#)” by Sonnega and Smith, 2015). As a whole, these studies reveal that health plays a large role in the timing of retirement (e.g., Aaron and Callan 2011; Cahill et al. 2013), especially in early and unplanned labor force exit (Dwyer 2001) and perceptions of forced retirement (Szinovacz and Davey 2005). HRS data include widely used questions about expected age at retirement, which have been shown to relate closely to actual retirement. McGarry (2004) studied how changes in health affect retirement expectations, finding large effects of self-rated health on when workers expected to retire. Importantly, she also showed that changes in retirement expectations were affected to a much greater degree by changes in health status than by changes in income or wealth.

Similar findings emerge in other countries as well. Studies in Canada (Park 2010) and Europe (García-Gómez 2011; van Rijn et al. 2014)

revealed that a leading cause of early and unplanned retirement is poor health that results in a diminished capacity to work. Results from the well-known Whitehall II study showed that health is a strong predictor of early retirement in British civil servants (Mein et al. 2000). More recently, the Survey of Health, Ageing and Retirement in Europe (SHARE) showed that poor self-reported health is a strong predictor of labor force exit even after controlling for factors predictive of poor health such as obesity, problem use of alcohol, job control, and effort-reward balance (van den Berg et al. 2010). Jones et al. (2010) examined the effect of health on early retirement in 12 waves of the British Household Panel Survey. In the sample of men age 50–65 and women age 50–60, health was a highly significant risk for early retirement. Interestingly, however, the relatively low incidence of health problems in this age group means that relatively few retirements result from poor health. Other studies consider alternate paths to retirement potentially affected by poor health. A recent meta-analysis of longitudinal studies found poor health is a major cause of workforce exit, especially through disability, unemployment, and early retirement (van Rijn et al. 2014).

Finally, research in this area distinguishes particular aspects of health that may affect the timing of retirement. For example, although some workers with chronic health conditions expect to retire at younger ages (Dwyer 2001), others may experience an unexpected health event that causes them to have to leave work (McGeary 2009). Health conditions that commonly lead to early retirement include musculoskeletal conditions (e.g., back pain or problems), cardiovascular conditions (e.g., heart problems, stroke), circulatory problems, and mental illness (e.g., anxiety or depression) (e.g., Karpansalo et al. 2004).

Marital Status

The decision regarding whether and when to retire is often made collaboratively among spouses/partners, and research has shown that spouses often coordinate the timing of their retirement with one another (Gustman and Steinmeier 2000). Although marital status and having children have not been shown to predict early retirement,

Kim and Feldman (1998) found that individuals with an employed spouse are less likely to take early retirement incentives compared to individuals whose spouse is not working. Perceived pressure from spouses (i.e., the antithesis of support) impacted individuals' intentions to retire early. In fact, perceived spousal pressure for early retirement was the strongest predictor of early retirement (van Dam et al. 2009).

Men with a working spouse were much less likely to exit the labor force themselves, accounting for health and other demographics (Ozawa and Lum 2005). How much spouses enjoy spending time together is a strong predictor of whether or not they time their retirement to coincide (Gustman and Steimeier 2004). The timing of retirement among couples is also related to gender and marital quality, with higher levels of marital conflict taking place when one individual retires while the other is still working (Moen et al. 2001).

Family Caregiving

In addition to early retirement due to one's own health, workers may also depart early to care for a family member (Matthews and Fisher 2013). This may take the form of caring for an infirmed family member or providing care to children or grandchildren.

Spousal Caregiving

Pienta and Hayward (2002) found that women were more likely to take their partner's health status into account when formulating a decision to retire than they are to consider their own health status. In fact, personal health status was not a significant predictor of retirement decisions for women, but was for men.

Dentinger and Clarkberg (2002) found that when women were required to provide physical care to their disabled husband, these women were significantly more likely to retire early. Conversely, though, men who were required to provide physical care to their disabled wife were more likely to delay retirement. Such results could be interpreted using a sex-role perspective wherein men may be more likely to perceive a need to shoulder the financial burden of having an ill spouse, whereas women more frequently

assume the caregiving role. The stress associated with family care demands may be exacerbated by the suddenness with which such demands may develop.

Children and Grandchildren

Other caregiving responsibilities related to early and unplanned retirement include taking care of grandchildren (Matthews and Fisher 2013). Some workers, and more likely women than men, may be drawn to or “pulled” into early retirement in order to care for grandchildren. A few studies have found that early retirement is negatively related to the number of children one has as well as having financial responsibility for children (Matthews and Fisher 2013). One explanation is that women may enter the workforce because of the need to financially support their children. Therefore, continued economic pressure may prevent women from early retirement to ensure that children are supported.

Job and Organizational Characteristics

Characteristics of work and the work environment are related to early retirement, though most of these issues do not lead to unplanned retirement and are therefore not discussed here in much detail. Early and unplanned retirement may result from organizational efforts to reduce the size of their labor force. This may happen by offering wage, bonus, or health insurance incentives to entice workers to retire early (Zhan 2013) or forced layoffs, producing both voluntary and involuntary mechanisms by which workers may retire early. In other words, an employee may retire earlier than he or she anticipated and without much advanced planning to accept an early retirement incentive from their employer. Many employers are reducing longer-term healthcare costs by reducing the amount of coverage or proportion of premiums paid to retirees. In an effort to retain high-quality health insurance, workers may opt to retire sooner than they originally planned in order to retain such benefits during retirement. This example would constitute a voluntary early unplanned departure. Early and unplanned retirement may also take place as a result of a layoff followed by not obtaining subsequent

employment elsewhere. Layoffs are an example of an involuntary cause of retirement.

Raymo et al. (2011) found that workers' prior experiences with involuntary job loss (unemployment) as well as working in jobs characterized by not offering retirement plans, health insurance benefits, and good wages were associated with a lower likelihood of early retirement.

Economic Factors

Pension Plans

As noted above, one of the more significant changes to retirement incentives has been the transition of both private and, to a lesser extent, public pensions from defined benefit to defined contribution plans. Defined benefit plans provide a certain monthly dollar amount received during retirement based on age, years of service, etc. Defined contribution plans (e.g., 401ks, 403bs) in the United States consist of financial savings and/or investment accounts to which employees and sometimes employers contribute money, usually a percentage of wages. The value of accounts fluctuates based on how money is invested. Generally, longer work tenure means more retirement savings. Defined benefit plans produce economic incentives for workers to retire when they reach a particular age or tenure with the organization, offering little financial benefit for continued work. Not surprisingly then, research demonstrates a robust effect of the presence of a defined benefit pension plan on earlier retirement (Mermin et al. 2007; Aaron and Callan 2011; Cahill et al. 2012)

According to Butrica et al. (2009), employee participation in defined benefit pension plans was reduced from 38% to 20% in the United States between 1980 and 2008. Participation in defined contribution plans increased from 8% to 31% during the same time period. This shift in pension plan type provides some economic incentives for employees with a pension plan to remain in the workforce – to continue saving for retirement and postpone spending down retirement savings. Likewise, the decline of defined benefit pension plans means that this cause of early retirement is likely to diminish over time.

Health Insurance

Prior to the Affordable Care Act of 2010 in the United States, the link between employment and health insurance meant that those wishing to retire early or who were forced to leave the workforce prior to the age of 65 (i.e., age of eligibility for government-sponsored health insurance through Medicare) could also risk going without health insurance. Most workers receive health benefits from their employers, but they often forfeit their insurance when they retire. Not surprisingly then, health insurance provision has been shown to affect retirement decisions. For example, potential costs of health insurance reduced retirement rates in workers age 51–61 (Johnson et al. 2003).

Some work places offer health insurance as a benefit to their retired employees, and this may have an impact on early retirement. In a review of the literature, Gruber and Madrian (2004) reported that the availability of retiree health insurance increases the odds of retirement by 30–80%. Others have shown that it substantially increases the probability of retirement by age 62 (French and Jones 2011). Nyce et al. (2013) investigated this effect in a large data set representing individual data from 54 US firms. Presence of employer-provided health insurance has its biggest effects between ages 62 and 64, increasing the rate of retirement at 62 by 6.3% and nearly 8% at age 63. Health status may affect the value individuals place on employer-provided retiree health insurance. For example, Blau and Gilleskie (2008) demonstrated that the cost of health insurance has a modest effect on retirement rates for men in good health but a large effect on retirement decisions of men in poor health. Specifically, having retiree health insurance available appears to provide a path to early retirement for men in poor health.

Lastly, aspects of public and private insurance programs vary across countries, and thus effects vary by country, as some nations have government-sponsored health insurance that is provided independent of labor force status. For example, Zissimopoulos et al. (2007) found that the retirement rate is higher in England compared to the United States, and the overall earlier age at retirement by age 55 and beyond is partly

accounted for by the availability of public health insurance. In other words, workers are more likely to retire early when public health insurance is provided.

Wealth

Theoretical economic models of savings and labor force participation posit that higher levels of wealth are associated with a higher probability of labor force exit (Gustman et al. 2011). In general, empirical results support this hypothesis: early retirement is more likely when individuals have greater financial resources. For example, among American workers between the ages of 55 and 66, greater wealth was generally associated with leaving the workforce (Aaron and Callan 2011), although interestingly greater education was associated with remaining at work. However, research demonstrating an empirical effect of personal wealth on retirement reveals relatively modest effects, net of other factors (Bloemen 2011). For example, Gustman et al. (2011) found that the recent economic recession, on average, had a modest effect on retirement. This is explained in part by the fact that a majority of Americans have no significant stock market investments.

It is important to note that economic resources, including personal wealth, pension wealth, and health insurance, are dynamically interrelated and decisions about work can unfold for many years leading up to retirement. Poor health is often a reason for leaving the workforce, yet low economic resources often have the effect of delaying retirement. Bound et al. (2010) followed men age 51–61 who were working in 1992 to evaluate the impact of health and financial resources on work choices. Men in good health were not likely to retire without fairly substantial economic resources behind them, whereas men in poor health were likely to retire even without pension benefits.

Outcomes

Retirement researchers have also extensively investigated outcomes of early and unplanned retirement. This section summarizes some of this research.

Economic

Economic outcomes of early and unplanned retirement are both macro- and microeconomics. At the macrolevel, early and unplanned retirement results in additional use of government resources (e.g., disability pensions, less employee contributions to Social Security). At the microeconomic level, Munnell and Sass (2008) indicated that many individuals do not save enough money for retirement and are therefore not likely to have the necessary financial resources to maintain their standard of living in retirement based on low savings rates. Early and unplanned retirement is likely to result in individuals spending down their retirement savings compared to individuals who remain in the workforce longer, because they have a longer amount of time on which to rely on their own financial resources. To the extent that individuals retired at earlier ages and without anticipation of retiring, it is quite possible that they left the workforce prior to attaining all the financial resources needed for financial security during retirement. Munnell and Sass (2008) pointed out that working two more years has a significant impact on the preservation of retirement wealth.

Health

Research examining health consequences of early retirement emphasizes the need to distinguish between voluntary and involuntary retirements. Van Solinge (2007) suggested that retirement itself has no categorically harmful or beneficial effect on health. Instead, it is the degree of perceived control over the retirement process (i.e., voluntary vs. involuntary retirement) that adversely affects health and emotional well-being. A great deal of research has found higher levels of physical and mental health associated with voluntary retirement compared to involuntary retirement (Isaksson and Johansson 2000; Shultz et al. 1998). For example, research has shown that involuntary retirement was associated with an increase in problem drinking behavior during retirement (Bacharach et al. 2008). This study found that after accounting for preretirement drinking behavior, having more control over the retirement decision was associated with less alcohol consumption and a lower risk of problem drinking behavior.

Methodological limitations, limited and cross-sectional data, differences in cultural norms, labor markets and economic incentives, and failure to differentiate between voluntary and involuntary retirement have likely contributed to inconsistencies in understanding the impact of retirement on health status. Dave et al. (2008) suggested there are two primary complications when attempting to identify the causal effect of retirement on health: unobserved selection effects (i.e., a sample selection bias) and endogeneity biases, which results in the inability to determine which comes first. A few studies have examined the effects of retirement on health. First, Dave et al. (2008) adjusted for selection bias (e.g., life history, retirement time preferences) and used a stratified sample, such that in waves prior to retirement individuals reported no major illness or health problems and no worsening of health between adjacent waves. Thus, any changes in health postretirement were likely due to factors exogenous to health. They found that these confounding biases accounted for the majority (80–90%) of the observed differences in health over time and that involuntary retirement was associated with greater adverse health effects. Second, Calvo et al. (2013) examined retirement timing in relation to physical and mental health. They found that retiring early (i.e., exiting the workforce at an earlier age than culturally and institutionally expected) can be problematic for both physical health and emotional health. Calvo et al. (2013) assessed the potential for reverse causality in the relationship between retirement timing and health by adjusting for endogeneity bias and controlling for confounding effects of unobserved factors (e.g., personality traits, genetic predispositions).

Contradictory results were found by Jokela et al. (2010) in a study of British social servants over 15 years. Jokela et al. (2010) found that both on-time retirement and voluntary early retirement were associated with better physical functioning and mental health compared to those remaining in the workforce. Moreover, results indicated that physical functioning and mental health prospectively predicted retirement timing. Compared to continued employment or having left the

workforce due to reasons other than retirement, poor mental health was associated with increased odds of subsequent voluntary early retirement, and those with poorer physical functioning were more likely to retire at the statutory age. Jokela et al. (2010) suggested that these results support a causal relationship between statutory and early voluntary retirement and positive health outcomes because analyses of reverse causality (using discrete-time survival analysis models) showed poor health increased the probability of retirement; thus it is unlikely reverse causality accounted for improved health postretirement. Further, longitudinal within-person analyses revealed that greater health benefits were obtained after retirement. Not surprisingly, both poor mental health and physical functioning increased the odds of ill health in retirement and were indicative of selection rather than causation.

Psychological Well-Being

An individual's transition and psychological adjustment to retirement is a dynamic, multifaceted process contingent upon many personal and contextual factors such as individual attributes, preretirement job-related variables, family-related variables, retirement transition-related variables, and postretirement activities (Pinquart and Schindler 2007; Wang et al. 2011). Because work is an integral part of people's lives, and is highly valued in society, work roles can serve as a source of psychological well-being by contributing to feelings of self-worth, meaningfulness, and personal identity (Steger and Dik 2009). Further, work can provide important social and financial resources. Given the significance of work, the loss of one's job through retirement can have adverse consequences for psychological well-being, especially when the event is unplanned, unexpected, or involuntary.

Early and unplanned retirees are especially vulnerable to maladjustment to retirement. A major determinate of well-being among older adults is perceived control over one's immediate environment (Lachman 2006). Similar to the empirical results regarding early retirement and physical health outcomes, research has shown a lack of perceived control over the timing or circumstances of retirement (e.g., unplanned or

involuntary retirement) is related to lower levels of well-being, including life satisfaction (Isaksson and Johansson 2000) and happiness (Quine et al. 2007). From a life course perspective, the timing of retirement can have a significant influence on psychological well-being; specifically, transitioning into retirement either earlier or later than expected or preferred is thought to be disruptive and stressful, leading to greater difficulty in adjustment (Quick and Moen 1998; Isaksson and Johansson 2000). For example, Wang (2007) found that individuals who retired earlier than expected experienced declines in health. Those who were in unhappy marriages consistently experienced declines in well-being following retirement.

Research indicates that psychological and financial preparation is also important for individuals' well-being in retirement (Bender 2012; Noone et al. 2013). Although a substantial body of literature suggests that early retirement is detrimental to psychological well-being, Potočník et al. (2010) found that retirees who acted in accordance with group norms favoring early retirement and retirees who perceived low capacity to continue working were more satisfied with early retirement and reported higher levels of well-being. Moreover, compared to retirees who entered retirement early by their own volition, retirees who perceived their retirement as forced or involuntary experienced lower levels of both satisfaction with early retirement and psychological well-being. These results are consistent with other studies that found when individuals transition into early retirement voluntarily, they can experience greater satisfaction with retirement and life and higher levels of psychological well-being (Quick and Moen 1998; Isaksson and Johansson 2000; Hershey and Henkens 2014; Noone, et al. 2013).

Although there is some heterogeneity in the empirical findings concerning the impact of early retirement on the transition and psychological adjustment to retirement, there is general agreement that unplanned and involuntary retirement is detrimental to retirees' well-being and adjustment. Further, it has been established that planning for retirement (both psychologically and

financially) and having control over the timing and circumstances of retirement are beneficial.

Family

Early and unplanned retirement may help address family caregiving needs, including the care of one's spouse or partner or other family members. Increasingly, workers (more often women than men) retire in order to have more time available to care for grandchildren (Matthews and Fisher 2013) (see "Antecedents").

Bridge Employment

Bridge employment is an increasingly common phenomenon, in which individuals continue working after they retire from a career job (Beehr and Bennett 2014). Feldman (1994) first highlighted the importance of bridge employment in relation to early retirement, and since then many researchers have paid a great deal of attention to the topic of bridge employment (e.g., Shultz 2003; Zhan et al. 2009). Bridge employment is relevant to early retirement because workers who may be considered early retirees in terms of their career job may continue to work in bridge jobs prior to leaving the workforce altogether. (See other entries on "► Bridge Employment.")

Bridge employment is increasing in prevalence. According to Cahill et al. (2005), half to two-thirds of workers transition to bridge jobs before retiring completely. Maestas (2010) reported that 44% of workers in 2004 were only partially retired, and a growing proportion of workers (initially 25% but recently more than 33%) return to work after retiring. Bridge employment can serve as a mechanism for workers to earn additional wages, easing the financial burden of early and unplanned retirement. Bridge employment may also fill a gap for individuals for whom work is an important role.

Conclusion

Early and unplanned retirement is important for understanding the retirement process. Economic

and health factors play a large role in shaping the timing of retirement as well as the degree to which retirement may be planned or unplanned. Recent changes to government pension plans have increased the age of eligibility to receive retirement benefits, thereby increasing the age that defines early retirement in economic terms. In general the age at which retirement benefits first become available is a strong predictor of retirement timing. However, there are many additional antecedents of early and unplanned retirement, including health status, marital status, kinship and family caregiving roles, and organizational incentives that encourage employees to leave the workforce. Early and unplanned retirement is associated with more negative than positive economic, physical, and emotional health outcomes. Although retirement timing is important, the extent to which the retirement process is voluntary or involuntary is a strong determinant of health and well-being among retirees, with much more positive outcomes associated with voluntary retirement and negative outcomes associated with involuntary retirement. Bridge employment, which refers to continued work after retiring from one's career job, is an increasingly common work arrangement particularly for early retirees.

Definition

Eating disorders are characterized by severe and persistent disturbances in eating behavior that may significantly impair physical health and psychosocial functioning in both men and women. According to the DSM-5 there are different types of feeding and eating disorders: pica, rumination disorder, avoidant/restrictive food intake disorder, anorexia nervosa, bulimia nervosa, and binge-eating disorder (American Psychiatric Association 2013). Eating disorders are common among women and have gradually increased over several years worldwide.

Disordered eating includes a variety of problematic eating behaviors ranging from dieting and extreme weight control methods (i.e., fasting, binge eating, and purging) to clinically diagnosed eating disorders (e.g., anorexia and bulimia nervosa). Accompanying these behaviors is also a range of disordered eating attitudes, such as the need to be thin as well as weight and shape fears. The majority of research on eating disorders concentrates on adolescents or young adult women, however, in the recent years data has emerged focusing on middle-age and older adults who may be experiencing eating disorders, namely anorexia nervosa, bulimia nervosa, and binge-eating disorder.

Eating Disorders as Defined by the DSM-5

The Diagnostic and Statistical Manual of Mental Disorders (American Psychiatric Association 2013) made several recent changes to the criteria for feeding and eating disorders to better characterize symptoms and behaviors of patients across the lifespan. Some of the changes included recognizing binge eating as a disorder, revising the diagnostic criteria for anorexia nervosa and bulimia nervosa, and including pica, rumination and avoidant/restrictive food intake disorder (the latter three were originally included in the Disorders Usually First Diagnosed in Infancy, Childhood, or Adolescence section of the DSM-IV-TR).

Anorexia nervosa is defined by a distorted body image, a pathological fear of gaining weight, and excessive dieting that leads to severe weight loss. This disorder mostly affects adolescent girls and young women. Some of the changes that were made from the DSM-IV-TR include taking out the word “refusal” in terms of weight maintenance since that signifies intention on the part of the patient and is difficult to determine. In addition, in the DSM-IV-TR a diagnosis of anorexia nervosa required amenorrhea, or the absence of at least three menstrual cycles. This criterion was taken out, because it cannot be applied to males, premenarchal females, females taking oral contraceptives, and postmenopausal females. Moreover, some women may report some menstrual activity but still show signs and symptoms of anorexia nervosa (American Psychiatric Association 2013).

It is important to understand that older adults may experience anorexia of aging, which is different from anorexia nervosa. Anorexia is a medical condition that is characterized by reduced appetite or dislike of food therefore leading to the inability to eat. Symptoms such as fear of gaining weight or distorted body image, which are key in anorexia nervosa, are absent in anorexia of aging. Anorexia of aging, which is involuntary weight loss and protein-energy malnutrition, includes the normal physiological changes that cause an increase in the proportion of body fat and decrease in lean muscle mass and extracellular fluid mass. This change in body makeup is usually a result of decrease in energy needs and therefore a decrease in appetite and calorie intake (Champion 2011).

Bulimia nervosa is characterized by recurrent episodes of binge eating followed by inappropriate behaviors such as self-induced vomiting to avoid weight gain, and self-evaluation that is disproportionately influenced by body shape and weight. In contrast to the DSM-IV-TR criteria, which required the frequency of binge eating and compensatory behaviors to occur twice a week, the DSM-5 specifies that these behaviors must occur once a week (American Psychiatric Association 2013). Older adults may especially engage in the inappropriate behaviors as they move

further away from the “cultural ideal” of looking young and thin.

Binge eating disorder is characterized as recurring episodes of eating significantly more food in a short period of time than most people would eat in the same circumstances. These episodes are also defined by feelings of lack of control over eating (e.g., a feeling that one cannot stop eating or control how much one is eating). A person with a binge eating disorder may eat more rapidly than normal whether he or she is hungry or not. The individual may experience feelings of guilt, embarrassment, or disgust and may binge eat alone to cover the behavior. Marked distress is usually associated with binge eating. Additionally, this disorder occurs, on average, at least once a week over three months (American Psychiatric Association 2013). Older adults suffering from binge eating disorder may feel lack of control or willpower. In addition, loneliness, depression, and other psychiatric or medical comorbidities may impact older adults’ eating habits.

Prevalence Rates of Eating Disorders and Older Adults

Anorexia nervosa and bulimia nervosa are 10 times more common in females than males, and binge-eating disorder is three times more common (Treasure 2007). Though in recent years studies have shown that one in six males also suffer from an eating disorder (Andersen 2002). Eating disorders have become a major public health issue as it is the third most common illness in adolescent females, and is affecting more women of all ages worldwide. Research suggests that more than 20% of women aged 70 and older were dieting and experiencing unhappiness with one’s body image and the desire to be thin; and these concerns do not disappear with age (Fisher et al. 1995). Anonymous questionnaires were administered to 1,500 Austrian women between the ages of 40 and 60 assessing for eating disorders (as defined by the DSM-IV), subthreshold eating disorders, body image, and quality of life. Subthreshold eating disorder was

defined by the presence of either binge eating with loss of control or purging behavior, without requiring any of the other usual DSM-IV criteria for frequency or severity of these symptoms. Of the 715 middle-aged to older adult women that responded, 33 (4.6%) reported symptoms meeting full DSM-IV criteria for an eating disorder. None indicated symptoms or behaviors consistent with anorexia nervosa, possibly due to the DSM-IV criteria of requiring amenorrhea. Another 34 women (4.8%) displayed sub-threshold eating disorder (Mangweth-Matzek et al. 2013).

There are different patterns or categories into which older adults may fit with regard to eating disorders. Some older adults have struggled with an eating disorder since adolescence and never received treatment. Others likely received treatment in their younger years but relapsed later on in life as a result of a stressful life event (e.g., death or illness of family member or friend). Another group may be older adults who were always pre-occupied with food and weight throughout their lives but experienced limited consequences of eating disorders when they were younger. Lastly, there is a small subset of older adults who developed an eating disorder later in life (American Psychiatric Association 2013).

Similar to adolescents and younger adults, middle aged and older adults also face devastating physical and psychological consequences of eating disorder. Issues such as social isolation, physical illness, bereavement, and minimal support are just a few factors that can impact the onset of late-life eating disorder (Cosford and Arnold 1992). Additionally, eating disorders in older adults are associated with anxiety, depression, and suicidal ideation and attempts (Hudson et al. 2007). Eating disordered behaviors may also increase the risk of medical morbidity, such as cancer and obesity (Ng et al. 2013).

Biology of Eating Disorders

Research on the biology of eating disorders has primarily focused on anorexia nervosa and

bulimia nervosa. Studies show a genetic predisposition and a variety of environmental risk factors that contribute to eating disorders. Clinical studies with twins show an agreement for anorexia nervosa of 55% in monozygotic twins and 5% in dizygotic twins, and bulimia nervosa being 35% and 30%, respectively. In addition, much of the research focuses on the neurobiology of eating disorders, looking specifically at neuropeptide and monoamine (especially 5-HT) systems, which are thought to play a central role in the physiology of eating and weight regulation.

Studies incorporating functional imaging of the brain show altered activities in the frontal, cingulate, temporal, and parietal cortical regions in both anorexia nervosa and bulimia nervosa, and there is some suggestion that these changes persist after recovery. Whether these changes are a result of the eating disorder or have somehow contributed to the risk of developing an eating disorder is not well researched (Lapides 2010; Kaye and Strober 1999).

Eating Disordered Behaviors: Signs and Symptoms in Older Adults

It can be difficult to determine or diagnose an eating disorder in older adults. However, some signs and symptoms can be recognized as clues to changes in eating behavior in older adults. For example, significant change in weight over a short period of time; behavior changes such as disappearing after a meal or using the restroom after eating; new use of laxatives, diet pills, or diuretics; wanting to eat alone rather than with family; skipping meals; loss of concentration; physical symptoms such as enamel loss, chronic sore throat, cracked lips, sensitivity to cold, excessive hair loss, dental damage, or heart and gastrointestinal problems (e.g., constipation); excessive consumption of high-calorie foods that are sweet (especially prominent in people with binge eating disorders). Furthermore, osteopenia and osteoporosis are common symptoms of longstanding anorexia nervosa and are associated with an increased fracture risk in older adults.

Additionally, it is suggested that physicians complete a physical for medical conditions and review medications as medical conditions (e.g., thyroid and gastrointestinal conditions), medications, and substance use can mimic symptoms of an eating disorder (e.g., nausea, weight gain or loss) (Lapides 2010; Lapid et al. 2010).

Contributing Factors to Eating Disorders in Older Adults

Triggers of eating disorders may appear similar for younger and older adults; however specific differences occur, as life stressors change as people age. Body image issues and body dissatisfaction are some of the common risk factors for eating disorders and increase with age as the human body experiences natural changes (e.g., wrinkles, graying hair, and weight gain). Additionally, the development of eating disorders in midlife can be due to other changes or transitions that occur as one ages. For example, loss of loved ones, widowhood, divorce, traumatic illness or disability, children moving out of the house, growing old and facing mortality, and loss of independence can all have an impact on eating behaviors of midlife or older adults (Lapides 2010; Zerbe 2008).

Certain medical conditions can also contribute to developing an eating disorder. For example, older adults are at a higher risk for developing high cholesterol, diabetes, and other cardiovascular diseases and may be advised by their primary care physicians to be mindful of and careful with their diet. Some older adults may become anxious about their diets, but also lack knowledge about proper nutrition that lower the risk for cardiovascular diseases. They may begin restricting their diets and lose weight unintentionally. Their anxiety may maintain their eating disordered behaviors. Other contributing factors to eating disorders for older adults may be lack of enthusiasm for life, attempts to obtain attention from family members, financial difficulties, medical problems, and dissatisfaction or objection of living situations (i.e., nursing home, skilled facilities) (Lapides 2010).

Overall, stress is the most common trigger of eating disorders in both younger and older adults; stressors often change as one develops and become more prominent. Eating disorders are usually not about weight or food, but a way of coping with other stressors in life that the individual does not know how to handle. Disordered eating behaviors are often a way to avoid and numb emotions and feelings. If during adolescence or young adulthood the individual learned maladaptive coping mechanisms to tolerate stress, then the individual may utilize these unhealthy coping methods later in life as an older adult (Lapides 2010).

In one study, 50 women who were treated in a residential program and who eating disorder symptoms began after the age of 40 were examined. On an eating disorder inventory, midlife women scored higher than younger women on scales of ineffectiveness, perfectionism, interpersonal distrust, and asceticism, but scored lower on drive for thinness, bulimia, and body dissatisfaction. Both midlife women and younger women reported moderately severe depression and anxiety symptoms. On the Minnesota Multiphasic Personality Inventory (MMPI), midlife women indicated more denial than younger women. These midlife women also endorsed a higher frequency of sexual abuse (63%) than reported by younger women with eating disorders. There was no significant difference between midlife and younger women in alcohol or other substance use; however, midlife patients abused cannabis much less and opioids more than younger patients. Though not statistically significant, midlife patients more often abused sedatives, hypnotics, and anxiolytics suggesting a higher tendency to abuse calming/sedating medications. About 22% of older women reported a history of self-harm and 28% had attempted suicide. Though this study was limited to only patients who were seeking treatment in a facility, this suggests that older adults with eating disorders may under report some of their distress and need serious consideration and treatment in the community (Cumella and Kally 2008).

Eating Disorders and Neurocognitive Disorders

Dementia is not one specific disease; rather, it is a clinical syndrome characterized by a loss of cognitive functioning that negatively impacts a person's abilities to complete day-to-day activities. Dementia can affect many body systems and produce a variety of problems, such as poor or inadequate nutrition. Individuals with dementia may decrease the amount of food they eat, forget to eat and drink, or believe they have already eaten. Changes in an older person's daily routine (e.g., such as meal time) or other distractions (e.g., how the food smells or tastes, environmental issues such as too much confusion) may affect their eating patterns. In some cases, people with advance dementia may lose control of the muscles used to chew or swallow and this could put the person at risk of choking. Additionally, people with dementia may lose the feeling of hunger and the desire to eat. Other comorbid factors such as depression, medication side effects, and constipation, can decrease the individual's interest in food (Ikeda et al. 2002).

Frontotemporal dementia (FTD) encompasses several clinical syndromes all sharing frontal pathology. The FTDs include behavioral variant FTD (bv-FTD), progressive nonfluent aphasia (PNFA), and semantic dementia (SD). A variety of behavioral changes noted in bv-FTD, include loss of insight, disinhibition, impulsivity, apathy, poor self-care, mood changes, mental rigidity, and stereotypic behavior. Some research with bv-FTD individuals has also found a high prevalence rate of changes in food preferences, appetite, and eating behaviors. Individuals with semantic dementia characterized by anomia and impaired comprehension, also show behavioral changes, such as changes in appetite and food preferences that are similar to those observed in bv-FTD (Ikeda et al. 2002).

One of the most prevalent dementia syndromes, Alzheimer's disease (AD), accounts for about 35% of all dementia cases. AD is characterized by early onset of memory impairment (poor consolidation and recognition of information), poor confrontation naming (dysnomia), deficits

in visuoconstructional skills, social withdrawal, and mood changes (symptoms of depression) can occur. Eating changes in AD have been shown to be less common. However, some research indicated anorexia is more common in AD (Ikeda et al. 2002). Research found more significant changes in eating behaviors in both bv-FTD and semantic dementia in contrast to Alzheimer's disease. Individuals with semantic dementia first typically see a change in food preference, whereas individuals with bv-FTD show changes in food preferences as well as alterations in appetite (Ikeda et al. 2002).

Though there is limited research on other types of dementias (e.g., vascular dementia) and eating disorders, overall, individuals with any type of dementia may suffer from a diminished interest to eat or forgetting to eat. Changes in food intake can lead to malnourishment and dehydration, increasing the risk of infections, abnormally low blood pressure, and other medical problems. Proper nutrition does not necessarily prevent weight loss in people who suffer from dementia, nor will it slow down the progression of the neurodegenerative process, however continuing to maintain a healthy weight and diet can support overall health and better quality of life. Primary care physicians, psychiatrists, psychologists, dietitians, family members and other caregivers play an important role in some of the treatment options for eating disorders in older adults.

Treatment Options for Eating Disorders

As people age, their interest in eating and enjoying food changes. Individuals with dementia have pronounced changes in taste or food preferences as well as changes in mood, behavior, and physical functioning, which can impact eating. Some general treatment goals for eating disorders in individuals both with and without dementia are to restore adequate nutrition, and weight to a healthy level, reduce excessive exercise, and stop bingeing and purging behaviors. Additionally, individuals that suffer from dementia may benefit from specific memory strategies (e.g., following a specific routine everyday or incorporating various

reminders or cues to remember to eat) or feeding tubes in later stages of the neurodegenerative disease. Multidisciplinary treatment teams such as a primary care practitioner, psychiatrist, dentist, nutrition specialist or dietician, and a mental health care professional may be needed to manage eating disorders (Fairburn 2010; Shapiro et al. 2007). In addition, health care professionals treating patients with eating disorders have to be mindful of different cultural and religious values and practices patients may possess.

Several psychological theories have been proposed to account for the development and maintenance of eating disorders, with cognitive behavioral theory being one of the most prominent with regard to treatment. Cognitive behavioral theorists propose that there are two main origins for the restriction of food intake. The first is the need to feel in control of life, which transfers into the need to control eating. The second is over evaluating one's shape and weight. In both cases, a dietary restriction is reinforcing. Following this, other processes such as social withdrawal, binge eating due to extreme and rigid dietary restraint, and negative impact of binge eating or concerns about shape and the sense of being in control, begin to play a role and serve to maintain eating disorders (Fairburn 2010; Shapiro et al. 2007).

Cognitive and behavioral approaches have been shown to successfully treat eating disorders based on studies with younger and middle-aged women and men. In addition, antidepressant medications may also be effective for some eating disorders as well as treating comorbid anxiety or depression. Medical consequences of an eating disorder can be devastating and life threatening, however, the internal dialog within the person and specific behavioral rituals that are constantly repeated can cause suffering and pain. The constant fear of judgment, self-imposing rules and demands can take over and cause negative emotions and perpetuate negative behaviors. Individuals with eating disorders often maintain negative view of themselves and their bodies. These negative thoughts can cause feelings of shame or anxiety that can then trigger behaviors to control weight. Cognitive behavioral therapy can focus on the specific factors that are maintaining the

disorder and set specific goals throughout the therapy. Three phases can occur over the course of cognitive behavioral therapy: behavioral phase, cognitive phase, and maintenance and relapse prevention phase. During the behavioral phase the patient and therapist come up with a plan to stabilize eating and eliminate symptoms. In the cognitive phase, the therapist begins cognitive restructuring where the individual begins to recognize and change problem thinking patterns. Negative thoughts and beliefs (e.g., I will only be happy if I can lose weight) are identified and restructured. In addition, other concerns and issues such as relationship difficulties, self-esteem concerns, and emotion regulation are focused on. The last stage of CBT focuses on minimizing triggers, preventing relapse, and maintaining progress previously made (Fairburn 2010; Shapiro et al. 2007).

In addition to psychotherapy, psychotropic medications have also been shown to play a role in treating eating disorders. Research on medication use for anorexia nervosa have not found medication to promote weight gain, though some studies suggested fluoxetine as an option in preventing relapse in patients after normal weight is restored. In contrast, fluoxetine has shown to reduce bingeing frequency in bulimia nervosa, as well as anxiety and depressive symptoms (Zhu and Walsh 2002).

While research demonstrates the benefits of medication, the best results were seen with a combination of psychotropic medication and psychotherapy (Zhu and Walsh 2002; Maine et al. 2010). Research shows that patients who received cognitive behavioral therapy demonstrated more improvement in symptoms than those who only received medication. However, medication is efficacious for patients who have not responded to psychotherapy. When patients who did not benefit from cognitive behavioral therapy or interpersonal therapy were administered a placebo or fluoxetine, significant results in favor of fluoxetine were found (Walsh et al. 2000). While older adults have not been the focus of eating disorder randomized control trials, interpersonal and cognitive behavioral therapies were successfully used to treat other later-life psychiatric disorders, such

as depression (Hudson et al. 2007), which often co-occur with eating disorders.

In addition to psychotherapy and medication, nutrition intervention, such as counseling by a registered dietitian is an important aspect of multidisciplinary treatment of eating disorders, and would certainly contribute to determining the course of treatment in older adults. The dietitian can perform a nutrition assessment to identify nutrition problems related to the eating disorder and implement a care plan that might establish healthy eating patterns and restore the individual back to a healthy weight. In addition, the dietitian can monitor and re-assess the individual's progress with the plan and jointly work with other health professionals to address the individual's needs. The trained dietitian can recommend keeping a daily food, hydration, and exercise log and this information can help identify if any new physical or medical problems may arise that can impact food intake and changes in weight. A full workup by a dietitian is critical given the complexity of eating disordered behaviors and disorders in older adults. A dietitian can monitor and refer older adults to other physicians or specialists as eating disorders can arise due to various causes (Walsh et al. 2000).

Conclusion

This chapter focuses on late-life eating disorders and eating disordered behaviors in older adults, and issues that have been largely overlooked or potentially under diagnosed. The dearth of information on eating disorders and related issues suggests that, although these issues are not common, it is possible for an older adult to have a disorder or issue with their eating. Those issues could be caused by various life stressors (e.g., abuse, loss of a loved one, loss of independence) and/or medical (e.g., neurodegenerative diseases, diabetes) or psychiatric (e.g., depression, anxiety) conditions, as is the case in many instances. Older adults are also not as physiologically resilient as younger adults. Physiological changes and vulnerability of an aging person could lead to more serious consequences of eating disorders much more rapidly than in a younger person. In rare instances,

but certainly possible, the eating issue could be a longstanding disorder or newly diagnosed condition. For these reasons, health care professionals need to be cognizant of the possibility of eating disorders in the elderly, given the serious consequences of misdiagnosing or leaving them untreated in any population.

Relevance for human aging; HPA axis alterations during aging: Impact on cognition

Introduction

Is aging associated with a more pronounced susceptibility to stress? Do older people respond differently to stress, and if so, how does this influence their cognitive performance? Might chronic stress be one of the reasons for the large interindividual variance observed in cognitive aging? The present chapter aims to answer these and related questions. A neuroendocrine perspective is taken, focusing on stress hormones and their action in the human brain. The response patterns of young people are described before age-related changes are discussed. Acute and chronic stress effects are then compared with each other, and finally, some possible lines of intervention are characterized.

Definition of Stress

A common definition is that stress occurs when a person perceives a challenge to his or her internal or external balance (homeostasis; De Kloet et al. 2005). Thus, a discrepancy between what “should be” and “what is” induces stress. A stressor can be physical (e.g., cold, hunger) or psychological (e.g., work overload, mobbing, neighborhood violence, marital problems), as well as acute or chronic. The subjective evaluation of the stressor and of available coping resources determines its impact on the individual (Lazarus 1993). Something perceived as a threat by one person might be perceived as an exciting challenge by another. There is thus substantial interindividual variability in the vulnerability to stress. As humans are social animals, a threat to the social self (social evaluative threat), in combination with uncontrollability of the situation, is especially potent in prompting stress (Dickerson and Kemeny 2004). As further outlined below, genetic susceptibilities, when combined with early adversity, render an individual more vulnerable in adulthood.

The Two Stress Systems: HPA and SNS

Stress leads to neuroendocrine responses aimed at facilitating adaptation. In this context, the hypothalamic-pituitary-adrenal (HPA) axis and the sympathetic nervous system (SNS) play the most important roles. SNS activity leads to the rapid release of (nor)epinephrine from the adrenal medulla, which constitutes the first response wave. Activity of the HPA axis on the other hand leads to the release of glucocorticoids (GCs; cortisol in humans, corticosterone in most laboratory rodents) from the adrenal cortex.

This response is slower and constitutes the second response wave (De Kloet et al. 2005). The two systems are illustrated in Fig. 1.

GCs are lipophilic hormones that can enter the brain, where they influence regions involved in cognitive functions (e.g., amygdala, hippocampus, and prefrontal cortex). These effects are mediated by the two receptors for the hormone: the mineralocorticoid receptor (MR) and the glucocorticoid receptor (GR), which differ in their affinity for GCs and in their localization. While MR activation leads to enhanced neuronal excitability, GR activation causes a delayed

Effects of Stress on Memory, Relevance for Human Aging, Fig. 1 Stress activates two neurohormonal systems: the rapidly acting sympathetic nervous system (SNS) and the slightly slower hypothalamic-pituitary-adrenal (HPA) axis. Activation of the hypothalamus stimulates the SNS to secrete (nor)epinephrine from the adrenal medulla. These catecholamines cannot easily pass the blood-brain barrier but can exert excitatory actions in the brain by stimulating the vagus nerve (hence the *dotted line*). The hypothalamus releases corticotropin-releasing

hormone (*CRH*), which stimulates the secretion of adrenocorticotropic (*ACTH*) from the anterior pituitary gland into the blood stream. *ACTH* stimulates the adrenal cortex to release glucocorticoids (GCs, mostly cortisol in humans), which can easily pass the blood-brain barrier and modulate brain functions involved in learning and memory (see text). GCs exert negative feedback effects (indicated by the *minus* symbol) on the hypothalamus and the pituitary gland, leading to reduced activity of the HPA axis in the aftermath of stress

suppression or normalization of the neuronal network (Joels et al. 2008). Their activation furthermore leads to an altered expression of responsive genes. In addition, GCs can exert more rapid non-genomic effects which, in part, are mediated by membrane-bound MRs (Joels et al. 2008).

After acute stress, the HPA axis' negative feedback leads to GC levels returning to baseline values within hours (De Kloet et al. 2005; Dickerson and Kemeny 2004). In periods of chronic stress on the other hand, persistent alterations of the HPA axis can occur, leading to continuingly elevated cortisol levels. However, elevated cortisol concentrations, as typically observed in major depression, are not always the consequence of chronic stress (Wolf 2008). For example, reduced cortisol levels occur in several stress-associated somatoform disorders (Fries et al. 2005) as well as in post-traumatic stress disorder (Wolf 2008).

Age-Associated Changes in HPA Axis Activity/Reactivity

Since HPA axis alterations are a close correlate of or even a determining factor in the onset of different diseases, the assessment of the integrity and functioning of HPA axis regulation is of major interest in older individuals in particular.

Aging is accompanied by several distinct alterations affecting basal HPA activity as well as the system's response to stress or pharmacological manipulations (Lupien et al. 2009). Regarding the circadian profile, several studies have revealed an increase in nocturnal nadir levels with age, meaning that older people are exposed to higher levels of cortisol during the night (Wolf and Kudielka 2008). A somewhat different picture has emerged for the cortisol awakening response (CAR), which occurs directly after awakening and is associated with a robust increase in cortisol concentrations during the first 30 min after waking up. During aging, this response appears to become more blunted, a phenomenon which has been linked to atrophy of the hippocampus (Pruessner et al. 2010), a structure critically involved in the supra-hypothalamic control of

the HPA axis and, at the same time, a structure of vital importance for episodic memory (see below).

Longitudinal studies indicate that not all older participants show an increase in basal cortisol levels over the years. A substantial interindividual variance exists, ranging from increasing or stable to even decreasing levels (Lupien et al. 2009). To summarize, the existing data point to altered basal cortisol concentrations during the nocturnal trough, while cortisol levels remain mainly unchanged or show only slight changes over the course of the day (Wolf and Kudielka 2008).

During the past decades, several studies have investigated the reactivity of the HPA axis using psychosocial laboratory stressors such as the Trier Social Stress Test. In this test, participants have to deliver a speech in front of an emotionally cold, nonresponsive committee. In addition, a difficult mental calculation task has to be performed. Based on observations made in rodents, older participants were expected to show a more pronounced and/or more prolonged stress response. Indeed, this is what several well-conducted studies observed, even though findings are not unequivocal (Wolf and Kudielka 2008), especially concerning some of the sex differences observed.

A different approach involves pharmacological stimulation of the HPA axis using, for example, CRH (with or without pretreatment with dexamethasone). The majority of these studies have found evidence for an enhanced HPA reactivity with aging, accompanied by an impaired negative feedback. Interestingly, these alterations appear to be more pronounced in older women (Otte et al. 2005).

The factors causing the HPA axis hyperactivity observed during aging in some individuals remain poorly understood. Possible candidates are early adversity or chronic stress (Lupien et al. 2009). However, metabolic alterations associated with glucose intolerance or type 2 diabetes (Convit 2005) should also be considered. Alternatively, degenerative processes in the central nervous system might be the starting point of the age-associated HPA axis alterations, since it is known that degeneration of supra-thalamic

control centers of the HPA axis (e.g., the hippocampus) leads to HPA axis hyperactivity. Of course, these explanations are not exclusive and might interact at multiple levels.

Stress and Cognition: Acute Effects

Stress affects the central processing of incoming information at multiple levels. Early influences on perception and attention have been documented, as well as later effects on working memory and long-term memory. The present chapter will focus on the influence of stress on long-term memory because it is the area which has been best characterized in young adults and at least partially investigated with respect to aging.

Long-term memory can be subdivided into declarative or explicit and non-declarative or procedural (implicit) memory. Based on its content, declarative memory can be further subdivided into episodic memory (recall of a specific event which can be located in space and time) and semantic memory (our knowledge of the world). The medial temporal lobe is critical for declarative memory, with the hippocampus being especially important for episodic memory (Wolf 2009).

Long-term memory can further be subdivided into different memory phases, namely, acquisition (or initial learning), consolidation (or storage), and retrieval (or recall). The literature regarding the effects of stress on episodic memory was initially somewhat divergent and confusing, with groups reporting both enhancing and impairing effects of GCs on this form of memory. However, it has become apparent that this is largely due to the fact that the different memory phases outlined above are modulated by GCs in an opposing fashion (Wolf 2009).

GCs enhance memory consolidation, this process representing the adaptive and beneficial side of the action of GCs in the central nervous system (see Fig. 2). It has been conceptualized as the beneficial effects of “stress within the learning context,” or “intrinsic stress.” The terminology used emphasizes the fact that a stressful episode is remembered better, an effect which is mediated by the action of stress-released GCs on the

hippocampal formation and which is very well documented in rodents. Studies have shown that an adrenergic activation in the basolateral amygdala (BLA) appears to be a prerequisite for the modulating effects of GCs on other brain regions (e.g., the hippocampus). Lesions in the BLA as well as beta-blockade abolish the enhancing effects of post-training GC administration (Roosendaal et al. 2009).

Comparable effects have been observed in humans: Immediate post-learning stress has repeatedly been linked to enhanced memory consolidation. Similar evidence comes from pharmacological studies, while neuroimaging studies have provided further evidence for a stress-induced modulation of amygdala and hippocampal activity (Wolf 2009). Pre-learning stress or cortisol studies have led to a somewhat less consistent picture. In this case, the exact timing of the stressor, the emotionality of the learning material, and the relation of the learning material to the stressor appear to be important modulatory factors (Wolf 2009).

While an enhanced memory consolidation is adaptive and beneficial, this process appears to occur at the cost of impaired retrieval (see Fig. 2). Using a 24 h delay interval, researchers were able to show that stress or GC treatment shortly before retrieval testing impairs memory retrieval in rats in a water maze. Further studies have revealed that, once again, an intact BLA and its adrenergic activation appear to be necessary for the occurrence of this negative GC effect (Roosendaal et al. 2009). Roosendaal has summarized these findings as indicative of stress putting the brain into a consolidation mode, accompanied by impaired retrieval. Such a reduction in retrieval might facilitate consolidation by reducing interference (Wolf 2009).

In humans, multiple studies have been able to demonstrate a stress-induced retrieval impairment using different stressors and different memory paradigms. Similar impairment has been induced using pharmacological cortisol elevations (Wolf 2009). Interestingly, the beneficial effects on consolidation and the impairing effects on retrieval in humans are more pronounced for emotionally arousing material. This observation fits the

E

Effects of Stress on Memory, Relevance for Human Aging, Fig. 2 Memory phase-dependent effects of stress on long-term memory. Immediate pre- or post-learning stress enhances memory consolidation, thus leading to

enhanced memory retrieval hours, days, or weeks later. In contrast, stress shortly before memory retrieval impairs long-term memory by temporarily blocking the accessibility of the memory trace

mentioned observation in animals that GCs can only exert effects on memory in the presence of adrenergic activity in the amygdala. This arousal can result from specifics of the learning material and/or specifics of the testing conditions.

retrieval (see Fig. 2). Within this framework, emotional arousal and a nonlinear dose-response relationship are important modulatory variables (Wolf 2009).

In a meta-analysis, time of day appeared as an additional modulatory factor. Studies in which cortisol was administered before initial acquisition observed impairing effects on memory when conducted in the morning, a time of high endogenous cortisol levels in humans. In contrast, studies in the evening were more likely to observe beneficial effects (Het et al. 2005). This supports the idea of an inverted U-shaped function between cortisol levels and memory in humans, with levels too low as well as levels too high at the time of acquisition being associated with impairments, especially when retrieval is tested while cortisol levels are still elevated (Het et al. 2005).

Age-Associated Changes in Acute Stress Effects

In sum, studies in animals and humans converge on the idea that GCs acutely enhance memory consolidation while impairing memory

Few studies have investigated age-associated changes in the impact of stress or stress hormones on memory. Findings thus have to be considered as somewhat preliminary. A pharmacological study observed a cortisol-induced memory retrieval impairment in both young and old participants (Wolf 2009). Stress studies have revealed a somewhat different picture, with older adults less impaired by the stressor. At the same time, stressed older adults appeared to be more susceptible to distraction. Interesting correlational findings have been provided by a neuroimaging study. In young participants, increasing cortisol

concentrations were associated with more neural activity in several memory-relevant brain regions. In older participants, the opposite pattern was observed: Here, increasing cortisol concentrations were linked to less brain activity in the hippocampus.

In sum, the currently available literature indicates that the memory of older participants is in some cases differently affected by acute stress (Wolf and Kudielka 2008). Importantly, enhanced and reduced stress responsivities have been reported. It is therefore likely that the impact of acute stress on aging is specific for certain processes and brain regions.

Stress and Cognition: Chronic Effects

The following paragraphs will focus on the impact of chronic stress on cognition in aging. First, the long-term consequences of early life stress will be summarized. These changes have an impact throughout the lifespan leading up to old age. Next, the impact of chronic stress on memory in adulthood is reviewed, before specific age-associated changes in the chronic stress effects associated with aging are highlighted.

Long-Term Consequences of Early Life Stress

Several studies support the notion that early stress exposure is associated with accelerated neurodegenerative processes and early onset of memory decline in the course of aging (Lupien et al. 2009). Neurodevelopmental impairments in association with early stress exposure may be one of the factors explaining such cognitive disadvantages at an older age. Changes in stress susceptibility programmed early on in life might account for such deficits (Schlotz and Phillips 2009). There is evidence for pre- and postnatal stress exposure being associated with a chronically increased reactivity of the HPA axis, potentially resulting from a reduced expression of central glucocorticoid receptors (Meaney 2001). Animal models

show increased corticosterone concentrations and lower GR density in the hippocampus in the offspring of stressed mothers. Also, postnatal maternal separation and poorer maternal care have been associated with reduced GR gene expression in the hippocampus, which, in turn, is associated with reduced feedback sensitivity of the HPA axis. Recently, a mechanism has been discovered in rodents that explains how environmental stimuli can impact gene expression. Permanent alterations of GR gene expression result from methylation/demethylation of specific GR promoters, a process associated, among others, with variations in maternal care (Meaney 2001). Initial evidence suggests that the human GR gene is also subject to early life programming (Schlotz and Phillips 2009). Moreover, elevated cortisol concentrations have, for example, been reported in association with reduced birth weight or pre-term birth.

In the following, the consequences of chronic stress exposure throughout life on cognitive functioning will be described. It will become apparent that individuals with an increased stress susceptibility (reflecting genetic susceptibilities and/or early adversity) are especially vulnerable to stress-induced cognitive impairments in adulthood and aging (Lupien et al. 2009).

Chronic Stress During Adulthood: Effects on Cognition

Animal research provides insights into the structural alterations caused by chronic stress. One main finding is that the integrity of the hippocampus and the medial prefrontal cortex is compromised, while, in parallel, the amygdala (the “fear center” of the brain) and parts of the striatum (the “habit center” of the brain) become hyperactive (Roosendaal et al. 2009). In the hippocampus, chronic stress leads to a retraction of dendrites (dendritic atrophy), and similar effects occur in the medial PFC (Lupien et al. 2009). This atrophy is reversible after stress termination, pointing to substantial neuroplasticity. In addition, stress leads to reduced neurogenesis in the

dentate gyrus and the mPFC. Even though the function of these newborn neurons is discussed controversially, impairment of memory and learning resulting from reduced neurogenesis is likely. At the behavioral level, impaired performance in hippocampal-dependent spatial memory tasks and impaired PFC-dependent set-shifting capabilities can be observed (Roozendaal et al. 2009).

In contrast to the hippocampus and the PFC, the amygdala becomes hypertrophic in conditions of chronic stress. Increases in dendritic arborization and spine density take place (Roozendaal et al. 2009). Moreover, activity of the CRF system in the amygdala, which is involved in anxiety, is enhanced. Chronically stressed animals show enhanced fear conditioning and are characterized by a more habitual and less goal-directed response style. Thus, the balance between brain regions involved in cognition is altered by chronic stress (Lupien et al. 2009). While “analytic” cognitive functions mediated by the hippocampus and PFC are impaired, “affective” fear-related amygdala functioning and habit-related striatal functioning are enhanced (Wolf 2008).

In humans, exposure to chronic stress (e.g., shift workers, airplane personnel, soldiers) is associated with cognitive deficits in several domains such as working memory and declarative memory (Lupien et al. 2009; Wolf 2008). These observed cognitive deficits can, in part, be explained by GC overexposure in the presence of chronic stress, a finding supported by studies administering GCs for days to weeks, resulting in cognitive impairments. Further evidence comes from studies with patients receiving GC therapy. Whether the negative effects on memory reflect acute or chronic effects is sometimes hard to disentangle, and at least one study showed a rapid reversal of the deficits after discontinuation of the GC treatment. Data from patients with Cushing’s disease point in the same direction, with cognitive impairments and hippocampal volume reductions reported. Hippocampal atrophy might be reversible once successful treatment has occurred. This would be in line with the remaining plasticity of this structure observed in animal studies (Wolf 2008).

Chronic Stress or Rising Cortisol Levels During Aging: Effects on Cognition

In older laboratory rodents, an increase in basal corticosterone levels and a less efficient negative feedback of the HPA axis can be detected. Studies have reported that enhanced HPA activity is associated with poorer memory in those animals (Lupien et al. 2009).

As reviewed above, increases in basal cortisol levels occur during human aging. In addition, pharmacological or behavioral challenge studies observe an increased HPA response. Moreover, HPA-negative feedback in older subjects is less efficient. These alterations might reflect age-associated diseases, stress exposure over the lifespan, genetic vulnerabilities, the long-term consequences of exposure to early life adversity, or a combination of the above (Lupien et al. 2009). In older adults, correlations between elevated or rising cortisol levels and cognitive impairments have been reported (Lupien et al. 2009). The association between rising cortisol levels and atrophy of the hippocampus is not sufficiently understood, and the current empirical situation is heterogeneous. Similar associations with other GC-sensitive brain regions (e.g., PFC) have received less attention so far.

Evidence for HPA hyperactivity has been observed in patients with Alzheimer’s dementia (AD). This could reflect the damage to HPA feedback centers in the brain, but it might also be causally involved in disease progression (Wolf and Kudielka 2008). Work in animals has documented that HPA hyperactivity can influence amyloid metabolism as well as tau phosphorylation, the two hallmarks of AD pathology. In human patients, treatment with prednisone resulted in exaggerated memory loss. Moreover, a genetic susceptibility to AD could be linked to the gene encoding 11 β -HSD, which influences local GC metabolism. In addition, at the self-report level, evidence exists that enhanced stress susceptibility is associated with a greater risk of dementia (Wolf and Kudielka 2008).

Another condition associated with HPA hyperactivity is the metabolic syndrome, as well as type

2 diabetes. There are close links between the stress system and the glucoregulatory system. Several authors have suggested that chronic stress facilitates the occurrence of the metabolic syndrome by influencing visceral fat deposition, impairing insulin sensitivity, or by changing eating habits toward unhealthier (comfort) food. Alternatively, the negative impact of glucose intolerance on the brain might lead to HPA hyperactivity and, in turn, elevated cortisol levels (Convit 2005).

Intervention Strategies

In laboratory animals, stress-induced dendritic atrophy and reduced neurogenesis can be prevented with antidepressants and anticonvulsants. Also, treatment with a glucocorticoid receptor antagonist is effective in preventing such stress-induced changes in neurophysiology. Similarly, memory impairments can be prevented with these drugs (Wolf 2008).

In humans, chronic stress without an associated psychopathology could be alleviated by psychological stress intervention strategies. Possible examples are stress inoculation training and mindfulness-based stress reduction training. In addition, social support is an effective stress-buffering factor.

Pharmacological treatment with beta-blockers can prevent the effects of acute GC elevations on memory retrieval. It remains to be shown whether similar approaches are effective in conditions of chronic stress. In addition, GR antagonists and/or CRF antagonists might be candidate drugs. Moreover, drugs that influence the local GC metabolism in the brain could also be effective. Depression is often associated with HPA hyperactivity. Successful treatment with antidepressants leads to a normalized HPA axis. One study observed that treatment with a selective serotonin reuptake inhibitor (SSRI) improved memory performance and reduced cortisol levels. More direct interventions targeting the HPA axis have been tested in laboratory animals, and clinical trials are on the way. In this context, CRF antagonists

and GR antagonists appear promising. In sum, reinstating appropriate HPA signaling appears to be a promising treatment approach both in chronically stressed animals and in human patients suffering from stress-related psychiatric disorders (De Kloet et al. 2007).

Intervention strategies specifically designed for older people could be developed based on the following findings. In rodents, behavioral (e.g., neonatal handling) and pharmacological (adrenalectomy with low-dose corticosterone replacement) intervention strategies, leading to stable HPA activity throughout life, prevent age-associated cognitive decline. Similarly, a pharmacological reduction of active GC concentrations in the hippocampus (inhibition of 11beta-HSD synthesis) is efficient in preventing memory impairments in aging mice. In humans, a pilot study showed that the 11beta-HSD inhibitor carbenoxolone improved some aspects of memory in older men and in older patients with type 2 diabetes (Wyrwoll et al. 2010). Future studies are needed to better investigate possible side effects of long-term treatment with these kinds of drugs. Regarding treatment of the metabolic syndrome, lifestyle modifications are often successful if started early enough. In addition, pharmacological approaches are available. They should be able to prevent or reduce memory impairment and hippocampal atrophy associated with diabetes and the metabolic syndrome (Convit 2005).

Summary and Outlook

This chapter illustrates that chronic stress has a negative impact on cognition throughout life. A lifespan approach in research on stress and cognition emphasizes the long-lasting effects of exposure to early life adversity. Genetic risk factors, in combination with early life adversity, render an individual more susceptible to stress and stress-associated diseases during aging.

By reducing early adversity, it would thus be possible to support the development of a more

resilient phenotype less susceptible to stress-associated cognitive disturbances in later life. Importantly, a previously unappreciated amount of neuroplasticity remains in adulthood, allowing an optimistic view of the potential to successfully treat stress-associated neurophysiological changes in the future. These interventions should aim at reinstating appropriate HPA signaling and will thus rely upon a thorough diagnostic neuroendocrine workup of the phenotype.

Taken together, considerable progress has been made in understanding the impact of acute and chronic stress on the human brain. This knowledge has substantial relevance for aging, since age-associated changes in HPA (re)activity have been found to occur, and the sensitivity of the brain to stress appears to be altered in aging. Preventing or diminishing the age-associated increase in HPA activity appears to be a promising future research avenue to foster successful (mental) aging (Lupien et al. 2009; Wolf and Kudielka 2008).

Synonyms

Elder maltreatment; Elder mistreatment; Mistreatment of older adults; Victimization of older adults

Definition

Elder abuse was first publically recognized in the United Kingdom and the United States in the 1970s. It is now a recognized phenomenon found around the world, led by the advocacy work of the International Network for the Prevention of Elder Abuse. The definition of elder abuse has expanded over time. However, across countries elder abuse is frequently defined as a single or repeated act, or lack of appropriate action, occurring within any relationship where there is an expectation of trust which causes harm or distress to an older person and typically encompasses six types of abuse: physical abuse, caregiver neglect, financial exploitation, psychological abuse, sexual abuse, and (in some countries) abandonment (World Health Organization 2002a). Since abandonment has received virtually no empirical attention, it is omitted from this review.

The trust component of the definition serves to distinguish elder abuse from other harms perpetrated against older adults. Abuse in later life, for example, focuses on domestic violence and sexual assault of older adults (particularly women). Although overlapping to a degree with elder abuse, it is narrower than elder abuse and typically espouses a very different theoretical position. Crimes against older adults (e.g., burglary, financial scams, assault) that are committed by strangers are not typically considered elder abuse, although homicide committed by a family member would be a form of elder abuse. And abuse of vulnerable adults (ages 18 years and

older with some statutorily defined vulnerability) may overlap with elder abuse but only when the vulnerable adult is over the age of 60.

Prevalence and Consequences of Elder Abuse

Nationally representative studies in the USA find that overall, one in 11 older adults experience some type of elder abuse in a given year, although prevalence varies by the type of abuse involved: financial exploitation (5.2%), caregiver neglect (5.1%), emotional/psychological abuse (4.6%), physical abuse (1.6%), and sexual abuse (<1%) (Phelan 2013). However, between 30% and 40% of reported abused older adults experience more than one type of abuse simultaneously. Prevalence studies conducted in the European Region find that about 2.7% of people age 60 and over have experienced physical abuse in the preceding year, 0.7% sexual abuse, 19.4% psychological abuse, and 3.8% financial abuse (World Health Organization 2011). Throughout Asian countries, prevalence estimates vary wildly from 0.2% to 62%, although again, prevalence rates vary by the type of abuse involved (Phelan 2013). In Portugal, it is estimated that 12% of older adults fall victim to elder abuse in a given year, although again prevalence rates vary across types of abuse (Gil et al. 2014). In Western Australia, the prevalence of elder abuse is estimated to be 4.6% (Phelan 2013). Due to methodological differences within and between countries, comparisons are imprecise. However, it is generally accepted that the prevalence of elder maltreatment increases among people with a disability, cognitive impairment, and/or dependence (World Health Organization 2011).

There is evidence that elder abuse is underreported, with only one in 24 cases reaching the authorities, with rates of reporting differing across types of abuse (Phelan 2013). Although elder abuse occurs in long-term care facilities (Payne 2011), the majority of elder abuse occurs in the community, where most (95%) older American adults reside. However, residence varies tremendously in other parts of the world. In the

European Region, for example, more affluent countries have higher rates of paid caregiving and institutional care compared to less affluent countries where care is provided primarily by family members (World Health Organization 2011).

The field is recognizing the unique ways in which historically marginalized groups are impacted by the experience of elder abuse (Teaster et al. 2014). Distinct ethnic/racial groups may perceive the experience of abuse differently, experience elder abuse in different ways, and even at different rates. Individuals who self-identify with certain groups (LGBT, veterans) may have unique vulnerabilities that place them at risk for abuse, including financial exploitation. For example, threatening an LGBT older adult with outing may be sufficient to produce silence.

The myriad consequences of elder abuse are not often recognized (Payne 2011). They include psychological problems such as depression, emotional problems, disruptions in social and family relationships, compromised health, physical injury, hospitalization, and mortality, restrictions on and elimination of autonomy such as institutionalization or imposition of a guardianship, changes in living arrangements, and loss of assets including one's home. In some cases, there are secondary victims as well. For example, family members or the state may become physically and/or financially responsible for the older adult, or those who stood to receive an inheritance will not do so. The economic costs to society (direct costs to health, social, legal, police and other services) imposes a substantial financial burden. The consequences of elder abuse routinely lead to a diminished quality of life for abused older adults regardless of nationality.

Case Identification and Reporting

Some countries (e.g., Israel, Brazil, South Korea, United States) have implemented a system for responding to reports of elder abuse, typically referred to as adult protective services (APS) (World Health Organization 2002b, 2011). Since the 1970s, all states in the USA have APS, a

government agency guided by state statute, although statutes vary considerably from state to state (Jackson 2015). Albeit somewhat controversial, all but one state (New York) have some form of mandatory reporting. Australia, in contrast, has eschewed mandatory reporting. APS is guided by the principle of self-determination and does not compel compliance with the provision of services unless the older adult is incapacitated or in certain emergency situations and the court approves such intervention. However, some states do compel compliance with an investigation. In practice, studies in the USA generally find that approximately a quarter of APS clients decline services, some of which will have a subsequent APS report. Over the decades, elder abuse has shifted conceptually to that of a crime, implicating the involvement of law enforcement and prosecution, although prosecution remains uncommon (Payne 2011).

Concern over financial exploitation (i.e., the illegal or improper use of an elder's funds, property, or assets) has consumed much of the attention towards elder abuse (Factora 2014). Financial exploitation has captivated the federal and state responders in the USA and Australia, with the majority of new movement within this defined area of elder abuse. As lawmakers bear witness to older adults being financially ruined, they have responded in kind with increased legislation (albeit not funding). There are now 39 states in the USA that criminalize financial exploitation (Jackson 2015). The primary form of financial exploitation prevention has been education, but researchers are suggesting that this may be ineffective for many older adults (Payne 2011).

The field of elder abuse has suffered from a lack of theory (Payne 2011; Bonnie and Wallace 2003). However, the adoption of a lifecourse approach is recommended for understanding elder maltreatment (World Health Organization 2011). While still thin, there have been modest empirical gains since the landmark release of the Institute of Medicine's *Elder Mistreatment: Abuse, Neglect, and Exploitation in an Aging America* (Bonnie and Wallace 2003), depicting the deplorable condition of the elder abuse field.

There is increasing recognition of the importance of distinguishing among types of abuse (Payne 2011), while recognizing that sometimes types of abuse co-occur or that one type of abuse may be a risk factor for experiencing other forms of abuse. However, there is still relatively little research that either increases basic knowledge or guides applied practice (Payne 2011). Furthermore, the research has been uneven, with less empirical attention to caregiver neglect and psychological/verbal abuse compared to other forms of elder abuse.

Detection of elder abuse remains challenging in all countries. In an effort to identify cases, elder abuse screens have been developed, although it is unknown how widely they are administered in any country. The U.S. Preventive Services Task Force recently concluded, however, that there are no valid and reliable elder abuse screens and could not recommend their use (Moyer 2013). Considerably more work is needed to develop psychometrically sound screening instruments for elder abuse. In the meantime, efforts in many countries (e.g., Canada) include public awareness campaigns designed to encourage community members to report suspected elder abuse. However, detection and reporting are related but distinct actions, with the decision to report considerably complex. Regardless, communities implementing public awareness campaigns must be prepared for the possible increase in maltreatment cases coming to the attention of those responsible for responding.

With few exceptions, the field suffers from a lack of forensic markers, which is interesting given the criminalization of elder abuse over the past couple of decades. Lack of forensic markers hampers the ability of geriatricians and other health care providers to differentiate between aging and abusive behavior (Bonnie and Wallace 2003), especially when victims are reluctant to disclose. Furthermore, insufficient knowledge surrounds the differentiation between accidental death and elder homicide. Forensic science also is being applied in the context of financial exploitation, with the utilization of forensic accountants in financial exploitation investigations.

Risk Factors of Elder Abuse

Consistent with a public health approach, much of the elder abuse research has focused on the identification of risk factors (i.e., factors that increase the odds of some phenomenon such as elder abuse). Researchers have identified over 50 risk factors for elder abuse, although only 13 are found consistently across studies (Johannesen and LoGiudice 2013). However, risk factors are differentially associated with types of abuse. Other than co-occurring forms of elder abuse, little is known about the ebb and flow of these risk factors or the interconnectedness among them. Also lacking from this literature is the identification of protective factors that buffer against elder abuse.

One risk factor that seems to cut across all types of elder abuse is dementia (Dong et al. 2014). In 2002, the prevalence of dementia among American individuals ages 71 and older was 13.9%, with another 22.2% having some form of cognitive impairment without dementia. However, it is important to remain cognizant that more people without dementia experience elder abuse. In response to the concern about identifying dementia among older adults, over 100 cognitive screens have been developed and many are in use in every day practice throughout the world. However, the US Preventive Task Force concluded that “. . . current evidence is insufficient to assess the balance of benefits and harms of screening for cognitive impairment” (Moyer and U.S. Preventive Services Task Force 2014).

The risk factor that consumes the most real estate in this field is social isolation. However, this concept is unrefined in the context of elder abuse, often being conflated with network size, loneliness, and living alone, and yet there are important distinctions among these concepts. The manner in which isolation manifests across types of abuse appears to differ as well. Some studies have found, for example, that while low social support was related to neglect, physical, sexual, and emotional abuse, it was not related to family-perpetrated financial exploitation. In contrast, other studies have found that living alone was related to financial exploitation, but not to

physical abuse (O’Keeffe et al. 2007). Social isolation likely plays an important role in victimization, but requires greater conceptual clarity. It has been proposed, however, that social connectedness may play a prophylactic role in elder maltreatment (World Health Organization 2011).

Gender has also been implicated in elder abuse, although scholars cogently argue that elder abuse is not a gendered phenomenon (Kosberg 2014). While the field awaits the development of victim profiles for each type of abuse, it is important to remember the heterogeneity that exists among older adults generally, and among elder abuse victims specifically. For example, the victimology literature asserts that there is a range of culpability expressed by victims (Doerner and Lab 2015). It may be more difficult for society to perceive an older adult victimized by a family member as a “pure victim” compared to an older adult victimized by a stranger.

Offenders have historically been excluded from elder abuse research as well as the response to elder abuse. Elder abuse offenders can be anyone, but are frequently family members, relatives, friends, neighbors, and professional caregivers, although the predominant type of victim-offender relationship appears to vary by abuse type (Jackson 2014). Furthermore, in Spain the main perpetrators for older people who are dependent or have disabilities were adult offspring, whereas for independent older people the perpetrators appear to be their partners (World Health Organization 2011). There are several offender risk factors that have substantial empirical support across studies from various countries (World Health Organization 2011; Payne 2011; Johannesen and LoGiudice 2013). These include psychopathology (substance abuse, mental illness, and/or criminal history), isolation, and financial dependence upon the victim. As with victims, appreciating the heterogeneity among elder abuse offenders is important. Prosecution has been the primary form of intervention for elder abuse offenders, and even that has been appallingly absent (Payne 2011). Development of offender interventions is urgently needed (Jackson 2014).

To truly understand and predict elder abuse, the ecological model instructs that there are risk factors at levels above and beyond the individual level (Payne 2011). For example, at the relationship level, the quality of the relationship prior to the occurrence of maltreatment may be an important predictive factor (World Health Organization 2011). Although the literature is scant, neighborhood-level factors (unsafe neighborhoods, high unemployment, and negligible social cohesion) have also been shown to be associated with elder abuse. At the societal level, elder abuse may be impacted by social policy and public attitudes such as ageism (i.e., stereotyping and discriminating against individuals or groups on the basis of their age).

Intervention

The field of elder abuse has placed very little effort into intervention development and even less on the evaluation of interventions. Studies find little encouragement in this domain, with some scholars questioning the underlying assumptions of protective services legislation (Payne 2011). It is becoming increasingly recognized that elder abuse cases range in complexity, with implications for interventions. Some cases are easily resolved, but many are not. It is clear that cases involving older parents and their abusive adult children are often particularly challenging cases in which to intervene due in part to parent’s fierce protection of their offspring and entrenched patterns of behavior. Efforts are underway to identify and address high-risk victims.

Newer interventions have incorporated known risk factors such as social isolation (World Health Organization 2011), conceding, however, that this type of intervention is time consuming. Some offenders suffer from caregiver burden syndrome, with programs developed to address this condition. However, a systematic review of respite care concluded that, although some evidence supports a positive effect on burden and depression among caregivers, the evidence was limited and weak (World Health Organization 2011).

In the United States and throughout Europe there are examples of shelters offering support for women who have left an abusive relationship. In the USA, the Weinberg Center for Elder Abuse Prevention has gained considerable prominence. However, little is known about the effectiveness of emergency shelters in reducing elder maltreatment. In general, there are insufficient evaluation studies exploring the effectiveness of interventions on elder maltreatment, both locally and globally. One approach may be to identify strategies for preventing violence in general as there may be some underlying risk factors that cut across both of these fields.

In the American context and in some European countries, even less is known about the practice of APS caseworkers and the effectiveness of the services they employ (Payne 2011). There is evidence that a report of abuse to APS increases the likelihood of institutionalization as well as mortality. However, APS caseworkers tend to perceive their interventions (e.g., institutionalization) as effective. The field has yet to identify and define successful outcomes beyond the cessation of abuse. APS caseworkers and older adults sometimes hold different views of the underlying causes of abuse (Payne 2011), suggesting they might perceive outcomes differently. Victim satisfaction with an APS intervention is largely unknown. However, one study found that the services most frequently offered (social services) were not the type of service that had the greatest impact (legal) on the abusive situation (Alon and Berg-Warman 2014). In this evidence-based driven world, APS is going to have to go under the microscope.

One practice that is growing in prominence across countries is responding to elder abuse cases through multidisciplinary teams (MDTs) (Brandl et al. 2007). Rooted in the biopsychosocial model, an MDT simply refers to a group of people bound by a common purpose, typically comprised of five features: sharing, partnership, interdependency, power, and process. MDTs promote the inclusion of professionals historically absent from society's formal response to elder abuse, for example, psychologists to conduct neuropsychological evaluations. Although the concept

has existed since the 1950s, demonstration projects in the USA were funded in the early 2000s which served to raise awareness of the model. This model is expected to proliferate in the coming years, although very few states have adopted this practice legislatively. Unfortunately, the empirical validation of MDTs is woefully small.

Conclusion

Elder abuse is a pervasive problem that affects all societies and countries. Considerable gains have been made in the field of elder abuse (research, practice, and policy) since it was first recognized in the 1970s. Although the knowledge base is growing, it remains underdeveloped. Very few interventions have been established, and far fewer have been evaluated. Practice continues to be based on experience rather than empirical evidence. And while there are now governmental policies of some kind in many countries (World Health Organization 2011), they are fragmentary and largely unfunded. It is sometimes easy for those in the field to become discouraged. And yet a look back over the past 35 years finds reason to be optimistic. For example, in 2002, the Toronto Declaration on the Global Prevention of Elder Abuse called on *all* countries to take action to prevent and ameliorate elder abuse. Many countries recognize the plight of abused older adults and are taking steps to respond. In the USA, for example, the Elder Justice Act (Pub. L. 111–148, 124 Stat. 119) was passed in 2009, the first federal legislation devoted exclusively to elder abuse.

As recommended by the World Health Organization, the adoption of a public health approach can facilitate a country's ability to prevent and ameliorate elder abuse. However, in the absence of a substantial investment in resources this fledgling field will continue to falter. Whether elder abuse has reached the level of a social problem in any country worthy of such investment remains dubious. However, in time society may look back and characterize this period as the turning point for many countries in the development of the field of elder abuse.

Eldercare and Work

Synonyms

Elder care; Informal care; Parent care

Definition

Eldercare is informal and unpaid care provided by family and friends that includes meeting a variety of physical, emotional, household, and financial needs. Caregiving can be divided into two broad

categories: hands-on activities, such as feeding, transporting, and dispensing medication, and managerial activities, such as planning, coordinating, and supervising formal care provided by others (Rosenthal et al. 2007). Care recipients may live in their own homes with their families or in residential facilities such as assisted living communities, nursing homes, or sheltered housing schemes.

Introduction

As populations age around the world, an increasing number of adults are working and caring for elders at the same time. In England and Wales, 11.9% of the female population and 9% of the male population provide some level of unpaid care with as many as 1.2% of the female population and 1% of the male population providing 50 h or more while working full time (Office for National Statistics 2013). In the United States, approximately 17% of the population takes care of older family members or friends while working full or part time (National Alliance for Caregiving 2015). Data from Australia, Canada, Israel, and the European Union show similar patterns of caregiving and employment (Cranswick and Dosman 2008; Fine 2012; Katz et al. 2011; Viitanen 2010). Overall, three times more people of working age are expected to care for two billion aging family members worldwide by 2050 (Carers UK 2013).

In most parts of the world, elders traditionally lived with their families in multigenerational households and were cared for by female relatives who did not work outside the home (Gross 2011). While women are still the primary caregivers in most families, eldercare arrangements are changing due to social, economic, and public policy trends. These trends include more women in the workforce, an increasing number of dual career households, delayed retirements, greater geographic mobility, shrinking family sizes, reduction of public spending on healthcare and social services, fragmented delivery of care to the aging, and a growing desire on the part of the elderly to remain in their own homes for as long as possible

(Bookman and Kimbrel 2011; Fine 2012; Kossek et al. 2010; Meng 2013; Yang and Gimm 2013).

With a growing number of women and men providing informal care worldwide and careers and caregiving responsibilities peaking at roughly the same time, eldercare has emerged as an important issue for employers. Although balancing caregiving and work can be stressful, employment may provide a psychological buffer. Thus, employers have a positive role to play by creating supportive work climates and offering workplace-based eldercare assistance. The following sections will highlight recent research on the relationship between eldercare and work with a special focus on two of the most challenging caregiving situations – end of life care and dementia. The general impact of caregiving on caregiver health and well-being, caregiver employment outcomes, and workplace-based eldercare assistance will be discussed.

Impact on Caregiver Health and Well-Being

From a theoretical perspective, caregiver health and psychological outcomes can be understood through the lens of a “social determinants of health” model. This model suggests that a range of individual and organizational factors, as well as wider societal and cultural factors, influence health and psychological outcomes for caregivers (Mikkonen and Raphael 2010). Salient factors include gender, income, and social status; working conditions; health and social services; social support networks; culture; and personal health practices and coping strategies. One example of a culture factor is gendered expectations of who provides care (Williams et al. 2011).

On a practical level, caregivers tend to develop more health problems than non-caregivers, but the effect is generally minimal (Pinquart and Sörenson 2003; Vitaliano et al. 2003). However, they are much more likely to experience increased psychological strain (Duxbury et al. 2011) and higher rates of depression (Pinquart and Sörenson 2003). Some possible explanations for the negative impact of eldercare on well-being include the

role reversal of children caring for parents, caregivers confronting their own mortality, and the emergence of unresolved family issues (Smith 2004). In addition, strong negative emotions such as anger, helplessness, confusion, and guilt may surface when eldercare responsibilities occur because of an emergency or escalate over time as the health of the care recipient declines (Gross 2011).

Research demonstrates that certain types of eldercare produce more stress and strain than others, including caring for a spouse and/or co-residing with a care recipient (Duxbury et al. 2011; Pinguart and Sörenson 2003). Moreover, women and individuals with fewer financial resources experience poorer outcomes no matter where they live or for whom they care (Austen and Ong 2014; Carers UK 2013; Feinberg and Choula 2012; Lee et al. 2001; Schroeder et al. 2012). In addition, caregivers who live in countries with weak social safety nets experience more stress and strain (Hansen et al. 2013).

The most physically and emotionally demanding caregiving situations entail caring for someone with dementia or at the end of life. Dementia patients require high levels of care and supervision, particularly when the syndrome is in the moderate to severe stages (Wimo et al. 2013). People with dementia may also develop neuropsychiatric ailments, including personality changes and mood disorders, as well as associated problem behaviors. These are symptoms that are particularly associated with burden in dementia caregivers (van der Lee et al. 2014; Chiao et al. 2015; Ornstein and Gaugler 2012). Given the significant and cumulative losses associated with the dementia disease trajectory, dementia caregivers may also experience anticipatory and “pre-death grief” (Lindaur and Harvath 2014). Furthermore, dementia caregivers tend to provide more care each month and over a longer period (Kasper et al. 2014). As a result of these multiple pressures, dementia caregivers experience high rates of burden, depression and anxiety, social isolation, physical ill health, and feelings of guilt and frustration (van der Lee et al. 2014; Chiao et al. 2015; Springate and Tremont 2014), although some authors have also documented

gains such as spiritual and personal growth and skills acquisition (Zarit et al. 2012; Sanders et al. 2005).

End of life care is also physically and emotionally demanding because caregivers undertake physical tasks, manage complex symptoms, and provide emotional support to a dying person while simultaneously managing their own, sometimes complicated, feelings of loss and grief (Williams et al. 2011; James et al. 2009; Mangan et al. 2003). As a result, end of life care is associated with a wide range of negative health and psychological impacts (Funk et al. 2010; Stajduhar et al. 2010). For example, a cross-country European survey estimates that between 28% (Belgium) and 71% (Italy) of end of life caregivers were physically and/or emotionally overburdened during the last 3 months of the care recipient’s life (Pivodic et al. 2014).

Caregiver Employment Outcomes

Employed caregivers report higher levels of stress and work-family conflict than non-caregivers, and employers perceive that caregivers are less productive (Keene and Prokos 2007; Zuba and Schneider 2013). While caregivers are more likely to experience disruption in their labor force participation than non-caregivers, it is debatable whether the stress of eldercare results in negative work outcomes for individuals who remain in the workforce (Zacher et al. 2012). Moreover, caregivers who continue to work may receive a psychological boost from combining the two roles.

Labor force participation. Research from around the world shows that caregiving impacts labor force participation, especially for women (e.g., Austen and Ong 2014; Feinberg and Choula 2012; Kotsadam 2011; Liu et al. 2010). Typical responses to the demands of caregiving include dropping out of the workforce permanently, reducing work hours, taking leave without pay, or retiring early (Dembe et al. 2008). Women are more likely than men to leave the workforce permanently. Other factors that increase the likelihood of exit include age, poor health, and lower socioeconomic status (Austen and Ong 2014;

Lilly et al. 2007; Meng 2013). There is also evidence that employment status is a risk factor for unpaid caring. Individuals not working or working part time are more likely to be the ones to provide care compared to those working full time (Hutton and Hirst 2000).

Intensity of caregiving is another factor that affects labor force participation for both women and men. Research in the United Kingdom shows that there is a “threshold effect” at 10 h a week, such that becoming an unpaid caregiver for 10 or more hours a week is associated with increased odds of leaving employment (King and Pickard 2013). Similarly, a Canadian study shows that higher intensity caregiving is associated with being fully retired for men and women aged 55–69. For women, high-intensity caregiving is also associated with working part time and being a labor force nonparticipant (Jacobs et al. 2014).

Type of caregiving also affects labor force participation. A large-scale nationally representative survey conducted by the Alzheimer’s Association (2014) found significant impacts on employment for dementia caregivers in the United States. Seventeen percent of workers gave up their jobs before or after assuming caring responsibilities, 8% took early retirement, and 13% moved from full- to part-time employment. Parallel research in the United Kingdom estimates that 21% of people caring for someone with dementia leave their jobs and 29% reduce their working hours (Centre for Economic and Business Research 2014). End of life caregivers are nearly 5% more likely to reduce their work hours than individuals caring for elders with a long-term, chronic condition (Williams et al. 2014).

Caregivers who reduce their hours or leave the workforce entirely incur long-term financial penalties in terms of lost wages and benefits and reduced retirement savings (Feinberg and Choula 2012). In addition, employers can incur costs because they will have invested resources to train and develop these employees. Many caregivers who leave the labor market will have valuable skills and experience because they are concentrated in the 45–64 age range (Carers UK 2013). Finally, there are public expenditure implications. For example, Pickard (2012) estimated

that the UK public expenditure cost of caregivers leaving employment is £1.3 billion per annum, covering £1 billion of lost tax revenues and £300 million in Carer’s Allowance.

Work-family conflict. While research consistently shows that eldercare affects labor force participation, there is less evidence to support assertions that the stress of eldercare causes negative work outcomes for those who remain in the workforce (Zacher et al. 2012). For example, employers perceive that eldercare causes employees to miss work (Katz et al. 2011). All caregivers are absent more frequently than non-caregivers, but employees with children miss more days than those taking care of elders (Boise and Neal 1996). Moreover, all caregivers experience higher levels of time- and strain-based conflict than non-caregivers, but there is no difference between those caring for children and those caring for elders (Lee et al. 2010). However, workers who take care of elders are likely to experience more frequent interruptions during the workday, most typically to make phone calls and accompany care recipients to appointments. This phenomenon is known as presenteeism and is a consequence of the fragmented delivery of services to the elderly, which require caregivers to coordinate care from multiple providers (Smith 2004). As with gendered outcomes for labor force participation, the impact of eldercare on absenteeism and presenteeism is greater for women, as well as workers in low-skill and low-status jobs (Austen and Ong 2014; Katz et al. 2011; Lee 1997; Zuba and Schneider 2013).

Employees with the most challenging caregiving responsibilities experience the most work-family conflict and work disruptions. For example, in the United States 54% of employees taking care of dementia patients reported unplanned absences from work, 15% took planned leave, and 8% saw their work performance suffer to point of being worried about dismissal (Alzheimer’s Association 2014). In the United Kingdom, as many as 6.6% end of life caregivers missed full days at work compared those caring for someone with a long-term, chronic condition (Williams et al. 2014).

Work as a buffer. Employed caregivers generally report better health than unemployed caregivers. This phenomenon may occur because employment is a protective factor or because the caregivers with the poorest health are those least able to work (Cannuscio et al. 2004). Nevertheless, research indicates that work may be a protective factor because it bolsters a caregiver's sense of efficacy, provides a sense of accomplishment, increases financial resources, and expands support networks and opportunities for respite (Utz et al. 2012; Zuba and Schneider 2013).

Two contrasting theories from the work-family literature explain how successfully (or not) individuals balance eldercare and work. Scarcity theory posits that an individual has a limited amount of time and energy for which caregiving and work compete (Marks 1977). On the other hand, role enhancement theory says that the benefits of one role spillover into the other, creating a net gain (Greenhaus and Powell 2006). Reid et al. (2010) studied which of these theories more accurately predicts employee behavior and found that the results vary greatly from individual to individual with some employed caregivers indicating that work enhances their well-being while others saying that it adds to their stress. Reid et al. (2010) conclude that an individual's subjective perception of the degree to which eldercare interferes with work is more predictive of role conflict and other negative outcomes than more objective measures.

Workplace-Based Eldercare Assistance

Although employer support has been shown to reduce work-family conflict and caregiver burden (Zacher and Winter 2011), research on the availability and effectiveness of workplace-based eldercare assistance is sparse (Kelly et al. 2014). In general, a country's public policy context is a major determinant of how active private employers are in this area. In countries with weaker family leave laws and welfare policies, private employers are more likely to provide assistance, but it is usually limited to the largest companies and certain employees (Dembe et al. 2008; Yang and Gimm 2013). Employers cite the cost of

benefits and the difficulty measuring effectiveness as hindrances to providing assistance (Katz et al. 2011).

Workplace-based eldercare assistance can be divided into three broad categories: compliance with family leave laws, formal employer-sponsored services and benefits, and informal support from managers and supervisors. Legal compliance is the most basic level of assistance that employers provide. If employers offer formal benefits, they usually take the form of information, education, and referral programs. In the United States, these would typically be available through Employee Assistance Programs (EAPs). Some employers may go as far as offering flexible hours and paid leave, as well as subsidies for respite and emergency care (Dembe 2008). Flexibility is both the most desired benefit and most beneficial in terms of reducing caregiver burden, but access varies greatly across countries, industries, organizations, and job categories. For example, in the United States flexible work hours are available primarily to professional and managerial employees (Sweet et al. 2014).

Even when employers offer eldercare benefits, employees frequently do not utilize them either because they are not aware of their existence or they worry about being stigmatized if they disclose their care duties (Dembe et al. 2008). Fear of stigmatization is a particular concern for employees with the greatest caregiver burden. For example, the lack of understanding that still exists around dementia means that people may feel uncomfortable about mentioning their care responsibilities at work. This may prevent them from seeking the support they need. Therefore, employers need to take active steps to ensure that all employees are made aware of workplace-based assistance. Employers may also participate in "dementia-friendly" initiatives designed to reduce the stigma of dementia, including the UK's dementia-friendly workplace initiative (Alzheimer's Society 2015).

End of life caregivers may require compassionate or family-friendly leave, in addition to bereavement leave due to the intensity and trajectory of care (Vuksan et al. 2012). Psychoeducational interventions for end of life caregivers

may improve coping and help to reduce distress and burden (Hudson et al. 2013). In turn, reducing caregiver burden and distress can support death at home rather than in hospital (Visser et al. 2004).

Conclusion

With populations aging around the world, more and more adults will find themselves juggling eldercare and work responsibilities. In order to minimize stress, maximize well-being, and ensure that caregivers can continue working as long as they want, forward-thinking employers – with the help of governments and the voluntary sector – should take the lead in developing creative and effective eldercare policies and programs to assist all employees. In order to create “aging-friendly societies” and workplaces, Bookman and Kimbrel (2011) argue that a “large-scale, cross-sector initiative is needed to coordinate efforts. . .to support all citizens from diverse cultures and incomes as they age” (p. 132).

Synonyms

Convulsive therapy; Electroconvulsive therapy (ECT); Neurostimulation therapy; Somatic therapy

Definition

Electroconvulsive therapy (ECT) is a neurostimulation intervention used to treat severe neuropsychiatric diseases, such as major depressive disorder, bipolar disorder, and schizophrenia. To perform ECT, while the patient is under anesthesia, controlled electrical stimuli are applied to the brain via two electrodes that are placed on select areas of the scalp to generate a therapeutic tonic-clonic seizure. The generated seizure tends to be time limited and results in both motoric (typically the foot) and electroencephalographic manifestations. To result in therapeutic efficacy, a typical ECT course includes on average between eight

and fourteen sessions that are administered either two to three times per week. There are no absolute contraindications to ECT, but patients undergo comprehensive medical and neuropsychiatric examinations before undergoing treatment and are monitored by an interdisciplinary care team during and immediately after the treatment. Though ECT tends to be medically safe, it can result in transient adverse effects including headaches, body aches, and importantly cognitive difficulties. Regarding the latter, the cognitive difficulties include disorientation, decreased processing speed, anterograde amnesia, retrograde amnesia, verbal dysfluency, and executive dysfunction. Despite these transient adverse effects, ECT has been found to be one of the most effective neuropsychiatric treatments, particularly for major depressive disorder. Due to its usefulness when other neuropsychiatric treatments fail, modern neuropsychiatric practice continues to employ ECT.

Introduction

Introduced in the late 1930s, electroconvulsive therapy (ECT) is one of the oldest, most durable, and effective neurostimulation therapies in the neuropsychiatric armamentarium (American Psychiatric Association 2008). Initially developed for schizophrenia or other psychotic disorders based on the false assumption that seizures and psychosis were unable to coexist, ECT has since been found to be highly effective for major depressive disorder (MDD). Over the past two decades, numerous clinical investigations sponsored by the National Institute of Mental Health have informed the development and refinement of ECT (Fink 2014; Lisanby 2007). Such refinements have helped to minimize the side effects of ECT while maximizing the clinical benefits (McClintock et al. 2014). Indeed, despite the introduction of other neuropsychiatric treatments including pharmacotherapeutics, psychotherapy, and transcranial magnetic stimulation, ECT continues to be used in psychiatric practice as it tends to be relatively safe and effective in cases where other treatments fail.

Practice of Electroconvulsive Therapy

Neuropsychiatric practices across the globe, including the United States, employ ECT (American Psychiatric Association 2008). Though there have been no formal epidemiologic studies on the use of ECT, it is estimated that approximately one million people worldwide are treated with ECT. In the United States, the number of people treated with ECT is estimated to be approximately 100,000 annually. Across the United States, the practice of ECT varies due to various mental health laws, as in certain states its use is restricted to certain patients (e.g., patients aged 17 and older). A main factor that limits the use of ECT is the negative stigma associated with it secondary to its associated side effects (e.g., retrograde amnesia, anterograde amnesia). Also, after the publication of the National Institute for Health and Care Excellence (NICE) guidelines (National Institute for Health and Care Excellence 2003), which resulted in more stringent practice parameters, the use of ECT has decreased in the United Kingdom. Nonetheless, ECT has a global presence and its use may increase as more people are diagnosed with neuropsychiatric diseases, particularly when they are nonresponsive to other treatments.

Clinical indications (see Table 1) for ECT include MDD, bipolar disorder, schizophrenia, and catatonia (Mankad et al. 2010). For MDD, ECT tends to be reserved when other treatments fail, and the illness is chronic, severe, and life-threatening. For bipolar disorder, ECT is useful for both the manic and depressive episodes and is indicated when other treatments fail to abate the

Electroconvulsive Therapy, Table 1 Neuropsychiatric indications for electroconvulsive therapy

Behavioral disturbances of dementia (intractable to other treatments)
Bipolar disorder

Major depressive disorder
Parkinson's disease (intractable to other treatments)
Schizoaffective disorder
Schizophrenia

bipolar symptoms. For schizophrenia, ECT is indicated when other treatments are ineffective and may be useful for both the positive and negative symptoms. For catatonia, ECT is indicated as a first-line treatment, though it tends to be reserved until other treatments are determined to be ineffective. Among these four clinical indications, ECT has been found most useful for MDD and catatonia.

Administration of Electroconvulsive Therapy

An interdisciplinary healthcare team is needed to administer ECT (American Psychiatric Association 2008; Mankad et al. 2010). Such disciplines include (in alphabetical order) anesthesiology, clinical neuropsychology, clinical psychology, nursing, psychiatry, and social work. Before patients commence with ECT, they must undergo a comprehensive medical and neuropsychiatric examination to ensure that ECT is appropriate and safe. Components of the examination include a general medical and physical work-up, anesthesiology work-up, neuropsychiatric history including prior and current treatments, and global cognitive status examination. As needed, other medical work-ups may be recommended including electrocardiogram (EKG), x-ray (such as chest, spine, and head magnetic resonance imaging (MRI) or computerized tomography (CT)), and neurological examination.

Once a patient is cleared for ECT, the treatment team will provide education to the patient (and his/her care partner) about the ECT treatment process, perform informed consent procedures that will occur before the first ECT session and continue throughout the ECT course, and establish the ECT protocol to be used for the patient. During the provision of ECT, safety is a top priority. Before initiation of each ECT session, the patient is administered anesthetic agents to cause muscle relaxation (minimizes motoric seizure expression) and sedation (minimizes the treatment experience), a bite block is placed in the mouth to protect the teeth and tongue, and the patient is closely and continuously monitored (including

Electroconvulsive Therapy, Table 2 Electroconvulsive therapy parameters

Domain	Specific parameter
Stimulus waveform	Sine wave ^a Brief pulse Ultra brief pulse
Electrode configuration	Bitemporal Bifrontal Right unilateral Left unilateral ^a
Electrical dosage strategy	Empirical dose titration Age method Half-age method
Pulse amplitude	500 mA 600 mA 700 mA 800 mA 900 mA

mA milliamperes

^aSine wave pulse width is no longer used in modern ECT practice due to its associated adverse cognitive effects, and left unilateral electrode configuration is rarely used in modern ECT practice

pulse, blood pressure, respiration, EKG, and electroencephalography (EEG)) by the treatment team (American Psychiatric Association 2008; Mankad et al. 2010).

To administer ECT, four treatment parameters (Table 2) can be adjusted to provide maximum clinical outcome and minimize adverse effects. These parameters include stimulus waveform, electrode configuration, electrical dosage (American Psychiatric Association 2008), and pulse amplitude (Peterchev et al. 2015). Although the initial stimulus waveform was sinusoidal (sine wave), that waveform is no longer used and modern-day ECT devices no longer carry this option due to its adverse cognitive effects. Both brief and ultra-brief pulse waveforms have been found to be efficacious, and research suggests that the latter may have a more benign cognitive adverse effect profile (Tor et al. 2015). The initial application of ECT employed bitemporal electrode configuration, and thus, it is sometimes called the “gold standard.” However, research has suggested that electrode placement along with bifrontal and right unilateral electrode configuration when properly dosed is equivalent with regard to clinical outcome but that the latter two

placements may have less cognitive adverse effects (Kellner et al. 2010). In another electrode configuration, left unilateral has rarely been employed in clinical ECT practice due its adverse cognitive effects particularly with verbal cognitive functions.

When providing the stimulus for the ECT session, two stimulus dosing methods are used including the age and empirical dose titration methods. For the age method, dose is adjusted based on the age of the patient, with younger and older patients treated with lower and higher doses, respectively. For the empirical dose titration method, a stimulus is applied at the lowest dose necessary to produce a tonic-clonic seizure. While the age method tends to generalize the stimulus dose across age groups and the empirical dose titration method individualizes the dosage, both have been found to be safe and efficacious (Mankad et al. 2010). An ECT parameter that has received more recent attention is the pulse amplitude. Current ECT devices usually have the pulse amplitude automatically set at 800 or 900 mA, and many clinics rarely adjust the amplitude. Some computational and pilot evidence suggested that decreasing the pulse amplitude down to 500 mA could result in an efficacious treatment with benign cognitive adverse effects (Peterchev et al. 2015). However, the current evidence base is lacking to justify altering pulse amplitude in clinical practice.

Efficacy

While published rates of ECT antidepressant efficacy have been found to vary with as low as 20% and as high as 80% remission rates due to variability in ECT practice and patient populations, when judiciously employed following evidenced-based practices, ECT is a highly safe and efficacious treatment (Fink 2014; Trevino et al. 2010). Indeed, among all neuropsychiatric antidepressant strategies and in cases where antidepressant treatments have been ineffective, ECT has the highest efficacy rate with concordant large remission rates. Relative to psychotherapeutic and pharmacotherapeutic strategies that can at times

take up to 8 or 12 weeks to achieve remission, ECT results in a rapid onset of action with remission on average being achieved in approximately 3–4 weeks (Spaans et al. 2015). Such rapid rate of response and remission is critical for patients, particularly when the MDD is life-threatening such as in cases of MDD with catatonia.

The antidepressant effects of ECT apply to a broad range of depressive symptoms including melancholic and atypical features, psychosis, suicidal ideation, and catatonia. Importantly, ECT is safe and efficacious for populations in which medications may prove to be harmful. For instance, ECT is useful in elderly adults with MDD as there are no medication-medication adverse interactions. Also, ECT can be useful for women with perinatal depression as research has found it to be safe for both the woman and the developing fetus.

Unfortunately, relapse after acute treatment can be high, especially in cases where there is no continuation or maintenance treatment protocol (Fink 2014; Lisanby 2007). Research continues to be ongoing to find optimal strategies to prolong remission post the acute course including continuation ECT, continuation pharmacotherapy, continuation combined ECT and pharmacotherapy, continuation cognitive behavior therapy, and continuation depressive symptom-titrated ECT.

Efficacy in Elderly Adults

Electroconvulsive therapy is considered an important treatment in elderly patients with depression. This is the case as elderly adults frequently require treatment with a rapid onset as they may present with greater depressive symptom severity (e.g., agitation, psychosis) and higher suicide risk and potentially may respond more slowly to antidepressant medication. Research has found that elderly adults with depression show rapid response and remission with ECT. For example, a study that compared outcomes from elderly patients who participated in a randomized controlled trial (RCT) for different antidepressant medications with outcomes from another RCT conducted in patients who received different forms of ECT found that both speed of remission

(mean time to remission for ECT group 3 weeks vs. 4 weeks for medication) and remission rates (63% ECT group vs. 33% in the medication group) were superior with ECT. After adjustment for clinical and demographic differences, the ECT group was also eight times more likely to achieve remission compared to the medication group after 5 weeks of treatment (Spaans et al. 2015).

Adverse Effects

Electroconvulsive therapy is considered a safe procedure in the elderly, although not unlike any other medical procedure, there is the potential risk for adverse effects (Table 3). These risks, however, can be minimized through careful medical work-up, optimally by a multidisciplinary team composed of different specialists (e.g., anesthetist, cardiologists, psychiatrist, etc.). This is particularly important for the elderly, who frequently have medical comorbidities. Of these, preexisting cardiac conditions pose the most significant risk for adverse effects, including death. During ECT, the cardiovascular system is placed under increased stress due to activation of the sympathetic autonomic system that results in tachycardia, hypertension, and increased oxygen consumption. In modern ECT practice, with

appropriate anesthetic and cardiovascular management, evidence suggests that ECT can be administered safely even in elderly adults with premonitory cardiovascular conditions when appropriate precautions are put in place. For example, a retrospective review of the medical records of 35 elderly patients with a history of heart failure and reduced ventricular heart function found that ECT was safe, with no reported adverse effects (Rivera et al. 2011). Similarly, a case report of the oldest person (100 years old) to receive ECT who had severe aortic stenosis reported no cardiac complications over an extended period of ECT treatment that spanned 5 years (O'Reardon et al. 2011).

An additional adverse effect relevant to the elderly is increased risk of falls from ECT. However, it is important to note that falls are common in psychiatric settings, particularly among patients considered the older-old and those with medical comorbidities (e.g., motor dysfunction and cognitive impairment). A retrospective analysis of records from 1834 admissions to a psychogeriatric inpatient unit identified ECT as a significant risk factor after controlling for other confounders, including age, medication use, Parkinson's disease, and dementia (de Carle et al. 2001). Falls were additionally found to be more common during the day, which was considered to be potentially associated with short-term cognitive side effects. As such, it is recommended to use select ECT parameters to minimize cognitive side effects in elderly patients, as well as implementation of other precautions, such as increased surveillance.

A less common adverse effect is dental and oral injury due to clenching of the jaw from direct stimulation of the masseter muscles. These types of adverse events are rare and typically mild. Risk is increased with dental pathology prior to treatment, which can be identified and potentially mitigated via pretreatment medical work-up.

Electroconvulsive Therapy, Table 3 Adverse effects associated with electroconvulsive therapy^a

Medical adverse effects	Neurocognitive adverse effects
Headache	Decreased processing speed
Migraine	Disorientation
Myalgia (e.g., body aches)	Executive dysfunction
	Inattention
	Memory disruption Anterograde amnesia Retrograde amnesia
	Verbal dysfluency

^aMost adverse effects associated with electroconvulsive therapy (ECT) tend to be transient. The medical adverse effects tend to dissipate 24–48 h after treatment and can be managed with over-the-counter medication. The neurocognitive adverse effects tend to dissipate within 1 week after the last ECT session, though some effects have been found to persist up to 6 months

Medical Effects

Other common medical effects associated with ECT include somatic discomfort (e.g., headache,

muscle soreness, nausea) and postictal delirium. The most common medical side effect of ECT is headache, which commonly occurs during and following postictal recovery. An audit of subjective side effects reported by 70 patients who received ECT found that 11% of patients reported experiencing a severe headache, while 44% reported a mild or moderate headache (Benbow et al. 2004). Somatic complaints, including headache, are however common in depressed patients prior to ECT, which therefore makes it difficult to determine their etiology. For example, a study conducted in elderly patients found that approximately 20% of patients reported headache prior to treatment and that this proportion showed a nonsignificant increase following ECT treatment (Brodaty et al. 2001). Headaches during ECT are typically managed through prophylaxis with analgesic medications, or treated symptomatically. Muscle soreness/pain and nausea are also common. Muscle pain due to ECT is considered to be caused by the actions of the muscle relaxant (succinylcholine) or alternatively through excessive convulsive movements during treatment. In the case of the former, this is managed with prophylaxis using analgesic medications, while the latter can be addressed through an increased dose of muscle relaxant. Nausea in contrast may occur as a side effect of general anesthesia and is typically managed with antiemetics.

Postictal delirium is also known to occur in a minority of patients and is characterized by motor agitation, disorientation, and sometimes erratic behavior. Correspondingly, it poses a risk for injury for both patient and staff. A retrospective case-controlled study of 24 patients who experienced postictal delirium and 24 controls failed to identify any relevant clinical or treatment differences between groups, including age (Devanand et al. 1989). A more recent study similarly was unable to identify any predictors, other than a potential association with seizure length (Reti et al. 2014). Thus, while older age is considered a risk factor for delirium in other settings, it remains unclear whether elderly patients are similarly at increased risk for delirium after treatment with ECT.

Neurocognitive Effects

Cognitive side effects from ECT are frequently the most significant concern for patients and typically manifest in short-term deficits in orientation during postictal recovery immediately following ECT, memory (anterograde and retrograde), executive function, and processing speed. Elderly patients treated with ECT may have poorer baseline cognitive functioning due to age and illness, which potentially may confound the interpretation of cognitive side effects in this population (McClintock et al. 2011). In contrast to research on the cognitive side effects of ECT in relatively younger adult populations, research findings to date have been mixed in regard to the extent in which elderly patients experience cognitive side effects.

Recovery of orientation immediately following ECT, typically assessed at regular intervals during recovery, has been identified as a predictor of retrograde memory side effects from ECT (Sobin et al. 1995). Monitoring of recovery of orientation during the ECT course has therefore been recommended to assist ECT practitioners with identifying patients at increased risk for these side effects. Importantly, increased age has been associated with longer time to reorientate midway during the ECT course (Martin et al. 2015). Older age, therefore, may be a vulnerability factor for increased memory side effects with increased number of ECT treatments.

Research into other ECT-related cognitive side effects in elderly patients, however, has been mixed and shown stability, impairment, or improvement in cognitive performance on measures including tests of global cognitive functioning, memory, and executive function (Tielkes et al. 2008). For example, a recent study conducted in 62 elderly patients (aged 60–85 years) found no significant changes in performance on measures of anterograde and retrograde memory, processing speed, and executive function following ECT compared to healthy elderly controls, although the ECT patients were found to perform poorer on a test of verbal fluency at post treatment compared to controls (Dybedal et al. 2014). In contrast, another recent study in 42 patients aged 58–91 years found significant

improvements in global cognitive function and anterograde memory but no changes on measures of attention and executive function following ECT (Verwijk et al. 2014).

Potential reasons for these mixed results may include heterogeneity in ECT treatment methodologies (e.g., electrode montage, dosing method, pulse width, frequency of treatment, and choice of anesthesia), cognitive assessment methods (i.e., brief screening compared to more detailed neuropsychological assessment), and time of cognitive testing in relation to the last ECT treatment. The latter is potentially important as cognitive side effects tend to resolve within a few weeks following treatment (Semkowska et al. 2010). It is also possible that reported cognitive findings in the elderly may be unduly biased due to the study cohorts. For example, elderly cohorts tend to have relatively higher proportion of involuntary patients who may be unable to participate in cognitive testing. Moreover, research studies often exclude patients who are at greater risk for delirium (i.e., who are cognitively impaired at baseline), which in turn may underestimate overall cognitive side effects. This is potentially important, as patients with higher educational and occupational attainment (i.e., increased cognitive reserve) are less likely to show cognitive side effects following ECT (Legendre et al. 2003).

Thus, while the extent to which elderly patients experience cognitive side effects from ECT remains unclear, given the vulnerabilities in this patient population (e.g., increased prevalence of cardiac comorbidities, cognitive impairment, severe illness), it is recommended to implement careful patient monitoring of cognitive side effects during ECT treatment. Also, use of ECT treatment methods associated with lesser cognitive side effects (e.g., ultra-brief pulse width, lesser frequency treatment) should also be considered for elderly patients who at potential increased risk.

US Food and Drug Administration Recommendations

As ECT was grandfathered in and never formally approved or cleared by the US Food and Drug

Administration (FDA), it convened an advisory panel hearing in January 2011 to discuss the reclassification of ECT. Following that advisory panel meeting, the FDA released a draft of a guidance document (Center for Devices and Radiological Health document number 1823) in December 2015 that outlined their recommendations for ECT reclassification (US Food and Drug Administration, 2015). Per the document, the FDA suggested that ECT should be reclassified into Class II for patients age 18 and older with a diagnosis of MDD or bipolar disorder. A device classified into Class II represents a *high-risk* device that requires special controls to ensure device safety and utility. While such reclassification will allow greater access to ECT for patients age 18 and older with MDD or bipolar disorder, it by default suggests that ECT will be reclassified into Class III for all patients with other diagnoses. A Class III device is considered to be of the *highest risk* and has the greatest level of regulatory control. As such, patients younger than age 18 or those with neuropsychiatric diagnoses other than MDD or bipolar disorder in whom ECT has been found to be safe and useful may find it more difficult to be prescribed ECT.

The FDA also provided other recommendations in the guidance document. Regarding the practice of ECT, the document suggested the use of brief pulse waveform, unilateral electrode configuration on the non-dominant hemisphere (e.g., right unilateral), decreased stimulus intensity particularly with bitemporal electrode configuration, and two ECT sessions or less per week. As current ECT clinical practice has no mandated clinical neuropsychological assessment, the FDA recommended that clinicians monitor cognitive function before the initiation of and during the ECT course. The clinical neuropsychological assessment should include both patient self-report and observer-report of cognitive function. As ECT has been found to produce transient adverse cognitive effects, the FDA proposed that the label for ECT devices include the following warning: “Warning: ECT device use may be associated with: disorientation, confusion, and memory problems.”

As the guidance document is in review at this time and the FDA has invited comments from the

US community, it is unclear at this time which recommendations, if any, in the guidance document will be put into clinical practice. Given the safety and utility of ECT in patient populations where other treatments are intolerable or ineffective, the restriction of its use could prove problematic for the medical and neuropsychiatric communities.

Future Directions

Being one of the oldest, though with modern technical and practice updates, most efficacious, and relatively safe neurostimulation interventions, ECT has earned its place in the neuropsychiatric armamentarium. With the recent recommendations from the US FDA, the practice of ECT may change with new practice guidelines. Regardless of the final US FDA recommendations, future research is warranted to understand the mechanisms of action underlying the efficacy and side effects of ECT. Further, research is warranted to integrate ECT with other neuropsychiatric interventions (e.g., psychotherapy, transcranial direct current stimulation) to minimize adverse effects and maximize clinical, functional, and quality-of-life outcomes.

Synonyms

Emotion and emotional reactivity; Emotion regulation and emotion control; Emotional competence and emotional intelligence; Emotional understanding and cognitive-affective complexity

Definition

Affective well-being requires the frequent experience of positive emotions and the infrequent experience of negative emotions in daily life. Emotions denote fast and short-lived reactions to events that are important to an individual's well-being; these reactions can be described on different levels (physiological, subjective-experiential, and behavioral). Emotional competence includes several distinct facets, including the ability to regulate emotions, the ability to understand and make sense of own emotions, and the ability to infer and share others' emotions.

The Stability-Despite-Loss Paradox of Affective Well-Being

Affective well-being, the frequent experience of positive affect and the infrequent experience of negative affect in daily life, is a key aspect of individuals' general subjective well-being and prominent indicator of successful aging, increasingly thought to play a central role throughout the life span in a wide range of areas involved in human functioning (Kahneman et al. 1999). Perhaps one of the most important findings in psychological aging research has been that affective well-being remains relatively stable during most of the adult life span and early old age, although many individuals experience an increasing number of losses in cognitive, physical, and social domains. Prominent theories of emotional aging have suggested that this discrepancy results from older adults' high emotional competence, particularly the effectiveness of their emotion regulatory strategies (Scheibe and Carstensen 2010). In recent years, however, at least three qualifications to what has been called the stability-despite-loss paradox of subjective well-being have been reported. First, many aspects of subjective well-being, including affective components, become increasingly likely to decline during very old age beginning around age 80 (Baird et al. 2010; Kunzmann et al. 2000) and show normative decline several months or even years before individuals die (Gerstorf et al. 2010). Second, the

stability found in overall subjective well-being is not necessarily evident for all its dimensions (e.g., the frequency of sadness remains stable and even increases in very old age; Kunzmann et al. 2013). Third, certain subgroups of older individuals are at risk for low subjective well-being (e.g., individuals who have been burdened by losses that affect many life domains; Lucas 2007). These qualifications point to potential limits of emotion regulatory processes in old age and the need for theories of emotional aging that paint a balanced picture about older adults' strengths and vulnerabilities in maintaining long-term affective well-being. Before discussing relevant theoretical and empirical work on emotional aging, it might be useful to present definitions of the terms emotion and emotional competence.

Defining Emotion and Emotional Competence

Emotions have been defined as fast and short-lived reactions to events that are important to our personal goals and well-being. Emotions are manifested on different levels and typically characterized by certain cognitive appraisals, specific action tendencies, patterns of physiological activity, configurations of facial expressions, and inner feelings (Levenson 2000). Many researchers have acknowledged the importance of both positive and negative emotions for optimal functioning (Levenson 2000; Wrosch and Miller 2009). Although negative emotions may be unpleasant, they signal the individual that there is something wrong and motivate cognitive and behavioral processes that help regain a balance between the person and the environment. Seen in this light, the capacity to spontaneously react to significant and negative events with the appropriate emotion (e.g., fear to threat, anger to injustice) is an important contributor to longer-term emotional well-being. However, negative emotions may also be signs of or contributors to low affective well-being if they become chronic and decoupled from concrete and immediate causes.

Although emotions are often our best allies, helping us to respond effectively to the opportunities and difficulties we encounter, occasionally, it is necessary to regulate our spontaneous impulses and reactions. The ability to regulate

positive and negative emotions has been thought to be one central aspect of emotional competence (e.g., Scheibe and Carstensen 2010). In the broadest sense, emotional competence can be understood as "work" with emotions in ways that help us to keep on track and make progress with our immediate and longer-term goals. Moreover, three different dimensions of emotional competence can be differentiated: (a) regulating emotions so that they fit situational affordances and facilitate our goals; (b) understanding and sense making of emotions, including their causes, temporal dynamics, and consequences; and (c) responding empathically to fellow humans (i.e., being able to accurately infer others' emotions, share their feelings, and experience sympathy with them). These three dimensions of emotional competence have been thought to facilitate long-term affective subjective well-being, particularly in old and very old age (Kunzmann and von Salisch 2009).

Theories of Emotional Aging

Socioemotional selectivity theory. Socioemotional selectivity theory (SST; Scheibe and Carstensen 2010; Carstensen et al. 1999) is a motivational theory of social and emotional aging that has portrayed old age as a period during which individuals are particularly motivated to shape their lives so as to maximize the occurrence of emotionally satisfying moments. More specifically, according to SST, advancing age is naturally associated with endings and a limited lifetime. As a consequence, older adults have a strong present orientation involving goals related to current feeling states, emotional meaningfulness, and satisfaction. By contrast, younger adults, who typically have an extended future time perspective, prioritize longer-term goals aimed at expanding breadth of knowledge and optimizing future resources. Thus, SST predicts that people of different ages prioritize different types of goals. As people age and increasingly perceive time as finite, they attach less importance to goals that expand their horizons and greater importance to goals from which they derive immediate emotional meaning. Obviously, younger people also sometimes pursue goals related to

meaning, just as older people pursue goals related to knowledge acquisition. However, the relative importance placed on these two types of goals is thought to change with increasing age.

In support of SST's main predictions, a large body of evidence suggests that, in comparison with their younger counterparts, older adults are more selective in their choice of social partners and prioritize familiar and close social partners over unfamiliar and emotionally less important persons (Carstensen et al. 1999). In addition, older adults report greater satisfaction and more positive experiences with members of their social networks than do younger adults. When conflicts occur, older adults typically respond with fewer negative emotions than young adults (Luong et al. 2011). Such age-related decreases in negative feelings and facial expressions during unpleasant social interactions concern particularly relationship-damaging emotions such as anger, aggression, or disgust, but not necessarily sadness (Blanchard-Fields and Coats 2008; Charles and Carstensen 2008). Also consistent with SST, in comparison to young adults, older adults seem to be more likely to appraise their partner positively during a conflict and to engage in deescalating conflict management strategies (Luong et al. 2011).

There is also substantial evidence for systematic age differences in basic affective information processing. Older adults appear to be generally more sensitive to positive information and less sensitive to negative information than young adults, a phenomenon termed the "positivity effect" (Reed and Carstensen 2012). SST states that this positivity effect results from an age-related shift in motivational states (i.e., a shift from goals related to knowledge acquisition to goals related to emotional meaning) that causes an age-related increase in the allocation of cognitive resources toward emotion regulation (Mather 2012). Given that the majority of studies interested in affective information processing have not elicited emotions or systematically manipulated emotion regulation strategies, however, the idea that "positivity effects" serve emotion regulation goals and lead to better emotional outcomes

is still in need of further investigation (Isaacowitz and Blanchard-Fields 2012).

Dynamic integration theory. According to dynamic integration theory (DIT; Labouvie-Vief 2003), high longer-term subjective well-being encompasses processes of affect optimization but also processes of affect differentiation. Affect differentiation involves tolerance for and sense making of negative and ambivalent experiences and, thus, ideally results in a deeper and more complex understanding of the self, others, and situations. DIT poses that diminishing cognitive resources, particularly those referring to basic information processing functions (e.g., logical reasoning, processing speed, or inhibition), will cause a decline in cognitive-affective complexity with age. As a consequence of their increasing difficulty to make sense of negative feelings, older adults are thought to increasingly favor affect optimization over affect complexity. Indeed, cognitive-affective complexity and affect optimization may mutually inhibit one another. On the one hand, in circumstances that involve reduced cognitive resources and, thus, cognitive-affective complexity, relatively effortless processes of affect optimization may prevail. On the other hand, the more individuals "use" affect optimization and, thus, avoid or quickly downregulate negative experiences, the less likely will they be able to acquire and maintain a complex and differentiated understanding of emotionally significant phenomena that inherently encompass both positive and negative aspects. Consistent with this idea is evidence from an age-comparative study that simultaneously assessed how individuals typically deal with marital conflict and what they know about marital conflict. In comparison with their younger counterparts, older adults were more likely to avoid conflicts with their partner and, at the same time, possessed less complex and elaborated knowledge about marital conflict; age differences in conflict avoidance were negatively associated with age differences in the complexity of knowledge about marital conflict (Thomas and Kunzmann 2013). The age-related diminution in the complexity of knowledge about marital conflict is further consistent with a large number of

studies interested in cognitive-affective complexity more generally (Labouvie-Vief 2003).

According to DIT, optimal functioning involves an integration and flexible coordination of affect optimization and affect complexity (Labouvie-Vief and Medler 2002). Seen in this light, the age-related increase in affect optimization, as, for example, manifested in older adults' positivity effects or avoidance of social conflicts, is a double-edged sword: it promotes a positive affect balance in the moment, but this effect is caused by age-related decline in basic cognitive functions and, ultimately, comes at the cost of an increasingly less differentiated understanding of emotionally significant phenomena. In the long run, a one-sided strategy to optimize affect may result in lower rather than higher levels of affective well-being.

The strength and vulnerability integration model. The strength and vulnerability integration model (SAVI; Charles and Luong 2013) states that understanding age-related stability and change in affective well-being requires considering interactions between older adults' improved emotional competence on the one hand and their decreased physical reserves on the other hand. Consistent with SST, the model poses that older adults' strengths lie in their high motivation and expertise to engage in effective emotion regulation. As an extension of SST, SAVI draws attention to older adults' physiological vulnerabilities and states that these vulnerabilities may render regulating distress and other negative emotions difficult and costly. For example, age-related changes in cardiovascular and neuroendocrine systems can lead to greater blood pressure and cortisol reactions to stressors among older adults relative to younger adults. Heightened and prolonged physiological reactivity most likely impairs older adults' ability to use those emotion regulation strategies that typically would help them lower distress and regain their typical level of affective well-being. Put differently, according to SAVI, because of their physiological vulnerabilities, some older adults may not be able to successfully use their motivation- and experience-based strengths. Particularly if exposed to chronic and complex

stressors with implications for multiple life domains, older adults may be at a greater risk for dysregulation and, thus, lower subjective well-being than young adults. Findings from Wrzus and colleagues (2013) are consistent with this idea. The authors found that older adults reacted with greater unpleasantness to complex and demanding stressors than their younger counterparts, but this age difference was not evident when the stressors were more circumscribed. In addition, in comparison with their younger counterparts, older adults showed reduced heart rate variability, a sign of poor physiological regulation, when they encountered complex stressors, but there were no age differences in heart rate variability when stressors were circumscribed. According to SAVI, in complex and taxing situations, age-related biological vulnerabilities come to the foreground and make it difficult for older adults to mitigate negative reactivity. Also consistent with this idea is work suggesting that older adults react to highly arousing negative stimuli with greater unpleasantness than their younger counterparts, whereas this age difference is reversed or nonsignificant if the stimuli are not particularly arousing (Streubel and Kunzmann 2011). Finally, recent research demonstrated that older adults who exhibited high levels of chronic illness were at a greater risk of experiencing sharp increases in feeling of loneliness over 8 years of study, particularly if they were unable to cope effectively with their health problems (Barlow et al. 2015). Together, the ideas put forward in the SAVI model could imply that older adults have the least benefit from their strengths when they need them most, namely, when age-related stressors and critical life events are serious and long lasting rather than mild and circumscribed.

The discrete emotion approach to affective aging. The discrete emotion approach to affective aging (DEA; Kunzmann et al. 2014) is based on a program of research conducted over the past decade (Kunzmann et al. 2013; Kunzmann and Grünh 2005; Kunzmann and Richter 2009; Kunzmann and Thomas 2014). DEA builds on the assumption that each stage in the life cycle (e.g., young adulthood, midlife, or old age) is

characterized by a specific configuration of constraints and opportunities, each residing in the environment, the person, or both (Baltes 1987; Freund 2007; Heckhausen and Schulz 1995). DEA states that these age-specific configurations can change the salience and adaptive value of particular positive and negative emotions. So far, DEA has focused on two stages in the adult life span, that is, young adulthood and old age, and posed that these two life stages are differentially associated with the salience and adaptive value of anger and sadness.

Young adulthood has been described as a phase of growth during which individuals have great opportunities to develop their potentials. Thus, processes of optimization rather than maintenance or compensation have priority in this life phase (Baltes and Baltes 1990). Young adults typically pursue many long-term goals focused on acquiring new resources, such as knowledge, information, or competencies (Carstensen et al. 1999). In young adulthood, individuals have a strong need to accomplish their goals, and perceptions of high personal control as well as a tenacious pursuit of goals are highly prevalent and closely tied to well-being (Wrosch and Heckhausen 1999). As compared to older adults, young adults also tend to be more assertive and willing to engage in social conflicts to accomplish their social goals (Luong et al. 2011).

In marked contrast, old age has been characterized as a phase during which social, cognitive, and physical resources become increasingly limited and processes of maintenance and compensation gain importance (Heckhausen and Schulz 1995; Baltes and Baltes 1990). Given the limited resources in old age, perceptions of low personal control and goal adjustment processes become increasingly frequent and adaptive in this phase of life (Wrosch and Heckhausen 1999). In addition, the awareness of a limited lifetime and the fragility of life seem to promote a tendency among older adults to relate to others in intimate and caring ways (Luong et al. 2011).

According to DEA, discrete emotions that indicate and promote individuals' progress in dealing with age-typical challenges are particularly salient, that is, easily elicited and frequently

experienced. Thus, discrete emotions that indicate young individuals' progress in developing their potential and that promote tenacious and assertive behaviors in the face of obstacles should be particularly salient. Anger serves as a prototypical example: it is elicited by the appraisal that one's goals are blocked by others, triggers a reactant "moving against" state of action readiness, promotes goal persistence, and facilitates assertive behaviors (Kunzmann et al. 2014).

In old age, by contrast, discrete emotions that indicate the individual's progress in dealing with losses (including the awareness of life's finitude) and that promote disengagement from unattainable goals in socially responsible ways should be particularly salient. Sadness is a prototypical example: it is elicited by the appraisal of a situation as an irreversible loss, triggers processes of adaptive goal disengagement, and is compatible with social closeness (Kunzmann et al. 2014).

Corroborating evidence for DEA's assumptions stems from a growing body of research on multidirectional age differences in sadness and anger reactivity. Research has documented that older adults tend to react with less anger-related emotions to social conflicts than their younger counterparts (Blanchard-Fields and Coats 2008; Charles and Carstensen 2008). Age differences in sadness reactions to social conflicts, by contrast, have been shown to be reversed (i.e., higher among older adults) or nonsignificant (Blanchard-Fields and Coats 2008; Charles and Carstensen 2008). Other studies have investigated age differences in emotional reactions to nonsocial stimuli. In this line of work, older, as compared with younger, adults reported less anger in response to anger-eliciting stimuli, but equal or higher sadness in response to sadness-eliciting stimuli (Kunzmann and Grünh 2005; Kunzmann and Richter 2009; Labouvie-Vief et al. 2003; Seider et al. 2011; Haase et al. 2012). Although most of the evidence refers to age differences in subjective reactivity, at least two studies, using sad films as stimuli, reported that the often observed age-related diminution in physiological activity (Levenson 2000) was not evident in their research; that is, older adults showed similar (Kunzmann and Grünh 2005) or greater

physiological reactivity (Seider et al. 2011) than young adults. It also deserves to note that similar age differences in the experience of anger and sadness were reported in two studies measuring the frequency of emotions during the past month (Kunzmann et al. 2013) and on a typical day using the day reconstruction method (Kunzmann and Thomas 2014). Finally, there is preliminary support for possible adaptive consequences of an age-related experience of anger and sadness. A laboratory study assessing affective responses to neutral films showed that anger predicted higher long-term subjective well-being in young adulthood, but not in old age. Conversely, sadness was related to high subjective well-being in old age, but not in young adulthood (Haase et al. 2012).

Taken together, DEA addresses the role of discrete emotions in young adulthood and old age, which are two stages in the life cycle that differ markedly in terms of their profiles on at least two psychologically influential dimensions: power control (high in young adulthood and low on old age) and affiliation communion (high in old age and low in young adulthood). To the extent that discrete emotions are differentially compatible with these age-typical profiles and promote adaptive ways in dealing with the challenges and opportunities that emerge, they should also differ in their age-related salience and potential adaptive value. Anger and sadness appear to be two negative emotions that clearly differ in both power control and affiliation communion; additional discrete negative and positive emotions that could serve age-related functions most likely include fear, disgust, pride, regret, and compassion.

Age Differences in Three Facets of Emotional Competence

The remaining part of this review will focus on studies that have assessed emotional competence in vivo by using performance-based tasks. Much of what is known about age and emotional competence has been based on self-report measures. Although these measures have their strengths (e.g., they reveal people's beliefs and judgments about how they deal with emotions), they are likely influenced by impression management

strategies (people may be hesitant to describe themselves as emotionally incompetent), introspective limits (do we know how emotionally competent we are?), and implicit aging theories (if older people believe that individuals should become better at regulating their emotions as they age, they are likely to say that they do so). This is why we consider approaches that study emotional competence under standardized conditions and use performance-based tasks.

Emotion regulation. Relatively few laboratory studies have investigated age differences in emotion regulation in vivo. In these studies, younger and older adults have been instructed to regulate their emotional reactions (e.g., subjective feelings or facial expressions) before or while they were presented with emotion-evoking stimuli. The effectiveness of emotion regulatory attempts was operationalized as the difference in emotion reactivity during no-regulation versus regulation conditions. The theoretical framework for most of these studies has been provided by Gross and colleagues' process model of emotion regulation (Gross 1998). This model describes how different types of strategies aimed at regulating one's emotions are used before, during, and after exposure to a negative event. Anticipatory strategies such as attentional deployment or cognitive reappraisal have been shown to be more effective than response-focused strategies (e.g., behavioral suppression). In fact, the latter strategies have more circumscribed effects and may even be associated with physiological costs.

With respect to age differences in emotion regulation, several studies have shown that older and younger adults are similarly successful at reducing outward expressions of emotion (Kunzmann et al. 2005; Phillips et al. 2008). As to cognitive forms of emotion regulation, a growing number of studies indicate that older adults' regulatory strengths are associated with their use of strategies that are relatively effortless. For example, older adults are more successful at using positive reappraisal compared to younger adults, but are less successful at using detached reappraisal (Shiota and Levenson 2009). In positive reappraisal the individual attends to the emotional aspects of a situation and attaches a positive

meaning to these aspects; in detached reappraisal the individual thinks of the situation in a neutral or rational manner. Given that positive reappraisals keep one's focus on the emotional aspects of the situation, it arguably is less cognitively demanding than detached reappraisal that requires a person to ignore all emotional aspects. Consistent with this assumption, research has demonstrated that detached reappraisals have higher cognitive costs than other major emotion regulation strategies, such as distraction (diverting attention from an emotional situation; Sheppes and Meiran 2008). Corroborating the idea of age-related gains in cognitively undemanding emotion regulation strategies, older adults were better at using distraction (think about a positive memory) while watching negative film clips than young adults (Phillips et al. 2008). Studies interested in age-related positivity effects in attention to positive and negative stimuli also deserve note. Evidence from these studies suggests that temporarily decreasing cognitive resources through dual-task paradigms eliminates older adults' tendency to focus on positive stimuli and/or avoid negative stimuli. Although these studies have not elicited emotional reactions or instructed certain emotion regulation strategies, they provide evidence for the idea that even age-related gains in arguably less effortful processes of emotion regulation require a certain amount of cognitive resources (Mather 2012).

In sum, the reviewed evidence suggests multidirectional age differences in emotion regulation. While the effectiveness of some strategies may increase with age (positive reappraisal, attentional deployment), the effectiveness of other strategies remains stable (behavioral suppression) or declines (detached reappraisal). At first sight, this performance-based evidence is at odds with results from self-report studies, indicating that older adults believe that they are generally more effective in regulating their emotions than younger adults (Kunzmann et al. 2005). However, to the extent that older adults use strategies that work for them and avoid strategies that are more effective for young adults, overall gains in emotion regulation competence could be observed among older adults. Future research is needed to

investigate the idea that age is associated with an increasingly selective choice of those emotion regulation strategies that rely on intact resources (Urry and Gross 2010).

Empathy. Empathy is fundamental to building and maintaining satisfying social relationships and an important source of prosocial behavior (Davis 1994). Given the importance of social and emotional goals among older adults (Carstensen et al. 1999), empathy may also be among the most influential predictors of successful aging and particularly affective well-being.

There is broad agreement that empathy is a multidimensional concept that involves both cognitive (e.g., the ability to accurately infer another's emotions) and affective (e.g., the ability share another's feeling and to feel sympathy for him or her) dimensions (Davis 1994). Age-comparative work on empathy underscores the usefulness of this distinction, by showing that cognitive and affective facets of empathy exert multidirectional age differences: while the ability to accurately infer others' emotions seem to decline with age (Ruffman et al. 2008), affective facets have been shown to remain stable or to increase with age (Richter and Kunzmann 2011; Sze et al. 2012b). Although the underlying mechanisms for these multidirectional age differences have to be further investigated, it is likely that the age-related decline in empathic accuracy is due to parallel age-related declines in basic cognitive resources, such as logical reasoning, processing speed, or inhibition (e.g., Richter et al. 2010; Wieck and Kunzmann 2015). Emotional congruence and sympathy arguably rely less on such cognitive resources and are more dependent on age-friendly automatic and effortless processes related to certain forms of emotion regulation.

Much of the work interested in age differences in the cognitive facets of empathy relied on tasks that require individuals to recognize emotions depicted in decontextualized facial, vocal, or written material. Isaacowitz and Stanley (2011) considered it possible that such tasks systematically underestimate older adults' empathic accuracy, which may be particularly dependent on the contextual richness of a task. For example, Sze and colleagues (2012a) reported that age-related

decline in emotion recognition was less visible if the tasks were based on dynamic, genuine, and contextualized stimuli. A problem with this interpretation is, however, that the authors' contextualized tasks required participants to make overall judgments of valence rather than specific judgments pertaining to the intensity of discrete emotions. Thus, the absence of age deficits may be due to the lower difficulty level rather than the contextual richness and ecological validity of the task. In fact, an earlier study, manipulating contextual richness and keeping the rating part of the task constant across conditions, suggested that contextual richness does not moderate age differences in empathic accuracy (Richter et al. 2010). In addition, there is evidence suggesting that the negative effect of emotionally incongruent contextual information on empathic accuracy becomes greater with age (Noh and Isaacowitz 2013). Thus, the current evidence speaks against the idea that age deficits in empathic accuracy vanish in ecologically valid tasks. In order to demonstrate what older adults can do under ideal conditions, additional factors need to be taken into consideration. Recent work suggests that task motivation is a promising candidate. With the presence of a strong task motivation, older adults have been shown to perform equally well in empathic accuracy tasks as young adults (Richter et al. 2010; Wieck and Kunzmann 2015). This evidence is consistent with the selective cognitive engagement model, stating that older adults become increasingly selective as their cognitive resources decline and that selective resource allocation is a key to maintaining performance in situations that are particularly meaningful and relevant (Hess 2014).

In sum, the current evidence for age and empathy suggests multidirectional age differences. Overall, older adults appear to have greater difficulty in inferring other people's emotions, but emotional congruence and sympathy remain stable or even increase. Several researchers have discussed the question of whether older adults' deficits in empathic accuracy have implications for the quality of their social relationships and ultimately their long-term affective well-being

(Isaacowitz and Stanley 2011). Although this may be the case, two findings may contradict this possibility and deserve note: (a) age deficits in empathic accuracy seem to not occur in contexts that are personally relevant to older adults and (b) relatively stable and high levels of emotional congruence and sympathy may compensate for potential weaknesses in empathic accuracy.

Emotional understanding. Evidence for age differences in emotional understanding primarily stems from research by Labouvie-Vief and her colleagues. More specifically, the authors repeatedly investigated cognitive-affective complexity in several studies with individuals aged 10–80 (and older) using cross-sectional and longitudinal designs (Labouvie-Vief 2003). In some of these studies, the authors asked their participants to think aloud about situations in which they felt particular emotions (e.g., anger, fear, happiness) or about their self and relations to significant others. The answers were transcribed and later evaluated by independent raters with a coding scheme based on four levels of cognitive-affective complexity (Labouvie-Vief et al. 1989). In this scheme, a high level of cognitive-affective complexity is represented by a tolerance for negative and conflicting feelings, a clear differentiation between own and others' feelings, a deep understanding of the dynamics and causes of emotions, and an appreciation of the uniqueness of individual experiences. Findings consistently suggest that cognitive-affective complexity increases during adolescence and young adulthood, peaks in early midlife, and begins to decline during late middle adulthood (Labouvie-Vief 2003; Labouvie-Vief and Medler 2002; Labouvie-Vief et al. 1989). To the extent that cognitive-affective complexity contributes to individuals' optimal functioning, its age-related decline needs to be considered a risk factor for low long-term affective well-being.

Conclusions

Empirical and theoretical work interested in emotional aging documents a complex picture of the

nature of emotion in old age. Older adults' strengths seem to lie in their ability to proactively shape their lives so as to avoid a great number of stressors and negative events. If such events cannot be avoided, older adults appear to be particularly motivated to downregulate the negative implications of problematic circumstances. As long as these events are relatively circumscribed and mild, older adults can take full advantage of their motivation and expertise-based strengths. However, regulatory problems may occur if the stakes are high or when older adults experience the onset of severe age-associated cognitive and physiological vulnerabilities. It is also evident that age differences in emotional reactivity are multidirectional – even if older adults typically experience a variety of negative emotion less often and with less intensity, certain negative emotions, such as sadness, directly relate to the age-relevant theme of loss and increase with age in salience. The functional implications of this enhanced emotional reactivity in particularly taxing and/or loss-related situations are largely unknown and need further investigation.

Across three domains of emotional competence, it became evident that those abilities that require cognitive resources (certain strategies of cognitive emotion regulation, empathic accuracy, or cognitive-affective complexity) cannot be considered a particular strength among older adults. By contrast, age-related gains have been documented in emotional competencies that rely on relatively effortless and automatic processes, such as positivity effects in attention and memory, the sharing of others' feelings, positive reappraisals of stressful events, or behavioral strategies to avoid certain negative experiences preemptively. To the extent that older adults can selectively optimize those competencies that rely on available and relatively intact resources, we can expect to observe age-related gains in emotional competence and ultimately long-term affective well-being. However, as of yet, whether the predominant theme of emotional aging is one of gain or loss cannot easily be determined, and multi-sided views of emotional aging are needed as they are most useful in reaching an accurate and comprehensive answer.

Definition

Emotions influence cognitive processes such as memory and reasoning, but also cognitive appraisals and control processes are important in our experience of emotions. Emotion–cognition interactions are the interface between these different aspects of mental experience.

While cognitive and affective psychology have long been considered as two relatively independent subareas in aging research, there has been a recent surge of interest in investigating the interaction between cognition and emotion. While many cognitive functions decline with age, emotional abilities remain intact and may even improve across adulthood. These different developmental trajectories raise a number of important questions. Does intact emotional processing enhance aspects of cognitive processing in older adults? Is age a potential moderator of cognition–emotion interactions? Do emotional processes place different loads on cognitive function in younger and older adults? The present essay will present research on emotion–cognition interactions in aging from different perspectives. First, the socioemotional selectivity theory (Carstensen 2006) will be introduced, and it will be described how valenced task material and current mood states influence cognitive performance in younger and older adults. Second, age differences in the involvement of cognitive control in dealing with emotional challenges are discussed. Finally, age differences in specific functions combining cognitive and affective processes will be considered. The essay ends with a conclusion and brief outlook.

Socioemotional Selectivity Theory and Effects of Emotional Task Material on Cognition in Younger and Older Adults

The idea that cognition–emotion interactions may be influenced by adult aging has been suggested by theories from lifespan developmental psychologists, providing the conceptual framework for the majority of empirical work. The most

prominent framework is the *socioemotional selectivity theory*, a lifespan theory of motivation, which assumes that the subjective sense of remaining time has profound effects on basic human processes, including cognition and emotion (Carstensen 2006). More precisely, when time is perceived as open ended as in youth, gathering information, experiencing novelty, and expanding breadth of knowledge are prioritized goals. When time is perceived as constrained, as in old age, goals tend to emphasize current feelings and emotion states, particularly regulating emotional states to optimize psychological well-being in the moment. As people age and increasingly perceive time as finite, the theory predicts that they ascribe greater importance to goals from which they derive emotional meaning. The age-related shift in goal priorities should effect cognitive functioning, as it changes the focus of attention and memory.

Socioemotional selectivity theory predicts that older adults should favor processing of information likely to maintain or enhance well-being, which will often mean a bias toward positive information. This hypothesis motivated many studies manipulating the emotional valence of cognitive task material. Results often showed an age-related increase in the preference for positive over negative information in attention and memory, the so-called positivity effect. A clear age-related shift in emotion–cognition interactions was confirmed by a recent meta-analysis (Reed et al. 2014), which showed that younger adults tend to show a negativity bias: that is preferential processing of negative over positive material, while older adults show instead a positivity bias. The majority of the studies reported look at age differences in memory for positive and negative information, finding that older adults remembered more positive information than negative, while younger adults showed the opposite pattern of bias. However, this review combined studies which varied substantially in the tasks used to look at emotional biases, and the authors point out the importance of testing for possible moderators. They found that age-related positivity biases are strongest when the memory task does not impose specific instructions on encoding, for

example, in incidental learning tasks where participants do not know that their memory will subsequently be tested.

Another moderator of age changes in emotional biases suggested by a second meta-analysis (Murphy and Isaacowitz 2008) is type of cognitive task assessed. Specifically, memory paradigms yielded overall stronger effects than attention paradigms, and within memory measurements, emotional effects in older adults were stronger in recall paradigms compared to recognition paradigms. While most studies examined emotion effects on retrospective memory for past events, some recent studies have looked at whether emotion influences age-related differences in prospective memory, which is the creation and enactment of an intention, such as remembering to attend an appointment at a specific time. For example, age differences in the influence of positive and negative compared to neutral target cues indicating the right moment to initiate an intended action on its correct fulfillment have been examined (Schnitzspahn et al. 2012). Results did not support a specific positivity bias in old age but instead indicated an age-related emotional salience effect: older adults were better at carrying out the intention in response to both negative and positive words compared to neutral. Similar findings from other studies of age–emotion interactions in prospective memory, using different tasks and materials, support the idea of enhanced emotional salience for both positive and negative material in remembering intentions in old age.

These findings underline the importance of examining valence effects across different cognitive abilities to test the generalizability of the positivity effect. Information processing and encoding may be influenced differently by emotion valence depending on the specific requirements of the examined cognitive function. Besides task type, general cognitive resources seem to play a critical role in the positivity effect (Reed and Carstensen 2012). The positivity effect emerges when resources are relatively available and undivided but is absent when resources are rather poor or divided. Further, positivity emerges during controlled stages of information

processing, but not for relatively automatic processing. These findings led to the conclusion that positivity reflects top-down motivational controlled cognition in older adults that can be influenced by situational and contextual factors (Reed and Carstensen 2012).

The Influence of Mood States on Cognition in Younger and Older Adults

Research motivated by the socioemotional selectivity theory examined emotion–cognition interactions by experimentally manipulating the valence of the task material and its influence on cognitive performance in the respective task, while the participants' mood is assumed to be neutral. A second line of research addresses emotion–cognition links by using neutral cognitive task material after inducing a positive or negative mood and compares subsequent performance to a neutral mood condition. Thus, the emotional state of the participant instead of the valence of the task material is varied. These manipulations are of interest because it is known that mood states can influence cognitive performance in younger adults: for example, being induced into a positive or negative mood may cause more heuristic processing, which can improve performance on some creative tasks but impair performance on constrained tasks which demand concentration and detailed processing. Only very few studies examined age-by-mood interactions in influencing cognitive performance. In general, two possible but contradictory outcomes can be predicted. On the one hand, age effects in cognition may be exacerbated when participants have to deal with a cognitive task and an acute mood state in parallel. As suggested by the socioemotional selectivity theory, older adults are assumed to focus on the regulation of their emotional state which may compete with the ongoing cognitive activity and requires processing resources which are already limited in older adults. On the other hand, dealing with emotions may be a better practiced, more streamlined process in old age. Accordingly, older adults

may automatically and more effectively regulate their emotions during mood induction than the young, resulting in less impairment in a cognitive task following a mood induction. This could lead to reduced age effects in positive/negative mood conditions compared to neutral ones. Also, in line with widely reported positivity biases, there might be different effects of positive and negative mood states in old age.

Results to date have been mixed and indicate that age differences in the effect of mood on cognition may be influenced by task demands. It has been found that negative mood disrupts older, but not younger, adults' planning performance (Phillips et al. 2002) but fails to influence either age groups recall memory performance (Emery et al. 2012) or working memory (Scheibe and Blanchard-Fields 2009). In contrast, negative mood impaired the performance of delayed intentions in younger but not older adults (Schnitzspahn et al. 2014). Concerning positive mood, an impairing effect on planning in younger adults was found (Phillips et al. 2002), which was even more pronounced in older adults. Furthermore, positive mood exacerbated false memories in older but not younger adults, whereas correct recall was not influenced (Emery et al. 2012). In contrast, the performance of delayed intentions was impaired under positive compared to neutral mood in younger but not older adults (Schnitzspahn et al. 2014). Thus, results range from reduced age effects of mood state on cognition to no age differences in mood–cognition interactions and to exacerbated age-related mood effects on cognitive performance.

The studies outlined above differed in the nature of mood manipulations used and cognitive tasks investigated. Clearly the understanding of how mood and cognitive functioning interact in aging is still in its infancy, and more research is needed to better understand age differences in mood effects on cognitive performance. More information is needed, through specific task manipulations on the pattern of age differences in mood–cognition interactions. It is possible that the interaction is similarly moderated by measurement type and cognitive resources as the positivity effect. Depending on the brain areas

associated with different cognitive functions and their overlap with the brain regions required during emotion regulation, cognitive performance in tasks measuring the respective functions may be more or less influenced. Besides qualitative differences between cognitive tasks, quantitative differences in their difficulty and hence requirement of cognitive resources may also influence mood effects. Relatively easy cognitive tasks may still be performed well under certain mood states, while performance in difficult tasks should be disturbed. However, task type and difficulty cannot explain the differential age effects observed in some of the studies described above. The most promising candidate here may be age benefits in emotion regulation processes which will be presented in more detail in the following section.

Aging, Cognition, and Emotional Skills

The first part of this review focused on the influence of emotional factors (i.e., valence of the task material and mood) on cognitive performance and thus considered emotions as one possible factor influencing cognition in general and age differences in cognitive performance in particular. However, emotion–cognition interactions have also been examined in the field of emotional aging. The main research questions in this area are the lifespan development of emotional skills and the involvement or necessity of cognitive resources. The following paragraphs will focus on emotion regulation and emotion recognition, their development in aging, and the role of cognition.

Emotion regulation skills are involved in monitoring and controlling our inner experience of emotional states. There is substantial evidence of age-related improvements in emotion regulation skills to downregulate negative affect and promote positive affect (Kryla-Lighthall and Mather 2009). As already briefly mentioned above, successful emotion regulation requires active use of cognitive control strategies or executive functioning and leads to an attentional shift toward one's emotional state and away from other ongoing activities. Given reported age benefits in emotion

control, it has been suggested that emotion regulation could be less costly in a cognitive sense in older adults compared to younger ones as they have more experience, and therefore emotion regulation may become more effectively and automatized. This prediction was tested (Scheibe and Blanchard-Fields 2009) by asking younger and older adults to perform a working memory task after a neutral or a negative mood induction. Importantly, instructions were varied between participants in the negative mood group. Some participants were asked to try to maintain the intensity of their negative feelings, while others were asked to change the negative feelings as fast as possible into positive ones. While the instruction to regulate the negative mood after its induction did not affect older adults' performance in the subsequent working memory task, it impaired the performance among the young. This occurred despite evidence of a strong mood induction in both age groups and successful ability to follow emotion regulation instructions in both groups. This finding indicates that intentional downregulation of negative emotions may be less costly in older age. Indeed, the allocation of cognitive resources needed to effectively regulate emotions seems to vary by age.

Another research question that has attracted attention concerns cognitive mechanisms underlying differences between younger and older adults' emotion regulation and their predictive value for mood outcomes. Specifically, it has been suggested that age-related positivity effects in attention and memory that has been described above actually reflect motivated cognition operating in the service of emotion regulation (Isaacowitz 2012). Focusing on positive information while paying less attention to or remembering fewer negative aspects of stimuli could plausibly help to achieve or maintain well-being. This hypothesis has been addressed in several studies using eye tracking in order to examine differences between younger and older adults in visual attention to emotional material. Their findings show a greater preference for “positive looking” in older adults, resulting in a viewing behavior toward positive and away from negative material (Isaacowitz 2012). These age differences in

preferences have been replicated using different materials and seem strongest when participants are in negative mood state or are explicitly instructed to regulate their emotions. Positive looking has been found to help some older adults regulate their mood, but these effects were moderated by individual differences in attentional abilities. Thus, older adults with good attentional abilities were able to use attentional deployment in the form of positive looking to successfully regulate their mood. These findings confirm that positivity effects reflect top-down processes requiring cognitive resources when used to regulate their emotions by older adults.

Another important emotional skill is the ability to recognize the emotions of others. We use non-verbal cues from facial expressions, vocal tone, and body posture to decide whether other people are angry, sad, or happy. Meta-analyses on age effects in emotion recognition suggest an overall age-related decline (Ruffman et al. 2008). This finding is true across modalities (faces, voices, bodies/contexts, matching of faces to voices) and different basic emotions (anger, sadness, fear, surprise, happiness). Some emotions (anger and sadness) and some modalities (face–voice matching) create particular difficulties, while a trend for older adults to be better than younger adults at recognizing disgusted facial expressions was reported. It has been suggested that general cognitive decline might account for the age-related changes in emotion recognition. However, this seems unlikely because the pattern of age effects did not match the difficulty levels of the emotions, as younger and older adults showed difficulties in different emotions.

Reviewing the literature, the authors (Ruffman et al. 2008) conclude that there is no consistent evidence that general cognitive decline accounts for older adults' pattern of emotion recognition difficulties. Instead, it is suggested that specific neuropsychological changes in frontal and temporal volume and neurotransmitters may cause the observed age-related impairments (Ruffman et al. 2008). Interestingly, a positivity effect in terms of absent or reduced age effects in labeling positive emotions and clear age impairments when recognizing negative emotions could not

be confirmed in emotion recognition. It seems that older adults do not profit from their benefits in emotion control and their strong motivational focus on emotions and well-being in this specific domain. Recent studies indicate that older adults' poorer performance in recognizing emotions may be ameliorated by manipulations which improve the ecological validity, personal relevance, or motivational context of emotion recognition tasks. For example, it has been reported (Sze et al. 2012) that age-related declines in recognizing emotions from traditional stimuli such as photographs of facial expressions are reversed to result in age-related improvements when rating emotions online using more naturalistic stimuli, in this case videos of dyadic interactions which included contextual information.

Functions Combining Cognitive and Emotional Aspects and Their Development in Aging

After considering the influence of emotional factors on cognition and the involvement of cognitive factors in emotional abilities, the final section will present the development of empathy and wisdom in aging. Both constructs involve cognitive and affective processes and thereby allow the study of emotion–cognition interactions and possible age differences within the same ability.

Empathy requires the cognitive understanding of another person's feelings as well as an appropriate affective response. The latter concerns the affective facet of empathy that comprises the degree to which one shares the feelings of another person and the capacity to experience and express sympathy or emotional concern. Results concerning age differences in empathy are mixed but suggest differential age effects for the different components. As reviewed above, older adults are often reported to perform worse than young on tasks of emotion recognition, which can be considered part of cognitive empathy. However, these age effects may depend on the motivational nature of the task. In one of the few experimental studies to directly look at age differences in cognitive and affective aspects of empathy within the same

paradigm (Richter and Kunzmann 2011), age effects in understanding another person's emotional state (cognitive empathy) were no longer observed when the person was talking about a topic of high relevance to older adults. Concerning the affective facets of empathy, older adults' competencies remain stable or even improve across adulthood: older adults report and express greater sympathy for others than younger adults (Richter and Kunzmann 2011). Taken together, cognitive facets of empathy may be more vulnerable to age-related decline than emotional facets. Accordingly, age differences in empathy may vary between studies depending on the type of measurement used and in how far it focuses more on the cognitive or affective facet.

Wisdom integrates several facets in terms of psychological functioning. The deep insight into self, others, and the world comprises the cognitive facet. Complex emotion regulation allowing the tolerance of ambiguity represents the emotional facet. The assumption of a positive association between wisdom and age is very common in the general population as experience cumulates with age, although most people consider old age as neither necessary nor sufficient for wisdom (Staudinger and Glück 2011). Empirical findings can be distinguished according to the type of wisdom measured. *Personal wisdom* refers to individuals' insight into their selves and their own lives and describes an ideal end point of personality growth. This approach is based in the tradition of personality research and mostly uses self-report measures. Studies do not report a linear positive relationship between personal wisdom and age and sometimes even observed negative relations (Mickler and Staudinger 2008). Declining cognitive resources may make abstract thinking, which is required to satisfy some wisdom criteria such as self-relativism, more difficult for older adults. In addition, lower levels of openness to experience and societal restrictions of growth opportunities in old age may hinder the further development of self-insight.

General wisdom describes individuals' insights into life in general. Approaches to the empirical study originated from cognitive research and are performance based. They have a

strong connection with an expertise approach but expand classical cognitive ability measures by including emotional and motivational aspects. In a typical paradigm, participants are presented with difficult and existential life problems and are asked to give advice. Responses are recorded and evaluated according to prespecified wisdom criteria. In general, older adults perform as well as younger adults in such tasks. Age benefits were observed on typical dilemmas of old age and when age has been combined with wisdom-related experiential contexts (e.g., professional training as clinical psychologist), while younger adults performed better on typical dilemmas of young adulthood (see Staudinger and Glück 2011 for an overview). Performance is best predicted by measures located at the interface of cognition and personality, such as a judicial creativity and moral reasoning, but not by fluid and crystallized intelligence or personality alone. The different age effects found depending on the measurement type assessing wisdom suggest that required cognitive resources may play an important role. Negative age effects may arise when measures heavily relying on complex cognition are used, while no age effects or even benefits can be expected in tasks allowing older adults to make use of knowledge and heuristics about life problems acquired through experience and practice.

Conclusion and Outlook

Younger and older adults differ in the way that emotion and cognition combine. The empirical findings summarized above all seem to support the claim that age moderates emotion–cognition interactions as age differences were the rule rather than the exception. Importantly, many studies observed age benefits which may seem surprising given the general cognitive decline accompanying aging. Better emotion control and a strong focus on emotional well-being in older adults seem to make it easier for older adults to work on tasks requiring cognitive and emotional processes. Older adults seem to profit more than young from valenced task material, are generally cognitively less impaired by current mood states, and

are superior in emotion regulation skills: indeed emotion regulation seems less cognitively demanding for older people than young. Other age-related benefits include good performance in tasks requiring complex abilities such as empathy or wisdom, when the tasks allow them to use their emotional strengths and knowledge. These findings are very encouraging, as they show how motivational and emotional strengths can be used to compensate for age-related cognitive decline. However, there is clearly a limit for compensation, and as mentioned in several examples above, age benefits diminish or turn into age-related impairments when the (cognitive and emotional) tasks get too difficult or older adults do not have sufficient cognitive resources available. This pattern is predicted by the *dynamic integration theory* (e.g., Labouvie-Vief et al. 2014), which emphasizes that emotional gains in old age may be reversed where the demand on available information processing is exceeded. For example, older adults show greater interference between mood states and cognition where the cognitive task is very demanding, and older adults perform worse than young when decoding other people's emotions in situations devoid of context. Accordingly, recent conceptual developments build on the socioemotional selectivity theory and expand it by defining the limits of age benefits. Two of them will be outlined in the following.

The *cognitive control framework of aging and emotional well-being* (Kryla-Lighthall and Mather 2009) posits that older adults will experience emotional enhancement to the extent that they are capable of exerting cognitive control to direct attention and memory in ways that help satisfy emotional needs. Thus, cognitive control is suggested as the key mechanism underlying the transformation of age differences in goals into differences in emotional well-being. In line with the socioemotional selectivity theory, it is argued that cognitive control as an emotion regulation tool becomes increasingly useful with advancing age as emotional well-being becomes more important. However, the theoretical framework also describes limitations of age-related changes caused by neural structures. While the amygdala, considered as the primary affective appraisal

structure, remains stable with age, emotion and cognitive control regions of the brain including the prefrontal cortex deteriorate significantly. First findings suggest that healthy older adults can still maintain their emotional well-being to some extent by recruiting additional cognitive resources and thereby compensate for their losses by exerting more cognitive effort (Kryla-Lighthall and Mather 2009).

The theoretical *model of strength and vulnerability integration* (Charles and Luong 2013) adopts a broader, more applied perspective. In line with the socioemotional selectivity theory, it suggests that across adulthood, expertise and motivation to regulate one's emotions increase. However, it is further suggested that certain situations that increase in prevalence with age (i.e., social isolation, neurological dysregulation, and chronic stress) preclude the use of these emotion regulation strategies on a daily level. It is further argued that these situations will lead to equal or even lower levels of emotional well-being and greater physical consequences in the cardiovascular and the neuroendocrine systems in older compared to younger adults as a result of their physiological vulnerabilities.

To sum up, while old age is often characterized as a period of cognitive decline, there are also emotional gains during this time of life. Older adults are better at using their emotions to focus cognitive resources on the key aspects of a situation which will enhance mood. Older adults are also good at effectively and efficiently regulating their emotions in a way which might mean less impact of mood fluctuations on cognitive performance. These skills of managing emotions and cognition likely have positive impact on well-being in old age.

Synonyms

Organizational citizenship behavior toward the environment; Organizational environmental sustainability; Proenvironmental behavior

Definition

Older employee behavior performed at work, either voluntarily or as required by an organization, that contributes to the preservation of the natural environment by reducing harm to, or strengthening, the ecosystem.

Employee Green Behavior at Work and Aging

Environmental sustainability is emerging as a driver of human activity in the twenty-first century. Evidence of this can be seen in global emissions targets and the investment in technology intended to enable societies to grow without compromising the natural environment or jeopardizing the livelihood of future generations (World Commission on Environment and Development 1987). It is likely, however, that to forestall or avoid the worst effects of human activity (anthropogenic climate change), human activity itself will need to change (Ones and Dilchert 2012).

Scientific evidence points to human economic activity as the key driver of environmental degradation (Ones and Dilchert 2012). Many organizations and industries have therefore taken it upon themselves to address their role and to attenuate their negative environmental impact while at the same time accentuating their positive impact (Robertson and Barling 2015). When we consider the amount of time many people spend at work throughout their lives (Terkel 1974), organizational efforts to increase employee activity that contributes to environmental sustainability (i.e., employee green behavior; Ones and Dilchert 2012) might well be a vital cog in the machinery of a sustainable society.

Environmental sustainability is one of several significant issues with implications for organizations. In addition to economic activity, climate change is also being driven by changes in global population (Intergovernmental Panel on Climate Change: 2014). In this regard, a contemporaneous issue facing many countries is an aging population, caused by increased longevity, a decline in fertility, and the procession of the baby boomer bulge into old age (McDaniel and Zimmer 2013). According to the Bureau of Labor Statistics (2015), over 67 million employees in the United States are aged 55 or over, representing approximately 43% of the total labor force. Looking to the future from a more global perspective, Kuenen et al. (2011) estimate that the dependency rate (number of people over 65 per 100 workers) will

double from 12% in 2010 to 25% in 2050 as the baby boomers exit the workforce. Organizational success in the twenty-first century will be determined in part by the ability of organizations to respond effectively to significant issues (Ones and Dilchert 2012), such as environmental sustainability and an aging population. The focus of this entry is to integrate research on aging and employee green behavior and provide insights into whether or not employees become greener as they gray.

How Are Aging and Environmental Sustainability Interrelated?

As should be expected with concurrent issues of such magnitude, the issues of an aging population and environmental sustainability are interrelated. On the one hand, climatic changes pose health risks for older people – who are more vulnerable to changes in the environment. For example, research has shown that periods of extreme heat are associated with increased mortality rates among the elderly (Åström et al. 2011). Moreover, and as the Intergovernmental Panel on Climate Change (2014) has now established, periods of extreme heat are likely to become both more frequent and more extreme in future years.

At the same time, the members of an aging population and workforce have evolving needs (e.g., mobility, health; Klein et al. 2012) that place increased demands on natural resources, thereby incurring environmental costs. Although there is reason to believe that an individual's overall CO₂ emissions should decrease slightly above the age of 65 (Zaghenni 2011), there are three additional important considerations that need to be appraised and that bring into question these presumptions.

First, the business sector uses considerably more energy and produces vastly more waste than the domestic sector (Davis and Challenger 2011). As a consequence, workplace activity is going to be the largest contributor to global emissions and a significant contributor to employees' carbon footprints (Goodall 2010). Second, governments are raising retirement ages to cope with the financial burden of supporting such a large cohort (Hertel and Zacher 2016). Third, while

overall emissions may trend downward, they are still expected to remain well above the minimum threshold (5.5 t per person) that MacKay (2009) suggests is necessary to avoid a worst-case scenario (i.e., concentration of CO₂ in the atmosphere exceeding 450 parts per million, which is associated with a 2 °C increase in average global temperature; Intergovernmental Panel on Climate Change: 2014).

With these issues in mind, and taking into account that many employees today work beyond what was once accepted as the traditional retirement age (65 years; Hertel and Zacher 2016), it seems reasonable to conclude that estimates of individuals' emissions decreasing after age 65 might not be as robust as currently thought. Moreover, even in the event that estimates of declining emissions after the age of 65 turn out to be correct, any decreases (while nominally positive) would be superficial because it would still exceed the proposed per person threshold for emissions by some 200% (Mackay 2009). In acknowledgment of the contribution of workplace activity to greenhouse emissions, and assuming that the longer a person works, the larger their own carbon footprint, the question of how an aging workforce engages with environmental sustainability becomes vitally important. We next provide an overview of the current state of research in relation to this question.

Employee Green Behavior

Employee green behavior refers to individual actions in the workplace that contribute to environmental sustainability (Ones and Dilchert 2012). The need to define these behaviors in the context of the workplace arises because of the extent to which an individual has autonomy over his or her behavior. Whereas the decision to be environmentally friendly at home is largely volitional and driven by psychological (i.e., person) factors (Bamberg and Möser 2007), in the workplace it may be either encouraged or discouraged by social norms, expectations, and task demands (Ones and Dilchert 2012). Ones and Dilchert (2012) indicate that as much as 29% of green behavior at work is required by the organization. Considering the normalization of organizational

environmental sustainability through increased social, regulatory, and normative pressure (Klein et al. 2012), it is likely that companies will increasingly embed green behaviors into employees' required tasks. Accordingly, reviews on green behavior at work have a focus on constructs and processes unique to the workplace.

In response to an increase in organizational and academic interest in environmental sustainability (Ones and Dilchert 2012), several researchers have conducted reviews of employee green behavior (e.g., Norton et al. 2015). These reviews document the role of contextual factors such as policies and goals and person factors such as environmental attitudes and perceived green organizational climate in the green behavior of workers in general.

Employee Green Behavior Among Older Workers

Although our understanding of aging and workplace behavior in general is relatively mature (Hertel and Zacher 2016), the impact of aging on employee green behaviors is in its infancy. Although the aforementioned reviews on employee green behavior have not investigated age specifically, subsequent analysis of the studies included in the largest and most recent review (Norton et al. 2015) does serve to highlight relationships between age and employee green behavior. Broadly, these studies form four categories: (1) report the effects of age, (2) control for age but do not report any effects, (3) report age as a demographic variable, and (4) do not measure age. Of the 69 studies included in the review, the majority (37) fell into the fourth category, while 13 fell into the third category and 3 are included in the second. Moreover, of the 16 studies that did report effects, findings were mixed. Nine studies reported no relationship between age and employee green behavior, two reported negative effects, and five reported positive findings. It should be noted, however, that most studies report bivariate correlations only. In short, there seems to be a lack of evidence regarding the specific relationship between age and green behavior in the workplace.

Why Employees Might/Might Not Become More Green as They Gray

In light of a paucity of data from which to draw conclusions about aging and employee green behavior, it is necessary to consider explanations for how these two constructs might relate based on data from related areas. The following positions are drawn from the broader literatures on aging, general work behavior, and green behavior at home.

Arguments for a Positive Relationship

On the one hand, there is evidence that environmental values strengthen as people age, and green behaviors at home therefore become more prevalent (Whitmarsh and O'Neill 2010). In this regard, stronger environmental attitudes in older people may be explained from a cohort perspective. Research suggests that environmental attitudes (as a predictor of employee green behavior; Norton et al. 2015) are relatively stable after early adulthood (Inglehart 1990). Thus, the predisposition to green behavior among contemporary older employees might be explained by the emergence of an environmental discourse during their early adulthood (Wiernik et al. 2013).

Conversely, there is also evidence of a U-shaped relationship between environmental behavior at home and age (Klein et al. 2012), suggesting that the effect might not necessarily be straightforward. Specifically, green behavior at home is more prevalent in early and late adulthood, but less common during middle adulthood. This effect may be attributed to the prioritization of family-oriented rather than environmental values as people raise their children in middle adulthood (Hertel and Zacher *in press*).

In this regard, a life span perspective may be particularly helpful. Consider, for example, the concept of generativity, which refers to one of the motivations in Erikson's (1950) stages of psychosocial development. In this respect, generativity describes an individual's desire to help guide the next generation. From this perspective, and in light of omnipresent environmental issues, there might be justification to hypothesize that individuals should engage in more green

behavior as they age. In doing so, older employees might be seen to be attempting to limit their environmental impact, the costs of which future generations would incur. This also taps into a central belief at the heart of most definitions of environmental sustainability – which is to preserve the ecosystem for the benefit of future generations (World Commission on Environment and Development: 1987).

Another argument for why employees might become greener as they gray draws on positive relationships of age with conscientiousness and agreeableness (Hertel and Zacher 2016; Wiernik et al. 2013). First, conscientious employees are more likely to engage in citizenship behavior (Hertel and Zacher 2016; Wiernik et al. 2013), which encompasses approximately two-thirds of employee green behavior (Ones and Dilchert 2012). Second, and relatedly, older workers might be more agreeable to the idea of environmental sustainability if the organization demonstrates a value toward it (e.g., by announcing a shift to purchasing renewable energy). Both of these arguments implicate the important role of organizational values toward the natural environment. These establish a need within the organization for environmental initiatives, to which older adults might be more agreeable, and provide cues toward areas where citizenship behavior might be appreciated. For example, older employees in organizations with prominent environmental values might be more inclined to align their behavior to these values, including performing citizenship behaviors that contribute to the organization's environmental mission.

Finally, older adults are more inclined to value frugality by being economical and avoiding waste (Wiernik et al. 2013). This is relevant to environmental sustainability as environmental initiatives often focus on recycling, avoiding waste, and conserving resources (Ones and Dilchert 2012). Curtailing the consumption of resources is often an early step toward environmental sustainability, as reducing costs associated with waste provides direct financial benefits to organizations (Kane 2015). Pursuing frugal environmental behavior may also be a source of intrinsic satisfaction

(Lee et al. 1995). Thus, for older employees who value frugality, engaging in green behavior at work may have beneficial outcomes and contribute to overall job satisfaction.

A positive relationship between aging and green behavior would also provide organizations with three additional opportunities to benefit simultaneously from an aging workforce and move toward environmental sustainability. First, a positive effect of aging on environmental values might be effectively utilized by having older employees lead the way in communicating and championing green initiatives (Wiernik et al. 2013). Second, if older adults are in fact more conscientious than their younger colleagues, they might be more predisposed to prosocial activity such as making environmentally friendly suggestions or leading green teams. Third, older employees possessing a greater appreciation for frugality might in effect serve as environmental advisors to purchasing officers, emphasizing a need to resupply resources only when necessary and suggesting environmentally friendly alternatives. Such roles may have positive outcomes for older employees as well, such as intrinsic satisfaction derived from frugality (Lee et al. 1995). Alternatively, organizations might find that campaigns that emphasize the financial cost of leaving lights on are especially effective for older employees, who have a heightened appreciation for being economical. Thus, a positive relationship between aging and green behavior could make older employees valuable assets for organizations seeking to engage with environmental sustainability.

Arguments for a Negative Relationship

On the other hand, the idea that green behavior at home decreases with age is supported by the argument that, as people age, they have greater disposable income and therefore become less willing to sacrifice comfort and convenience (Wiernik et al. 2013). For example, whereas younger individuals might be more willing to open a window on a hot day, older adults may be more inclined to use air conditioning (Klein et al. 2012). Applied to the workplace, older workers might prefer to

engage in behavior that prioritizes convenience above environmental interests (e.g., printing documents to read instead of reading them on the screen). Alternatively, older employees may engage in non-green behavior out of necessity to optimize declining personal resources such as physical ability (Baltes and Baltes 1990). For example, an older employee might print a document to review with one page to a sheet because s/he wants a larger size print.

A life span perspective also supports a negative relationship between age and green behavior. According to this perspective, older adults might be less motivated by future consequences. Given that climate change is an intergenerational issue (Intergovernmental Panel on Climate Change: 2014), reduced sensitivity toward long-term consequences removes a significant motivation to behave in an environmentally conscious way (Klein et al. 2012). Accordingly, older employees might be less affected by environmental campaigns in the workplace that focus on future consequences of their behavior. This may be particularly relevant for initiatives with goals that extend into the future – beyond the expected retirement age of older employees.

Another argument for a negative relationship draws on the hypothesis that habits crystallize over a person's life span, and accordingly individuals become more resistant to change, including efforts to move to more environmentally sustainable ways of work. According to this argument, older employees would be less likely to replace old practices (e.g., traveling for meetings) with new practices that incorporate environmental interests (such as teleconferencing). The empirical evidence does not support this stereotype, however. In fact, there is evidence that resistance to change can even decrease with age (Hertel and Zacher 2016). In this regard, evidence that people become more agreeable and conscientious as they age suggests that people become *more* open to change as they age (Hertel and Zacher 2016). Nonetheless, there are valid reasons to conclude that people become less likely to engage in green behavior as they age and that older employees may demonstrate fewer green behaviors at work.

If in fact employees become less likely to engage in employee green behaviors as they age, organizations might need to install contingencies to mitigate such an effect. First, organizations could address the issue of convenience by (a) making green behavior more convenient and (b) reducing the impact of non-green behavior. An example of making green behavior more convenient is for managers to provide information and/or training on how to schedule computers to turn off and start up in order to avoid drawing power overnight and during weekends. Another example would be for organizations to provide tablet computers with styluses to allow people to make handwritten notes on documents without having to print them first. An example of a mitigating tactic would be to dedicate a printer for draft documents that uses recycled paper and ink cartridges and a default setting that saves ink and prints double-sided.

To address issues from a life span perspective, organizations might consider reframing environmental goals and messages to be more inclusive of older employees who see themselves close to retirement. Options for this strategy include creating short-term goals for projects that are likely to extend beyond older employees' tenure. Alternatively, listed companies could offer stock options as part of retirement packages so that older employees can maintain a vested interest in the company's performance beyond their employment. Another intervention targeting the life span perspective is to tailor environmental messages to encompass the broader effects of environmental sustainability for the general community and future generations.

Where environmental sustainability will require the adoption of new behaviors, organizations will likely need to implement interventions to change non-green habits. This could manifest in training programs that challenge assumptions about habitual behavior (e.g., that shutting down and powering up a computer uses more electricity than leaving it on or is bad for the device) and explain and demonstrate green alternatives. Such a strategy could be integrated with organizational values and norms for innovation and continuous

improvement, as messages utilizing social norms are particularly effective for older employees (Wiernik et al. 2013).

Research Recommendations

With the emerging significance of an aging population and the need for organizations to become environmentally sustainable, there is a real need for research on how older employees might better engage with green behaviors. At the very least, researchers should report employee age as a variable in research on employee green behavior. Beyond this, it would be interesting to investigate the potential for cohort effects on environmental attitudes and behavior. In this case, the effect of aging on employee green behavior may be moderated by an individual's experience of the prevailing social attitudes during early adulthood, which have changed over time (Wiernik et al. 2013). In this regard, the environmental message individuals receive in early adulthood might be more important than the effects of aging. Alternatively the effects of aging might be moderated by personality traits (e.g., conscientiousness, agreeableness) or the degree of concern for future generations (i.e., generativity). In effect, the effects of aging on employee green behavior may vary from one person to the next.

In this entry, we have outlined theoretically grounded arguments for why aging might have positive and/or negative effects on employee green behavior. Only empirical evidence can elucidate the extent to which, and under what circumstances, these positions are true. Research providing insights in this area is likely to have significant practical implications for how organizations respond to the challenges of an aging working force and environmental sustainability. Should evidence support the argument for a positive effect of aging on employee green behavior, a next step might be to investigate the effects of such behavior on older employees' job satisfaction and work motivation. Conversely, evidence for a negative effect of aging on employee green behavior would shift the focus of research toward interventions designed to overcome an emerging resistance in older adulthood to employee green behavior.

Conclusion

Aging and environmental sustainability are significant and contemporaneous issues with implications for organizations. In spite of the reality of an aging workforce and the need for organizations to operate in environmentally sustainable ways, there is practically no research to date that has studied the effect of age on employee green behavior. What empirical evidence does exist is insufficient in both quantity and consistency to infer any conclusions. From a broader perspective, there appear to be valid arguments for both positive and negative relationships between age and employee green behavior. When interpreting existing research on aging and environmental behavior more generally, it is important to acknowledge the possibility for cohort effects. Specifically, our current understanding is derived using data from a cohort who may not have been exposed to the same environmental messages as generations that will be entering older adulthood in coming decades. Nonetheless, from our understanding of aging and workplace behavior more generally, older employees may be particularly useful to organizational initiatives that promote green behavior.

Employment of Older Workers

Aging labor force; Mature employees

Older Workers

The growing number of men and women who are working longer and the aging of many labor markets are global phenomena without precedent. More older people are working, despite large country differences (OECD 2014). Many people in the world will live an additional 30 years after they have reached the traditional age of retirement from paid work, and this is forcing a reenvisioning of the future of work and what “retirement” means. A complex array of factors, such as increasing longevity, declining fertility rates, changing labor market dynamics, and retirement policies and practices, are creating a new demography of work.

Many countries are carrying out reforms to encourage longer working lives, to incentivize worker retention, and to respond to the looming

challenges of rapid population aging (Sonnet et al. 2014). In some countries this is a reversal of earlier policy aimed at early exit of older people from the labor force, when developed countries responded to recessionary times in the 1980s by pushing older workers out of the labor market through redundancies and early retirement.

Definition

The definition of an older worker varies from country to country and from context to context. For example, to take chronological age as a start point, the OECD older workers scorecard uses the ages of 55 years to 64 years. Others use the age of 50 to begin discussions about “older workers,” and in some cases older workers are deemed to start from 45 years old. In the USA the Age Discrimination in Employment Act (ADEA) forbids age discrimination against people from the age of 40 years, which many might regard as the start point of middle age.

Whatever the chronological definition used, it is clear, however, that in many countries there is now a difference between the “young old” (those up to 65 years of age) and the “old old” those who may be in their seventies, eighties or even nineties and still in paid employment. It is startling to note the projection that in 35 years’ time, Japan is likely to have 550,000 people over the age of 100.

Clearly, too, thousands of older people are involved in work that is unpaid, particularly women who are often caring for older partners and other dependents. In some cases women are caring for both children and dependents. However, whether older workers are paid for their labor or not, responses to older workers are impacted globally by social attitudes and economic growth and stability. For example, policy in developed countries relating to the category of “older worker” is often indexed to a nominal age of retirement where individuals receive universal state or privately funded pension payments.

Looking at the markers of age for older workers, it is clear that some regard workers as old when their physical capacities decline and their stamina retreats impacting on job

productivity. Others suggest an older worker is marked by declines in cognitive or intellectual capacities impacting on performance. For others chronological age alone marks out an individual as an older worker particularly if that is linked to incentives for early exit from the labor market. There is evidence, too, that perceptions of age differ by gender.

Population Aging and Work

The number of people worldwide aged 60 years and older is expected to triple by 2050, according to projections by the United Nations Population Division. Not only that, the share of the population in older age groups is increasing. At least four trends are apparent in population aging that impact on the employment of older workers in general. First, population aging is not confined to some countries only but is everywhere, including the youngest countries and developing nations. For example, the six Gulf countries, which have traditionally relied on expatriate workforces, acknowledge that their two main demographic challenges by 2050 will be population aging and a slowdown of the increase in national workforces. Second, population aging is a major life force and impacts not only on employment in terms of job demands but also health, economic security, and social cohesion. Third, population aging is occurring quickly and the pace is accelerating, and, fourth, it is taking place at different rates around the world. For example, in Asia, while Japan was the first country to face the “age wave,” South Korea and China follow and then India and Pakistan (Hayutin 2009).

The supply and demand of jobs in a global labor market is characterized increasingly by job mobility and migration to find work. Older workers are not immune from these trends. They are also crucial to vital sectors where worker shortages are profound. The World Health Organization in 2013 estimated that there would be a shortage of 12.9 million healthcare workers by 2035. In areas of great need like sub-Saharan Africa, shortages are particularly acute. Nursing, for example, is an occupation which is aging rapidly (Graham and Duffield 2010).

The Diversity of Older Workers

While extending working lives will maximize older adults’ income security, not all older people want to work or can access jobs. There are many reasons why people work longer including both positive and negative factors, often referred to as either “push” or “pull” elements or supply- and demand-side factors. It is a mistake to assume that older workers are a homogeneous group and therefore one policy size will fit all.

Many women, in particular, are more likely to be forced to work longer because they have earned less over their working lives and they are living longer. Their earning potential may be influenced by women’s traditional occupational segregation in lesser-paid work (such as cleaning, clerical, and caring work) and/or because of work interruption when bearing and raising children and having primary or sole responsibility for family and domestic life. The global financial crisis also disproportionately impacted on older adults and saw many lose significant portions of their retirement assets at a time of intensified competition for jobs and resources. However, it has been shown that irrespective of age, women usually face dimmer job prospects than men.

Older workers are a multifaceted and diverse group. Categories of older workers include those who are retained in paid employment beyond the conventional retirement age when an employer needs their skills, older people who reenter the labor market for job satisfaction and feelings of self-esteem that the structure of work gives them, and those who downscale to different, lesser-paid jobs. The majority of older workers are part-time by choice or by demand, and many are employed on temporary contracts only because that is all that is available to them. Increasingly, too, there are thousands of older people who are self-employed including farmers in agricultural sectors and in small businesses around the world, including some older workers who “buy” themselves a job through self-employment.

The different types of older work have prompted new terms such as “job shifting,” which can mean moving from a highly paid and full-time position to a lesser-paid, part-time job as

an older worker, and “encore career,” a term covering thousands of Americans in particular who have shifted in the second half of their lives to second careers in areas like the environment, non-profit sectors which blend income and social impact (Freedman 2007).

Motivations for Working Longer

Some people want to work longer at an older age. In some cases this aspiration is made easier by the general shift over time from manufacturing and service industry jobs, which required sustained physical labor and took a toll on older bodies, to the knowledge economy where physical body demands are less onerous. It is no surprise, for example, that in many countries, such as South Africa, Australia, Canada, and the United Kingdom, the education sector is one area which older workers find attractive in terms of retention of their skills and labor.

Others are compelled to work longer at an older age than their parents, for example, to increase their financial security. There is less certainty that some countries can absorb the full costs of their aging populations especially where there are limited existing retirement income schemes or state pensions.

It is clear that education matters. Across OECD countries, well-educated people are more likely to work longer than the less skilled. This gap, though, probably cannot be separated from the deepening inequality divide between those who are well educated and better-off and those who are poor and unskilled with low educational attainment, irrespective of age.

Perspectives About Working Longer

It is clear that there are both challenges and opportunities associated with older workers. Two perspectives have traditionally dominated discussion about working longer. First, there is the perspective that sees working longer as beneficial to individuals, families, communities, and society. This is reflected in the title of a major OECD report

published in 2006 *Live Longer, Work Longer* (OECD 2006) which implicitly suggests that extending a working life will increase life span. Often this perspective is referred to as positive aging or active aging, and it is a policy framework used by Western governments in particular to place working longer in a favorable social context. In the positive aging context, older workers are seen as “productive,” contributing economically (Butler 2009) and increasing their own self-esteem and self-efficacy through the structure of work. In this optimistic scenario, the choice to continue on working as an older person is characterized by individual autonomy and the human rights of older people (Office of the Human Commissioner for Human Rights 2012). Humorist and writer George Bernard Shaw once said, “A perpetual holiday is a good working definition of hell.”

The second perspective suggests that older people may be more likely to be in “precarious work” (International Labour Organization 2012) as opposed to “decent work.” Precarious work is characterized as uncertain, risky, and unpredictable, sometimes without employment protections in the law, often casual work without certainty of hours from day to day or week to week, and mostly low paid and contingent (Sargeant and Frazer 2009). The idea has been popularized by Guy Standing’s work in which he describes the “precariat” as “the new dangerous class” (Standing 2011). He states that “old agers have become a source of cheap labour, paid low wages, given few benefits, easily sacked.” This is undoubtedly true of some older workers only, particularly women, ethnic minorities, and migrant workers, who are often in “precarious work” that creates greater economic inequality, insecurity, and instability.

Social Attitudes, Discrimination, and Older Workers

Ageism, which constitutes negative societal attitudes about age, and age discrimination at work are of concern throughout the world. Age discrimination means older people are disadvantaged in

individual or cumulative aspects of work such as job hiring, pay and reward systems, promotions, job assignments, training opportunities, and fringe benefits. This is despite different cultural contexts in which older people are revered for their wisdom and knowledge and regarded as “elders” with dignity and respect in family structures and communities.

Age discrimination is often invisible and covert and often not easy to prove despite statutory prohibition in many countries. The emphasis on age discrimination is not necessarily because of a new appreciation of the need for fairness. Fredman (2011) says it gains its chief impetus from macro-economic imperatives, but this should not obscure the fact that it is unjust. The impacts of exclusion from the labor market of older people on the basis of age should not be underestimated in terms of poverty, ill-health, and depression, as well as self-esteem and social isolation.

Experiments in Spain, Sweden, Scotland, Germany, Norway, New Zealand, and Australia, among other countries, have shown that if matching applications from job candidates with equal qualifications are presented to employers, the younger applicant will be preferred. Older applicants were not preferred, not on the basis of merit or competencies, but simply on the discriminatory basis of their age (Wilson et al. 2007). However, employers seldom identify chronological age as the criterion on which they have preferred one candidate over another. It is often very difficult for a mature job seeker to establish that old age was the grounds on which they did not get a job.

Age discrimination laws usually include the whole employment cycle starting from job advertisements which are expected not to refer to the age of applicants through to exiting from the labor market through retirement or redundancy. Laws prohibiting age discrimination have been used by specific occupational groups such as airline pilots, judges, and university teachers, among others, to challenge mandatory retirement ages in various countries with mixed success. In the European Union, for example, the courts can say that an objective justification for not employing older people is the need for intergenerational fairness or to balance the age structure of an organization,

or the need for health and safety considerations, or the need to recruit and appoint young people.

The mass media, and the news media in particular, have been criticized for promoting the cult of youth as celebrities in sport, leisure, and fashion and in the world of work. This led to the comment that the “mass media has powerfully and negatively influenced both public opinion generally, and employers’ attitudes specifically, on the subject of older workers” (McGregor 2005). Concern has also been expressed consistently at the way older workers are stereotyped in print advertisements and commercials and online marketing, despite the potential purchasing power of older workers in paid employment (Treguer 2009).

Changing Employer Practices

A variety of human resource strategies are necessary to attract, retain, and accommodate older workers, in addition to labor market and pension policies. Companies need to retain and transfer institutional knowledge, for example. They also need older workers to mentor and coach younger and intermediate workers. Corporates, companies, and small businesses need to manage diverse workforces that are representative of their own client and customer bases, and they need to be able to keep older workers productive.

Many transnational corporations and multinational companies can afford enlightened and progressive employer policies and practices that balance their workforces by age. Companies around the world, such as Singapore Health Services Ltd., with 20% of its 15,000 workforce above 50 years of age, have innovative human resource policies (Tan 2009). These include reemploying retirees, flexible work arrangements such as flexitime, project work and part-time work and customized employment contracts, job sharing, and telecommuting.

However, a challenge for many smaller organizations is that older workers are often the most expensive. Higher pay has often been linked to seniority and job tenure. Some employers wish to rationalize both succession planning and wage costs, without breaching age discrimination

legislation. Whether older workers, especially middle-class baby boomers, would accept or can afford lesser wages as retirees or be attracted to different jobs for less money is a moot point. However, tailoring wage and benefit systems accordingly may become urgent in some sectors.

Employability of Workers

Many older workers, who have choice about whether to work or not, make an individual decision about job retention, on their own personal sense of employability. This could include consideration of their currency in the skills, knowledge, and technology required by their occupational choice. Sometimes this is professional registration, sometimes it is new software, and sometimes it is the inability to be productive and keep up in a factory environment. In some cases the decision is health related. Older workers may develop age-related illnesses or disabilities that curtail working longer and prompt exit from the labor market.

In other cases, inadequate workplace design such as insufficient lighting or inadequate ergonomic support (making computers easier to see, hear, and use) pushes an older worker out of the labor market. An English study showed older workers found it difficult to work in open-plan environments because of noise, light, and cold temperatures and older workers say they want to learn new technology at their own pace, in face-to-face situations rather than in environments where they are expected to either rely on Internet packages or compete with tech-savvy, younger workers (Myerson 2009). Work intensification and “job creep” in areas like aged care, where more is expected in less time along with increasing employer expectations, are other reasons older workers give for exiting.

An issue of increased salience to older workers is lifelong learning to sustain employability. Adult learning for job training either to refresh or renew job-related knowledge and skills and financial incentives to encourage it are not necessarily mainstream policy even in countries where older

workforces are impacting on economic growth. Global research shows that older workers often feel they are discriminated against in selection for training opportunities (McGregor and Gray 2002).

Future Trends

There is much research “on” or “about” older workers. Comparatively little is known about the perceptions and experiences of older workers themselves, and their voices have become the “missing voices” in policy frameworks around older workers, aging, and employment. It is critical that future research addresses this omission. It is also essential that older workers are not viewed by legislators, policy makers, and employers as one homogeneous grouping. No other population groupings, such as children, or young people, or the middle aged, span 30–40 years of life. A single description whether it be old age or older worker is insufficient. It is therefore imperative that national statistical collections, censuses, and international data collections allow for disaggregation past the age of 65 years to develop a more sophisticated mapping of older people. This will help governments, policy agencies, employers, and older people themselves plan for the future.

The idea that older workers are taking jobs from young people and that this could provoke or incite intergenerational tensions with younger people has been largely discredited. The idea of a fixed number of jobs with winners and losers is a variation of what economists call the “lump of labor” fallacy. Research shows that there is no evidence that increasing the employment of older persons reduces either the job opportunities or wage rates of younger workers (Munnell and Wu 2013). Global problems of youth unemployment have many patterns and complexities that are different to those influencing older worker unemployment and access to employment. However, an under-researched area requiring future scholarship and debate concerns the intergenerational transfers and accommodations that will have to take place in workplaces of the

future. As the aging population increases and as the labor market gets older, how will older people work? What incentives will they require not to retire? Only some of the answers to these significant questions are known today.

Definition

Encephalopathy is a broad term for any brain disease that affects brain functioning.

Encephalopathy refers to a broad category of conditions that disrupt normal brain functioning. Like many broadly defined conditions, etiology and clinical presentation vary extensively. Etiologies can include vascular conditions, autoimmune disorders, infectious and viral agents, cancer, paraneoplastic syndromes, hypoxia, systemic medical illness, neurodegenerative disorders, prion disease, medications, metabolic conditions, traumatic brain injury, and toxins. Symptoms may include delirium, altered mental status, seizures, cognitive deficits, motor impairment (e.g., weakness), psychosis, personality changes, and other psychiatric symptoms (Roos and Brosch 2012).

The average age of onset for these conditions varies somewhat according to etiology; however, older age is almost universally a risk factor for the development of encephalopathy, with the majority of patients presenting over the age of 50 (Paterson et al. 2012). Risk for developing encephalopathy increases with age, such that as adults move into their 40s, 50s, and 60s, risk for onset of these conditions intensifies.

The most common forms of encephalopathies present with clear changes in mental status and/or delirium. For example, hepatic encephalopathy presents in the context of liver failure with confusion, altered consciousness, and ultimately coma and/or death. Similarly, uremic encephalopathy can develop in patients with acute or chronic kidney failure. Subdural hematomas, most often secondary to traumatic brain injury, can cause an encephalopathy marked by headaches and changes in consciousness. Wernicke's encephalopathy (WE), caused by a thiamine deficiency secondary to chronic alcohol use, HIV/AIDS, and malnutrition, is marked by confusion, ataxia, and weakness (Weathers 2013). These acute medical disturbances are typically treated in primary medical settings and are unlikely to be seen by most geropsychologists.

However, several encephalopathies can present with a more insidious onset and with

predominant psychiatric and cognitive symptoms. These syndromes are more likely to present with subacute delirium that may not be immediately obvious. Unlike a classic delirium, subacute presentations are marked by cognitive changes over days and weeks rather than a more rapid, 24-h window (Flaherty 2011). As such, these conditions are frequently misdiagnosed as neurodegenerative diseases or psychiatric illnesses. Practitioners who work with older adults must be familiar with these diseases in order to make appropriate referrals for diagnosis and treatment, especially given that so many of these disorders are treatable and reversible.

This entry will give a brief overview of several types of encephalopathies that are more likely to present outside of traditional acute care settings or neurology clinics. First, this entry will review anti-NMDA receptor encephalopathy (ANRE), which presents with predominant psychiatric features. Next, the entry will review voltage gated potassium channel encephalopathy, Hashimoto's encephalopathy, herpes simplex encephalopathy, and spongiform encephalopathy (i.e., prion disease) all of which often present with marked cognitive changes. Notably, both cognitive and psychiatric changes are common among individuals with these encephalopathies and understanding core symptom profiles may be helpful in making appropriate referrals.

Anti-NMDA Receptor Encephalopathy

N-methyl-D-aspartate (NMDA) receptors are glutamate receptors found throughout the central nervous system and are thought to be involved in cognitive functioning and psychiatric illness, particularly psychosis. Anti-NMDA receptor encephalopathy (ANRE) is an autoimmune disease, a condition in which the body mounts an immune response against itself. In the case of ANRE, the immune system develops antibodies to attack NMDA receptors in the brain. ANRE is characterized by acute psychiatric and neurological symptoms including psychosis, seizures, fatigue and/or reduced consciousness, breathing difficulty, and abnormal movements (Vitaliani

et al. 2005). While the median age of onset is 24, cases of ANRE have been reported in older adults up to 76 years of age (Dalmau et al. 2008). ANRE is often associated with a type of tumor, an ovarian teratoma, which is found in almost 59% of patients with the disease. In the subset of cases that are associated with malignancies, the immune response to the tumor also attacks parts of the central nervous system, which is known as a paraneoplastic syndrome. In a case series by Dalmau et al. (2008) the median age of onset was 23 and predominantly female (91%). The symptom presentation is often dominated by psychiatric symptoms including psychosis. In a popular book published in 2012, author Susannah Cahalan provides a first-hand account of her experience with this disease. Her initial symptoms included psychosis and emotional lability, and providers diagnosed her with an alcohol use disorder and schizoaffective disorder (Cahalan 2012). This is not uncommon for patients with ANRE; many have gone undiagnosed for months because they were thought to have primary psychiatric disorders. Other features include seizures (76%), reduced alertness or unresponsiveness (86%), autonomic dysfunction, such as difficulty breathing and slowed heart rate (69%). Ultimately, Cahalan (2012) was transferred to an inpatient neurology department in response to onset of seizures. Many patients also exhibit abnormal movements, often orofacial dyskinesias such as grimacing or chewing movements, or limb posturing, which can sometimes be mistaken for seizures (Dalmau et al. 2008). Nonspecific flu-like symptoms (e.g., fever, headache) are also common just before the onset of the acute neurological and psychiatric symptoms (Sansing et al. 2007).

While many patients exhibit seizures as part of the ANRE clinical syndrome, most patients will exhibit abnormalities on electroencephalogram (EEG) monitoring, including slowing without overt epileptic activity (Dalmau et al. 2008). Approximately half of patients exhibit abnormalities on magnetic resonance imaging (MRI), which most commonly consist of hyperintensities observed on T2 and FLAIR images in medial temporal structures and the cerebellum (Sansing et al. 2007). Impairments on cognitive testing are

common. Diagnosis is confirmed by testing the cerebrospinal fluid (CSF) for antibodies to the NMDA receptor (Sansing et al. 2007). For Cahalan, it took over a month to receive an accurate diagnosis (Cahalan 2012). Accurate diagnosis is critical because ANRE is responsive to treatment, which usually involves immunotherapy, such as corticosteroids or plasma exchange, as well as surgical tumor removal (Dalmau et al. 2008). Many patients achieve full recovery or exhibit only mild lasting deficits; however, some patients experience severe lasting effects and the disease can be fatal (Dalmau et al. 2008).

Voltage Gated Potassium Channel Antibody Associated Encephalopathy

Voltage gated potassium channel encephalopathy (VGKC) is an autoimmune condition that is particularly common in adults over 50 and presents more often in males than females. In healthy adults, voltage gated potassium channels regulate neurotransmitter release but with abnormal expression of these antibodies, an encephalopathy may develop.

The clinical profile of VGKC is marked by acute cognitive changes, seizures, and hyponatremia (Bettcher et al. 2014). Some research suggests that seizure activity may represent the first symptom of VGKC, although they may not be clinically obvious if they are focal temporal seizures that do not generalize and present with tonic-clonic movements. In a comprehensive literature review, Radja and Cavanna (Radja and Cavanna 2013) found that seizures were present in 85% of patients diagnosed with VGKC; seizures often preempted subsequent cognitive changes. Severe episodic memory impairment is a core feature of VGKC; over 97% of patients present with memory impairment (Radja and Cavanna 2013). Changes in executive functioning and language have also been observed. Neuropsychological tests measuring verbal fluency and set-shifting appear to be particularly sensitive to the language and executive functioning changes associated with VGKC (Bettcher et al. 2014). Finally, psychiatric symptoms are

also common in this population, affecting approximately 33% of patients (Radja and Cavanna 2013). Specific symptoms include agitation, insomnia, hallucinations, and depression. In case studies, patients have presented with schizophrenia-like syndromes that progress to delirium, stressing the presence of affective symptoms in this disorder (Parthasarathi et al. 2006).

MRI findings among patients with VGKC are consistent with the neuropsychological profile; in particular, the medial temporal lobes appear to be hyperintense on imaging in approximately 80% of patients (Bettcher et al. 2014; Radja and Cavanna 2013). This is consistent with a limbic encephalopathy in which autoimmune diseases primarily target the limbic system. Phenotypically, limbic encephalopathies are associated with neuropsychiatric symptoms (e.g., psychosis, anxiety), subacute behavioral changes, cognitive decline, seizures, and fluctuating course. Neuroimaging in limbic encephalopathy cases can present with abnormalities in the medial temporal lobes, although this is not identified in all cases (Paterson et al. 2012). These conditions rarely affect the medial temporal lobes in isolation, and for VGKC, additional involvement of the lateral frontal lobes, basal ganglia, and white matter structures has been identified.

VGKC is highly responsive to treatment with immunosuppressants (Radja and Cavanna 2013). Over time, cognition typically improves markedly, and patients report subjective improvements in all cognitive domains and psychological domains, as well as remission of seizures (Radja and Cavanna 2013). However, longitudinal evidence suggests that some patients continue to have cognitive difficulties in one or more domain even after treatment (Bettcher et al. 2014).

Hashimoto's Encephalopathy

Hashimoto's encephalopathy (HE) is a rare condition that was first characterized by Brain et al. (1966) in a 48-year-old male who presented with stroke-like symptoms of aphasia and right hemiplegia (Brain et al. 1966). The causes of HE are not clearly understood, but it is thought to be

associated with Hashimoto's thyroiditis (HT), an autoimmune disorder in which antibodies attack the thyroid gland. In rare instances, the autoimmune reaction may cause an inflammatory response in the thyroid receptors of the brain's limbic system. Although the autoimmune reaction is not limited to the limbic system, it is nonetheless referred to as a limbic encephalopathy. Only a small fraction of Hashimoto's thyroiditis patients may develop HE; it is estimated that HE occurs in only 2.1/100,000 people (Ferracci et al. 2004), while HT occurs in approximately 1/1000 people. Hashimoto's encephalopathy may present in patients of all ages, including older adults, with a mean age of onset in the mid 40s (Chong et al. 2003). Approximately 80% of reported cases are female. Due to the heterogeneity of presentation, subtypes have been proposed: steroid-responsive encephalopathy associated with autoimmune thyroiditis (SREAT) (Castillo et al. 2006) and nonvasculitic autoimmune inflammatory meningoencephalitis (NAIM) (Caselli et al. 1999). Regardless of type, a defining trait of HE is that it is steroid-responsive. High serum antithyroid antibody must be present in order to diagnose HE, while other diagnostic tests may vary (Wood-Alum and Shaw 2014).

Patients who present with HE may display a wide range of symptoms, which can make the syndrome difficult to identify. Older adult patients often present with more subtle symptoms, such as anxiety or cognitive impairment, but they may also exhibit other psychiatric symptoms including psychosis, fluctuating states of consciousness and attention. Many patients may present with stroke-like symptoms such as aphasia, hemiparesis, weakness, blindness, headache, gait unsteadiness, and seizures can also occur (Weathers 2013; Chong et al. 2003; Wood-Alum and Shaw 2014). Because of these varying characteristics, patients presenting with these symptoms may be misdiagnosed and thus treated inappropriately. Additionally, elevated antithyroid antibodies may be present with other nonthyroid related autoimmune disorders; therefore, blood labs alone cannot diagnose HE. Other diagnostic tests may include electroencephalography and/or neuroimaging (Wood-Alum and Shaw 2014).

The treatment of HE is varied due to the rarity of the disorder; therefore optimal dosage, duration, and course of treatment is unknown. The initial case identified by Brain and colleagues (1966) reported symptomatic remission with levothyroxine treatment alone (Brain et al. 1966). Subsequent studies have reported an approximate 65% effectiveness with levothyroxine alone, while steroid treatment alone has yielded an estimated 98% effectiveness (Wood-Alum and Shaw 2014). Additional treatments may include a combination of medications and/or intravenous immunoglobulin therapy or plasmapheresis for more resistant cases. Despite the lack of clear diagnostic and treatment criteria, steroidal treatment generally yields good prognoses and remission of symptoms.

Herpes Simplex Virus Encephalitis

Encephalitis caused by the herpes simplex virus (HSE) is the most common form of sporadic and fatal encephalitis in the world (Whitley et al. 1998). Unlike HE, VGKC, and ANRE which are caused by autoimmune disorders, HSE is caused by viral infection. Approximately 1250 cases are diagnosed annually, half of the cases are diagnosed in adults over 50 (Tyler 2004), and HSE affects men and women equally (Berk and Myers 2010). Typically, the herpes simplex virus-type I (HSV-1), commonly known to cause orofacial lesions, causes HSE. The HSV-2 variant associated with genital lesions and neonatal infections is the source of only 10% of documented HSE cases. Patients with compromised immune systems appear to be particularly vulnerable to HSE. Primary HSV-1 infections among individuals with no previous history of HSV-1 antibodies are responsible for approximately 1/3 of HSE cases, while recurrent infections cause the remaining 2/3 of HSE cases (Widener and Whitley 2014).

In HSE, HSV-1 produces inflammation in the CNS that leads to hemorrhage and necrosis of brain tissue (Widener and Whitley 2014). HSE most frequently affects the medial temporal lobes and the orbitofrontal regions of the brain,

but cases have been documented with focal lesions in the brain stem rather than the cortex (Tyler et al. 1995). At present, the particular triggers for onset of HSE remain unclear. Researchers hypothesize that HSV-1 targets the cortex through the olfactory bulbs, thereby leaving the orbitofrontal and medial frontal lobes particularly vulnerable to the deleterious effects of the disease (Widener and Whitley 2014). However, others have argued that the trigeminal nerve serves as the primary pathway through which the virus targets the CNS (Tyler et al. 1995).

Initial symptoms associated with HSE include changes with cognition including altered mental status and speech deficits as well as concurrent fever and headache (Berk and Myers 2010). Given the vulnerability of temporal regions in HSE, patients frequently show neuropsychological deficits in language, (e.g., naming and semantic knowledge) as well as episodic memory. As with other types of encephalitis, early symptoms are frequently psychiatric. In cases of HSE, acute personality change and olfactory hallucinations are common. The presence of olfactory hallucinations and nasal field defects are important potential indicators for HSE (Berk and Myers 2010). Additionally, patients with this diagnosis often experience temporal lobe seizures and hemiparesis.

In addition to carefully reviewing symptoms, diagnosis can be confirmed by CSF analysis, EEG, and imaging. Early in infection, CSF will show elevated lymphocytes and red blood cells suggestive of hemorrhage and/or damage to the blood–brain barrier (Berk and Myers 2010; Widener and Whitley 2014). EEG pattern is typically abnormal with slow waves most notable in the temporal lobes; occasional lateralization is also highly suggestive of HSE. Finally, MRI scans are highly sensitive to HSE-related brain changes, particularly in early stages of the disease. Early MRI changes reveal edema and hyperintensities in the orbitofrontal and medial temporal lobes. Additionally, early imaging often identifies changes in the insula and external capsula with later involvement of the cingulate (Widener and Whitley 2014). Although brain biopsy used to be the only definitive diagnostic mechanism of HSE, polymerase chain reaction (PCR) now represents

the gold standard for both assessing the presence of HSV in the CNS and monitoring treatment response in patients with HSE (Widener and Whitley 2014).

Early diagnosis and treatment with acyclovir for HSE is imperative. Without treatment, the mortality rate for HSE is over 70% (Berk and Myers 2010; Widener and Whitley 2014). Even among patients who receive treatment, long-term cognitive consequences are frequent; only 2.5% of patients diagnosed with HSE ultimately recover normal neurological and cognitive status (Ward and Roizman 1994). Prognosis is directly related to prompt treatment as level of consciousness at treatment onset is correlated with outcomes (Berk and Myers 2010). Additionally, worse prognosis is associated with older age at onset and symptom duration longer than 4 days prior to treatment initiation (Widener and Whitley 2014).

Prion Diseases

Prion diseases, also referred to as spongiform encephalopathies, are responsible for a variety of rapidly progressive dementias. Normal prion proteins are found in the membranes of cells. Prion diseases are caused by misfolded prion proteins that propagate throughout the central nervous system. Prion diseases can occur spontaneously, as a result of an inherited genetic mutation, or acquired through infection or other mechanism of transmission. In the USA, the incidence rate of prion disease is about 1 in 1 million, and sporadic Creutzfeldt-Jakob disease (CJD) comprises most of the diagnosed cases. As it represents the most common form of prion disease, and often presents with cognitive, motor, and behavioral symptoms, CJD will be discussed in more detail. Geschwind (Geschwind 2015) described the clinical syndrome and diagnostic considerations in CJD and other prion diseases (Geschwind 2015).

Many dementias caused by neurodegenerative conditions, such as Alzheimer's disease, progress slowly and gradually over many years. In contrast, CJD is characterized by a very rapid course; the median length of survival is 5 months and most

patients do not survive past 1 year. The disease most often affects older adults with the typical age of onset falling between 55 and 75. Patients in this age group presenting with a rapid decline in cognitive functioning should raise concern for CJD or another spongiform encephalopathy (Geschwind 2015).

The clinical syndrome for CJD includes behavioral symptoms, gait abnormalities, extrapyramidal symptoms such as dystonia and Parkinsonism, and myoclonus (muscle twitching). Initial symptoms most commonly include cognitive symptoms, characterized by memory loss, language dysfunction, executive functioning difficulties, and confusion. Other early symptoms that occur in about one third of patients include fatigue, headache, dizziness, and changes in appetite and sleep. Almost half of patients experience behavioral symptoms at some point during the disease course, which include agitation, depression, aggression, apathy, or personality change, and are therefore often misdiagnosed with psychiatric disorders. One third of patients experience language dysfunction (aphasia), difficulty with motor planning (apraxia), neglect, and difficulty with arithmetic calculations. CJD affects vast areas of the brain and because of the variability in symptom presentation it can be challenging to accurately diagnose (Geschwind 2015).

Diagnostic tests include EEG, MRI, and CSF. EEG abnormalities may not appear until later in the disease course. MRI, particularly fluid-attenuated inversion recovery (FLAIR) and diffusion-weighted imaging (DWI) sequences, reveals abnormalities in the deep gray matter nuclei as well as hyperintensity in the cortical gyri, known as cortical ribboning. CSF tests may not always reveal abnormalities in patients with CJD but a minority of patients may have elevated proteins found in CSF (Geschwind 2015).

Wernicke's Encephalopathy

Wernicke's encephalopathy (WE) results from thiamine (vitamin B1) deficiency often secondary to poor nutrition and poor vitamin absorption in those who chronically abuse alcohol. In addition

to poor diet and alcohol misuse, other risk factors include bariatric surgery, chronic vomiting or diarrhea, and chemotherapy in those undergoing treatment for cancer (Sechi and Serra 2007; Zahr et al. 2011). Some individuals also have a genetic susceptibility for reduced thiamine affinity (Guerrini et al. 2005). Thiamine is involved in important neurological processes such as the production and maintenance of myelin, communication between neurons, and producing neurotransmitters such as GABA. Lesions in brain areas most vulnerable to thiamine deficiency can be observed after as little as 3 weeks of thiamine depletion (Schenker et al. 1980).

WE is rare with 2% prevalence rates in the USA, and it affects men almost twice as often as women. The classic triad of WE symptoms includes altered mental status, eye movement changes, and unsteady gait, although these symptoms are not universal. Altered mental state secondary to WE includes confusion, slowed thinking, apathy, reduced awareness, and concentration difficulties (Sechi and Serra 2007). Eye movement abnormalities occur in approximately one third of patients and can include gaze palsy and involuntary quick jerking of the eyes known as nystagmus. Motor and gait abnormalities most often present with poor coordination and unsteady gait. Gait ataxia in WE patients is typically characterized by a wide stance with short, unsteady steps (Lough 2012). Psychiatric symptoms such as agitation and hallucinations have also been reported (Zahr et al. 2011).

WE can occur with or without Korsakoff's syndrome, although the majority of patients with untreated WE will develop Korsakoff's syndrome. Patients with Korsakoff's syndrome exhibit profound anterograde amnesia with relatively preserved implicit learning and general intelligence. Confabulation often accompanies the memory impairment, particularly in the earlier stages of the syndrome. Executive functioning deficits are also common (Zahr et al. 2011). Korsakoff's syndrome is associated with atrophy of the thalamus, mammillary bodies, and frontal lobes, which can be observed on imaging. CSF is usually normal in patients with WE/Korsakoff's syndrome, and EEG abnormalities do not appear

until later in the disease course (Sechi and Serra 2007). Unfortunately, this syndrome does not improve even with treatment to correct thiamine deficiency (Butters 1980).

WE is important to identify correctly because if untreated, it can lead to coma and death. WE can be differentiated from more commonly seen neurodegenerative disorders in older adults based on the rapid onset. In addition to the clinical signs, blood tests to determine thiamine levels and MRI findings have the most diagnostic utility (Lough 2012). However, the nonspecific nature of the symptoms make it easy to misdiagnose. Early symptoms often include headache, fatigue, and irritability and can present differently across individuals. Furthermore, symptoms can be difficult to differentiate from acute alcohol intoxication when patients present to medical settings (Thomson 2002).

Conclusions

Encephalopathies are varied in etiology and presentation. Despite this variability, there are certain categories of symptoms that are common across these syndromes. Cognitive changes, fluctuations in consciousness, and psychiatric symptoms are highly prevalent in encephalopathies, regardless of specific etiology. With disease progression, seizures are common. Given that patients with these symptoms may present in primary care clinics, geriatric medical clinics, as well as psychiatry and psychology departments, it is important that providers outside the scope of neurology practices are familiar with potential presentations of these disorders. Additionally, older adults are at increased risk for encephalopathy, and it is important for providers to be aware of the varied etiologies and symptoms that are associated with these conditions. Symptoms that indicate any alteration in brain functioning, such as cognitive and psychiatric changes, should raise suspicion for encephalopathy. Notably, onset of encephalopathy symptoms is typically acute rather than gradual. However, the onset of a subacute delirium with more gradual symptom onset (i.e., over days and weeks rather than hours) is common

among the atypical encephalopathies described here. The presence of seizures often triggers a referral to a neurologist, but this symptom often manifests later in disease progression. Patients with encephalopathy, particularly those presenting with cognitive and behavioral changes, may go undiagnosed for many months. Immediate treatment is associated with the best outcomes, therefore recognizing early signs and symptoms of these disorders in older adults is imperative.

End of Life Care

Brian D. Carpenter
 Department of Psychology, Washington
 University, St. Louis, MO, USA

Synonyms

Death; Dying; Hospice care; Palliative care; Terminal illness

Definition

The end of life can occur at any age, though it most often occurs in later life, when people are most vulnerable to the range of diseases and illnesses that compromise physical health. The end of life is preceded by *dying* and culminates in *death*, a technical distinction of some importance because both dying and death are distinct phenomena about which people have varying expectations, fears, and wishes. In its most clinical definition, dying refers to the process of physiological decline that leads to a complete cessation of vital bodily functions such as respiration and circulation. The dying process can be short or protracted; of a single cause or multifactorial; painful or relatively peaceful; brought about by a person's own hand, by another's hand, or by accident; a result of internal processes or external forces; and wished for or fought against. Clearly, dying is a multifaceted experience, with biological, psychological, and social elements. Death, meanwhile, is the end product of dying. Dying is the process, death the result.

End-of-life care refers to the wide range of services and supports that can be provided not only to an individual who is dying but also to family members and friends. It also involves a variety of professionals who provide the care, but of course have thoughts and feelings about the experience themselves. This care has many facets and attributes, such as its intensity, location, scope, and financing. Those facets and attributes often evolve in response to the specific reasons why a person is dying. For instance, acuity of the situation calls for different interventions: a person who has a sudden, massive heart attack will need different things than someone experiencing gradual decline associated with a slow-growing tumor. The cause of the situation might also demand different interventions: dying as a result of a natural disaster will involve a different experience than dying as a result of a common, age-related disease. Timing also matters: dying while still in early childhood is vastly different from dying past age 100.

Across these facets, the goal of end-of-life care is, in general, to enhance the quality of life near

the end of life for people with a life-limiting illness and their care partners. There are, of course, many ways to achieve that quality, which themselves span biological, psychological, and social strategies. In practice, end-of-life care usually (and optimally) includes a collection of strategies and interventions, designed and implemented by a team of caregivers, all striving to enhance a person's experience in this important, ultimate developmental milestone.

Life Span Developmental and Biopsychosocial Perspective

Dying and death can occur at any point in the life span, and the timing of those events matter. It is useful to consider three different contexts in order to gain a comprehensive understanding of a person's dying and death. The first is to recognize that dying and death occur at a particular time in the development of the *individual*. As a person progresses through life, she grows in many different domains – physiological, psychological, social, and spiritual – and the point of her development influences her experience of dying and death. For example, the psychological resources available to a person who is dying are likely to be different for a younger person than an older person. Not only do basic cognitive functions (e.g., insight, reasoning, judgment) evolve and change across a person's life span, but so too does their perspective on life, based on the accumulation of experiences they have had and their relative place in their own history. Likewise, from a social perspective, death is more expected, more of an “on-time event,” for an older adult than it is for an adolescent. Therefore, the death of any 16-year-old, regardless of circumstances, can seem more tragic than the death of a 90-year-old who has had a lengthy life.

The second important context is that of the *family*, the most central social network for most people. When an individual begins to die, she does so within a family network that is itself changing over time, with its own developmental history and milestones. When a parent is dying, the family will experience it differently if the

children are very young, if the children are young adults launching their own lives, if the children are middle aged with their own growing family, and if the children are old and might even predecease their parent. In all these scenarios, the parent is still a parent, but the family itself is in a different developmental place. Consequently the parent's dying will affect the family in different ways, just as the family will affect the parent in different ways.

The third important context is the *culture*. This context incorporates specifics about the nation, region, state, province, principality, neighborhood, community, and at the most minute level, perhaps even the building where a person lives. Broadly speaking, the location in which a person is dying influences the experience, with its unique structure, resources, and systems. So too do the set of norms and values that characterize the group of people in which the dying person is situated. This context also incorporates the particular point in history at which a person is dying. Dying and death in the late 1800s were different processes than dying will be in 2050: changing technology, medical advances, mores and values, legislative policies, reimbursement structures, and other features all influence a person's journey through dying.

To return to the original point, dying is a unique experience for that *person*, in that *family*, in that *culture*, and at that place in *time*.

Mental Health at the End of Life

People near the end of life grapple with a variety of challenges that could have an impact on their mental health. These include serious medical conditions that bring a host of symptoms such as pain, fatigue, dyspnea, nausea, and constipation; intrusive treatments that often have side effects as debilitating as the disease they are meant to treat; functional limitations that interfere with activities of daily living and prompt increased dependence on others for assistance; the sheer amount of time spent in organizing and attending appointments with health-care providers, requiring a person to step out of the routine most people follow and live

instead according to other people's schedules and availability; financial obligations related to treatments and short or long stays in institutional settings; and, of course, living with the knowledge of one's foreshortened future and the uncertainty of what that future might bring. It is no wonder, then, that people who are dying are vulnerable to sadness, worry, and dread. Still, not every person who is dying is distressed.

The World Health Organization defines mental health as, "A state of well-being in which every individual realizes his or her own abilities, can cope with the normal stresses of life, can work productively and fruitfully, and is able to make a contribution to her or his community" (World Health Organization 2001). Note that this definition does not focus on the *absence* of significant psychological distress, but instead the *presence* of activities that promote continued engagement with life, even as death nears. Therefore, psychological assessment and intervention should focus on classic mental health symptoms, such as depression and anxiety, but they should also address ways to enhance psychological well-being more broadly. People who are dying also may benefit from interventions that help them clarify their goals and values, adopt useful coping skills, use effective communication strategies, maximize remaining abilities, and grapple with questions about identity and meaning in the face of mortality.

Moreover, to assume that dying is an entirely negative experience overlooks the varied positive outcomes that some people experience. That includes an incentive, however unintended, to review one's life and to reach a level of understanding and appreciation of what one has accomplished. An enhanced depth of relationship with friends and family is also possible, as is achieving a clarity of purpose necessitated by limited time remaining. Getting one's "house in order" can lead to reconnection, reconciliation, and renewal in unexpected ways.

Significant psychiatric problems do occur as people are dying, however, and their detection and treatment should be pursued with the same diligence as would be the case in any other group. Frank clinical syndromes are common in people with severe illnesses. These include depressive

disorders (e.g., major depressive disorder), anxiety disorders (e.g., panic disorder, specific phobias), trauma- and stressor-related disorders (e.g., posttraumatic stress disorder), substance-related disorders (e.g., alcohol-use disorder), sleep-wake disorders (e.g., insomnia disorder), and, perhaps more rarely, eating disorders (e.g., anorexia nervosa, bulimia nervosa). These are the syndromes listed and described in taxonomic systems such as the International Classification of Diseases (ICD) and the Diagnostic and Statistical Manual of Mental Disorders (DSM-5). Equally influential to quality of life is the presence of subsyndromal symptoms that, though less severe, are nonetheless distressing. Examples of those symptoms include apathy that leads to unhelpful social isolation, restlessness that depletes energy that could be spent on more affirmative activities, and rumination that distracts from important contemplation. Subsyndromal symptoms are common and deserve equal attention and intervention.

Mental health considerations are relevant to family and friends as well. Even before death, symptoms of grief may appear in a caregiver, and that sadness may be a natural response to an impending death. For example, in the case of a patient with advanced dementia, caregivers may begin to grieve as the disease follows its natural course, sometimes years before death. After death, grief is also a natural response. Although some experiences are common during bereavement (disbelief, sadness, longing, guilt), they are not ineluctable in sequence or duration. Variations in the experience are likely depending on the circumstances of the death, nature of the relationship with the person who died, and the time since death, among other factors. However, there is a difference between expected grief and *prolonged grief disorder*. The former is a natural emotional reaction to loss that does not impair a person's functioning to any great extent and typically resolves with time. The latter, on the other hand, is a more severe form of grief with a distinct symptom pattern that can include intense yearning for the deceased, bitterness over the loss, and difficulty accepting the loss. Prolonged grief disorder also appears to have a different response to treatment (Prigerson et al. 2008).

Psychological Assessment

Caring for people at the end of life requires knowing how they are thinking and feeling about their experience. Therefore, astute psychological assessment is the linchpin of care. When learning about a person with serious illness, psychologists will want to investigate traditional mental health symptoms, such as current and past anxiety and depression, but a comprehensive assessment will extend far beyond those symptoms. It is equally important to know about a range of topics covered in a usual clinical interview – a person’s educational and work history, social support network, financial concerns, and spiritual philosophy – but also other features of a person’s psychology that may matter to their current circumstances, preferred learning style, past coping strategies, and personality. Of course, extensive knowledge about a person’s medical circumstances represents an important foundation for many, if not most, conversations. That includes asking patients about their understanding of their disease, prognosis, and current treatment regimen (and comparing that to information provided by the patients’ health-care team, noting any discrepancies). A comprehensive psychological assessment involves multiple methods that may include interviews, questionnaires, and observations. Moreover, a comprehensive psychological assessment is multimodal and may involve input from patients themselves but also family, friends, medical records, and an array of health-care providers.

Given that some people who are dying may be quite limited in their ability to provide information themselves, due to cognitive or physical limitations, thought and care need to be given to how and when to obtain assessment details. Clinicians will need to consider the impact of sensory limitations, speech and language abilities, stamina, and consciousness that may fluctuate due to disease, treatments, and the dying process. Maximizing a patient’s communication abilities means understanding these factors and managing the assessment, so tools (e.g., reading glasses, large-print materials) and timing (e.g., at the patient’s best time of day, when there are few distractions

and symptoms are well managed) are to the patient’s benefit.

When a person is dying, there are likely urgent or at least proximate medical needs that dominate the situation, but it would be a mistake to overlook the role that frank psychopathology may play in the quality of a person’s life at the end of life. The prevalence of psychiatric symptoms is quite high in people with life-limiting illness, and clinicians should investigate their presence as they would in any referral. Although studies vary widely in their estimates, mood and anxiety disorders may be present in more than a third of patients (Solano et al. 2006), and disorders based on DSM-5 or ICD-10 diagnostic criteria should be fully investigated. Self-report questionnaires can be used to assess symptom severity (as well as progress in treatment). Well-validated instruments include the Hospital Anxiety and Depression Scale (HADS), the Patient Health Questionnaire (PHQ-9), the General Health Questionnaire (GHQ-12), the Geriatric Depression Scale (GDS), and the Geriatric Anxiety Inventory (GAI).

One overarching suggestion in any kind of assessment is to remain mindful of the overlap between physical and psychiatric symptoms. It can be difficult, but very important, to tease apart symptoms that are due to a disease or its treatment from symptoms due to a psychological process. Indeed, the two may be interrelated. For instance, low energy may be a symptom of depression or an effect of chemotherapy, or both. Dyspnea may be a symptom of anxiety or related to chronic obstructive pulmonary disease, or both. Consequently, focusing on cognitive symptoms (e.g., hopelessness, worthlessness, guilt, fear, dread, rumination) may be more useful when determining the reason for a patient’s symptoms (American Psychological Association 2007).

A final consideration has to do with the challenge of measuring constructs that are manifestly important when talking with patients who have serious illnesses but that defy the tools we have available. Patients (and caregivers) talk about forgiveness, acceptance, peace, dignity, and readiness to die, but scale development and assessment innovation have not been as important to the field as those concepts are to patients.

Psychological Interventions

Psychological challenges appear throughout the experience of living with serious illness. Psychological support can be useful throughout the experience as well. Beginning with the point at which a life-limiting diagnosis is made, psychologists can help patients understand their diagnosis, manage emotional reactions, communicate treatment preferences, and mobilize supports. As illness progresses, psychologists can offer both supportive and change-oriented interventions to promote adaptation to shifting circumstances. Following death, psychologists can provide services to the bereaved. Psychological interventions are relevant not only to patients but also to their informal caregivers and to their health-care providers, who may from time to time seek opportunities to help them cope with the stress of working in end-of-life care.

Selecting a treatment approach depends on the goals of the patient and targets for intervention. Treatments for psychopathology or subsyndromal symptoms that have been validated in other patient populations are reasonable alternatives to consider: evidence-based cognitive-behavioral, interpersonal, and brief psychodynamic approaches may be useful, though those treatments have not been validated in patients with serious illness, and modifications may be needed in end-of-life circumstances (Kasl-Godley 2011). Other approaches may contain elements with obvious face validity for people who are dying. Acceptance and Commitment Therapy (ACT) (Hayes et al. 2012), with its focus on acknowledging symptoms rather than trying to change or dismiss them, may help patients whose symptoms may, in reality, not improve. Likewise, existential therapies that concentrate on meaning making in the face of mortality have obvious application (Spira 2000).

Recently, several new types of psychotherapy have been developed that are specifically designed to address the psychological well-being of patients near the end of life. The two with the most empirical data so far regarding their efficacy are Dignity Therapy and Meaning-Centered Group Therapy. Dignity Therapy (DT)

(Chochinov et al. 2005) uses a set of facilitated questions posed by the therapist to help patients identify past accomplishments, values, and goals. Themes that are addressed include generativity, the continuity of self, role preservation, the maintenance of pride, hopefulness, and concerns about the aftermath of one's death. DT sessions can be recorded, and a transcript can be used to create a "legacy document" that captures the patient's life in a form that can be shared and retained by family members. Patients and family member report that DT is helpful, although its impact on anxiety, depression, and quality of life is less clear. Meaning-Centered Group Therapy (MCGT) (Breitbart et al. 2004) combines existential and cognitive-behavioral techniques to help very ill patients restore meaning to their life. MCGT involves eight, weekly group sessions, 90 min in length that include didactics, discussion, and experiential exercises to help patients understand their illness and sustain hope and meaning. Recent evaluations of MCGT have found significant improvement in sense of meaning, faith, and spiritual well-being and significant decline in symptom-related distress and a desire for death.

Competence in Diversity and Inclusion

People arrive at the end of their life having traveled many different paths. Therefore, although dying ends in the same, universal cessation of basic biological functions, how it happens, and how people feel about it, vary widely. Each person has a unique developmental history that shapes his/her experience at the end of life, and health-care providers need to consider how individual differences might matter. Moreover, differences across nations, regions, and cultures can affect how an illness is experienced, how choices are weighed, how the health-care system operates, and the dynamics of personal and professional relationships. Generalizations about how racial or ethnic groups approach end-of-life issues may be a starting point, but only a starting point. It may be more useful to pay attention to cultural scripts, but recognize variability within groups based on socioeconomic status, acculturation, spiritual

beliefs, and other factors likely to vary from person to person (Smith et al. 2009).

In the usual domains of psychological practice – assessment and intervention – several considerations are important. Norms on many common assessment instruments are rarely available for particular groups based on age, gender, race/ethnicity, and socioeconomic status, and they are even more rare for people within those groups who are dying. Consequently, there is relatively little information about what is “normal” at the end of life in terms of psychological constructs in the domains of emotion (e.g., variations in positive and negative affect), cognition (e.g., decision-making processes), and personality (e.g., locus of control). In terms of evidence-based psychological treatments, interventions designed for the end of life are so fledgling that there have been virtually no systematic evaluations of their effectiveness in subgroups of diverse patients. Therefore, providers will have to be flexible and open-minded in their practice, making sure to inquire about the background, experience, beliefs, and preferences of the particular patient and family with whom they are working.

Palliative Care and Hospice

One common point of confusion among the public, and even some health-care professionals, is the relationship between palliative care and hospice. Palliative care is a broad category of care designed to help people coping with serious illness. This type of specialty care is, according to the World Health Organization, “an approach that improves the quality of life of patients and their families facing the problems associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial and spiritual” (<http://www.who.int/cancer/palliative/definition/en/>). As such, palliative care is provided to people throughout the disease trajectory, from diagnosis to death; in a variety of care settings, from home to outpatient and inpatient; to any type of patient, from children to older adults;

and with any type of severe disease. Palliative care generally involves a holistic, interprofessional approach to care that can benefit both patients and family members. A growing body of research suggests that not only does palliative care improve quality of life, but it also extends life for some patients while at the same time reducing costs (Higginson and Evans 2010; Morrison et al. 2011).

Hospice, by contrast, is a particular type of palliative care. This service adopts a palliative care philosophy when supporting patients very near the end of life. Like palliative care, hospice can be offered to any type of patient, with any type of life-limiting illness, and can be provided at home or in a residential or institutional setting. In the United States, hospice has included a suite of services, reimbursed by the Medicare Hospice Benefit, as a complement to other health-care services a patient might receive. Traditionally, patients are eligible to receive hospice care when a physician certifies that a patient has fewer than 6 months to live. In addition, hospice is offered if patients are no longer pursuing curative treatments. In recent years there has been some movement to reduce these restrictions, with some pilot programs testing more relaxed eligibility criteria. In general, however, hospice is reserved for patients very close to death, whereas palliative care is appropriate, and perhaps most beneficial, when initiated early in the course of a disease.

Interprofessional Collaboration

Because end-of-life care aims to enhance quality of life broadly, it addresses patient needs in many domains. A biopsychosocial-spiritual approach to care recognizes the complex interplay among a patient’s medical condition and treatments, psychological adaptation to serious illness, the social context in which the experience of illness occurs, and a person’s spiritual interpretation of their circumstances. As a result, a team of professionals is typically involved in providing end-of-life care. That team can include a broad range of professionals from many disciplines, all of whom have something important to add to a patient’s care.

A typical palliative care team, for instance, includes a physician, nurse, social worker, and chaplain. In some settings, end-of-life care is also provided by psychologists, psychiatrists, occupational therapists, physical therapists, speech-language pathologists, pharmacists, dieticians, aides, and homemakers. Hospice also utilizes volunteers for peer support. Of course the most essential members of the team are the patient and the family, who bring their own perspective, expertise, expectations, and needs.

The concept of collaborative care has evolved in recent years, as the importance of an integrated effort has become more apparent. Teams were first known as “multidisciplinary,” with professionals from different disciplines developing their own independent treatment plans for patients that were later shared among team members. The terminology changed to “interdisciplinary teams” when team members from different disciplines were encouraged to assess and develop a treatment plan collaboratively. More recently, the term “interprofessional team” has come into widespread use, with an even greater emphasis on team members understanding and appreciating the contributions of each discipline. Therefore, a true interprofessional team that provides end-of-life care would concentrate its efforts on sharing information and expertise to develop an integrated care plan that involves several disciplines, each contributing unique expertise that dovetails with that of other disciplines. Effective interdisciplinary care depends on several factors, including timely and comprehensive communication among team members, a shared philosophy about care, transparent decision-making, a clear delineation of roles, respect for the competencies each discipline brings to the care plan, and provision of mutual support (Hanks et al. 2009). This model of care is likely to become even more preeminent as its benefits become more widely substantiated.

Supporting Formal Caregivers

Emotions run high in much of end-of-life care because the decisions are complex, time is limited, and the stakes are high. Stress is unavoidable,

and a genuine challenge for providers is finding a way to manage it. Without doing so, burnout is likely. Signs of burnout include emotional exhaustion, pessimism, cynicism, and self-doubt (Maslach 2001). Providers who are burned out may find themselves disengaging from patients, maintaining a more safe emotional distance in order to avoid any disappointment or sadness. Risk factors for burnout include occupational time pressure, frequent exposure to suffering, interprofessional team conflicts, and uncertainty about one’s professional competence. At the same time, protective factors include having ample time to spend with patients and families, receiving adequate training about communication principles, stable personal and professional relationships, and positive professional appraisal (Pereira et al. 2011). In the face of burnout, effective interventions involve obtaining peer consultation and supervision, seeking continuing education, establishing a satisfying work-life balance, and recognizing when down time is needed and taking it (Vachon 2006).

One role that psychologists can play in end-of-life care is supporting other providers in their work. With expertise in the interplay among thoughts, emotions, and behavior, psychologists are in a unique position to educate and intervene to help individuals and teams manage the challenges of the intensity of end-of-life care. As they educate staff about the mental health needs of their patients, so too can they educate staff about how to promote their own mental and physical health. Psychologists also may be called in to facilitate support or process groups to help teams work more effectively.

Ethical Issues

That so many ethical issues arise in end-of-life care is perhaps an indication of the importance of this moment in a person’s life. It brings to a close every other chapter of life that preceded it, and it is therefore invested with great meaning for individuals, families, and cultures. At the same time, ethical issues arise in end-of-life care because it is a nexus for complicated, fast-moving, multifaceted

situations that involve many people and many difficult decisions. Broadly, many of these ethical issues center on autonomy: the extent to which an individual has the opportunity (and ability) to live and die when, where, and how they wish. People have strong preferences regarding the end of their lives, and those preferences intersect with beliefs within the family, proscriptions dictated by faith traditions, and guideposts articulated by legal doctrine and public policy. Ethical quandaries arise when there is tension between opposing beliefs or ideas. For example, ethical principles are in conflict when deciding whether a patient who is in severe pain should be treated with morphine (respecting the ethical principle of beneficence), even though that treatment might lead to the patient's extreme sedation and might even hasten death (the ethical principle of nonmaleficence). Many health-care organizations have in place trained ethics committees to help patients, family, and staff weigh complex decisions, though these decisions are rarely easy.

Conclusion

Dying and death are universal human experiences, yet conversations about them are relatively rare in contemporary society. That is generally true within the field of psychology as well, although there is an obvious role for the discipline in research, education, and practice in this area. Indeed, as science reveals the increasingly interconnected nature of the body and the mind, and as health-care adopts integrated, interprofessional models, psychology has much to add to end-of-life care. Assessments and interventions with patients and families are foundational contributions, even if they are in their fledgling stages of development. There are great opportunities, great challenges, and great satisfactions in this work, present at the zenith of life.

Definition

The English Longitudinal Study of Ageing (ELSA) (Steptoe et al. 2013a) is a multidisciplinary panel study that collects a comprehensive array of measures on a representative sample

of men and woman aged 50 and over who are living in England. Repeated measures covering health, economics, psychology, lifestyle, and social connections are collected from the same individuals over time, allowing researchers to study the dynamics of the aging process.

The ELSA Sample and Study Design

ELSA is sampled from the Health Survey for England (HSE), a large annual cross-sectional survey on the health of the population of England (Mindell et al. 2012). Sample members recruited at wave 1 (2002/2003) were individuals who had previously taken part in 1 of 3 years of the HSE (1998, 1999, and 2001) and were aged 50 or over at the time of the wave 1 interview. Subsequent ELSA data collection waves have taken place biennially, in 2004/2005 (wave 2), 2006/2007 (wave 3), 2008/2009 (wave 4), 2010/2011 (wave 5), 2012/2013 (wave 6), and 2014/2015 (wave 7). The eighth and ninth waves of data collection are planned for 2016/2017 and 2018/2019, respectively.

New study participants are recruited during some waves in order to compensate for the aging sample population and to refresh the younger age groups. This serves to maintain representation of all ages 50 and over in ELSA. Refreshment sampling to date has recruited members aged 50–52 at wave 3 (HSE 2001–04), aged 50–74 at wave 4 (HSE 2006), aged 50–55 at wave 6 (HSE 2009–11), and aged 50–51 at wave 7 (HSE 2011–12), with plans to continue to recruit new sample members aged 50–51 at future waves.

The “core members” of the ELSA sample are individuals aged 50 and over, living in private residences, who were recruited through HSE at either the first wave of ELSA or at any of the subsequent refreshment samples. The data also includes interviews with “young partners,” who are individuals under the age of 50 whose partners are core members and “new partners” in the correct age range who entered relationships with core members after those members were recruited to ELSA.

Mode of Interview

Data are collected from respondents in their own home, every 2 years and by means of a computer-assisted personal interview (CAPI) that is delivered by a trained interviewer. The CAPI includes questions on the respondents' demographics, household membership, work and retirement activities, economic circumstances, health, and behavior. A self-completion questionnaire includes questions on well-being, social participation, quality of life, and social networks, along with questions considered to be sensitive. The main interview takes approximately 85 min to complete for an individual interview and around 2 h when two people within the same household are interviewed concurrently.

At waves 2, 4, and 6, core members who completed a main interview were offered a visit from a qualified nurse, where a blood sample was taken and a series of performance and biomedical tests were conducted. The nurse visits took place soon after the main interviews and were of similar duration to the main interviews.

Unless they expressly ask to leave the study, all participants who decline to be interviewed in a given wave are offered a full interview at each future wave. From wave 3 onward, individuals electing to leave the study, or those who had declined to take part in two consecutive face-to-face interviews, were offered a telephone interview as an alternative to the standard interview. The telephone interviews were approximately 10 min long and respondents were asked a small number of questions about their health, work and benefits, marital status, and accommodation. As well as providing limited information in their own right, these telephone interviews are also a useful strategy for retaining sample members who might otherwise leave the study, with some agreeing to a full interview at future waves.

Individuals at wave 1 were not recruited if they lived in institutions such as retirement homes, elderly care facilities, hospices, or prisons. From wave 3 onward, any respondent who had previously taken part in a main interview at wave 1 but had later transitioned into a care home or other institution was deemed eligible for interview. As a

consequence of this, researchers now have the opportunity to study the circumstances that surround a respondent's move from a private residence to an institution. In situations when study participants have been unable to consent to an interview for themselves, because of a physical, mental, or cognitive disability, a proxy informant, usually a close family member or friend, has been asked to complete a 20-min interview on the participant's behalf. The proxy interview focuses mainly on key demographic information and general health status, omitting attitudinal questions that a third person is unlikely to be able to answer. Prior contact with a respondent who later requires or requests interview-by-proxy gives opportunity to researchers to ascertain what factors and mechanisms might contribute to later life disability or impairment.

An end of life (EOL) interview was introduced into ELSA at wave 2. The EOL interview aims to capture important information about how a deceased study member's life might have changed in the years before their death and how their assets were distributed after their death. Like proxy interviews, EOL interviews are generally undertaken with a close family member or friend and include questions on the health of the deceased, any care or support they had received, their mood and memory, problem behavior and financial questions such as funeral expenses, inheritances, and private health care. EOL interviews have taken place at waves 2, 3, 4, and 6 with a response rate of 66% ($n=135$), 54% ($n=375$), 58% ($n=242$), and 74% ($n=242$) from all issued cases, respectively.

Response Rates

Cross-sectional response rates at a given wave of ELSA are calculated by dividing the total number of respondents by the total number of individuals deemed eligible for that wave. Response rates are based on core members and not on those who have died, who have moved to an institution or care home, or who are living outside the UK. Waves 1, 2, 3, 4, 5, 6, and 7 have achieved response rates of 66%, 82%, 73%, 74%, 80%,

78%, and 77%, respectively. These response rates include both those who were eligible for wave 1 and refreshment sample members who joined the study at later waves. By wave 6, 56% of all eligible wave 1 core members had given an interview at every wave of ELSA.

Much like other panel studies, the success of ELSA is dependent on the retention of respondents for follow-up interviews. Loss to follow-up can occur because respondents are no longer eligible for interview, and for ELSA, this includes those who have died or who have moved outside of the UK. The majority of respondents who are deemed ineligible to participate in ELSA are participants who have died: 23.5% ($n=2680$) of the core sample members at wave 1 ($n=11,391$) had died by wave 6. There is strong evidence to suggest that within the ELSA sample, participants with higher numeracy are less likely to drop out of the study compared with their less-numerate counterparts. Higher levels of education also appear to predict lower levels of attrition, but this association appears to be limited to younger respondents (i.e., those aged 50–64) (Banks et al. 2011). Lower retention rates have also been reported in ELSA compared with HRS, but the mobility of respondents, maturity of the study, interviewer quality, and sampling methods were not found to be sufficient to explain the gap in attrition between the two studies; rather it was suggested that higher incentivization in HRS compared with ELSA and cultural differences in the willingness of the two populations to take part and remain in scientific surveys might explain the difference (Banks et al. 2011).

Weighting: Cross-sectional and longitudinal weights are produced to minimize any bias resulting from differential nonresponse and to ensure that the respondent sample is representative of the population of interest (adults aged 50 and over living in private households in England). At wave 1, a weight was derived to minimize any unrepresentativeness of the sample population due to nonresponse at HSE, refusal to be interviewed post-HSE, and nonresponse at wave 1. Derivation of the weight involved calibration of the age-sex profile of core member

respondents to that of the population represented by the Census 2001. Wave 2 weights were calculated to adjust for differential nonresponse between waves 1 and 2 and population representativeness. From wave 3, refreshments were added to the main sample, requiring the need for separate cross-sectional and longitudinal weights. Separate weights have been produced to address differential nonresponse for interview completion, completion of the self-completion questionnaire, participating in a nurse visit, and giving a blood sample at waves 2, 4, and 6. A detailed description of the weights can be found in the user guides and technical reports that can be accessed at <http://www.elsa-project.ac.uk/>.

Linkage to administrative data: Since ELSA's inception, respondents have been asked to give their permission to link their survey data to National Health Service (NHS) Hospital Episode Statistics (HES) data, which contain details of diagnosis, treatment, length of stay, and type of discharge. Respondents have also been asked to give permission to link their records to the NHS Central Register mortality data and cancer registration data. Year and age of death information for deceased respondents is available. Analysts who wish to utilize the detailed mortality data, HES, or cancer data are able to request special permission to access this data. Permission from respondents was also obtained to link survey data to official records of national insurance contributions, welfare and benefit receipt, and details of any tax credits they may be claiming, and these data will be available to analysts shortly.

Data Access

Anonymized archived data from ELSA are available from the UK Data Service (UKDS, <https://www.ukdataservice.ac.uk/>). The main dataset is made available to *bona fide* researchers on submission of a request to UKDS. The archive data are used primarily by academics and government departments. Requests for restricted data (geographically more detailed and/or relating to administrative data linkages) can be made by

application to the ELSA Linked Data Access Committee; an application form can be found at www.ifs.org.uk/elsa.

International Comparisons of Health at Older Ages

To enable cross-country comparisons, ELSA has been developed with close consideration of its two sister studies, the Health and Retirement Study (HRS; USA) and the Survey of Health, Ageing and Retirement in Europe (SHARE; 20+ European countries and Israel). HRS, ELSA, and SHARE have also been used as models for the development of other aging studies such as the Irish Longitudinal Study on Ageing (TILDA), the Northern Ireland Cohort for the Longitudinal Study of Ageing (NICOLA), the China Health and Retirement Longitudinal Study (CHARLS), the Korean Longitudinal Study on Ageing (KLoSA), the Mexican Health and Aging Study (MHAS), the Japanese Study of Aging and Retirement (JSTAR), and the Brazilian Longitudinal Study of Health, Ageing and Well Being (ELSI-Brasil). Understanding which factors drive national differences in factors such as retirement, chronic disease, and mortality is pivotal for informing policies aimed at improving health and well-being. For example, comparison of disease rates in ELSA and HRS populations revealed that at every wealth level the English population in late middle age has lower levels of diabetes, hypertension, heart disease, myocardial infarction, stroke, lung disease, and cancer and lower mean levels of C-reactive protein, high-density lipoprotein, and cholesterol levels than their US counterparts (Banks et al. 2006). Although older adults in the USA appear to suffer higher burdens of chronic disease, they have been reported as being cognitively healthier than older adults in England (Langa et al. 2009), and when health is operationalized into functional domains that include measures of pain, cognition, disability, depression, and physical performance rather than defined by absence of disease, English adults were found to be only slightly healthier than US adults (Cieza et al. 2015).

Content of Waves 1–7

Respondents are not always subject to the same questions at every wave of ELSA. Instead some questions are rotated on and off successive waves of the study, often to allow time to include new questions. The information in Table 1 provides a broad overview of the content included in ELSA. The primary content of the survey is arranged in separate modules that broadly focus on health, work, financial circumstances, cognitive function, and psychosocial measures. A number of substudies are also ongoing and each primary module and substudy is briefly detailed below.

Health Module

The health module includes self-report measures of general health and physician-diagnosed conditions including mental illnesses, longstanding illness/disability, symptoms indicative of particular health conditions and health behaviors. There are also objective measures relating to gait speed, physical performance, anthropometrics, and biological markers. During wave 6, a module on sexual relationships and activities was introduced to the study. A report covering sexual activity, problems with sexual functioning, and concerns about sexual health has subsequently been published (Lee et al. 2016). Information on drug prescription and adherence data was first collected during the nurse visit at wave 6 and will be repeated at wave 8, with the aim of producing a unique national longitudinal dataset on medication use in an aging population. The name of each prescribed medicine was recorded and allocated a code number corresponding to the British National Formulary (BNF) listing. Collection of polypharmacy data should provide an opportunity for a deeper understanding of the factors that contribute to successful use of prescribed drugs in older people. At wave 7, an objective measure of hearing ability was introduced to the study to further complement the self-reported hearing questions that were already present in the survey. The HearCheck device, developed and produced by Siemens (Munich, Germany), is a handheld device with an ear cup that is held against the respondent's ear (Parving et al. 2008).

English Longitudinal Study of Aging (ELSA), Table 1 Information collected in the ELSA, waves 1–7. For measures not administered at every wave, the brackets denote the wave of data collection

Demographic data	Consumption
Household membership	Housing (rent and mortgage)
Living relatives	Vehicle and durables ownership
Marital status	Fuel, leisure, clothing (2–7), food, health insurance
Ethnic group and country of birth	Transfers, charitable giving/child trust funds (2,4–7)
Educational qualifications	Expectations
Age completed full-time education	Mortality, employment, inheritances, and bequests
Occupation of main carer when respondent was 14 years old	Income
Parents age and cause of death	Adequacy
Income and assets	Ability to work
Earnings	Movement into nursing home (2, 6, 7)
State benefits	Perceived financial position (2–5)
Sources of income	Future housing and care needs (6,7)
Financial and physical assets	Paying for care and knowledge of care funding (7)
Primary housing wealth and mortgage debt	Health
Business wealth	Self-reported health
Debt	Disability and mobility; aids, sources of help, who pays
Life insurance	Eyesight and hearing (self-report)
Lifetime receipt of inheritance and gifts (6,7)	Objective HearCheck hearing test (7)
Pensions	Dental health (3,5,7)
Current pension plan and past pension details	Physician-diagnosed conditions (self-report)
Current contributions	Falls, fractures, pain and joint replacements
Accrued pension wealth (self-reported)	Urinary incontinence and bowel incontinence (6,7)
Knowledge of female state pension age (3–7)	Menopause (4–7)
Knowledge of male state pension age (6,7)	Sexual function and attitude (6)
State pension deferral (4–7)	Cancer screening (5, 6,7)
Employment	Polypharmacy (6)
Job details, normal pay and hours	Psychiatric and emotional problems
Health and work disability (2–7)	General health questionnaire (GHQ-12)
Age and reasons for retirement if retired	CES-D depression scale
Employer name and permission to contact	Health behaviors
Desired, offered, and requested workplace adaptations (2–7)	Physical activity – in general and at work
Social and civic participation	Alcohol consumption
Provision of unpaid help	Smoking status and history
Informal caregiving and volunteering	Consumption of fruit and vegetables (3–7)
Civic, social, and cultural participation	Sleep duration and disturbance (4,6)
Accessing local amenities and services (1–2,4–7)	Cognitive function
TV watching (4–6)	Memory: word list recall, immediate and delayed recall
Social networks and support	Memory: prospective (1–5)
Social isolation and loneliness	Executive function: letter cancellation – accuracy and speed of mental processing (1–5)
Transport	Executive function: word finding (1–5 and 7)
Social capital (1, 3,7)	Numerical ability (1,4,6,7)
Perceived discrimination (5)	Literacy (2,5,6,7)
Religiosity (5)	Fluid intelligence (6)
Digital inclusion (6,7)	Backward counting from 20 (7)
Psychosocial factors	Serial 7s counting backward from 100 (7)
Control and demand	Naming objects (7)
Effort–reward balance (2–7)	Quality of cognitive interview (interviewers assessment)
Subjective social status	Proxy interview of cognitive function – IQCODE scale (2–7)
Age at which middle age ends and old age begins (1,3,7)	Physical examination and performance
Self-perceived age (2,4,6,7) and desired ages (2,4)	Walking speed (for ages 60 and over)
Experience and perceptions of aging ()	Height and weight; waist and hip circumference (2,4,6)
Sense of collectiveness (4)	Blood pressure
Altruism (4)	Lung function
Pet ownership (5)	Chair stands; balance, leg raises, and grip strength (2,4,6)

(continued)

English Longitudinal Study of Aging (ELSA), Table 1 (continued)

Psychological and social well-being Quality of life (CASP-19) Satisfaction with life scale – (2–7) Ryff well-being scale (2 subsample) Positive affect (5) –6? Personality (5) Time use and affect (6,7) ONS well-being questions (6,7)	Blood assays DNA extraction and storage (2,4,6) Total LDL and HDL cholesterol and triglycerides (2,4,6) C-reactive protein, fibrinogen (2,4,6) Glucose, glycated hemoglobin (2,4,6) Hemoglobin and ferritin (2,4,6) White blood cell count (4,6) IGF-1, DHEAS (4) Vitamin D (6) Biological samples: Cortisol – from hair (6), from saliva (2,4)
--	--

The participant is asked to indicate when they hear a beep, and a detection threshold is recorded.

Financial Circumstances Module

ELSA captures detailed information on all aspects of the household budget and on economic circumstances including wealth holdings, household income, pensions, consumption, future expectations, employment, and retirement and work disability (see Table 1). In an aging world, where individual pension provision is becoming an increasingly important issue and more complex decisions need to be made at increasingly older ages, it is vital that individuals are able to understand the financial choices available to them in terms of savings, annuitization, insurance, and other related choices. Using these data, it has been shown that numeracy levels are strongly correlated with knowledge and understanding of pension arrangements, perceived financial security, measures of retirement saving, and investment portfolios, even after controlling for factors such as cognitive ability and educational qualifications. This suggests that simple retirement planning information could be beneficial to low-numeracy and low-education adult groups (Banks and Oldfield 2006).

Engagement of older adults in paid work is becoming a policy issue of major importance, in part because of the economic pressures of an aging population. ELSA captures details on many aspects of employment including current work status, types of work performed, and reasons for remaining in or for leaving work. The study also contains questions on whether health problems limit the respondent's ability to carry out paid work and the level of physical activity

required to carry out a current job. It is not only through paid work that older adults contribute to society as many partake in productive activities such as volunteering and caring and details of these activities are also captured in ELSA.

In recent years, there has been an increasing focus on the wealth holdings of older people, especially with respect to different types of costs that older adults will face, such as funding their future retirement needs and payment for long-term care. To help understand these issues, a new set of questions on perception of social care were added to the existing social care questions at wave 7 and included questions on whether respondents expect to need formal social care at home, whether they expect to pay for it, and their knowledge of care funding.

Cognitive Function Module

The cognitive measures in ELSA are designed to assess cognitive ability across a number of dimensions, including learning and memory, word-finding ability, executive function, speed of processing, and numerical ability. At wave 7, the cognitive function questions were adapted to temporarily remove a measure of fluid intelligence and to add questions to identify early signs of dementia. New measures of cognitive function, taken from the mini-mental state examination were added at wave 7, which involved asking the respondent to count backward in ones from 20, to count backward in sevens from 100, and to name items and people from a standardized description. Cognitive test scores used in ELSA have been demonstrated to indicate risk of death from a number of chronic diseases (Batty et al. 2016).

Psychosocial Measures Module

ELSA includes a significant number of measures related to psychological well-being, including scales for determining depression (CES-D), satisfaction with life (SWLS), and quality of life (CASP-19). Notably, these scales have been used in conjunction with other markers of health and physical performance in an attempt to understand the complex relationship well-being forms with physical health. High levels of well-being are a significant contributor to healthy aging, but maintaining positive well-being can present a challenge in older adults who are experiencing ill health, caring for a sick or disabled spouse, or suffering from bereavement. Higher levels of happiness and enjoyment have been found to be associated with reduced later life disability and mobility (Steptoe et al. 2014a), and increased pleasure and enjoyment of life have been linked to a reduced risk of incident frailty in ELSA participants (Gale et al. 2014). A sense of purpose and meaning in life has also been linked to increased survival (Steptoe et al. 2014b). It is clear that determinants of well-being in older adults extend beyond health concerns and higher levels of well-being have been reported in respondents who participate in social activities such as volunteering and paid work, providing that they felt adequately appreciated for their contributions (McMunn et al. 2009).

In addition, ELSA contains questions on social activities such as going to the museum, theater, cinema, and eating out and participation in organizations such as social clubs, religious groups, or committees. Data on the emotional closeness and amount of contact with a spouse or partner, children, and friends are also collected. It has been demonstrated that higher levels of social isolation, defined in terms of contact with family and friends and partaking in civic participation, is an independent predictor of survival (Steptoe et al. 2013b). ELSA collects information on the use of the Internet and email, and these measures have been linked to reductions in cognitive decline in older adults (Xavier et al. 2014). Questions on perceived discrimination were introduced to ELSA at wave 5. A recent study using data on perceived age discrimination revealed that individuals who

were older, less wealthy, and more educated and who had retired were more vulnerable to this type of perceived discrimination (Rippon et al. 2014).

Substudies

Objective Physical Activity

Self-reported measures of physical activity have been used to demonstrate that taking up physical activity in later life is associated with reduced risk of developing major chronic disease, depressive symptoms, and physical and cognitive impairment (Hamer et al. 2014). Physical activity measures based on self-report are limited because they rely on accurate recall and accurate reporting. Respondents often fail to take into account the totality of their activity throughout the day, thus the need for objective data. During wave 6, a subsample of 330 respondents were given wrist-worn accelerometers for 7 days so that objective measures of physical activity could be recorded. The data are currently being analyzed.

Risk Preferences

A risk module aimed at measuring participants' willingness to take risk and to delay reward was carried out in wave 5 on a subsample of 1060 ELSA respondents. The module involved two incentivized tasks and the chance to win small amounts of real prize money. The risk module was designed as a computer-assisted self-administered interview but with a computer-assisted personal interview (CAPI) for those who wanted, or needed, the interviewer to assist them with operating the laptop.

Dementia

The inclusion of an assessment of dementia in the sample is vital if ELSA is to contribute to the better understanding of cognitive impairment at older ages. ELSA will conduct interviews in 2017 with about 1,000 ELSA participants aged 65 and older who have previously participated in four to eight waves of data collection. Respondents will be asked to complete additional cognitive tests that will provide accurate information about

cognitive abilities applicable to the diagnosis of dementia and the identification of mild cognitive deterioration. The tests will match those administered in HRS and which are themselves derived from the Aging, Demographics, and Memory Study (ADAMS).

Retrospective Life History Interview

At wave 3, data from 7,855 participants were collected on upbringing, early life adversity, family structure, schooling, employment and earnings, parity and reproductive history, living conditions in residences at different stages of life, relationship with parents when they were a child, childhood health, smoking, and other important events in their lives. To aid recall of past events, a “Life History Calendar” was used to help individuals remember past circumstances more accurately. The aim of the interview was to collect data to understand the life course of respondents and to analyze associations between earlier life experiences and well-being, health, and economic circumstances in later life. A recent study that utilized these measures revealed that material poverty in childhood is linked to higher levels of depression, poorer memory, and slower walking speed in later adult life (Tampubolon 2015). A separate study has reported associations between early parenthood, larger family size, and poorer health outcomes in older adults (Grundy & Read 2015).

Anchoring Vignettes

Interpretation of measures across different groups within a population sample, or across national contexts, is problematic because different groups may interpret similar situations differently. To try and circumvent this problem, respondents were asked in wave 3 to complete supplementary self-completion questionnaires on health or work disability that contained anchoring vignettes. Respondents were first asked to rate, on a five-point scale, various aspects of their own circumstance; they were then asked to do the same thing

for a hypothetical person with the same background and age as the respondent. Differences between the ways respondents rated hypothetical persons compared with themselves were then examined. Anchoring vignettes have recently been used to show that cultural differences in terms of mental health norms explain some of the differences in self-reported depressive symptoms between respondents in ELSA, SHARE, and HRS (Mojtabai 2015).

ELSA Genome-Wide Association Study: It is seldom that large-scale population studies possess both genome-wide genotyping data as well as a large array of phenotypic data. The inclusion of such information in ELSA has great potential to augment what is already known about how genomic variation is linked to disease risk and how certain characteristics interact to modify genetic susceptibility. In 2013/2014, we used the Illumina Omni 2.5–8 chip (Illumina Inc, San Diego, Ca., USA) to perform genome-wide genotyping of around 2.5 million single nucleotide polymorphisms (SNPs) and related genomic features for approximately 7,400 ELSA participants. The same genotyping chip had previously been used in HRS, enabling direct comparisons of the ELSA and HRS samples to be carried out without the need for imputation-based meta-analysis. The ELSA GWAS data have been deposited in the European Genome-phenome Archive (EGA) and are available to *bona fide* researchers. Data access is regulated by the ELSA Genetic Data Access Committee (EGDAC). Applicants can request access to the ELSA GWAS data with or without linkage to phenotypic information or can apply to commission genotyping, because not all the SNPs have been genotyped.

Ethics: All participants gave written informed consent at the recruitment wave to participate in the study and have given separate written permissions to allow linkage of their data to administrative data sources. At each subsequent wave, the participants’ consent to participate was reaffirmed in writing. Telephone interviewees gave verbal consent to participate.

Ethical consent for the study was granted by the NHS-REC and by the University College London Research Ethics Committee.

Management of ELSA

From inception until 2014, the principal investigator of the study was Professor Sir Michael Marmot. In 2014, Professor Andrew Steptoe took over this role and is the current principal investigator and Professors James Banks and James Nazroo have been co-PIs of the study since its inception. Dr Nina Rogers manages the study. ELSA is a collaboration between the Department of Epidemiology and Public Health at University College London, the Institute for Fiscal Studies, the University of Manchester, and NatCen Social Research. The study has been supported in specialist areas by expert groups at the University of East Anglia, the University of Cambridge, the University of Exeter, and the University of Nottingham.

Funding

Around half of ELSA's funding since wave 1 has come from the US National Institute on Ageing (NIA). Various UK government departments have provided substantial amounts of funding to ELSA and current sponsors include the Department for Work and Pensions, the Department of Health, and the Department for Transport. Previous funders of the ELSA include the UK Department of Education and Skills, the Department for the Environment, Food and Rural Affairs (DEFRA), Her Majesty's Treasury, the Department of Trade and Industry, Her Majesty's Revenue and Customs (formerly the Inland Revenue), the Office of the Deputy Prime Minister, and the Office of National Statistics (ONS). The Economic and Social Research Council currently coordinate funding between the UK government funders and ELSA.

Entrepreneurship and Aging

Rebecca Funken and Michael M. Gielnik
Institute of Strategic HR Management, Leuphana
University of Lüneburg, Lüneburg, Germany

Synonyms

Elder entrepreneur; Gray entrepreneur; Second career entrepreneur; Senior entrepreneur; Third age entrepreneur

Definition

Older entrepreneurship is the discovery, evaluation, and exploitation of future goods and services when in age 50 and above.

Introduction

The world’s population will age dramatically. Increased life expectancy, declining fertility

rates, and the aging baby boom generation lead to a rising proportion of older people. By 2050, people aged 65 and above will constitute over 26% of the population in developed countries (Cohen 2003). The increase in older people will affect how and to what extent older people remain active participants in the workforce. A growing number of older people will stay in their jobs or remain economically active through other means (Kautonen et al. 2011). An interesting aspect of this changing involvement of older people in the economy is the phenomenon of the older entrepreneur (de Bruin and Dupuis 2003), also known as gray entrepreneur, senior entrepreneur, third age entrepreneur, elder entrepreneur, and second career entrepreneur (Weber and Schaper 2004).

Definition of Older Entrepreneurs

Entrepreneurship is defined as the discovery, evaluation, and exploitation of opportunities to create future goods and services (Shane and Venkataraman 2000). This definition implies that entrepreneurship is a process with different phases of discovering, evaluating, and exploiting rather than a single event (Baron and Shane 2008). Outcomes of entrepreneurship include new businesses (i.e., new venture creation) but also business growth and innovations when managing the business. Entrepreneurship can thus be a continuous, lifelong process.

There is no agreement in the literature about what age the term “older” comprises (Weber and Schaper 2004). A possible cutoff point could be the retirement age, which is around 65 in many countries (Weber and Schaper 2004). However, many issues that confront older people in the workforce are also relevant for people in their fifties (de Bruin and Dupuis 2003). Some authors include people as young as 45 years of age, whereas for others the term “older” includes people of 60 years and above (Weber and Schaper 2004). Most scholars opt for a midpoint and define older entrepreneurship as starting a new business or being self-employed with age 50 and above (Ainsworth 2015).

Older entrepreneurship can thus be defined as the discovery, evaluation, and exploitation of future goods and services when in age 50 and above.

It is important to distinguish older entrepreneurs from older business owner. Older entrepreneurs recognize and evaluate business opportunities and then exploit or implement these opportunities to create something new (Shane and Venkataraman 2000). They can do this in the start-up phase to create a new business or within an existing business to grow and develop this business. Older business owners, in contrast, are defined as owning and managing a business, but they do not necessarily act entrepreneurially in the sense of identifying, evaluating, and exploiting new business opportunities. Older business owners own the business because they have either founded the business themselves or gained ownership through purchase or inheritance of the business. When the business owners have founded the business themselves, they have acted entrepreneurially at that time. Business owners who do not continue to identify and exploit new opportunities are not considered to be entrepreneurs. Thus, the tasks of the older entrepreneur differ from the tasks of the older business owner. The older entrepreneur deals with the identification and exploitation of new opportunities, whereas the older business owner manages an operating business. The difference between the concept of older business owner and older entrepreneur is also evident in data on the prevalence of older entrepreneurship.

Prevalence of Older Entrepreneurship

In general, the probability of being a business owner increases with age (Blanchflower 2001). People are gradually more likely to become a business owner through founding, buying, or inheriting a business and thus “flow into entrepreneurship” (Blanchflower 2001). Once being self-employed, many business owners manage their businesses until retirement or at least for a time of several decades.

In contrast, the probability of being an entrepreneur and starting a new business follows an

inverse U-shape (Kautonen et al. 2014). Start-up activity gradually increases up to middle age and then decreases (Reynolds et al. 2004). The age group of 25–44 is more likely to start a business than any other age group (Reynolds et al. 2004). Consistently, the interest in becoming an entrepreneur decreases with age (Blanchflower 2001). Even though older people possess more human, social, and financial capital to start a business than younger people (Kautonen et al. 2011; Weber and Schaper 2004; Rogoff 2007; Singh and DeNoble 2003), they are less interested in self-employment (Blanchflower 2001). Hence, older people do not lack the skills or requirements for entrepreneurship but are less interested in entrepreneurship than younger people. Among workers in employment aged 50–75, only 14% would prefer to be self-employed (Curran and Blackburn 2001). The main reasons against self-employment are “no guarantee of income” (65%), “to late/feel to old” (60%), and “no job security” (50%) (Curran and Blackburn 2001).

Research on Motivation and Older Entrepreneurship

It is important to distinguish between research on older entrepreneurship as an outcome and research on older entrepreneurship as a predictor. The first line of research seeks to understand factors that drive or inhibit older people to engage in entrepreneurship. The second line of research examines older entrepreneurship as a predictor for performance measures. This paragraph describes the first line of research on older entrepreneurship as an outcome. The subsequent paragraph describes the second line of research on older entrepreneurship as a predictor.

Time Allocation Model

The time allocation model posits that the decreasing interest in entrepreneurship is the result of an age effect (Zacher and Gielnik 2014). The model suggests that the relative return of a business reduces as people become older. People allocate their time between income generating activities and leisure time to maximize the expected utility.

Waged labor results in an immediate income. In contrast, starting a new firm requires spending a certain number of weeks or months to exploit the opportunity. It takes time before a new firm is established and generates revenue. Consequently, the resulting income is delayed to some point in the future. As people age, the amount of time left is decreasing. As a result, people depreciate the value that is given to delayed income from entrepreneurship. Furthermore, with age the income from waged labor is increasing due to accumulated work experience. Thus, as people age, the opportunity costs to engage in entrepreneurship rise. Taken together, the delayed income from entrepreneurship and high opportunity costs compared to waged labor make it less attractive for older people to start a business.

Opportunity–Necessity Model

The opportunity–necessity model seeks to distinguish between different pathways that lead to entrepreneurship at older age (Rogoff 2007). According to the model, there are two different pathways why older people engage in entrepreneurship. Older people engage in entrepreneurship because they either have to (“necessity”) or want to (“opportunity”) (Rogoff 2007). The two different pathways are important to understand older people’s underlying motivation for entrepreneurship. There are economic and social reasons that make it necessary for older people to engage in entrepreneurship (“necessity pathway”). One of the main economic reasons for older people to engage in entrepreneurship is that retirement funds shrink with negative effects on older people’s wealth. To compensate for the shrinking retirement funds, older people remain motivated to earn a salary (de Bruin and Dupuis 2003). Self-employment then becomes an attractive option when older people are not able to stay in their jobs or find a new job. One of the main social reasons is that aging is often seen as a time of decline. Negative stereotypes against older workers are thus common in the population (de Bruin and Dupuis 2003). Age discriminatory practices in recruitment make it difficult for older people to remain in or enter the traditional labor market (Kautonen et al. 2011; Zacher and Gielnik

2014). Thus, starting a business might be a viable option for older people to stay economically active and have an income.

According to the opportunity argumentation, older people have characteristics that are favorable for entrepreneurship (Curran and Blackburn 2001). During their working lives, older people gain experience, acquire knowledge, build professional networks, and accumulate financial assets (Singh and DeNoble 2003). These factors facilitate discovering and exploiting opportunities.

Early Retirement: Self-Employment Model

Scholars describe in a deductive model the motivation of older workers who chose entrepreneurship as a transition into (or out of) retirement (Singh and DeNoble 2003). Entrepreneurship offers flexibility that makes it an attractive form of bridge employment for older workers. Entrepreneurs can more easily vary their hours and conditions of involvement (de Bruin and Dupuis 2003) and thus balance demands from personal life and work (Ainsworth 2015). Three types of early retirees that start a business are differentiated (Singh and DeNoble 2003). The “constrained entrepreneur” always wanted to become self-employed but was not able to follow this dream because of established or perceived constraints (e.g., liquidity, family). The “rational entrepreneur” compares his or her current career options with self-employment. This comparison is often based on financial reasoning but can also include non-monetary aspects (e.g., respect, fulfillment). The “reluctant entrepreneur” becomes self-employed because of a lack of employment opportunities on the traditional labor market.

Contingency Model

The contingency model posits that the assumption of a general decline of entrepreneurial activity with increasing age is too simplistic (Kautonen et al. 2014). Rather, older people’s engagement in entrepreneurship is dependent on contingency factors like perceived age norms (Kautonen et al. 2011) and type of business (Kautonen et al. 2014).

Age Norms. Perceived age norms influence entrepreneurial intentions of older people

(Kautonen et al. 2011). These age norms refer to perceiving entrepreneurship as socially acceptable at any age and especially at the third age. Three mechanisms transfer the effect of perceived age norms on entrepreneurial intentions (Kautonen et al. 2011). The effect of perceived age norms influences entrepreneurial intentions via how positive individual's attitudes toward entrepreneurship are, how the individual perceives the amount of support from family and friends, and how the individual perceives their own ability to become an entrepreneur (Kautonen et al. 2011).

Business Type. The relationship between age and the engagement in entrepreneurship depends on the type of business people pursue (Kautonen et al. 2014). Scholars identified three different types of businesses that differ regarding the risk involved and regarding the prevalence in different age groups (Kautonen et al. 2014). First, "owner-managers" are growth-oriented and have ambitions to hire others. Being growth-oriented and ambitious requires having a higher-risk propensity. With age, the risk propensity declines and with it the willingness to engage in entrepreneurship as an owner-manager. In accordance with the model of Lévesque and Minniti (2006), the relationship between age and entrepreneurship follows an inverse U-shape for owner-managers. Second, "self-employers" want employment for themselves but are not intending to invest in the business or hire others. Similar to waged labor, self-employment involves a low-risk propensity and profit is distributed rapidly. The relationship between age and entrepreneurship for self-employers is significantly different from that of owner-managers. The close resemblance to waged labor and the human capital of older people lead to an increase in self-employment with age even for people in their 60s. Third, "reluctant entrepreneurs" are pushed into entrepreneurship because of a shortage of other employment options. They mostly engage in low-risk forms of self-employment and have a shorter investment horizon. Research shows that for reluctant entrepreneurs, the effect on entrepreneurship is relatively unaffected by age. In summary, with increasing age, entrepreneurs shift from

growth-oriented businesses to low-risk businesses, such as simple forms of self-employment.

Research on Older Entrepreneurship and Performance

Research on older entrepreneurship as a predictor of performance suggests that the performance of older entrepreneurs differs from the performance of younger entrepreneurs (Weber and Schaper 2004). Being an older entrepreneur might be advantageous but can also be a possible constrain. Whether older entrepreneurs outperform younger entrepreneurs (or vice versa) depends on the performance measure like survival rate, growth, or family succession. It is important to note that in entrepreneurship research, all these performance measures are considered to be relevant.

Survival Rate. In general, survival rates among new businesses are relatively low with 63% of firms surviving after 4 years (Robb et al. 2010). The likelihood of success in the first 4 years significantly increases if the primary business owner is older than age 45 (Robb et al. 2010). Entrepreneurship scholars argue that older people possess human, social, and financial capital favorable for the survival of a business (Weber and Schaper 2004; Ainsworth 2015). During their working lives, older people gained professional knowledge and build up formal and informal networks that can increase the likelihood of survival (Weber and Schaper 2004). In addition, older people are more likely to have accumulated financial assets through prior employment which can be invested into the business (Singh and DeNoble 2003).

Growth. Even though businesses of older entrepreneurs have a higher survival rate (Robb et al. 2010), these businesses are less likely to grow (Autio 2007; Gielnik et al. 2012). The age group of 18–34 years starts 45% of growth-oriented start-ups compared to 22% in the age group of 45–64 years (Autio 2007). Furthermore, age is negatively related to business growth in terms of sales, profit, transaction volume, income, and number of employees (Gielnik et al. 2012). Scholars argue that the negative effect of age on

business growth is a result of a decrease in people's focus on opportunities (Gielnik et al. 2012). Focus on opportunities is a cognitive–motivational construct that describes how many new goals, plans, options, and opportunities people believe to have in their personal future (Gielnik et al. 2012). Research showed that companies with CEOs high in focus on opportunities increased their number of employees on average by 2.24 employees over a period of 4 years, while companies with CEOs low in focus on opportunities remained with the same number of employees over this time period. Similarly, companies with CEOs high in focus on opportunities increased their sales level by 38% percent over 4 years, while companies with CEOs low in focus on opportunities did not change their sales level over this period (Gielnik et al. 2012). With age several individual and contextual factors negatively influence people's focus on opportunities. Individual capabilities (e.g., information processing capabilities), which are important to maintain a focus on opportunities, decrease with age. In addition, contextual factors like age-related norms and environmental constraints may lower people's focus on opportunities. However, the decline in focus on opportunities and venture growth is not inevitable (Gielnik et al. 2012). Mental health buffers the negative effect of age on people's focus on opportunities. This means that for business owners who remain in good mental health, age does not have a negative effect on their focus on opportunities and business growth.

Family Succession. With age, family succession becomes more important for business owners (Zacher et al. 2012). Age is often seen as a general time of decline and withdrawal (de Bruin and Dupuis 2003). According to the socioemotional selectivity theory (Carstensen et al. 1999), age is not simply a matter of decline but can be considered in terms of shifting goal priorities. With increasing age, people are more aware that time is limited. As a consequence, goal priorities shift from advancing one's own career to passing on knowledge and skills to the younger generation (Zacher et al. 2012). With increasing age, family business owners increase in generativity which

means that they direct their focus to generative motives (Zacher et al. 2012). Older family business owners focus less on their own career goals, occupational gains, or accomplishments and direct their focus to developing and guiding members of the younger generation (e.g., their children or grandchildren) in the family business (Zacher et al. 2012). Older business owners' generativity is an important mechanism in the family succession process. Generativity explains why older family business owners are more successful in finding a successor and in smoothly managing the succession process (Zacher et al. 2012).

Conclusion

The topic entrepreneurship and aging gains more and more attention because of the ongoing sociodemographic changes in our society. There is no clear-cut relationship between age and entrepreneurship, but people's ontogenetic development has benefits as well as drawbacks for entrepreneurship. Factors that influence whether or not age positively affects entrepreneurship can be found on the cultural/societal level, the firm level, and the individual level. Thus, a comprehensive approach taking into account all levels is necessary to fully understand the relationship between age and entrepreneurship.

Definition

Focusing on environmental influences on aging and behavior, this entry particularly addresses theories that help to describe, explain, and modify/optimize the psychological relationship between the aging person and his/her physical environment.

Introduction

More than four decades ago, (Lawton and Nahemow 1973) conceptualized the maintenance and augmentation of positive affect, the avoidance of negative affect, and the adaptation in later life at large as a dynamic that largely depends on the existing competence of an aging individual (person variable, P) and the environment (E) in which the individual is operating. The fundamental idea that contexts (and not merely genes, physical-biological conditions, or personality factors) may drive aging processes and outcomes has a long-standing tradition in social gerontology

and its emphasis on social relations and the social contexts of aging. However, the role of the immediate physical, spatial, and technical environment put forward by Lawton and Nahemow's work has largely been neglected in geropsychological research (e.g., Wahl 2001; Wahl et al. 2012). This is surprising, because in child and adolescent psychology (Bronfenbrenner 1999), as in life span developmental science at large, co-construction, the assumption that developing individuals are shaped by contexts and vice versa, always has been a widely accepted view (Valsiner 1994; Youniss 1987). Going further, it is important to argue that – particularly in its early and late phase – the human life span is highly sensitive if not vulnerable to environmental input and P-E interactions, including the physical component of the environment.

Research targeting the relationship between the environment and the aging individual has had a strong link with psychology from the beginning (e.g., Lawton 1977; Lawton and Nahemow 1973; Wahl 2001), although it has also been seen as an important interdisciplinary area. Therefore, terms such as *environmental gerontology* and *ecology of aging* used in this entry are intended to emphasize the strong behavioral component of the field and its role within geropsychology.

A Case History: When Aging in Place Fails

Ms. A is an 89-year-old woman who lives in her medium-sized house in a small, urban community in Kansas. She had been married for 66 years to her husband Will, who passed away 3 years ago. Ms. A has a daughter living with her family near NYC, which is rather far away; no other relatives live closer than 4 h away by car. However, social support conditions are working well; her neighbors and some friends provide help when needed. Although Ms. A has good health overall, significant cognitive decline started about 2 years ago, during which substantial mobility and vision impairment have occurred. Ms. A increasingly has to struggle with her place and enjoys it as her place in the world. For example, she now

experiences her home, neighborhood, and spatial infrastructure for the first time in life as a barrier: She now has anxiety when using the staircase, the bathroom, and the kitchen. The garden no longer is “her” garden and indeed is now unused, and driving the car evokes feelings of insecurity and incompetence, but driving is necessary to maintaining independence. Dealing with her physical-spatial living situation over the next 2 years increasingly impacts her daily routine and negatively affects her well-being and feelings of autonomy, with the latter belonging to the things she always was very proud of in her life. It also becomes increasingly difficult to keep her informal support network going, and due to ongoing cognitive decline, she is now entering a phase in life in which “full control” in some necessary tasks is no longer possible. One question becomes an intrusive one: “How long will I be able to tolerate this struggle with my place and indeed survive the struggle mentally in good shape?” At the age of 93 years, she will have arranged, together with her daughter, relocation to a nursing facility located 20 miles from her hometown. “Her” place and long-standing and highly valued day-to-day social interactions are left behind.

One may ask what would have happened to Ms. A in another physical setup (e.g., no large distance to next shopping mall, staircase, optimal housing modifications, installation of a computer with Skype and e-mail possibilities, etc.). One may also ask what it likely meant to Ms. A to undertake this relocation and spend her last years at a different place than the one in which she lived for decades. These are key questions of an environmental perspective on aging, as well as of late-life development at large. Let's follow these questions based on a treatise of a number of P-E concepts and theories and a selection of empirical findings.

Fundamental Principles of Psychological Aging and the Environment

Three principles build the cornerstones of environmental perspectives on aging: (1) importance of P-E transaction and developmental

co-construction, (2) importance of explicitly considering the environment with a focus on the physical-spatial dimension, and (3) importance of optimizing ecological validity in research. First, the classic formula dating back to German psychologist Kurt Lewin – that behavior is a function of the person’s as well as the environment’s characteristics ($B = f[P,E]$) – has found a central place in the social and behavioral sciences; aging is no exception. Environmental gerontology also has close affinity with *environmental psychology*, in which the concept of “person-environment transaction” has been promoted as a key issue (Altman and Rogoff 1987). A major assumption is that it is difficult – if not impossible – to separate P from E and that the understanding of an ongoing complex and mutual shaping of P and E throughout the life span is adequate. Moreover, it may be that this intimate intertwining of P and E grows along the life span and may indeed reach its climax in old and very old age (Zingmark et al. 1995). Furthermore, life span development is seen as a never-ending sequence of ecological transitions in which new P-E territories are continuously conquered, while other P-E territories are left behind. A major transition in late life (see again Ms. A) is the transition to a sheltered environment, such as a nursing home.

Second, Powell M. Lawton (1977), a key figure in the psychology of aging and the inauguration of environmental gerontology, has defined the environment in the first edition of the *Handbook of the Psychology of Aging* very broadly; this definition includes social others and social groups, as well as all its physical components (the natural or man-made ones). However, the predominant contribution of environmental gerontology to geropsychology can be seen in its emphasis on the physical and spatial environment (Wahl 2001; Wahl et al. 2004, 2012) such as features of the objective home environment (e.g., lighting in kitchen, barriers in bathroom) and distance between one’s home and public transport. Wahl and Gitlin (2007) have suggested the term *physical-social environment* to address the issue that the physical component of the environment is hard to separate from its social component and vice versa (see also Wahl and Lang 2004).

For example, a certain space infrastructure (e.g., distance between rooms) in a nursing home may provoke or hinder social communication (see already Lawton’s “environmental docility hypothesis”; Lawton 1977, 1982). Third, environmental gerontology always put much emphasis on the need to enhance ecological validity in psychological aging research (e.g., Wahl 2001). Focusing on issues such as under which conditions older adults are “feeling at home” (Oswald and Wahl 2005) or offering a detailed description of the role of environmental barriers in the home or immediate surrounding directly brings research to the daily ecology of old age. More generally put, environmental gerontology’s argument is that older adults always operate in naturally occurring physical-social environments; therefore, reconstructing daily ecologies of aging must have a high priority. It is interesting to mention in this context that the issue of ecological validity seems to have increased in importance at large in geropsychology in the past two decades or so, via event-sampling in situ research strategies and ambulatory-assessment strategies (Hoppmann and Riediger 2009).

Mission of Environmental Gerontology within Geropsychology

In light of the three principles outlined in the previous section, the overarching aim of environmental gerontology is to describe, explain, and modify/optimize the relationship between the aging person and his/her physical-social environment. With regard to *description*, environmental gerontology puts strong emphasis on day-to-day contexts of aging individuals, reinforcing the notion that daily ecology settings deserve strong attention in gerontological research. A major reason for this emphasis is that older people spend most of their time (i.e., about three-quarters of their daytime) in the home and immediate home environment (Baltes et al. 1999; Oswald and Wahl 2005). Furthermore, older individuals tend to live in the same place for a long period of time, typically for decades, not for years (Oswald and Wahl 2005). Such long-term living and aging at the

same location seems to evoke rich cognitive and affective ties to the place one lives, known in German as *Heimat* (homeland) – or, put in scholarly language, addressed as place identity and place attachment to the very specific genius loci of “my place.”

The phenomena to be *explained* in environmental gerontology are classic outcomes in aging research and gero-epidemiology, such as positive and negative affect (Lawton 1977), well-being (Oswald et al. 2011), and autonomy (Oswald and Wahl 2005; Oswald et al. 2007). Furthermore, there is a set of specific variables addressed by environmental gerontology theories and empirical studies, such as the emergence of feelings of being at home, place attachment (and detachment) processes, place identity, usefulness of one’s physical environment, and housing-related control beliefs (Oswald et al. 2007). Also, explaining the experience and outcome related with enduring change of space/place, such as transitions to long-term institutions and assisted living (but also from home to home), has been a classic area of environmental gerontology (e.g., Wahl and Oswald 2010).

Striving for *optimization* reflects the ambition of environmental gerontology to improve aging by means of “place improvement” or, as it also has been coined, “place therapy” (Wahl and Weisman 2003). Major examples include evidence-driven home modifications, adding to the development of new housing solutions for the diversity of aging individuals, or designing public spaces and “age-friendly” environments at large.

Established Theoretical Accounts and a Selection of Empirical Findings

Impact of Physical Environments

A classic view has been the Ecological Theory of Aging (ETA; Lawton 1982, 1989; Lawton and Nahemow 1973; Scheidt and Norris-Baker 2004). The basic assumption of this theory has been that the capacity to adapt behaviorally to existing physical-social environmental pressure profoundly decreases as people age, due to an increasing number of functional limitations.

Thus, older people need to react to environmental pressure in order to remain independent and feel well in terms of high positive affect and low negative affect (Lawton 1982). The ETA was criticized for portraying the role of the aging individual as too passive. Consequently, in a later extension of the ETA (Lawton 1989), the environmental proactivity hypothesis was introduced, which assumes that older adults are not simply “pressured” by their environments but that they also strive to change proactively environmental conditions according to their own needs and goal priorities in order to maintain independence and well-being. For example, new cohorts of older individuals seem to increasingly make goal-directed P-E transitions, such as moving to an assisted-living facility or closer (but not too close) to their families, in order to prevent being overwhelmed by environmental pressure in the foreseeable future.

The ETA has since gained considerable, though not consistent, empirical support (Scheidt and Norris-Baker 2004; Wahl and Oswald 2010). For example, Wahl et al. (2009) provided a literature analysis of all studies published between 1997 and 2006 in peer-reviewed journals, which addressed relationships between the physical home environment and endpoints such as activities of daily living, amount of help and support needed, and falls. A total of 21 studies found supportive or at least partially supportive evidence for substantial linkages between environmental barriers and hazards in the home and disability-related outcomes, while only four did not. The subset of studies also considering the fit or lack of fit between the aging persons’ functional limitations and the given physical barriers revealed the strongest relative linkages with disability-related outcomes. The drawback of the available body of empirical work is that most studies have been cross-sectional, thus not allowing any causal interpretation.

Role of Perceived Physical Environments

Major concepts in this area include place attachment, place identity, and the meaning of home. Theories on place attachment and place identity (Altman and Low 1992; Brown and Perkins

1992; Stedman 2002) point to a gamut of processes – operating when people form affective, cognitive, behavioral, and social bonds to the environment (Burholt and Naylor 2005) – transforming by this means “space” into “place” (Altman and Low 1992; Rowles and Watkins 2003). Often, these aspects of physical, social, and personal bonding are assessed by global attachment evaluations – e.g., on indoor versus outdoor place attachment (Oswald et al. 2005) – but there are also efforts using qualitative methodology to empirically approach place attachment and identity (Oswald and Wahl 2005).

Empirical research in this area, for example, supported the age-related increase of place attachment and place identity (Zingmark et al. 1995). Similarly, the work of Burholt and colleagues (e.g., Burholt and Naylor 2005), Scharf and colleagues (2005), and Peace (2005) provided evidence confirming that attachment to place is an important feature of quality of life in old age – particularly in old and very old individuals – underpinning core elements of the aging person such as self, identity, and quality of life. Aspects of meaning of home have gained particularly strong attention in the now-classic work of Rowles (1983) and Rubinstein (1989; see also Oswald and Wahl 2005).

Need for Simultaneous Consideration of Objective and Subjective Person-Physical Environment Relations

At the core of the framework suggested by Wahl et al. (2012) is the assumption that two processes, experience-driven P-E belonging and behavior-driven P-E agency, help to better understand and integrate existing P-E interchanges as people age. P-E belonging reflects a sense of positive connection with the physical-social environment (e.g., Bakan 1966; Baumeister and Leary 1995), while P-E agency refers to the process of becoming a change agent in one’s own life by means of intentional and proactive behaviors imposed on the physical-social environment (e.g., Bandura 1991).

In contrast, processes of P-E agency include the full range of goal-directed behaviors related to making use of the objective physical-social

environment, such as environment-related cognition and perceived control over the environment. These behaviors include reactive and proactive aspects of using, compensating, adapting, retrofitting, creating, and sustaining places, which is especially important in old age because of decreasing functional and cognitive capacity. The model also assumes that both P-E belonging and P-E agency must be considered in any qualification of P-E relations in later life.

Emerging empirical evidence for the model came from the ENABLE-AGE project, in which, for the first time, a maximum of indicators regarding P-E belonging as well as P-E agency have been assessed in parallel in advanced old-age individuals in a range of European countries (Iwarsson et al. 2007). As has been found, for example, P-E fit processes and housing-related control processes speaking to objective constellations of remaining competence and respective objective physical-social home environments – as well as P-E belonging processes – contributed to the prediction of endpoints such as autonomy, well-being, and depression (Oswald et al. 2007).

Most recently, Golant’s model of residential normalcy highlights subjective environmental experiences of residential comfort and mastery as well as related adaptive coping strategies to maintain or achieve residential normalcy in existing objective physical environments (Golant 2015). According to the model, if older people feel comfortable and in control of their environment at home, they have achieved residential normalcy and may no longer feel the need to change anything. However, if there is a perceived incongruence on the behavioral or experiential level, they perceive themselves as being out of their mastery and/or comfort zone. Consequently, they will try to re-achieve residential normalcy by ways of assimilative or accommodative coping strategies (Brandtstädter and Greve 1994) with respect to the immediate home environment.

Technology as a Major New Environment of Aging

The Internet, the “automation” of everyday technology (e.g., teller machines, ticket machines,

computer and telephone voice menus, car technology), and sensor- or GPS-based assistance are rapidly changing the way older people organize and experience their everyday life (e.g., Schulz et al. 2014). Future cohorts of older adults will benefit from a full range of technology products designed to support them as they “stay connected” and age well, despite accumulated loss experiences. This requires a full new set of empirical research including outcome studies that are currently only available to a limited extent (see again Schulz et al. 2014).

Reconsidering the Case of Ms. A and an Outlook

Environmental perspectives on aging can be considered a major part of geropsychology, able to add the role of the physical-social environment to the understanding of aging processes and outcomes. Furthermore, there is the need in many areas of geropsychology to pay full attention to technology environments (such as those dealing with social relations (e.g., social interaction via the Internet)), in the experience of vulnerable phases late in life (e.g., care robotics), as well as in developmental regulation at large (i.e., technology as a means to exert control over one’s environment; see again Valsiner 1994). Environmental gerontology may become an important helper in order to enrich these key areas of geropsychology.

Returning to Ms. A’s case, a sole “personal” view of her situation appears to be too narrow, in light of P-E theories. The place she lived for years had become a major part of her quality of life, and leaving this place late in life – likely close to the end of her life – appears, through the lens of environmental gerontology, to be a major loss and psychological threat. At the same time, making the best use of housing modifications and the installation of technological aids, such as Skype or the use of a robotic system, may have had the potential to prevent or significantly delay her relocation to a nursing home. On the other hand, the progression of her cognitive vulnerabilities may also have undermined the efficiency of even the

most optimized environment. In a sense, the situation of many older individuals, particularly those in advanced old age, appears in environmental gerontology terms as an ongoing “struggle with place.” In future cohorts, agency and proactive dealing with this struggle may be expected to increase, for example, via increased competencies to use all kinds of technology and accept a smart home environment. This may indeed also allow individuals to stay put, even in the face of major cognitive impairment.

It is a limitation that most ongoing longitudinal studies of aging only measure the physical and technical environment in which aging individuals live to a minor extent. Such a tendency toward “decontextualization” of aging seems problematic and hinders the empirical testing of environmental theories based on longitudinal data.

Definitions

The implications of the demographic change have long been known. Falling birthrates and a steady increase in life expectancy lead to considerable changes in the age structure of the workforce. Older employees will be more numerous in the future, and they will have to remain in employment for longer.

The purpose of designing workplaces for older employees is to give consideration to age-related impairments in their performance, whilst at the same time exploiting and fostering their particular abilities. Following analyses of the physiological changes and identification of the specific hazards faced by older people, design measures for workplaces for older employees were developed and implemented in practice for demonstration purposes at a selection of model workplaces. Work ability of older employees can moreover be retained and enhanced through well-planned personnel development.

In the end it is important not to focus especially on older employees. Each age or generation has its own capabilities and challenges which have to be considered in order to preserve a healthy workforce with high work ability.

Demographics is currently a buzzword, with its impact upon both the private lives of individuals and the world of work. Older people are becoming more numerous as a group, younger people less numerous. Two main trends are driving this development. Firstly, average life expectancy is rising; secondly, the birthrate is falling. For the world of work, this means that the average age of workforces is rising, and younger personnel are becoming increasingly hard to recruit. What are the consequences of this for preventive occupational safety and health activity? How can work be organized such that it can be performed equally well by younger and ageing workforces?

What Changes Can Be Seen in the Performance of Older Workers Over Their Working Lives, and What Are the Impacts of These Changes?

Views of older and ageing workers' performance differ widely. "Old and wise" was a phrase that

Ergonomics and Demographics, Fig. 1 Incapacity for work in days (data from the German Social Accident Insurance Institution for the woodworking industry (Holz-BG), 2006) and accidents per 1,000 equivalent

full-time workers (data from the Holz-BG, 2007). The intention here is not to compare the absolute figures (which are from different years), but to illustrate the trends within each of the two curves

reflected the value attached at one time to the wisdom and experience of age. By contrast, modern society is strongly biased towards youth, whether in advertising, in the recruitment of labour, or in the desire to remain young or at least to appear to be so.

Who exactly are these “older workers”? At what age does one become “older”: 45, 50, 60? And what actually changes?

Who Exactly Are the “Older” People?

Many publications or studies define older people as persons aged 45 (or 50) and over. By contrast, the gerontologist Andreas Kruse of the University of Heidelberg asserted in 2006 that ageing is a lifelong process beginning at birth and ending at death. Since this process is continual, and changes take a somewhat different form and occur at different times from one person to the next, it is virtually impossible, and also not constructive, to define a calendar age above which one belongs to the older demographic. A definition proposed by the Organisation for Economic Co-operation and Development (OECD) has gained currency, according to which older workers are persons “in the second half of their working lives, not yet in retirement and in good health.”

It is evident that “older workers” are an issue for the social insurance systems. The statistics show that although older people are ill less frequently, when they do fall ill they are incapacitated for work for longer periods than their younger counterparts (Fig. 1). This pattern also applies to absences from work owing to illnesses unrelated to work and to occupational accidents. Absences from work by older employees thus give rise to higher costs for both the health and accident insurance institutions.

What Changes Occur as People Get Older?

Any individual will notice for themselves that ageing is accompanied by numerous changes. Often, only characteristics or abilities that deteriorate are considered (deficit model; see for example (Landau and Weißert-Horn 2007)):

- *Age-related hearing loss*

Age-related hearing loss primarily affects the higher frequencies, which older persons are no longer able to discern as clearly as before.

- *Presbyopia*

Even people with good eyesight typically begin to need glasses when they reach the age of around 45. The useful field of vision that can

Ergonomics

and Demographics,

be viewed without movement of the head also drops with increasing age (Boyce 2003).

- *Need for more light*

Generally speaking, it is assumed that at the lower end of the illuminance range, older people require approximately twice the illuminance at their workplaces than younger people.

- *Decrease in physical performance*

This includes several aspects. Firstly, general agility deteriorates with rising age. Beyond that, muscular performance and maximum physical force also decrease. The cardiovascular system is also no longer as fit as it was in younger years.

However, Fig. 2 shows clearly that the decrease in physical force is not limited to older age. Human physical force peaks at the age of 20–25. If a person does not then train, their physical force deteriorates continuously. The average force values for women are consistently around 30% lower than those for men. There is therefore no clear point at which a person becomes “old” in terms of physical performance.

- *Increase in recovery time*

This increase is a direct consequence of the deterioration in physical performance: when the performance of the cardiovascular system is reduced, the body takes longer to reach the rest state (resting heart rate) following physical exertion.

- *Increase in reaction time*

Researchers have demonstrated that older people’s reactions are slower in certain situations. The differences are, however, in the

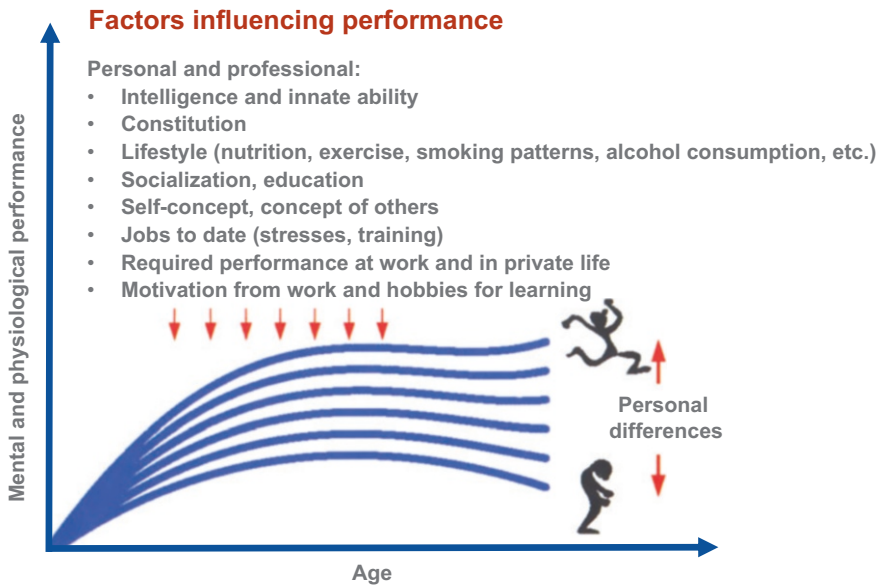

order of milliseconds. The question therefore arises as to what work situations exist in which the longer reaction time is actually relevant.

- *Deterioration in mental performance*

Different age groups exhibit differences in terms of memory and the ability to retrieve stored information. However, older people do not always perform less well than their younger counterparts. Older people are often better than younger people at retrieving consolidated knowledge stored in the long-term memory. Other abilities, such as the capacity for coping with stress and confidence in decision-making are also frequently better among older people.

Some of these abilities can be trained. It is known, for example, that regular training of muscles enables their performance to be maintained at a high level even as a person ages. Well-trained male athletes aged between 65 and 70 can still attain peak oxygen uptake values – a measure of the muscle’s endurance capacity – that exceed the average values for women across all ages (Hollmann and Hettinger 2000, p. 315).

Not every aspect of deteriorating physical performance can be compensated for by training. Sensory performance in particular is improved only marginally by training. It can, however, be supported by technical aids. In addition, the performance curves differ widely from one person to the next. The values shown in Fig. 2 are average values. A range of factors are at play here that assist in compensating for deficits in old age and

Ergonomics and Demographics, Fig. 3 Changes in the characteristics of human beings as they age occur at different points in time and vary strongly from one individual to the next (Modified in accordance with (Buck et al. 2002))

also in strengthening or developing new abilities. This shows that ageing has a strong biographical component and is also linked to an individual's employment history (Fig. 3).

Abilities that are enhanced in older age or are more and more attained until then include (competence model, refer for example to (Maintz 2003)):

- *Interpersonal skills*
Older people have more experience in dealing with other people. This includes dealing with customers, as well as colleagues.
- *Effective communication*
Owing to their greater social competence, older workers are often more successful in discussions with customers. Firstly, they are more familiar with their company's products or services; secondly, their long experience makes them more familiar with frequently recurring customer needs.
- *Experience*
Older people can deal with vocational challenges better owing not only to their occupational experience but also to their life experience as a whole. Occupational and life

experience can often be linked or are mutually beneficial.

- *Regained flexibility in use of time*
As a rule, older employees no longer have children at home to look after. They can therefore often manage their time more flexibly than young parents. Their commitments to caring for family members can, of course, restrict this flexibility.
- *Company loyalty*
Surveys have shown this to be a characteristic particularly valued by employers: where employees have had the opportunity to work continuously for a company over a long period of time and to experience recognition within it, their loyalty to their employer is also very strong. This can make them more reliable.

Strategies for Corporate Action Against the Backdrop of Demographic Change

Analysis of the deteriorating and improving abilities of ageing employees reveals key areas in which companies or employers can take measures to support and assist their staff. According to

Ilmarinen and Tempel (2002), companies can address the following four fields of action:

1. Promotion of good health
2. Training and skills development
3. HR management and corporate culture
4. Work design and organization

Design of workplaces suitable for older workers is not sufficient on its own. It is important that ageing be understood as a process. A corporate strategy that merely reacts to deficits as they arise is not effective. Mental and physical fitness in old age is the result of a lifelong process. Both the accident and health insurance institutions are on hand to provide expert advice to companies.

The example below from the field of action of work design and organization addresses the area of workplace design.

Design of Workplaces

In order for the health and performance of older workers to be retained within the work process and beyond, ergonomic measures at the workplace are absolutely essential. Firstly, attention must be paid to the optimum design of tools and work equipment; secondly, however, the proper use of these elements and health-conscious behavior on the part of the workers are relevant.

Constraints and Hazards at the Workplace

Section “[What Changes Can Be Seen in the Performance of Older Workers Over Their Working Lives, and What Are the Impacts of These Changes?](#)” showed that human beings change as they age. Many abilities remain virtually unaffected by the ageing process or mature only in the course of an individual’s life. Some skills, however, are largely or even completely lost. Examples of changes in old age that tend to make coping with the flow of work more difficult or that can lead to additional health risks include the following:

- Deteriorating vision
- Changes in the perception of noise and deteriorating hearing ability

- Deterioration in general agility
- Reduction in muscle performance, i.e., loss of physical strength
- Reduction in the performance of the cardiovascular system

Should vision deteriorate, poor or uneven lighting, for example, may lead to hazards and a higher accident risk (Zieschang and Freiberg 2006). Should the work require the exertion of substantial muscle force, the worker may be able to perform it only with restrictions, or not at all.

Ergonomic Workplace Design: Model Workplaces

Ergonomically, sound design of workplaces can mitigate or even fully compensate for age-related loss of performance. Good ergonomic design and the necessary adjustments to specific workplaces for the minimization of health risks also benefit younger coworkers at the same workplaces, since they increase occupational safety in general. Special workplaces for older workers, or sheltered workplaces, which are also more likely to be rejected by older workers owing to their special status, then become superfluous.

The workplaces should be designed in the first instance according to the following principles:

- Inherently sound workplace design in accordance with human engineering and ergonomic criteria results in only a small number of additional special measures being required in order for workplaces to be adapted to the needs of older employees.
- Younger employees also benefit from good ergonomic workplace design.
- The aim is not for special “workplaces for old people” or “sheltered workplaces” to be created. Younger workers are also to be able to work at the redesigned workplaces. Social exclusion resulting from age is thus prevented.
- Wherever possible, consideration should be given to the particular abilities of each individual employee.

Good ergonomic design and productivity should not and need not be mutually exclusive (Zieschang and Freiberg 2006). Various design elements are explained below with reference to model assembly and video display unit workplaces.

Model Workplace for an Assembly Task

The workplace was first to be designed according to good human engineering practice and equipped with basic elements. These include:

- An adequately dimensioned and nonreflective work surface
- Assembly trays located appropriately for the task within the worker's reach
- A height-adjustable work chair
- An adjustable footrest
- Adequate lighting

In order for materials and the corresponding tools to be matched more easily, it is advantageous for the assembly trays for the screws and the corresponding screwdriver bits to be color coded.

Various elements were then adapted (Fig. 4) that are geared to the needs of older workers and facilitate performance of the work or indeed make it possible in the first instance (Hoffmann and Zieschang 2005):

- *Design of the lighting*

Older workers require up to 100% more light. In order to meet this requirement, two lamps were installed for supplementary use as needed. The European standard EN 12464-1 (2003) requires a maintained illuminance value of 300 lx for moderately fine assembly tasks in the metal manufacturing and processing industries and of 500 lx for other industrial sectors. The lamp employed at the model workplace yields an average illuminance of 1,200 lx in the working area on the assembly bench. Switching on an additional lamp of the same type approximately doubles the illuminance to 2,300 lx. Since older workers are more sensitive to glare, it must be ensured that this is not caused by the installation of additional lamps.

Ergonomics and Demographics, Fig. 4 Model workplace for an assembly task (Source: IAG)

The combination of two lamps at the model workplace did not give rise to glare.

- *Design of the legibility*

An illustrated description of the individual assembly steps, with clearly structured diagrams, assists in understanding and learning the procedure and avoiding mistakes. High legibility was attained by means of a sufficiently large font, clear contrast, and large images.

- *Reducing the physical stress*

In order to relieve the locomotor system, a holding fixture was used for the power screwdriver, and trolleys provided for the delivery of materials to the workplace and roller conveyor belts for dispatch of the assembled workpieces. If possible, the weight of the loads to be manipulated was to be kept low.

A forearm rest provides relief and improves fine-motor performance. These rests can be fitted to the table and removed from it quickly and easily as required by the individual.

A holder, fitted to the edge of the assembly bench and removable at any time, into which the workpiece subassembly can be inserted during assembly, prevents the parts from slipping out of the worker's hand. Less stress is thereby placed upon the worker's motor functions, and assembly can be performed more quickly. Should no holder be present, a rubber surface can be used as an alternative to assist the worker in gripping small parts. The color selected for the surface should provide a clear contrast to the parts to be handled.

An assembly bench with electrical height adjustment enables each worker to adjust the bench to the working height most suitable for them. Where permitted by the task, the worker should alternate between a seated and standing position, thus preventing imbalanced posture and muscle tension. Should budgetary constraints or other reasons rule out purchase of a height-adjustable bench, other measures must be taken to ensure movement and variation in activity at the workplace.

Further organizational tasks such as collection of the components and transport of the finished subassembly to a location a few meters away also have the function of promoting more movement at the workplace. The worker is forced to stand up in order to put the workpiece aside. Although this entails additional time, the resulting movement at the workplace counters the onset of fatigue, which in turn has a positive influence upon productivity.

Model Workplace for VDU Tasks

This workplace was also designed in the first instance with consideration for ergonomic aspects and equipped with basic elements. These include:

- A nonreflective desktop of adequate area
- An office chair with height adjustment and armrests adjustable for height and width
- An LCD display
- A light-colored keyboard with dark characters
- A standard mouse
- Adequate general lighting

If an ergonomic sitting posture necessitates an adjustable footrest, one must also be provided.

The issue most frequently raised regarding the design of video display unit (VDU) workplaces for older employees is the relationship between age-related deterioration in vision and VDU work. Conditions in the work environment, such as noise, the climate, and the space requirement, must also be considered.

With increasing age, the lens of the eye becomes less elastic, resulting in a deterioration in its accommodative ability. The continual change in focus between screen, keyboard, and documents used for the work increases the strain upon the eyes, consequently leading to premature fatigue. Workers suffering from complaints such as impaired vision may attempt to compensate for them by adopting unfavorable sitting and head postures. Optical aids such as reading glasses, varifocal glasses, or contact lenses often fail to meet the particular requirements posed by a VDU workplace. Under certain circumstances, presbyopia (age-related vision impairments) can be corrected by means of suitable spectacles specially designed for use for work at video display units. In this case, the working conditions and viewing distances for the individual at the workplace must be determined beforehand, in addition to the examination by an eye specialist. The correct relationship between VDU work and recovery time or task alternation can also prevent excess strain upon the eyes.

The model workplace is adapted to the needs of older workers as follows (Fig. 5):

- *Design of the lighting*

Presbyopia and deteriorating ability to adapt to lighting conditions can be compensated for in part by increased illuminance. The European standard EN 12464-1 requires a maintained illuminance of 500 lx for VDU and office work (EN 12464-1 2003). A mean illuminance of 850 lx was measured at the model workplace with general room lighting. The value was increased to 1,600 lx by means of an additional asymmetrical workplace lamp suitable for VDU work. The glare effects caused by high illuminance values were

avoided by suitable design of the display (character display in positive video).

- *Noise abatement*

Older people are more easily disturbed by background noise than are young people. Where possible, sources of noise (such as printers, photocopiers, and fax machines) should be kept away from the workplace. Where several workplaces are located in a single room, telephone calls and conversations may constitute sources of noise. These can be controlled by sound-absorbing elements such as acoustic ceilings, front panels of cabinets, or suitable partitions.

- *Reducing the physical stress*

Asymmetric stress and a lack of movement, caused, for example, by a seated work position at a video display unit, accelerate the natural age-related wear of joints, intervertebral disks, and the spine. In order to promote movement, the model workplace was equipped with an electrically powered desk that permits work in either a seated or standing position. Alternatively, a high-level desk, either free-standing or adapted to the existing desk, can be used.

Organizational measures, such as locating the printer in an adjacent room or placing the telephone at a higher level in the immediate working area, for example on a side table, force the worker to stand up and exercise.

In order to ensure sufficient movement during sitting, swivel office chairs are recommended that ensure active sitting, i.e., alternation between sitting in forward, middle, and rearward positions.

Preventive Activity for All Age Groups

The purpose of designing workplaces for older workers is to give consideration to age-related impairments in their performance, while at the same time exploiting and fostering their particular abilities. Following analysis of the physiological changes in older people and identification of the specific hazards facing them, the design measures described in section “[Ergonomic Workplace Design: Model Workplaces](#)” for workplaces for older employees were developed and implemented in practice for demonstration purposes at various model workplaces. In the process, it was frequently observed that once a workplace had been designed with consideration for good ergonomic practice, only minor further adjustments to the particular needs of older employees were then needed. Workers in all age groups benefit from the preventive health benefits of ergonomic design. That all age groups benefit has also been shown by a study in which persons of different ages performed assembly tasks at a model workplace. The evaluation revealed no significant differences between the older and younger

workers. In other words, the workplace is equally well suited to persons of any age.

The model workplaces illustrate the need for ergonomic design, and can therefore be used for the purpose of training on the subject, and also in the context of consulting with companies.

However, good ergonomic design of workplaces also has its limits. Some occupations present considerable physical or mental stresses when performed over a long period of time and cannot be performed through to the statutory retirement age. How the work ability and health of the affected workers can be retained despite this is described in the next section.

Personnel Development for Occupations of Limited Duration: How Can Employability Be Assured Through a Change in Occupation?

Construction worker, metal production worker, nurse, forester – in many sectors of the economy, occupations are found that can be performed only for a limited duration. According to Behrens (1994), occupations of limited duration are those that, primarily for health reasons, cannot be performed by the majority of workers through to the statutory retirement age and often not even to the age of 50.

In the long term, the high stresses in these occupations lead to premature attrition and high levels of strain upon the workers. Older workers are particularly affected by the cumulative effects of the stresses in occupations of limited duration. They are often unable to work through to the statutory retirement age and must instead leave the occupation prematurely.

Two approaches are conceivable by which the worker's employability can be assured. The first approach involves all measures for extending the time spent working in the occupation in which the individual was trained (see section "Design of Workplaces"). This should always be the preferred approach. These measures may, however, not suffice, in which case the second approach

must be taken. The second approach involves the timely provision of advice and training for a change in task or occupation. The consulting concept developed for this purpose is based upon a number of empirical studies (Ulbricht and Jahn 2010; Jahn and Ulbricht 2011; Rahmfeld and Jahn 2012; Seibt and Seidler *in press*; Saifoulline and Jahn 2015). In these studies, a comprehensive risk analysis was performed for the model occupations of nurse, cleaner, construction worker, teacher, and metal caster. Experts with many years' vocational experience, individuals who had successfully changed vocation, occupational physicians, and managers with responsibility for personnel were interviewed in the course of these studies.

The consulting concept essentially comprises four steps:

1. Identification of early-warning indicators
2. Analysis of the risk factors in the current occupation
3. Requirements for a follow-on occupation
4. Provision of advice on a switch to a suitable occupation

Identification of Early-Warning Indicators

The effects of occupational stresses are often not recognized until an advanced stage and sometimes not until it is already too late. It is important that they be recognized and addressed early in order for retention of employability to be assured. The early-warning indicators are a sign of occupational health hazards and risks that could lead to the employee leaving his or her occupation prematurely.

Early Warnings from Superiors

Often, it is direct superiors who realize at an early stage that a worker's health and performance are suffering. A drop in work performance or more frequent absences from work may be indicators. The task of the worker's superior is to discuss with the worker what the reasons could be for the impaired work performance and health. Together with the worker, the superior examines whether the impairments could be counteracted by

changes in the organization or design of the work. It is then the superior's responsibility to implement these changes.

Such discussions with personnel can be conducted as part of the regular annual interviews, after 10 years' employment at the company, following changes in a worker's family situation, in the event of variations in performance, or when a worker indicates a need for them.

Early Warnings from Occupational Physicians

During occupational medical prophylaxis, occupational physicians are in a position to identify early-warning indicators of health impairments of occupational origin. A relationship based upon trust between the physician and the employee and between the physician and the company is a criterion for sound diagnosis and for effective, early consultation when a risk of work-related disease first becomes apparent.

The following diseases may be early-warning indicators in a metal production worker aged under 45:

- Degenerative diseases of the musculoskeletal system (e.g., signs of attrition in the spine region)
- Rheumatic diseases
- Coronary diseases, vascular changes
- Diseases of the respiratory tract (such as asthma)
- Mental disorders (such as depression)
- Sleep disorders

Analysis of the Risk Factors in the Current Occupation

If early-warning indicators are diagnosed during occupational medical examinations, the employee is offered a consultation. Responsibility for the consultation can be assigned to the occupational physician, the employee's immediate superior, the human resources department, the staff council, or the disability manager. The demands of the present job and sources of stresses in the family and social context are analyzed during the consultation. In addition,

the employee's skills and his or her career development goals are determined by a skills analysis.

Requirements for a Follow-On Occupation

The outcome of the requirements and skills analysis is a definition of the criteria to be met by an alternative job or occupation which eliminate the critical stresses associated with the existing job and which best match the employee's skills.

Provision of Advice on a Switch to a Suitable Occupation

Based upon the results of the analysis, the employee is advised on possible alternative jobs or alternative occupations. Alternative career paths are first developed in conjunction with the employee. Following the decision for a particular career, an integral part-time training concept is developed for preparation for the follow-on job/occupation. Career matrices can be used for this purpose. These include:

- A vertical career path within the company
- A sideways career move within the company
- A change to a job or occupation outside the company

An example of a career matrix is shown in Table 1 with reference to the metal sector.

Vertical career paths leading to management positions are forms of personnel development that, where permitted by the employee's performance, exploit his or her knowledge and experience and counteract health risks before health impairments arise. Such career paths should be opened to middle-aged employees in the company in particular.

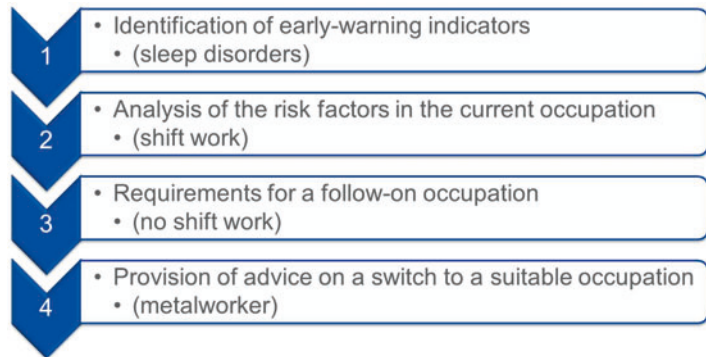

Sideways career moves channel the vocational knowledge and experience and permit their transfer between different departments, thus benefiting the company. The purpose of the change in job is often to prevent or minimize health risks. For large companies in particular, it is the easiest way of bringing about a change.

Figure 6 shows by way of example how this consulting approach is implemented.

Ergonomics and Demographics, Table 1 Vertical career paths and sideways career moves in companies with reference to the example of the metal sector

	Change in job	Change in occupation
In the company	<p>Vertical career path For example, as a foreman: Shift foreman Day foreman For example, as a technical employee: Quality assurance employee Production planning employee</p> <p>Sideways career move To early shift For example, as a metal caster in continuous casting</p>	<p>Vertical career path For example, in occupational medicine: Paramedic in the emergency services Employee in occupational medicine</p> <p>Sideways career move To early shift For example, as a mold builder in the mold workshop As an employee in the logistics department</p>
Outside the company	<p>Vertical career path For example, as a technical employee: Self-employment (own production company) Engineering degree</p>	<p>Sideways career move Return to previous occupation (e.g., truck driver, cook) In a new occupation (e.g., caretaker, metalworker, media designer)</p>

Ergonomics and Demographics, Fig. 6 A strongly simplified example of careers advice for a change of occupation (Saifoulline and Jahn 2015)

Example

1. The occupational medical examination of a metal caster in a casting plant identified sleep disorders as an early-warning indicator of significant impairments to well-being and in particular to cognitive performance.
2. The requirements analysis revealed the most critical factor for stress to be shift work against the background of the employee’s family obligations and his 10-year history of shift work.
3. The following requirements were defined for the follow-on occupation, in consideration of the employee’s many years of experience in the casting plant and his close affinity to the occupation:
 - No shift work
 - Flexible working hours, in order to reconcile work and family life
 - An additional qualification building upon existing vocational knowledge and experience
4. An alternative career in this case is training as a metalworker.

A Digital Guide for a Sideways Career Move

In the “Horizontal career changes” project, the approach described here for identification of a suitable occupation for a possible career change was extended to all skilled vocations. A digital

guide was developed in this project that provides companies with assistance in suitable personnel planning. Taking the form of an information portal, it supports affected individuals in the search for an alternative occupation that is as equivalent and as suitable as possible. An integrated ICT instrument contains a database of occupational profiles of all skilled vocations. A person looking for an alternative occupation creates their own personal profile by completing an electronic questionnaire. A specially developed algorithm compares the properties of the personal profile with those of the occupational profiles. The properties considered in the profiles can be divided into three categories: qualifications, preferences, and health. The result is a list of suitable alternative occupations, ranked by match level. The ICT instrument also permits detailed analysis of the results.

The alternative occupations proposed by the ICT instrument constitute preliminary information that cannot and should not replace a personal consultation. Rather, the digital guide is intended to draw attention to the problem of occupations of limited duration and to generate interest in a change of occupation. It is important that this then be followed by a personal consultation.

The digital guide is available for use free of charge on the Internet (in German only) at <http://wegweiser-berufsumstieg.de>.

Conclusion

Owing to the demographic shift, the proportion of older workers has been rising rapidly for some years and will continue to rise in the future. This increasingly shifts the focus to the retention of work ability. Through knowledge of the performance criteria for older employees, ergonomically optimized design of workplaces, and well-planned personnel development, work ability can be retained and enhanced. The beneficiaries are ultimately not only the ageing workforces but also younger employees.

Electroencephalogram; Evoked potentials

Definition

Event-related brain potentials (ERPs) represent the synchronous activity of populations of cortical neurons measured at the scalp. This entry considers age-related differences in ERPs related to language, episodic memory, and outcome processing.

Overview

Event-related brain potentials (ERPs) represent the synchronized activity of populations of cortical neurons measured noninvasively at the scalp that are time-locked to some event of interest (e.g., the onset of a stimulus or a button press) (Luck and Kappenman 2012). ERPs provide excellent temporal resolution to examine the unfolding of information processing over time that is superior to hemodynamic measures such as functional magnetic resonance imaging (fMRI) or near-infrared spectroscopy (NIRS). In contrast, the spatial resolution of ERPs is inferior to that of fMRI, although distributed source analysis in combination with multivariate statistical techniques may provide a reasonably precise method for estimating the cortical generators of the ERPs. The ERP technique has been widely used to study information processing related to perception, cognition, emotion, and action (Luck and Kappenman 2012).

ERPs have been used extensively to examine age-related differences in neural recruitment related to topics of interest to cognitive and social neuroscientists including age-related variation in the automaticity of sensory processing, the slowing of processing speed, the encoding and retrieval of episodic memories, and the monitoring of response conflict and errors (Friedman 2012). The direct measure of neural activity makes the technique well suited for studies of neurocognitive aging as issues related to age-related variation in the coupling of the vascular and neural systems inherent in fMRI are not an issue for ERP researchers. This entry provides an overview of the effects of aging on a number of ERP components related to cognitive information processing. For those interested in the effects of aging on ERPs associated with early sensory or perceptual processing, Friedman (Friedman 2012) provides an excellent review of this literature.

The P3s

The P3 or P300 is the most extensively studied ERP component that represents at least two

distinct components (i.e., P3a and P3b) that can be dissociated based upon their psychological characteristics, neural generators, and neuropharmacological underpinnings (Polich 2007). The components contributing to the P3 are most commonly observed in the oddball task that compares the ERPs elicited by a frequent standard stimulus relative to a lower-frequency target stimulus (i.e., oddball) and/or a task-irrelevant distractor stimulus. The P3a/P3b components are both observed with auditory, visual, and somatosensory stimulation, indicating that they reflect information processing beyond the primary sensory systems. The amplitude of the P3a is maximal over the frontal midline, while the amplitude of the P3b is maximal over the central–parietal midline (Polich 2007). The P3a commonly peaks between 250 and 400 ms after stimulus onset, while the P3b can peak from anytime time between 300 and 600 ms after stimulus onset depending upon task demands. The P3a is thought to reflect stimulus-driven attentional orienting, and the P3b is thought to reflect the allocation of attention to stimulus categorization that facilitates subsequent memory processing (Polich 2007). A P3a-like component has been described in a number of different paradigms resulting in various labels being applied to this component of the ERPs including the P3a, the novelty P300, and the no-go P300. Systematic comparison of the ERPs elicited in various paradigms using multivariate statistical techniques demonstrates that these three “components” in fact reflect the same phenomenon (Polich 2007). In complex tasks used in the cognitive aging literature, the ERPs measured at the scalp often reflect a mixture of the P3a, P3b, and other components that share temporal–spatial overlap. This makes it important to carefully consider aspects of paradigm design and/or utilize statistical techniques that allow one to tease apart the contribution of different components during study design and data analysis.

The P3 has been used extensively in studies examining the effects of aging on information processing (Friedman 2012). The underlying topography of the P3a and P3b appears to be similar in younger and older adults, although this may be obscured in the manifest scalp-recorded

ERPs. Consistent with the speed of processing theory of cognitive aging, the latency of the P3 increases in a fairly linear fashion from 20 to 80 years of age (Polich 1996). This effect may be somewhat stronger for auditory than visual stimuli, increase as target frequency decreases, and be greater for oddball tasks requiring counting responses relative to button presses. The age-related slowing observed for the P3 is greater and more consistently observed than the effect of aging on earlier ERP components related to sensory processing (Polich 1996), which may highlight differences between sensory and cognitive aging (Friedman 2012).

In addition to the age-related increase in the latency of the P3, a number of investigators have reported that the distribution of the P3 becomes more anterior in older adults relative to younger adults, reflecting an “anterior shift” in the oddball task (Fabiani et al. 1998). The anterior shift appears to be stronger for older adults with lower executive function than those with higher executive function. The reason for the anterior shift has been debated in the literature. It appears that the effect may at least partially result from the greater contribution of the P3a to the ERPs elicited by target stimuli in older adults than in younger adults, while the P3b distinguishing target from standard stimuli may be relatively preserved in later adulthood. Age-related differences in the contribution of the P3a and P3b elicited in the oddball task and other paradigms highlight the potential importance of using carefully designed paradigms in combination with appropriate statistical techniques to gain a clear understanding of the effects of aging on the latent ERP components that are manifest in the scalp-recorded ERPs.

The Medial Frontal Negativities

Over the last two decades, there has been an explosion of interest in transient negativities observed over the medial frontal region of the scalp in a number of different paradigms (Friedman 2012; Cavanagh and Frank 2014). These include the error-related negativity (ERN) that distinguishes errors from correct responses in

a variety of tasks, the N2 and medial frontal negativity (MFN) that distinguish incongruent trials from congruent trials in the flanker and Stroop tasks, and the feedback negativity (FN) or feedback-related negativity (FRN) that distinguishes gains from losses in gambling and reinforcement learning tasks. Each of these components has been linked to neural generators in the anterior cingulate cortex (ACC) in studies using both dipole source modeling and distributed source analysis. Consistent with these findings, converging evidence from studies using fMRI in humans and single-unit recording in primates has revealed neural activity related to choice errors, response conflict, and negative feedback in the ACC (Cavanagh and Frank 2014; Gehring et al. 2012).

The ERN represents a transient negativity over the medial frontal region of the scalp that in healthy younger adults is greater in amplitude for errors than correct responses (Gehring et al. 2012). The ERN typically peaks between 50 and 100 ms after an error is committed and reflects the activity of an endogenous error monitoring system, as feedback indicating the presence of the error is not required to elicit the component. The ERN is typically followed by the error positivity (i.e., Pe) that can extend from the frontal to the parietal region of the scalp and last for 300–500 ms after the response. The psychological processes represented by the ERN and Pe have been extensively debated, and current consensus appears to be that the ERN is related to the detection and possibly correction of the error or the restoration of goal-directed processing, while the Pe is related to conscious awareness that an error has occurred.

The effect of aging on the ERN has been studied in a variety of paradigms including choice response tasks, response compatibility tasks (e.g., flanker or Stroop task), and reinforcement learning tasks (Friedman 2012). In almost all cases, the amplitude of the ERN is reduced in older adults relative to younger adults when measured as the difference between errors and correct responses. The effect of aging on the ERN most commonly appears to result from a decrease in the

amplitude of the ERPs elicited by errors in older adults, although some evidence indicates that aging can also be associated with an increase in the amplitude correct-related negativity (CRN) in older adults that thereby reduces the difference in amplitude between errors and correct responses. Potential moderators of the effect of aging on the ERN have not been extensively explored, with some limited work demonstrating that the effect of aging is not sensitive to individual differences in physical fitness. Together, the results of the extant literature lead to the suggestion that aging is associated with a decrease in the efficiency of the endogenous error monitoring system that involves the ACC and is reflected by the ERN.

The MFN is elicited in a variety of stimulus–response compatibility tasks and reflects greater negativity for incongruent (incompatible) than congruent (compatible) trials that can be observed when the ERPs are locked to either stimulus or response onset (Friedman 2012). In the flanker and Simon tasks, the MFN or N2 tends to be greatest in amplitude between 200 and 300 ms after stimulus onset, while in the Stroop and Stroop-like tasks, the component is greatest in amplitude between 300 and 500 ms after stimulus onset. The difference in the timing of component across tasks is likely related to variation in the time course of information processing, as the flanker or Simon tasks tend to produce substantially shorter response times than the Stroop task.

The effect of aging on the MFN is less consistent than the effect of aging on the ERN, but there have also been fewer studies (Friedman 2012). In studies using a Simon-like task wherein the ERPs were locked to the response, the amplitude of the MFN was similar in younger and older adults (Friedman 2012). In contrast, in studies using the color-word or counting Stroop tasks wherein the ERPs were locked to stimulus onset, the amplitude of the MFN was attenuated in older adults relative to younger adults (West and Schwarz 2006). Given the existing literature, it is difficult to know whether variation in the effect of aging observed across studies results from differences in the cognitive processes measured by the tasks that were utilized in the various studies or the method

of data processing. There is some evidence that individual differences in executive function may moderate the effect of aging on the MFN observed in the Stroop task and that the presence of age-related differences in the MFN is sensitive to the amount of interference that is encountered in the task (Friedman 2012; West and Schwarb 2006). Gaining a greater understanding of how individual differences and task-related factors influence the effect of aging on the MFN is clearly one avenue for future research.

The FN represents a transient negativity over the frontal central region of the scalp that is greater in amplitude following negative outcomes (i.e., losses or negative feedback) than positive outcomes (i.e., gains or positive feedback) in gambling and reinforcement learning paradigms between 250 and 350 ms after feedback is presented (Cavanagh and Frank 2014). Studies examining the effect of aging on the FN have consistently revealed that the amplitude of this component is smaller in older adults than in younger adults and that this results from a reduction in the amplitude of the ERPs elicited by negative outcomes (Hämmerer et al. 2011). In various studies, the reduction in the amplitude of the FN in older adults has been associated with a mild decrement in associative learning, a tendency to switch following gains and losses, and a tendency to be more conservative than younger adults. These findings may indicate that an age-related reduction in the efficiency of feedback processing could have widespread effects on efficient information processing.

In summary, aging is associated with a reduction in the amplitude of medial frontal ERP activity related to error monitoring and feedback and conflict observed in a variety of paradigms. At the neurobiological level, these data may indicate that aging is associated with a decrease in the functional integrity of the ACC and related neural structures; at the psychological level, the effect of aging on the MFNs and the ACC may contribute to an age-related reduction in degree to which negative or undesirable outcomes guide future information processing or decision making.

Episodic Memory

ERPs have been used extensively to examine the neural correlates for encoding and retrieval processes related to episodic memory in studies of item recognition and source memory (Wilding and Ranganath 2012). Successful encoding is commonly associated with slow-wave activity over the frontal and parietal regions of the scalp that can be greater in amplitude over the left than right frontal regions. The left frontal slow-wave activity has been associated with semantic retrieval and integrative processing that facilitates episodic encoding. The ERP correlates of successful retrieval are somewhat dependent upon the task that is used to probe episodic memory. In recognition memory paradigms, there are three components that consistently distinguish remembered items (hits) from forgotten (misses) or new (correct rejections) items; these include the FN400, the left parietal old–new effect, and the right frontal slow wave. The NF400 is greatest in amplitude over the medial frontal region of the scalp and has been associated with item familiarity, being similar in amplitude for recognized old items regardless of whether or not the memory includes source information or recollection. The left parietal old–new effect represents greater positivity for old items than for new items between 400 and 600 ms after stimulus onset that is typically greater in amplitude when recognition is associated with source information or recollection. The right frontal slow wave is observed less consistently than the other two components and has been associated with monitoring or meta-memory processes. In paradigms requiring source judgments or cued recall, successful retrieval is commonly associated with slow-wave activity that can be broadly distributed over the scalp from the frontal to the parietal regions. As will become clear in the paragraphs that follow, the effect of aging on ERPs related to successful encoding and retrieval in episodic memory has been quite mixed with some studies revealing minimal age-related differences in ERP activity related to episodic memory, while others reveal dramatic reductions in amplitude in older adults or ERP components that are seemingly

unique to older adults (Friedman 2012; Friedman et al. 2007).

ERPs measured at encoding reveal slow-wave activity that distinguishes between stimuli that are later remembered relative to those that are later forgotten (Hämmerer et al. 2011). The amplitude of slow-wave activity associated with encoding verbal stimuli can be attenuated in older adults relative to younger adults, and this appears to be one source of age-related declines in episodic memory (Friedman 2012). Age-related differences in ERPs related to successful encoding may reflect the failure of older adults to spontaneously utilize processing that promotes recollection or to engage in sustained integrative semantic processing that facilitates later memory. Consistent with this idea, the amplitude of the subsequent memory effect in the ERPs is similar in amplitude when individuals encode natural scenes that are thought to foster relational processing during encoding.

There is considerable variability in the effect of aging on the ERP correlates of episodic memory in studies examining recognition (Hämmerer et al. 2011). A number of studies have reported that the amplitude of the FN400 is similar in younger and old adults, a finding that converges with the behavioral literature in demonstrating that familiarity is preserved in later adulthood (Friedman 2012). However, in other studies, the amplitude of the FN400 was reduced in older adults relative to younger adults, or there was no difference in the amplitude of the ERPs elicited by hits and correct rejections in the time window where the component was observed in younger adults (Wang et al. 2012). A similar pattern has been observed for the left parietal old–new effect. In some studies, the amplitude of the component is similar in younger and older adults when source information or recollection is associated with memory retrieval; however, in other studies the amplitude of the left parietal old–new effect is attenuated in older adults, or there is no difference between hits and correct rejections. One possible explanation for variation across studies is related to the demands of the memory test, as age-related differences appear to be reduced or absent when recollection or source information is required for a

successful memory judgment relative to when individuals could rely on familiarity to support successful recognition (Friedman 2012). Another possibility is that the mixed results result from variation in the characteristics of the older adults included in the samples across studies. Supporting this idea, limited work has demonstrated that individual differences in memory performance, education, and executive function may moderate the effect of aging on parietal ERPs related to episodic memory.

In addition to examining the effect of aging on the FN400 and left parietal old–new effect that are related to recognition memory in younger adults, some studies have also reported ERP components over the frontal region of the scalp associated with successful recognition that may be limited to older adults (Friedman 2012). There are not a sufficient number of studies that have examined ERPs unique to older adults to draw firm conclusion regarding the functional significance of this neural activity. The frontal ERP activity may be greater in amplitude for low-performing individuals relative to high-performing individuals, leading to the suggestion that it likely does not reflect compensatory recruitment that underpins preserved episodic memory in later adulthood.

Studies using ERPs consistently reveal two effects of aging on the neural correlates of source memory (Li et al. 2004). In younger adults, the retrieval of source information is associated with left parietal activity that resembles the old–new effect and slow-wave activity over the right frontal region. The amplitude of both of these components is attenuated in older adults, and in some studies the amplitude of the ERPs does not differ between old and new items in older adults. These findings are consistent with the age-related decline in source memory that is commonly observed in behavioral studies. In older adults, there is slow-wave activity extending from the frontal to parietal regions that reflects greater negativity when source information is retrieved relative to new items. This slow-wave activity is generally absent in younger adults. Some investigators have suggested that age-related differences in the ERP correlates of source memory may reflect variation in the type of information that

younger and older adults rely upon when making source judgments. Consistent with this idea, the left hemisphere ERP activity was reduced or eliminated in older adults when participants were instructed to use self-referential processing during encoding that presumably focused individuals to rely on a source of information known to promote episodic memory (Dulas et al. 2011).

Language

Since the discovery of the N400 in 1980, this and other ERP components (e.g., P600 and late frontal positivity) have been widely used to study various aspects of information processing related to language comprehension (Friedman 2012; Kutas and Federmeier 2011). ERPs provide an excellent tool for investigating relatively natural language process without the imposition of artificial response demands that are required when using some behavioral measures. The N400 represents a negativity in the ERPs over the central to parietal midline that varies in amplitude with the degree of fit between the meaning of a stimulus (i.e., word, picture) and the prior semantic context. Like the N400, the late frontal positivity is also sensitive to semantic aspects of information processing. This component may be related to ambiguity resolution as it is most pronounced when a word is inconsistent with a highly constrained semantic context. In contrast to the N400, the P600 represents a later positivity over the parietal region that is more sensitive to variation in syntactic variables rather than semantic features of the stimulus or linguistic context. The effect of aging on the P600 has only been investigated in a few studies, which appear to demonstrate that aging has little effect upon syntactic processing related to this component (Friedman 2012).

The effects of aging on the N400 and the linguistic variables that contribute to the generation of this component have been intensely investigated (Friedman 2012; Wlotko et al. 2010). With visual or auditory + visual stimuli, the latency of the N400 increases by about 1.5 ms per year, and its amplitude decreases by .05-.09 microvolts per year

between 20 and 80 years of age (Kutas and Iragui 1998). The effect of aging on the latency of the N400 may be reduced or eliminated with auditory presentation of connected speech. Importantly, this method of presentation does not eliminate the effect of aging on the amplitude of the N400. Understanding the nature of the effects of aging on the N400 may provide insight into the development of age-associated neuropathology, as variation in the amplitude of the N400 and P600 has been shown to predict conversion from mild cognitive impairment to dementia over a 3-year period (Olichney et al. 2008).

The reason for the age-related decrease in the amplitude of the N400 has been examined in a number of studies (Wlotko et al. 2010). There is general agreement that the effect of aging on the N400 does not result from an age-related decline in semantic memory (Friedman 2012). In contrast, the results of a number of studies lead to the suggestion that an age-related decline in the use of contextual information to form expectations or make predictions during online comprehension may account for the effect of aging on the N400 (Wlotko et al. 2010). Also, other research demonstrates that the effect of aging on the N400 may result from the coordinated recruitment of the left and right hemispheres to support processing of multiple meanings of words (i.e., dominant versus nondominant) or to integrate different features (i.e., concreteness versus imagery) of words (Wlotko et al. 2010). Consistent with this idea, the amplitude of the late frontal positivity related to ambiguity resolution is attenuated, or this component is absent, in older adults. This effect of aging on the late frontal positivity would be consistent with the idea that older adults generally do not activate multiple meanings of ambiguous words during online comprehension, thereby reducing the need for ambiguity resolution.

The effect of aging on language comprehension and particularly ambiguity resolution may be sensitive to individual differences in verbal fluency, an important executive function (Wlotko et al. 2010). Two studies have demonstrated that individual differences in verbal fluency are correlated with ERP amplitude over the frontal region of the scalp when individuals are required to

resolve ambiguity related to homographs or semantic incongruity, with high-fluency older adults being more similar to younger adults than low-fluency older adults. This effect appears to be relatively limited to frontal processes as it does not extend to the N400.

Conclusions

The literature reviewed in this entry clearly demonstrates the utility of using ERPs to examine the effects of aging on neural activity related to various aspects of cognition. In some instances, the ERP data converges nicely with the cognitive aging literature (e.g., the linear effect of aging on the latency of the P3 and N400 components) (Polich 1996; Kutas and Iragui 1998). In other instances, the ERP data reveal qualitative differences in neural recruitment between younger and older adults that may not be expected within the context of a cognitive behavioral perspective (e.g., age-related variation in left and right frontal slow-wave activity related to source memory) (Li et al. 2004). Also, there is growing evidence that various individual differences may moderate the effect of aging on neural recruitment reflected by ERPs (West and Schwarb 2006; Wlotko et al. 2010) and that understanding these differences may provide insight into the development of age-associated neurodegenerative disease (Olichney et al. 2008).

Everyday problem-solving

Definition

Everyday cognition refers to the ability of individuals to solve cognitively complex real-world or “everyday” problems. Specifically, studies of everyday cognition focus on assessing the real-world manifestation of basic cognitive abilities such as memory, reasoning, knowledge, and processing speed by testing older adults’ ability to solve problems using ecologically valid stimuli such as a medication label or food nutrition label.

Everyday Cognition and Everyday Problem-Solving

Terms such as “practical problem-solving” or “everyday/real-world problem-solving” are used interchangeably, and both are often applied to studies of everyday cognition. However, practical or everyday/real-world problem-solving refers to the larger domain of research focused on examining the ability of older adults to solve any kind of real-world problem. Everyday cognition refers to a subdomain of practical or everyday/real-world

problem-solving, which is characterized by cognitively complex real-world problems typically drawn from domains of instrumental daily functioning such as medication use, financial management, or food preparation. These types of problems typically have one “correct” answer, and therefore, the focus is on objective performance.

Another subdomain of practical or everyday/real-world problem-solving focuses on socio-emotional or affective problems that older adults might face in their daily lives (Blanchard-Fields 2009). Studies examining these socially and/or emotionally laden real-world problems typically focus on identifying the coping strategies employed in response to these problems. While socioemotional problem-solving is an important area of research, only everyday cognition is discussed here.

Theoretical Underpinnings

The study of everyday problem-solving in general and everyday cognition specifically began, in part, by questioning whether psychometric tests of cognition were appropriate assessments of older adults’ cognitive functioning (Denney 1989; Willis and Schaie 1986). Some argued that despite significant and normative age-related declines in many cognitive abilities, the majority of older adults retained their ability to effectively function in their daily lives. In addition, psychometric tests were designed for and validated in samples of children and young adults in an academic setting. Thus, for older adults, who are many years removed from school environments, psychometric tests may not be sensitive measures of cognitive competence. In addition, context-free psychometric tests might underestimate older adults’ ability because they do not allow them to call upon a lifetime of accumulated knowledge to solve the problem. That is, in their everyday lives, older adults can draw upon domain-relevant experiences to support and/or enhance their cognitive performance, and so relatively “a-contextual” laboratory-based assessments of cognition may produce an underestimation of true performance

competencies. These concerns with psychometric tests led some researchers to propose that measures comprised of real-world problems and stimuli that older adults might face in their daily lives might be a more accurate way to assess cognitive competency (Denney 1989; Willis and Schaie 1986).

The early everyday problem-solving research focused on identifying the kinds of problems older adults experienced in their everyday lives. These studies found that the everyday problems older adults often experienced fell into one of two overarching categories: socioemotional or instrumental. Early studies assessing individual differences in performance included both problem types, such as the seminal work by Denney (1989). However, as the field matured studies tended to focus on examining problem-solving either within instrumental domains of functioning (Willis and Schaie 1986) or socioemotional domains (Blanchard-Fields 2009).

Measuring Everyday Cognition

There are a number of different measures used to assess everyday cognition. An excellent overview of the various measures is provided by Law and colleagues (2012). Assessments of everyday cognition tend to have at least four things in common. First, as previously mentioned they generally focus on instrumental tasks of daily living which older adults must be able to solve effectively in order to remain independent. Items describe a real-world problem such as “You woke up this morning and your refrigerator is not working” and/or present real-world stimuli, such as a bank statement, and ask participants to solve problems based on those stimuli. Second, the real-world problem is clearly defined, so older participants know exactly what they are supposed to solve. For instance, there is little ambiguity as to what is the real-world problem in the following statement: “You woke up this morning and your refrigerator is not working.” Third, the desired goal or end state is also apparent from the problems (e.g., you want your refrigerator to work). Fourth, most measures are performance based rather than

self-report. Though some interesting findings have come from subjective measures of everyday cognition (Farias et al. 2013; Marshall et al. 2014), such assessments are often unrelated to objective performance (Tucker-Drob 2011).

Sources of Individual Differences in Everyday Cognition

Over the past 25 years, research on everyday cognition has primarily focused on identifying sources of individual differences in older adults’ performance. Not surprisingly, given the early rationale for studying everyday cognition, much of the research has centered on the mapping of age differences as well as understanding the underlying role basic cognitive abilities play in everyday cognitive performance.

Age-related Differences and Changes. As previously mentioned, the study of everyday cognition was, in part, predicated on the idea that psychometric measures of cognition might underestimate older adults’ true cognitive competency. Furthermore, performance on real-world measures of cognition might be preserved because elders can call upon domain-specific knowledge when solving real-world problems. Unfortunately, there has been very little evidence to support this assumption, with many cross-sectional studies reporting a negative relationship between age and everyday cognition (Allaire and Marsiske 1999; Burton et al. 2006; Diehl et al. 2005). In fact, results from a meta-analysis of over 33 age-comparative studies indicated that older adults performed significantly worse than middle-age and younger adults on measures of everyday problem-solving, particularly on items drawn from the instrumental domains of daily living (e.g., financial and medication management) (Thornton and Dumke 2005).

In addition to negative age differences, a number of longitudinal studies have found evidence of long-term decline in everyday cognitive functioning (Tucker-Drob 2011; Yam et al. 2014; Gross et al. 2011). Tucker-Drob reported that three different measures of everyday cognition exhibited significant and negative decline over a

5-year period (Tucker-Drob 2011). In a follow-up to that study, Yam and colleagues reported that everyday cognition exhibited a quadratic over a 10-year period (Yam et al. 2014). Specifically, an early increase in everyday cognitive performance due to practice effects was overshadowed by significant declines in performance over time.

Taken together, these findings suggest that older adults' ability to solve cognitively complex everyday problems is, in general, compromised with age. However, it is possible that in some situations, perhaps where tacit knowledge for the problem or context is strongly age-related, differences may be minimized. For instance, Artistic and colleagues reported that older adults performed better than younger age groups on everyday problems set within an "older adult context" (Artistic et al. 2010). Presumably, older adults benefited from their familiarity with the context of the problem and their domain-specific knowledge of the problem. Unfortunately, the authors did not adequately assess domain-specific knowledge. It is important to note that age is not an explanatory variable but merely an index of chronological time. That is, an individual's age does not cause declines in everyday cognition, but instead a more proximal predictor(s) associated with age is driving the declines. Additional research is still needed to understand what factors can explain the age-related differences and age-related declines in everyday cognitive functioning. One such explanatory construct is basic cognitive functioning.

Basic Abilities

Given that everyday cognition is characterized by the ability to solve *cognitively* complex real-world problems, it should come as no surprise that basic cognitive abilities provide the foundation for everyday cognitive performance. That is, everyday cognition can be considered the application of basic cognitive abilities to real-world problems such that an amalgam of basic abilities is responsible for cognitive performance within everyday contexts. Evidence from cross-sectional studies suggests that lower performance on basic ability tests

(e.g., inductive reasoning, memory, processing speed) is associated with lower everyday cognitive functioning (Allaire and Marsiske 1999; Burton et al. 2006; Diehl et al. 2005). In fact, Allaire and Marsiske reported that as much as 80% of the individual differences in everyday cognition were accounted for by basic cognitive abilities, particularly memory and inductive reasoning ability (Allaire and Marsiske 1999). Yen and colleagues reported that inductive reasoning and a factor representing learning and memory were both significantly related to everyday cognitive functioning, while processing speed was not related to everyday cognition (Yen et al. 2011). Informant-based subjective everyday cognition functioning is also significantly negatively related to neuropsychological clinical assessments of memory and executive functioning (Farias et al. 2013).

Evidence of the association between basic cognitive abilities and everyday cognition also comes from more recent longitudinal studies (Tucker-Drob 2011; Gross et al. 2011; Yam et al. 2014). Yam and colleagues found that 10-year decline in everyday cognition was not as dramatic as the decline observed for memory and speed (Yam et al. 2014). However, the negative trajectory for everyday cognition was greater than what was observed for verbal ability and was significantly similar to that of reasoning ability. In fact, reasoning accounted for 85% of the intercept and 96% of the slope variance in everyday cognition. Tucker-Drob reported that decline over 5 years in three different measures of everyday cognition was significantly related to decline in basic ability measures assessing reasoning, processing speed, and memory (Tucker-Drob 2011). In fact, a single latent change factor could significantly account for change in each of the basic ability and everyday cognition tests, suggesting that these declines are the "manifestation of a common underlying process." Further evidence of this common underlying process comes from Farias and colleagues (2013), who reported that lower total brain and hippocampus volume were related to worse everyday cognition (Farias et al. 2013).

Other Sources of Individual Differences. While the lion's share of research has focused on everyday cognition as it relates to age

and/or intellectual ability, some researchers have explored other sources of individual differences. For instance, markers of health such as blood pressure and number of chronic conditions have been associated with everyday cognition. For instance, Whitfield and colleagues found that the number of chronic conditions and perceived change in health status were significantly related to lower everyday cognitive performance even after controlling for demographic characteristics (Whitfield et al. 2004). In addition, lower blood pressure is associated with worse everyday cognition ability even after controlling for age and performance on tests of basic cognitive abilities. In addition to indices of physical health, higher levels of depression have been shown to be directly and indirectly (through basic cognitive abilities) associated with lower everyday cognitive performance (Yen et al. 2011). There is also evidence that depression is related to everyday cognition (Paterson et al. 2015). Higher scores on a standard measure of depression were significantly related to worse everyday cognitive functioning in older adults. The predictive salience of depression remained even after controlling for age, gender, and education.

Predictive Outcomes of Everyday Cognition

As previously discussed, early research on everyday cognition focused on cataloguing the problems older adults faced in their day-to-day lives. As the field developed, studies turned to exploring age differences and the association between basic cognitive abilities and everyday cognition. More recently, a growing group of researchers have turned to examining the extent to which everyday cognition predicts meaningful outcomes. If everyday cognition is thought to assess cognition in the real-world, then it should be strongly related to real-world outcomes. Moreover, everyday cognition was, in part, originally designed as an “alternative” to traditional measures of intelligence or cognitive functioning. Therefore, if it does not provide added value beyond basic cognitive abilities, then there may be no need to include

assessments of everyday cognition in addition to basic cognitive ability tests. It is important to note that when everyday cognition is used as a predictor, there should not be an assumption of causality. That is, everyday cognition does not necessarily cause the outcome, but it is related to explaining individual differences in the outcome.

One such outcome is mortality, where lower performance on measures of everyday cognition is uniquely related to a greater likelihood of death (Allaire and Willis 2006; Weatherbee and Allaire 2008). For instance, Weatherbee and Allaire reported that performance on a measure of everyday knowledge was a significant and unique predictor of death even after controlling for a number of basic cognitive abilities (Weatherbee and Allaire 2008). In another study, everyday cognition was a significant and unique predictor of nearness to death (Allaire and Willis 2006). Perhaps related to morality, older adults who performed better on measures of everyday cognition were more likely to remember to take their medications even after controlling for performance on basic cognitive ability tests (Neupert et al. 2011). Thus, performance on everyday cognition may be an indirect indicator of mortality risk, in that it can identify older adults who are likely to adhere to their health provider’s prescribed medication and/or treatment plan, which can sustain their health and quality of life and reduce their mortality risk. Not surprisingly, everyday cognition also serves as a unique predictor of older adults’ self-reported instrumental functioning (Allaire and Marsiske 2002; Allaire et al. 2009), accounting for all individual differences in subjective instrumental functioning associated with basic abilities and also adding unique explanatory power (Allaire and Marsiske 2002).

Cognitive Impairment. Everyday cognition is also used as a predictor of mild cognitive impairment (MCI) which is considered the transitional period between normal cognition and dementia. Cross-sectional studies of community-dwelling elders report that performance on various measures of everyday cognition significantly predicts impairment or MCI status even after controlling for performance on cognitive screening or basic cognitive ability measures (Allaire et al. 2009;

Burton et al. 2009; Allaire and Willis 2006). Allaire and colleagues reported that older adults with MCI performed significantly worse on the three instrumental subdomains of an everyday memory test and that performance on the subdomain assessing of financial management was a significant and unique predictor of MCI status even after controlling for a battery of basic cognitive ability tests (Allaire et al. 2009). Thomas and Marsiske reported that everyday cognitive performance was worse in older adults with amnesic MCI, then nonamnesic, and then unimpaired (Thomas and Marsiske 2014).

Studies from the clinical literature have also found that everyday cognition plays a central role in differentiating between impaired and nonimpaired older adults. For instance, a study using an informant and proxy subjective assessment of everyday cognition, while not ideal, found that items such as “remembering a few shopping items” or “balancing a checkbook” significantly discriminated MCI from non-MCI older adults (Marshall et al. 2014). In addition, this same study also found that older adults with poorer everyday cognition were more likely and more quickly to progress from normal to impaired status. However, this study did not control for basic cognitive abilities. Other studies have also reported that differences between MCI and non-MCI older adults are particularly salient when the everyday task is memory laden (Farias et al. 2013).

Interventions

Since the late 1970s, a considerable amount of research has focused on the extent to which older adults’ basic cognitive functioning is amenable to intervention. As part of this research, measures of everyday cognition have been used as outcome variables. Their use in outcome batteries is to determine if the cognitive training intervention impacts domains related to but still unique from the basic abilities which are the focus of the intervention. However, there is little evidence that interventions focused on improving basic cognitive abilities have a robust or reliable impact on older adults’

everyday cognition functioning. For instance, results from the ACTIVE study have suggested that while improvements in trained abilities are evident, these gains do not consistently transfer to measures of everyday cognition (e.g., Rebok et al. 2014).

Given this lack of transfer, some studies have examined whether everyday cognition is amenable to direct intervention. For example, Thomas and Marsiske (2014) examined the outcome of providing simple verbal instructions or prompts such as “look harder” or “try again” when a participant was unable to correctly answer a question on an everyday cognition test. The results suggested that prompts significantly improved performance. Promoted performance did not exhibit significant age-related decline like unprompted performance. Moreover, participants with MCI benefitted the most from prompts with prompted performance similar to that of the unprompted performance of non-MCI participants. Another study adapted the strategies used to train inductive reasoning ability and applied them to real-world or everyday problems (Williams et al. 2014). Participants from assisted living facilities that received this training experienced significant gains in everyday cognitive performance relative to participants that did not. In addition, these gains were maintained 3 months later.

Conclusion

With the burgeoning older adult population, there will be an increasing concern among older adults about experiencing cognitive impairment and, subsequent, loss of functional independence. Understanding the antecedent of and outcomes associated with an older adult’s ability to perform cognitively demanding real-world tasks is at the core of everyday cognition. Even though everyday cognition is correlated with basic abilities, it remains sufficiently distinct enough to warrant additional research. While studies have begun to point out that everyday cognition is a salient and unique predictor of important real-world outcomes, additional research is warranted to identify

modifiable determinants of impaired everyday cognition. Such research can be useful in designing successful interventional protocols to improve cognitive functioning and well-being.

Central executive; Controlled processing; Response inhibition; Set-shifting; Working memory updating

Definition

Executive functioning is an important concept in neuropsychology and broadly refers to our ability to plan and coordinate complex behavior. The term is used widely in describing performance on cognitive tasks that require planning, strategy use, self-regulation, focused attention, inhibition, and other supervisory functions.

Executive Functioning

Our executive functions allow us to organize the actions of lower-level cognitive processes in order to behave flexibly in the face of an ever-changing environment. A multitude of complex cognitive tasks have been developed to assess executive functioning, and healthy aging appears to impair performance on many of these measures. While it has often been proposed that executive functioning reflects the operation of a number of subprocesses, such as planning, strategy use, self-regulation, focused attention, and so on, the complex nature of the measures used to assess executive functioning has made this difficult to clearly establish. However, over the past two decades, a great deal of progress, using psychometric methods, has been made toward identifying core processes underlying executive functioning. The emerging view is that there are separable but interdependent components underlying performance of complex executive tasks. This approach has also been used to assess the effect of healthy aging on specific processes in order to better characterize the decline of executive functioning with age. Given the pervasive effect of age on cognition, much of this work has also attempted to establish whether the effect of age on specific functions is greater than would be expected given age-related decline in speed of processing. This entry does not aim at providing a comprehensive review of the topic; for such reviews see MacPherson et al. (2015), Jurado and Rosselli (2007) and Phillips and Henry (2008). Its aim is to briefly touch upon state-of-the-art issues in this field with emphasis on current theories of cognitive aging.

Fractionating Executive Functioning

In their highly influential paper, Baddeley and Hitch (1974) made the distinction between low-level storage buffers for verbal and visuospatial information and a higher-level controlling mechanism they termed the “central executive.” This executive component was said to coordinate the action of the “slave” storage systems and

allow flexible behavior in the face of constantly changing goals. Whether executive functioning reflects the action of a single general-purpose control system or multiple separable processes, working in concert, has since proven controversial. Neuropsychologists have developed a wide array of measures to assess executive functioning, and Table 1 provides a selective list of commonly used tasks. These measures are inherently complex, and, given this problem of task impurity, there is widespread disagreement as to what underlying abilities these tasks actually assess (MacPherson et al. 2015; Jurado and Rosselli 2007). Consequently, psychometric methods have proven useful in identifying potential core processes that support executive functioning. These methods assess patterns of shared variance between conceptually similar tasks and attempt to explain performance on an array of measures in terms of underlying, latent variables. The emerging view from this line of research is that the central executive can be fractionated into separable but highly interdependent executive processes (Jurado and Rosselli 2007; Miyake et al. 2000; Miyake and Friedman 2012).

In their review of the literature, Miyake and colleagues (2000) identified three executive functions, or processes, that are commonly referred to when explaining performance on measures of executive functioning. These three executive functions are as follows:

1. *Updating*: When information currently stored in working memory – the small amount of material that can be actively maintained in the face of concurrent processing – is no longer relevant to current goals, the space must be freed up via the removal of irrelevant items. This ability to clear and update working memory is crucial for the efficient use of this limited capacity workspace. Updating is typically assessed with tasks that require simultaneous storage and processing of information (see Table 1).
2. *Shifting*: In day-to-day life, it is rarely the case that one task can be completed without attention being diverted to another. This ability to switch between different mental sets necessitates that the appropriate rules for a given task are maintained and engaged/disengaged as required. Measures of shifting typically compare performance between conditions in which participants characterize stimuli according to a single rule, to conditions in which there are two or more rules to shift between (see Table 1). These measures of task switching are considered important indices of cognitive control.
3. *Inhibition*: Much of our behavior is automatic and based on well-learned responses to stimuli. However, it is often desirable to inhibit these prepotent responses if the automatic reaction is inappropriate. Typical assessments of this construct require speeded responses that run counter to well-learned stimulus–response mappings, for example, naming the color font in which the word BLUE is presented (see Table 1). Inhibition may also refer to the ability to ignore irrelevant information or the ability to resist the distracting effects of no-longer-relevant information, also known as proactive interference (Miyake and Friedman 2012).

Having identified these core executive functions in the literature, Miyake et al. (2000) administered a range of simplified executive functioning measures to a group of young, college-aged adults. Using latent variable modeling, they then assessed patterns of association between the different measures to examine whether their three proposed executive functions could be separated. A model separating the contributions of updating, shifting, and inhibition to performance on measures of executive functioning gave a better account of their data than a model with a single component. However, in the favored model, the correlations between the three components were moderate to large (0.42–0.63) suggesting that, while the three functions are separable, they are interconnected. What underlies this unity is very much up for debate, although it has been noted that the requirement to actively maintain task goals is a basic feature of all executive processes (Miyake and Friedman 2012).

The idea of separating updating, shifting, and inhibition has gained support from subsequent

Executive Functioning, Table 1 Commonly used measures of executive functioning

Measure	Description	Outcome measure(s)	Putative domains tapped
<i>Wisconsin card sorting test (WCST)</i>	Participants arrange cards, one at a time, into four piles. Cards can be sorted on the basis of multiple features (color, shape, number) but only one is the correct rule at any one time. Feedback is given after each card and the sorting rule changes without warning	The number of incorrectly sorted cards following a rule change. Referred to as the number of perseverative errors	Shifting (Miyake et al. (2000) found their shifting factor predicted performance on the WCST), inhibition, sustained attention
<i>Go/no-go</i>	Participants make a response (e.g., press a button) as quickly as possible if a certain condition is met (go trial; e.g., when an X is presented) but not otherwise (no-go trial; e.g., any other letter is presented). No-go trials are infrequent	Reaction time The number of hits (responses on go trials) and false alarms (responses on no-go trials)	Inhibition, goal maintenance (no-go rule)
<i>Verbal fluency</i>	Generate as many different words possible in a given time period. In the most common variants, participants generate words beginning with the same letter (phonemic fluency) or words belonging to the same category (semantic fluency)	The number of words produced. The number of repeated words (perseverative errors)	Inhibition, working memory updating, access to long-term memory (see Miyake and Friedman 2012)
<i>Working memory span</i>	This refers to a selection of tasks requiring simultaneous processing and storage of information. In operation span participants verify an equation (e.g., $(3 * 4) - 7 = 3?$) and then are given a word to store for later recall. Reading span is similar except that participant verifies a sentence then remembers the last word	The total number of items (e.g., words) recalled, or if an adaptive method is used the last level at which the participant met a criterion (e.g., two out of three trials correct)	Working memory updating, shifting
<i>The Stroop task</i>	In the most common variant of this task, participants must name the color font that a color label (e.g., BLUE) is presented in. This is compared to a baseline condition in which the participant either names the color of meaningless units (e.g., #####) or names color labels presented in black font	Reaction time difference between incongruent trials (the font matches the color label) and incongruent (mismatch) trials Difference between incongruent trials and baseline trials	Inhibition, cognitive control
<i>Trail-making task (TMT)</i>	These tasks are typically paper-and-pencil and require participants to connect randomly arranged dots. In a baseline version (Part A), the dots are connected in order of numeric label. In the comparison task (Part B), dots are connected by alternating between numeric and alphabetic labels (e.g., 1 → A → 2 → B...)	Difference between baseline and switching tests in terms of time taken to complete or number of errors made	Shifting, speed of processing

See Jurado and Rosselli (2007), Baddeley and Hitch (1974), and Lezak et al. (2012) (and the references therein) for more detail on each task and for additional tasks commonly used to assess executive functioning

studies using a similar individual differences approach (see Jurado and Rosselli 2007; Miyake and Friedman 2012 for reviews). Of course this list is an oversimplification, and there are other important processes that likely contribute to measures of executive functioning (see, e.g., Fisk and Sharp 2004; Lezak et al. 2012). In fact, a three-factor model would be insufficient to account for the large number of behavioral responses we can observe and measure either in healthy individuals or in those affected by brain diseases, which are thought to result from the function of an executive system (e.g., planning, selective attention, monitoring, decision-making, and others) (Lezak et al. 2012). Thus while conceptualizing executive functioning in terms of these separable but inter-related components is clearly a simplification, it provides a useful focus for discussing studies of the neural correlates and age-related decline of executive functions.

Neural Correlates of Executive Functioning

Damage to the frontal lobes has long been associated with profound behavioral changes. Patients with frontal lobe lesions can exhibit a range of deficits including an impaired ability to initiate goal-directed action and socially inappropriate, impulsive behavior (MacPherson et al. 2015; Lezak et al. 2012). Historically this has led to the suggestion that the frontal lobes, particularly prefrontal cortex, are the seat of executive control (see MacPherson et al. 2015 for a historical overview). However, further evidence from neuropsychology and neuroimaging studies has shown that this mapping of executive functions purely onto the frontal lobes is highly misleading. While measures of executive functioning are *sensitive* to frontal lobe lesions, they are certainly not *specific* as lesions to other areas have also been associated with impaired performance (MacPherson et al. 2015; Jurado and Rosselli 2007; Lezak et al. 2012). Studies assessing executive tasks along with neuroimaging measures, such as functional magnetic resonance imaging (fMRI) or positron-emission tomography (PET), have shed

further light on the neural correlates of executive functioning (Collette et al. 2006).

Early neuroimaging studies of executive functioning compared tasks presumed to pose some executive demand to baseline tasks without such demand and, in general, found activation of a wide-ranging network including both anterior and posterior areas (Collette et al. 2006). However, as multiple processes contribute to performance of executive tasks (Miyake et al. 2000), it is difficult to identify activation involved in, say, shifting with a single-task measure. Consequently, one notable study in the field used PET to measure regional cerebral blood flow (rCBF), while participants performed a range of tasks selected to place primary demand on updating, shifting, or inhibition (Collette et al. 2005). Consistent with earlier findings, Collette and colleagues (2005) found activation of a large frontoparietal network common to all tasks that they assessed. This network included the left superior parietal gyrus and right intraparietal sulcus along with regions of the dorsolateral prefrontal cortex.

As well as assessing common activation, the use of multiple measures allowed them to perform interaction analyses to identify areas disproportionately associated with one function relative to the others. This method of analysis suggested that the hypothetical processes of shifting, updating, and inhibition do exhibit separable patterns of activity. Performance of tasks involving the updating of working memory representations was associated with the activity in inferior frontal and frontopolar cortices as well as the intraparietal sulcus. Activity associated with inhibiting prepotent responses was found in the orbitofrontal cortex along with middle and superior frontal gyri. Finally, shifting was associated with greater rCBF to the left intraparietal sulcus.

While it is difficult to make strong conclusions on the basis of neuroimaging data, these findings complement the behavioral data nicely. There appear to be separable patterns of activity associated with the performance of tasks primarily assessing updating, shifting, and inhibition, as well as a large frontoparietal network engaged regardless of task demand.

Aging and Executive Functioning

Healthy adult aging is associated with reduced performance across a range of cognitive variables, and measures of executive functioning are no exception. For example, on the Wisconsin Card Sorting Test (WCST; see Table 1), older adults show an increased number of perseverative errors relative to younger adults (MacPherson et al. 2015; Phillips and Henry 2008). That is, following a change to the sorting rule, older adults are more likely to erroneously use the old rule to sort the cards and take longer to discover the new rule. Similarly, studies using the go/no-go task tend to find that older adults produce a greater number of errors (e.g., responses on no-go trials) and slower response times relative to younger groups (MacPherson et al. 2015; Phillips and Henry 2008). Further, structural neuroimaging studies have found evidence of pronounced deterioration of the frontoparietal network implicated in performance of many executive tasks. The frontal lobes in particular appear to be greatly affected by the aging process. Gray matter volume in the prefrontal cortex exhibits pronounced decline relative to other areas, and white matter hyperintensities are observed with greater frequency in the frontal lobes (Raz and Rodrigue 2006).

However, as highlighted above, multiple processes underlie performance on complex measures of executive functioning, and older adults may take longer or make more errors for many different reasons (Phillips and Henry 2008). Thus, in attempting to understand the effect of healthy aging on executive functioning, it is important to take a broad range of measures to separate out age-related decline in executive processes. Further, it is important to disentangle change to specific executive processes, such as a reduced ability to update the contents of working memory, from more general changes associated with age, such as reduced information processing speed (Albinet et al. 2012).

Fractioning Executive Functioning in Old Age

An important starting question, before discussing the decline of specific executive functions with

age, is whether the performance of older adults on complex measures of executive functioning reflects the operation of the same underlying abilities as in younger adults. That is, is it still possible to separate out the contributions of shifting, updating, and inhibition components or do abilities become dedifferentiated (i.e., less distinct) with age? Several studies have adopted an individual differences approach to assess the latent factor structure of executive functioning measures in older groups. In contrast to the idea of dedifferentiation, many of these studies have found that the three-factor solution gives a good account of performance in groups of healthy older adults (Fisk and Sharp 2004; de Fraix et al. 2009; Vaughan and Giovanello 2010).

It should also be noted, however, that other investigators have found two-factor solutions. For example, Hull and colleagues (2008) found that a two-factor model, with no distinction between updating and inhibition but with a separate shifting component, fitted their data just as well as the more complex three-component model. On the other hand, Hedden and Yoon (2006) found a separable inhibition factor in their group of older adults but were unable to separate shifting and updating factors (see also Androver-Roig et al. 2012). While these studies may suggest some degree of dedifferentiation with age, it is the case that even in college-aged adults, the existence of a distinct inhibition factor, that can be separated from the shared variance between the other executive processes, is a matter for debate (Miyake and Friedman 2012). The choice of measures used to construct the factors is likely to be an important reason for this discrepancy.

Interestingly, findings from the large-scale Victoria Longitudinal Study suggest that, in fact, the separability of different executive components may be a good indicator of general cognitive functioning in old age (de Fraix et al. 2009). That study assessed the structure of executive functioning in over 500 participants aged between 53 and 90. On the basis of a broad cognitive battery – assessing speed, reasoning abilities, as well as episodic and semantic memory – the group was split into high performers (termed “cognitive elites”), those performing at a normal level and

those who showed a mild level of cognitive impairment. At the baseline assessment, the three-factor model, with separable updating, inhibition, and shifting components, fit the data from the high and normally performing older adults. However, the three-factor model did not fit the data from the cognitively impaired group; their pattern of performance was explained by a single component, consistent with dedifferentiation of executive functions. Further, the cognitively healthy groups (high and normal performers) showed stability in their underlying abilities over a 3-year follow-up period.

Thus, much of the extant literature suggests that in groups of healthy older adults, it appears to be possible to separate the contribution of different underlying executive processes to complex measures of executive functioning, just as can be done for younger adults.

Does Age Differentially Affect Executive Functions?

Given that the contributions of shifting, updating, and inhibition appear to remain largely separable with age, the question becomes: does healthy aging affect all executive processes equally or do some processes exhibit a disproportionate age-related effect? The nature of executive functioning measures makes this an inherently difficult question to answer. As noted above, performance on a measure like the WCST may be impaired for a number of reasons, such as reduced speed of processing, failure to inhibit overlearned responses, an impaired set-shifting ability, or a mixture of these factors. However, some have adopted the multivariate approach of Miyake and colleagues (Miyake et al. 2000) to assess the effects of age on the separable but interconnected executive processes. These studies have also attempted to disentangle specific change from the more general age-related change to speed of processing.

One study assessing healthy adults' (aged 20–81) performance on a range of executive functioning tasks found a significant relationship between age and the factors reflecting updating, inhibition, and shifting ability (Fisk and Sharp 2004). However, when measures of processing

speed were accounted for in the statistical model, the amount of variance in executive functioning accounted for by age was greatly reduced. This reduction of age-related variance in executive functioning when accounting for measures of speed has been found many times (Albinet et al. 2012; Androver-Roig et al. 2012; Sylvain-Roy et al. 2014). However, despite the overall reduction in age-related variance, this study found that a significant relationship remained between age and the component representing the ability to shift between mental sets, suggesting that age may impair shifting ability *over and above* the reductions seen in information processing speed.

Similar conclusions have also been reached in a recent series of meta-analyses of the executive functioning and cognitive aging literature (Verhaeghen 2011). The estimated age effects on many measures of inhibition were no greater than that predicted by age differences in matched baseline measures (i.e., tasks with similar structure but without the requirement of executive control). This analysis did, however, reveal a disproportionate effect of age on task switching and was able to probe further into the possible origin of this deficit. The cost of having to switch between two sets of task rules can be expressed as the difference in performance (in this case RT) between blocks of trials in which a single-task rule must be applied as opposed to blocks in which participants must switch between rules. The resulting contrast gives the *global task-switching cost*. Alternatively task-switching costs can be calculated as the difference in performance between trials on which a switch was required (i.e., the previous trial used a different rule) versus trials where no switch was required (i.e., the previous trial used the same rule). Here the resulting score is referred to as the *local task-switching cost*. The meta-analyses revealed that older adults exhibited a disproportionate global task-switching cost, whereas the local cost was no greater than expected from matched baseline measures. This global task-switching deficit was interpreted as a reduced ability to simultaneously maintain two sets of task rules, whereas the lack of a disproportionate effect of age on local switching suggests

that the ability to engage the relevant task rules when a switch is required is well preserved (see also Phillips and Henry 2008). Thus the increased number of perseverative errors exhibited by older adults on tasks such as the WCST (MacPherson et al. 2015; Phillips and Henry 2008) would be interpreted as a failure to maintain and retrieve the new appropriate rule, rather than a failure to initiate rule following.

There is additional evidence that performance on measures of set shifting may be an important determinant of day-to-day functioning in old age (Vaughan and Giovanello 2010). This study extracted shifting, inhibition, and updating factors from the performance of 100 older adults (aged 60–90) on a range of measures. They also included self-report and performance-based measures of instrumental activities of daily living, which give an indication of a person's ability to live independently. While none of the executive processes predicted self-report measures of daily functioning, the shifting component significantly predicted performance-based measures. The authors conclude, given that self-report measures are prone to overestimation, the ability to shift between different mental sets appropriate to current goals may be an important determinant of an older adults' ability to manage daily life.

In summary, studies adopting a psychometric approach to assessing executive functioning across the life span and meta-analyses of the literature suggest that the ability to shift between mental sets, and more specifically concurrently maintain two sets of task rules, may exhibit disproportionate decline with age. However, it is important to note that findings are mixed as other groups have found evidence for a disproportionate effect of healthy aging on the ability to inhibit prepotent responses (Sylvain-Roy et al. 2014) or a more general effect of age across the subprocesses, even after accounting for age-related slowing (Albinet et al. 2012). Much of this ambiguity may be attributable to different studies using different measures of the underlying constructs and of processing speed. Further it appears that when these studies control for measures of processing speed, the variance in executive functioning attributable to age is greatly reduced

(Fisk and Sharp 2004; Albinet et al. 2012; Androver-Roig et al. 2012; Sylvain-Roy et al. 2014). While this may suggest that much of the decline in executive functioning is accounted for by senescent decline at a lower level in the processing hierarchy, this should be interpreted with caution. It is often assumed that measures of processing speed capture a more "primitive" aspect of cognition; however, many commonly used measures of speed appear to require controlled processing (Phillips and Henry 2008; Albinet et al. 2012). It is reasonable to suspect that slower speed of processing leads to poorer performance on executive functioning measures, but nevertheless it is also conceivable that speed of processing could be slowed by poor executive control; for example, older adults could take longer to process information *because* they are less able to inhibit prepotent responses. Thus a more thorough theoretical analysis of the mutual relationship between speed of processing and different executive functions is required to gauge their relative contributions to age-related decline on complex behavioral measures (Albinet et al. 2012).

Further Fractionation of Executive Functioning

While focusing on three core executive processes is useful for guiding discussion, further fractionation of executive functioning seems inevitable. For example, the concept of inhibition as discussed above was specifically framed around avoiding inappropriate but automatic responses, but this term may also apply to reducing the interfering effects of previously encountered material (proactive interference) or to preventing task-irrelevant information from distracting task performance (Miyake and Friedman 2012). The suggestion that older adults have a specific deficit in inhibiting distracting information is highly influential in the cognitive aging literature (Hasher and Zacks 1988). Indeed research does suggest that older adults are less able to ignore task-irrelevant distractors, and neuroimaging work has begun to shed light on the mechanisms underlying this. One fMRI study presented younger and older

adults with a series of images of faces and scenes to remember over a brief interval (Gazzaley et al. 2005). Their task involved selectively attending to one of these categories; for example, participants would have to attend to faces while ignoring the scenes presented. Looking at a specific scene-selective region of interest in the left parahippocampal gyrus, the authors found the expected suppression of activity when younger adults were ignoring scenes relative to trying to encode them. Their older adults, on the other hand, did not exhibit the same suppression effect. In fact this seemed to be driven by the very lowest performers in the older group, as high performing older adults exhibited the suppression seen in the younger adults. Thus *inhibition* appears to be multifaceted itself (Miyake and Friedman 2012), and it may be that age has a differential effect on its subcomponents.

Further, there is evidence that the ability to coordinate two tasks at once may be a distinct executive function. The latent variable study of Miyake et al. (2000) found that a measure of dual tasking did not load highly onto any of their three core executive processes, suggesting the possibility that dual tasking reflects a somewhat distinct function (see also Fisk and Sharp 2004). While performance on many measures of executive functioning changes with age, it appears that, under certain circumstances, the ability to coordinate two tasks at once is relatively unimpaired. For example, Logie and colleagues (2004) required participants to retain a sequence of digits while they tracked a moving stimulus with a stylus on a computer screen. Crucially, however, they measured participants' performance when completing these tasks in isolation, in order to titrate the demand of each task (i.e., the number of digits given and the speed of the tracking stimulus) in the dual-task condition. The small cost associated with performing the tasks concurrently was no greater in their older group compared to their younger group. However, a group of patients with Alzheimer's disease (AD) showed a large reliable performance cost. Given that each task was performed within proficient single-task levels, this suggests

that AD patients have a specific deficit in dual tasking.

In fact, recent work with a familial form of AD has suggested that a deficit in dual tasking may signify early changes associated with the disease (MacPherson et al. 2012). Carriers of a genetic mutation exhibited a pronounced deficit when performing the digit recall and tracking tasks concurrently, whereas noncarrier family members did not. Crucially, these carriers did not meet diagnostic criteria for AD and, given the typical age of onset in this cohort, would not be expected to for approximately 12 years. This raises the intriguing clinical possibility that measures of dual tasking, properly titrated, may differentiate between healthy and pathological aging at an early stage.

Neuroimaging of Executive Functioning in Older Adults

There have been many neuroimaging studies that have assessed age differences in activation patterns during the performance of executive functioning tasks. However, these studies are subject to the caveat mentioned many times above; namely that single tasks do not give sufficient insight into the processes underlying executive functioning. Future imaging studies assessing age-related activation differences across a wide range of tasks (as was done in the study of Collette et al. (2005) described above) would be highly informative establishing whether age has a general effect on the neural substrates of executive functioning or whether specific differences occur.

However, one clear finding from many neuroimaging studies across a broad range of tasks is that older adults exhibit patterns of *overactivation* relative to younger adults. This overactivation appears to be more extensive for tasks requiring executive control relative to tasks assessing memory or perceptual function and is primarily found in the dorsolateral prefrontal cortex (Spreng et al. 2010). The finding that this hyperactivity is usually exhibited by better performing older adults has contributed to the suggestion that it is

in some way compensatory and acts as a scaffold supporting less efficient brain areas (Park and Reuter-Lorenz 2009). However, this over-recruitment could represent a non-specific degradation of brain function or dedifferentiation of cognitive processes with age (see Spreng et al. 2010 for a review).

Interestingly, a meta-analysis of 24 functional imaging studies covering a range of executive functioning tasks and 22 studies assessing age-related change to gray matter volume has recently shown considerable overlap between areas overactivated by older adults and regions exhibiting disproportionate gray matter loss with age (Di et al. 2014). The clusters were found in the bilateral dorsolateral prefrontal cortex, and overactivation of this region was not associated with poorer task performance relative to younger controls. These findings could be leveraged in support of either the compensatory or general inefficiency/dedifferentiation views. That areas showing the greatest volumetric decline were also those exhibiting overactivation is certainly reconcilable with the argument that the additional recruitment is a product of degradation and neural inefficiency. However, that this activation was not associated with any gain or loss in performance could also suggest that hyperactivation serves to compensate for structural decline (Park and Reuter-Lorenz 2009). The compensation account is clearly very flexible, and it will take large longitudinal studies to establish the functional significance of hyperactivation during executive functioning and other tasks (Spreng et al. 2010; Di et al. 2014).

While more work needs to be done to link neuroimaging measures to behavioral measures of executive functioning in old age, it is interesting to note that there may be behavioral evidence for the compensation hypothesis from complex executive functioning tasks. In younger adults, Miyake et al. (2000) found performance on the WCST was best predicted by the shifting factor from their latent variable model. On the other hand, Hull et al. (2008) found that their working memory updating factor predicted WCST

performance best in their group of older adults. If we accept that age disproportionately affects shifting ability – although as discussed above the evidence is mixed – it may be the case that more intact executive processes can be called upon to support less well-preserved functions in the performance of multifaceted executive functioning tasks.

Conclusion

In summary, a great deal of progress has been made in recent years toward understanding the core processes underlying executive functioning. Studies adopting a multivariate approach have identified separable but highly interconnected factors representing the ability to inhibit prepotent responses, shift between mental sets, and update the contents of working memory. Contrary to the predictions of dedifferentiation, these diverse functions appear to remain largely separable in healthy old age although this may break down in mild-cognitive impairment.

However, whether or not executive processes exhibit differential decline is unclear. The studies discussed above suggest some reason to suspect that older adults have specific difficulty in shifting between tasks or maintaining multiple task rules. Nevertheless, findings are mixed, and this likely depends on the precise measures used to establish the underlying constructs. Further, it appears that much of the impairment exhibited by older adults on complex measures of executive functioning may attributable to more general decline, such as reduced speed of processing. Although it is important to note that commonly used measures of processing speed may include an element of executive control, therefore the effect of controlling for processing speed measures in analyses should be interpreted with caution. It seems likely that the substrates of executive functioning will be fractionated even further through the use of theory-driven tasks that aim to better isolate executive processes. Finally, the assessment of tasks which rely on executive functions which are age

insensitive, such as dual tasking, can open new diagnostic opportunities for the early detection of abnormal variants of aging, such as Alzheimer's disease.

Synonyms

Cognitive control; Executive control

Definition

Executive functions are higher-level cognitive control functions supporting the flexible adaptation to changing environmental demands. They include abilities such as updating, shifting, and inhibition, which are subject to significant age-related changes. These age differences are associated with age-related changes in the neural substrate supporting executive processes. However, the brain is plastic up to very old age, and executive functions can be improved by intensive cognitive and physical training in adulthood.

The Concept of Executive Functions

Executive control is an umbrella term for a broad set of higher-order cognitive processes supporting the flexible regulation of thoughts and actions in

the service of adaptive, goal-directed behavior. Executive control is especially required in novel, ambiguous, or complex situations, when there are no well-learned routines for action selection (Baddeley 2000; Jurado and Rosselli 2007). Executive abilities allow us to think divergently and creatively, for instance, when we are stuck with a problem and need to develop new solutions to overcome it. They help us to maintain a goal and focus our attention in the face of distraction, while staying flexible enough to adjust our behavior quickly to unpredicted changes in the environment. We need executive skills to resist temptation and to suppress inappropriate habitual behaviors. Executive functions enable us to plan ahead, to juggle multiple pieces of information in our mind and make new connections between them. It is thus not surprising that executive control is a strong predictor for various life outcomes, such as academic achievement, socioeconomic status, and physical health.

There is a fundamental debate as to whether executive functions can be best described as a unitary or multidimensional construct. While the former view holds that a single ability or common cognitive mechanism underlies all aspects of executive functioning (unity), the latter view assumes that executive functions involve related, but separable, components (diversity). The unity framework includes influential concepts such as the supervisory attentional system in the model of attention for action by Norman and Shallice (1986) or the central executive in Baddeley's working memory model (Baddeley 2000). Further, it has been suggested that perceptual speed and/or basic reasoning skills may form a common basis for executive control operations (Salthouse 2005).

In line with the idea of a unitary control system, studies using confirmatory factor analysis and structural equation modeling have typically revealed substantial correlations between the latent constructs underlying performance in executive control tasks (e.g., Friedman et al. 2011; Miyake et al. 2000). These studies, however, also showed that the latent factors explained unique variance and thus may represent separable abilities. Miyake and colleagues (2000), for

instance, demonstrated that interindividual differences in executive functions in young adults are better accounted for by a three-factor model with the latent variables *shifting*, *working memory (updating)*, and *inhibition* than by single- or two-factor models. Generally considered as core components of executive control, these factors describe the ability to (i) flexibly switch between different tasks, goals, or mental sets (*shifting*); (ii) update or monitor task-relevant information to be maintained in working memory (*working memory/updating*); and (iii) withhold prepotent responses and suppress attention to irrelevant stimuli as well as interfering thoughts and emotions (*inhibition*). The three main latent factors have been found to contribute differentially to more complex executive functions, such as planning or concept formation.

Notably, more recent work has shown that only the shifting and updating factors captured unique variance that was separable from a higher-order unity factor (“common executive function”; Friedman et al. 2011). Further support for a “hybrid” unity/diversity framework comes from neuroscientific studies showing that different executive control processes rely on overlapping but separable networks of neural activity (Jurado and Rosselli 2007; Collette et al. 2006). A fundamental cognitive mechanism that might underlie the common factor of executive control is the ability to stably maintain task goals in working memory (Braver and West 2008; Miyake and Friedman 2012), whereas updating and shifting have been linked to the ability to efficiently “gate” goal-relevant information into working memory (updating) and to quickly remove contents from working memory when they are no longer needed (shifting; Miyake and Friedman 2012; Herd et al. 2014).

Convergent evidence indicates that the basic organization of executive functions is similar in younger and older adults. While some studies replicated Miyake et al.’s three-factor structure in healthy elderly populations, others revealed two-structure solutions with the subcomponents (a) shifting and updating or (b) shifting/updating and resistance against proactive interference (for

review, Adrover-Roig et al. 2012). Importantly, single-factor models did not seem to provide an appropriate description of executive functioning in either of the abovementioned studies. Overall, it has been concluded that aging is associated with changes in the relative contribution of the different subcomponent processes to performance on executive control tasks rather than with a fundamental reorganization of executive functions.

Age-Related Changes in Executive Functions

Compared to other cognitive domains, such as procedural and semantic memory, language, or emotion regulation, executive control seems to be particularly affected by aging, with a sharp drop occurring after the age of 60 (Jurado and Rosselli 2007). Consistent with the unity/diversity view, both global and component-specific mechanisms have been shown to account for declines in executive functions with advancing age. Prominent examples for global mechanisms that are thought to impact all components of executive control are reduced information processing speed (Salthouse 2005) and impaired goal maintenance (e.g., Braver and West 2008; Miyake and Friedman 2012). Specifically, Salthouse and colleagues suggested that the apparent diversity of age-related cognitive deficits can be explained by a generalized slowing of cognitive processing. This argument is based on their observation that (i) measures of executive functions, reasoning, and processing speed were highly correlated and (ii) controlling for processing speed eliminated or strongly diminished age differences in executive functioning (Salthouse 2005). However, other studies found age-related deficits in executive control when differences in speed of processing were taken into account (e.g., Albinet et al. 2012). Moreover, commonly used measures of processing speed, such as the Digit-Symbol Substitution Test, are “impure” in that they also tap inhibition, shifting, and working memory, which may explain their shared variance with executive control tasks. Using hierarchical regression

analyses, Albinet and colleagues (2012) demonstrated that despite sharing common variance, processing speed and the three main control components are independently affected by chronological age. This finding argues against the view that age-related decrements in executive functions are exclusively mediated by generalized slowing.

Several theoretical frameworks contend that the ability to actively maintain behavioral goals or task sets in order to bias task-appropriate response selection plays a pivotal role in executive functioning (e.g., Braver and West 2008; Miyake and Friedman 2012). An elegant paradigm to examine age differences in the integrity and robust maintenance of goal representation is the AX-Continuous Performance Test (AX-CPT; Braver and Barch 2002). In this paradigm, participants are presented with different cues (“A” vs. “non-A”) that specify the appropriate rule for responding to a subsequent probe stimulus (“X” vs. “non-X”). When an “A” cue is followed by an “X” probe (AX trials), a target response must be given, while “X” probes preceded by “non-A” cues (BX trials) as well as all “non-X” probes (AY and BY trials) require a non-target response. Since AX-trials are presented more frequently than other trial types, “X” probes elicit a strong tendency to make a target response. Thus, failures to maintain a stable representation of the rule context (“A” vs. “non-A”) should lead to *higher* error rates when “X” probes are preceded by “non-A” cues (BX trials) but *lower* error rates when “A” cues are followed by “non-X” probes (AY trials). Consistent with the goal maintenance account, Braver and colleagues observed exactly this error pattern when comparing younger and older adults’ performance on the AX-CPT. Older adults produced more BX than AY errors, while the opposite was true for younger adults. Notably, these age differences were even more pronounced when distractors were presented during the cue-probe delay. This latter finding indicates that older adults are more susceptible to distraction, most likely due to their weaker maintenance abilities. Interestingly, increasing maintenance demands by manipulation the length of the cue-probe delay (1 vs. 5 s) resulted in differential

effects in younger and older seniors. While younger seniors’ performance did not differ between the two delay conditions, older seniors showed worse BX but better AY performance with longer delays.

Based on these findings, Braver and Barch (2002) concluded that the younger seniors’ deficits in BX trials result from their difficulties with updating – rather than maintenance – of the rule context. Thus, updating mechanisms might be more vulnerable to advancing age than maintenance, which shows impairments only at older age or under more challenging conditions (e.g., distraction). In line with this assumption, complex working memory tasks that require updating and monitoring, such as reading or operation span, usually reveal more substantial age differences than simple span tasks. In further support of a particularly high susceptibility of updating skills to cognitive aging, previous work identified updating as the most important predictor of older adults’ performance on tasks tapping complex executive functions, such as Tower of Hanoi (TOH) and Wisconsin Card Sort Test (WCST) (cf. Adrover-Roig et al. 2012). In younger adults, by contrast, the Miyake et al. study (Miyake et al. 2000) found inhibition and shifting to be the best predictors for TOH and WCST performance, respectively.

While the ability to update and maintain information in working memory is characterized by a constant age-related decrease, the ability to flexibly shift between tasks seems to be less affected by age. One frequently used experimental task to measure this skill is the task-switching paradigm including conditions in which participants are required to shift back and forth between two or more tasks (*mixed-task blocks*) and conditions that do not require task switches (*single-task blocks*). Shifting skills are measured as the difference in performance between task-switch and task-repeat trials within mixed-task blocks (*specific switch costs*). Further, by contrasting mixed-task blocks with single-task blocks, this paradigm allows to determine performance costs due to the greater maintenance demands in the dual-task situation (*general switch costs*). When the general age-related slowing of processing

speed is controlled for, age differences are usually only found for general switch costs but not for specific switch costs (e.g., Verhaeghen and Cerella 2002).

It is interesting to note, however, that the common component of executive control and the shifting-specific subcomponent often tend to be negatively correlated (e.g., Friedman et al. 2011). In a recent study, Herd and colleagues (2014) used neural network modeling to show that this might reflect opposite effects of stable maintenance on the two factors. Specifically, the authors demonstrated that stronger goal representations led to an overall decrease in reaction times for both task-switch and task-repeat trials in mixed-task blocks relative to single-task blocks, resulting in a reduction of general switch costs. This effect was smaller for task-switch trials, where participants needed to overcome the stronger goal representations, resulting in an *increase* of specific switch costs. Thus, spared shifting abilities in old age might actually be a byproduct of impaired maintenance skills. Further research is needed to determine how the putative shifting-specific processes – removal of no-longer-relevant information from working memory and automatic persistence of those contents – change with advancing age.

Robust goal maintenance is particularly important in the face of strong interference from competing response tendencies or goal-irrelevant information and usually considered to be a key determinant of inhibition (Miyake and Friedman 2012). Indeed, the abovementioned neural network simulations by Herd et al. (2014) revealed that in the Stroop color-word interference task, strong goal representations particularly benefitted incongruent trials and hence were associated with reduced interference effects. Interestingly, age-related impairments do not reliably occur for all types of inhibitory control. In particular, a number of findings have suggested that older adults' deficits in inhibitory processing as measured by the Stroop task or negative priming reflect global changes in processing speed or impaired sensory processing (e.g., Verhaeghen and Cerella 2002). However, in support of the goal maintenance account, West and colleagues

(Braver and West 2008) found that older participants showed disproportionately higher rates of intrusion errors (i.e., naming the word instead of the ink color) when color and word naming alternated in a trial-by-trial rather than block-wise fashion. Notably, this effect was separable from the switching demand itself and has been argued to reflect a weaker representation of the currently relevant task goal. Similarly, Mayr and colleagues (2014) suggested that older adults' higher susceptibility to irrelevant memory traces in interference tasks results from their difficulties to reestablish a stable maintenance mode after any kind of interruptions (e.g., conflict, task switch). More consistent age-related impairments have been observed in tasks that require participants to withhold their responses upon intermittently presented stopping signals (i.e., stop-signal tasks, go-nogo tasks) or tasks that require the inhibition of the automatic orienting response to salient visual distractors (anti-saccade tasks; cf. Buitenweg et al. 2012).

It is important to note that not all individuals are equally affected by cognitive aging. Indeed, in some older adults, executive functions are remarkably spared. Correlational data indicate that greater engagement in intellectual, social, and physical activities is associated with stronger resilience to cognitive decline in later life (for review, Reuter-Lorenz and Park 2014). Most theories of cognitive aging share the assumption that at least two mechanisms contribute to the protective effect of those environmental variables. First, an enriched lifestyle could directly counteract age-related changes in brain anatomy and physiology, thereby promoting brain health and increasing the threshold for cognitive deficits. Second, environmental enrichment is thought to enhance the ability to adapt to age-related brain pathology and to preserve cognitive function, for instance by compensatory recruitment of additional brain regions and alternative neural circuits. Conversely, depleting genetic and environmental variables, such as vascular risk factors, head trauma, or low socioeconomic status, have detrimental effects on brain health and aggravate the effects of aging on executive and other cognitive functions.

Neurobiological Underpinnings of Executive Control and Cognitive Aging

Executive control is inextricably linked to the functioning of the frontal lobes, especially prefrontal cortex (PFC). Evidence from neuroimaging and lesion studies revealed, though, that executive functions are supported by a distributed neural network, involving prefrontal and parietal areas as well as subcortical structures, such as basal ganglia, thalamus, or cerebellum (Duncan and Owen 2000). The results of these studies are largely in accordance with the view that both shared and unique mechanisms underlie executive functioning. Specifically, it has been shown that shifting, updating, and inhibition tasks elicit an overlapping pattern of activation in frontal (e.g., dorsolateral PFC, anterior cingulate cortex) and parietal regions (e.g., superior and inferior parietal lobe, precuneus). Component-specific activations have been found in distinct prefrontal, occipital, and temporal areas as well as subcortical regions (e.g., Collette et al. 2006). Consistent with the neuroimaging findings, data from lesion studies revealed that patients with brain damage to different frontal regions show both common and unique performance deficits on executive control tasks.

There are similarities between certain aspects of aging-related neurocognitive changes and the neuropsychological deficits displayed by frontal-lobe patients, especially those with lateral frontal damage. The idea that cognitive impairments in older adults are strongly linked to frontal dysfunction (“frontal lobe hypothesis”) has received substantial support from neurophysiological studies demonstrating that aging is associated with various changes in prefrontal structure and physiology, such as white matter integrity, grey matter volume, metabolic markers of neural integrity, and neurovascular factors (Raz and Rodrigue 2006). Although disruption of white matter integrity has been primarily associated with the generalized age-related decrease in processing speed, a number of studies demonstrated more specific correlations between separable white matter systems and age-related impairments in task-switching, working memory, and inhibition.

Reductions in grey matter volume in PFC have been found to predict performance on age-sensitive executive control tasks such as the WCST or TOH. Further, there is evidence indicating that changes in synaptic connectivity (e.g., reduced synaptic and dendritic density) might play a more important role in explaining cognitive decline in old age than white and grey matter disruption as such.

It is important to note that age-related changes in brain structure are not restricted to frontal cortex but occur throughout the brain. In fact, brain aging has been shown to progress along an anterior-to-posterior gradient rather than being specific to PFC. Moreover, it is well established that deficits in dopamine (DA) function contribute to many of the cognitive impairments observed in old age (Bäckman et al. 2000). DA levels decline monotonically with increasing age (at a rate of about 10% per decade), and markers of advanced DA depletion predict age-related deficits in executive functions, processing speed, episodic memory, reward-based learning, and decision making.

Braver and colleagues (Braver and Barch 2002) provided an integrated theoretical framework for the role of frontal and dopaminergic dysfunction in cognitive aging. According to this account, dorsolateral PFC (dlPFC) contributes to executive control by maintaining goal representations and other task-relevant context information and to use this information to bias (or contextualize) lower-level information processing in posterior cortical regions. The neurotransmitter DA is thought to play a key modulatory role over dlPFC function by regulating maintenance and updating (“gating”) of goal representations. Age-related deterioration in PFC and DA function, thus, are assumed to result in a specific impairment in the ability to actively update goal/context information into working memory and to maintain this information robust against interference. Consistent with the idea of a frontostriatal functional dissociation between maintenance (PFC) and updating (striatum), accumulating evidence points to complementary roles for DA in PFC and basal ganglia, with higher prefrontal DA levels promoting stabilization of goal representations and higher striatal DA levels

flexible updating (Cools and D'Esposito 2011). Thus, the loss of dopaminergic function with normal aging may contribute to both increased distractibility (i.e., impaired maintenance) and updating deficits that have been observed in older adults. In support of this notion, Raz and colleagues (Raz and Rodrigue 2006) found a pronounced age-related decline in frontostriatal DA activity and striatal volume.

Functional neuroimaging studies have provided ample evidence that brain aging is not only reflected structural changes but also differences in brain activity. Common aging-specific patterns of brain activity include over- and underactivation, a loss of functional selectivity of neural responses in different regions and networks (dedifferentiation), and altered functional connectivity among different brain areas. Most of these effects are thought to reflect compensatory mechanisms that accompany neurocognitive decline. Compensatory strategy changes, in turn, might initiate changes in brain structure, resulting in a complex interplay between structural and functional effects. A typical example of compensatory neural “scaffolding” is the “posterior to anterior shift” in functional brain activity with advancing age, which has been interpreted as an overrecruitment of frontally mediated control processes in response to the reduced distinctiveness of neural representations in posterior regions. Moreover, older adults often show greater and more bilateral PFC activity at lower levels of task demand than younger adults – a domain-general pattern known as hemispheric asymmetry reduction. Interestingly, both patterns also seem to be reflected in age-related changes in functional connectivity.

Despite the well-documented generality of compensatory neural mechanisms, a recent meta-analysis provided evidence for dissociable patterns of age differences in brain activity during working memory and inhibitory control tasks (Turner and Spreng 2012). Specifically, the authors found that working memory tasks were associated with more bilateral activation of dlPFC as well as greater activation of left supplementary motor area and inferior parietal lobule in older compared to younger adults. During inhibitory

control tasks, older adults showed a separable pattern of effects, involving stronger recruitment of right (but not left) inferior frontal gyrus and left presupplementary motor area. Nonetheless, the overall spatial distribution of working-memory versus inhibition-specific brain activation profiles was largely comparable in younger and older adults.

Plasticity of Executive Functions in Older Age

Given that executive functions decline with increasing age, there has been growing scientific interest in interventions designed to improve them. Recent studies have applied a wide range of cognitive and physical training interventions, revealing that cognitive plasticity (i.e., the potential modifiability of a person's cognitive abilities and brain activity) is considerable up to very old age (for reviews, Karbach and Verhaeghen 2014; Ballesteros et al. 2015).

Cognitive interventions can be divided into three major categories: (i) strategy-based trainings, (ii) process-based trainings, and (iii) multimodal interventions. Strategy-based trainings aim to improve specific cognitive operations – typically those that are most impaired in older age – by teaching participants an explicit strategy on how to solve the given task or problem. For example, the so-called method of loci helps individuals to improve their memory performance by associating the to-be-remembered items with a sequence of specific physical locations along a “mental route” in a familiar place such as their apartment. Although strategy trainings have been shown to result in considerably large and sustained performance gains, improvements are often limited to the trained task, with little evidence of transfer to untrained functions. Training regimes that involve a combination of multiple strategies or focus on more complex functions, such as reasoning, problem solving, or goal management, seem to yield a more generalized beneficial effect on untrained measures of executive function as well as indicators of daily life functioning.

Process-based cognitive intervention programs aim to improve specific cognitive processes, such as speed of processing or working memory, by training participants on tasks that are thought to heavily tax these functions. Only a relatively small number of studies have examined the effects of set-shifting in older adults (Buitenweg et al. 2012). Available evidence indicates that relatively short shifting practice (less than 10 training sessions) can yield significant performance improvements, particularly in terms of general switch costs. Most importantly, training-induced gains have been shown to transfer to untrained tasks and abilities, such as inhibition, attention, and reasoning. Specifically, several studies demonstrated that shifting practice results in reduced Stroop interference effects, better performance on verbal and spatial working memory tasks, and increased fluid intelligence scores in both younger and older adults. Transfer effects have been attributed to the fact that task-switching paradigms put high demands not only on shifting but also on maintenance and interference control and hence tap into multiple subcomponents of executive control. Additionally, transfer to more complex functions (e.g., reasoning skills) might derive from the requirement to efficiently coordinate multiple tasks. Despite promising initial findings, some studies have failed to obtain practice-induced transfer effects to untrained tasks after set-shifting training in older adults. Thus, more research is needed to determine the conditions under which shifting practice may compensate for age-related decline in executive control and associated impairments in daily functioning.

Working memory updating trainings in healthy older populations revealed substantial performance improvements on the trained as well as structurally similar tasks (Karbach and Verhaeghen 2014). In terms of transfer to other dimensions of executive control, intelligence, or reasoning, however, the findings are less consistent. Studies that have systematically assessed the potential of working memory updating training to improve executive control functions in the elderly are scarce. In younger adults, generalization of performance gains to other measures of executive

functions and intelligence are most commonly reported for adaptive trainings, i.e., when task difficulty is individually adjusted over the course of training to match participants' performance levels. Even though transfer effects of updating practice have often been found to be absent or considerably smaller in older participants, a number of recent meta-analyses found small, but reliable, transfer effects of working memory and executive function training to untrained cognitive skills, particularly fluid intelligence. Interestingly, these studies revealed that overall the magnitude of training-induced performance gains is comparable in younger and older adults. It should be noted, however, that not all meta-analytic studies found evidence for benefits of training on executive functions. These inconsistencies might be attributable to methodological factors such as the total number of included studies, criteria for study exclusion, heterogeneity of trained tasks and populations, as well as the specific coding of transfer measures.

Only a very small number of training studies that have been conducted with older adults focus directly on inhibition. As reviewed in Buitenweg et al. (2012), practice on tasks tapping inhibition, such as Stroop or Simon task, improved inhibitory control in elderly but the training-induced gains did not generalize to untrained tasks. A notable exception is a recent study by Mishra and colleagues (2014) that used an adaptive distractor-suppression training to enhance interference control in healthy aging. The training did not only affect behavioral and neural indicators of interference effects in the trained task but also had beneficial effects on unrelated measures of working memory and sustained attention.

Given that a general decrease in information processing speed is thought to play an important role in the age-related decline of executive functions, several interventions have targeted speed of processing in older adults. Speed of processing trainings have been shown to induce large and sustained improvements in speed scores. While some studies reported transfer to untrained functions such as visual-spatial abilities, attention, and everyday speed measures, training gains did not

generalize to executive control measures. Another relatively recent approach to improve executive control and other aspects of cognition in older populations are video game trainings. Results, thus far, show that video game playing can enhance several age-sensitive cognitive functions, including visuospatial attention, memory, and speed of processing, but training gains do not seem to transfer to executive functions.

In recent years, some progress has been made in identifying neural substrates of training-induced plasticity in older age (Brehmer et al. 2014). Training-related changes in brain structure (e.g., grey and white matter volume) have been observed in task-relevant areas rather than globally throughout the brain. Performance gains on executive control tasks were associated with activation increases, decreases, or a combination thereof, in frontoparietal control regions as well as subcortical areas. While activation increases are thought to reflect compensatory strategies, activation decreases are usually interpreted as an indicator of increased neural processing efficiency. In general, neural activation changes can be classified as functional redistribution or functional reorganization, with the former denoting quantitative changes in activation levels within the same or similar brain regions and the latter denoting qualitative changes in the spatial pattern of brain activation. Cognitive interventions often induce a reduction of age-related activation differences, such that after training, brain activation in the elderly approximated that in younger adults.

Interestingly, a number of working memory training studies revealed a pattern of activation decrease in frontoparietal regions in association with activation increase in the striatum. This pattern might reflect faster and less effortful updating of working memory representations due to more efficient information processing in corticostriatal circuits, e.g., as a consequence of more salient striatal updating (gating) signals. In younger but not in older adults, the training-related increase in striatal activation predicted transfer effects to a structurally similar untrained task that also activated the striatum. The latter finding is consistent with the idea that transfer is increased if the

training task and the transfer task engage overlapping cognitive processing components and brain regions.

Aside from cognitive training interventions, physical training, especially from the domain of cardiovascular training, can improve cognitive functions. These positive effects of physical exercise were particularly pronounced in the domain of executive control (Ballesteros et al. 2015). They have been reported for healthy older adults as well as for individuals with cognitive and physical impairments and have been accompanied by changes in cerebral blood flow and the modulation of activity in task-relevant brain areas. Hence, both cognitive and physical activity in older age may be effective ways to support executive functioning in the aging brain. Indeed, multimodal training approaches that combine various types of interventions, including social engagement, cognitive trainings, and physical stimulation, have yielded promising results in terms of improving executive functions and daily life functioning. The complexity of multimodal interventions, however, entails methodological challenges that have not been fully resolved yet. For instance, it is often difficult to determine to what degree single components and/or interactions between different components contributed to training gains.

Summary and Conclusion

Executive control functions include a number of processes such as updating, shifting, and inhibition, all of which are subject to significant age-related changes across the adult life span. These age differences have been linked to structural and functional alterations in the neural substrate supporting executive processes. Consistent with the “frontal lobe hypothesis” of cognitive aging, the greatest change in brain anatomy and physiology is evident in anterior brain regions. However, research on cognitive aging has also shown that the brain is plastic up to very old age and that executive control can be modulated by lifestyle factors as well as intensive cognitive and physical training in adulthood. Environmental

enrichment, including intellectual, social, and physical activities, is associated with stronger resilience to cognitive impairments in later life by (i) directly counteracting neurophysiological deterioration and (ii) compensatory recruitment of additional brain regions and alternative neural circuits to adapt to depleted neural resources and to preserve cognitive function. Given the contribution of executive functions to various life outcomes and daily life functioning, many studies have investigated the effectiveness of cognitive training interventions designed to improve executive control in older adults. Particularly, switching and updating training have yielded promising effects such that they appear to offer a great potential to improve not only trained but also untrained functions and skills, including inhibition, attention, and reasoning, across the adult life span. Nonetheless, a number of studies have raised questions about the robustness and consistency of transfer effects, especially in older adults. In particular, previous training studies have been criticized on methodological grounds. Key issues include expectation effects, test-retest effects, cognitive depletion effects due to extensive cognitive assessment, appropriate selection of the control group(s), nonrandom assignment of participants to experimental vs. control group(s), and comparability of results from studies using different training regimes. Thus, there is a clear need for carefully designed studies that integrate behavioral measures of cognitive plasticity with structural and functional neuroimaging data – within the broader framework of longitudinal and interindividual differences approaches – to systematically determine the factors that moderate the effects of training interventions on executive control functions in later life.

Expertise and Ageing

Ralf T. Krampe

Synonyms

Skill maintenance; Exceptional performance

Definition

The concept of expertise refers to individuals' superior levels of performance in specific

domains. Domains of expertise and the levels of performance necessary to attain expert status depend on historical and cultural contexts. Skills like writing or driving a car sufficed for expert status in earlier times, but they are minimum requirements for most jobs nowadays. Expert swordsmanship has come out of fashion while excelling in web design was unknown to our ancestors. In aging societies the question if and how expert levels of performance can be maintained into later adulthood has gained central significance. Workforces in most OECD (Organisation for Economic Co-operation and Development) countries are aging rapidly: the age group of 40–45-year-olds formed its largest segment in 2006, and between 1980 and 2006, the median age of the American workforce increased from 35 to 41 years (Ng and Feldman 2008). Fewer young people enter the workforce and those who do have nowadays enjoyed longer periods of training. A main factor is the increasing employment rate of older employees, which is largely the result of reductions in the traditional safety nets of funded (early) retirements even in European welfare states.

Cognitive aging research portrays a rather grim perspective on levels of functioning in older adults. Tests measuring the speed and accuracy of basal processes like visual search or comparison operations are referred to as performance IQ (Intelligence Quotient) or fluid intelligence in the literature, and performances on these tests show considerable age-related declines (Kaufman 2001). Due to the age-referenced definition of IQ, the average 50-year-old has to perform at roughly 85–90% the speed of a 25-year-old to obtain the same IQ score. Adults in their 60s typically take 1.6–2 times as much time compared with 20-year-olds to perform speeded tests or experimental tasks – a phenomenon called *general age-related slowing* (Salthouse 1996). Meta-analytic reviews also point to age-related declines in working memory and reasoning (Verhaeghen and Salthouse 1997), the ability to perform two tasks simultaneously (Verhaeghen et al. 2003), and cognitive control (executive functions) (Rhodes 2004). Cognitive control comprises planning complex actions, the maintenance of

task-relevant information (task sets), inhibition of irrelevant task sets, and switching task sets when performance conditions change. Onsets are later and rates of age-related declines are much shallower for “crystallized intelligence,” that is, abilities based on knowledge, experience, and culturally transmitted skills (Li et al. 2004).

Studies from organizational psychology appear to defy the negative implications from cognitive aging research. In what has been the most comprehensive meta-analysis of studies on the relation of age and job performance to date, Ng and Feldman (Ng and Feldman 2008) found that core task performance on the job and creativity was largely unrelated to age. In additional analyses Ng and Feldman found that the age \times core performance relation followed an inverted U-shape function: performance in core skills improved with age in younger workers (<40 years), presumably because of growing job-related experience, and it became slightly negative in employees age 40+. Related effects were small however, and the authors concluded that here is little to suggest from the meta-analytic reviews that older workers or employees cannot function in their jobs, lack creativity, or that their other performance aspects deteriorate noticeably relative to young adults. One reason for this apparent contradiction with findings from cognitive aging research may be the definition of “older” traditionally applied in organizational psychology (Ng and Feldman 2008). For pragmatic reasons (early retirement age, low workforce participation rates), the authors considered “older” to be individuals of age 40+. In standard textbooks of life span developmental psychology (Berk 2014), the period 40–65 years corresponds to middle adulthood, and participants in cognitive aging studies typically are in their late 60s or older. A second reason is that cognitive aging studies for the most part use psychometric tests and experimental tasks with unfamiliar materials and they compared young and older individuals’ performances in novel and untrained settings. Arguably, the specific skills, which have been acquired and exercised for considerable amounts of time in professional contexts, show a friendlier age-related development.

Expertise research differs from both cognitive aging and organizational psychology with respect to the type and the levels of performances studied. Expertise research focuses on domain-specific rather than domain-general functions. The broad varieties of job performance studied by organizational psychologists do not correspond to the narrower concept of expert-level performance. While the boundaries between expert and novice performance are far from well defined, authors (Ericsson and Smith 1991; Salthouse 1991) agree on defining expertise as a stable individual attribute. This attribute should not be based on experience (seniority) or social judgment, but on the actual level of performance. Expert performance must be replicable and measurable taking the requirements of a certain domain into account.

Extant models of expertise posit that experts have developed specific mechanisms, which allow them to circumvent the process limitations constraining normal (i.e., novice) performance (Chase and Ericsson 1981; Ericsson et al. 1993). This metaphor implies that experts do things differently and that their brains also differ from novice brains. Examples of cognitive mechanisms are chess players’ memory for game positions, the advance coordination of fingers in rapid typing, and hand-independent timing in pianists. Evidence for expertise-specific adaptations at the neural level comprises enlarged hippocampal regions in expert taxi drivers (Maguire et al. 2000) or enlargements in sensorimotor cortices in musicians (Amunts et al. 1997; Elbert et al. 1995). These examples illustrate that expert mechanisms are not “tricks of the trade” one can pick up in a crash course. Ericsson and colleagues argued that attaining international-level expertise in any domain typically requires 10 years or at least 10,000 h of *deliberate* practice (Ericsson et al. 1993). Deliberate practice is goal-directed learning, which requires careful monitoring of one’s own performance and the continuous search for ways to improve. At least during the initial acquisition phase, this occurs ideally under the auspices of a coach, who is an expert herself/himself. The deliberate practice model depicts expertise development as a long-distance race, during which the individual has to negotiate

effort, motivational, and resource constraints. Because its practice is inherently effortful, nature deliberate practice activities can only be sustained for limited amounts of time, and they call for sufficient recuperation. What distinguishes deliberate practice from leisurely exercise is the motivation to improve and to overcome weaknesses in one's own performance. Resource constraints relate to external (teachers, parental support) and internal (physical health, concentration) types of support or limitations. Discussions in the literature abide as to whether deliberate practice is only a necessary or a sufficient prerequisite of attaining expert-level status (Hambrick et al. 2014; Macnamara et al. 2014; Meinz and Hambrick 2010); however, all theoreticians agree that it is a critical factor. Several authors have argued for inherited individual differences or gene-environment correlations, which determine, for example, adult levels of musical accomplishment (Hambrick and Tucker-Drob 2015). A related question is whether individual differences in domain-general cognitive abilities (i.e., intelligence) determine only initial progress in learning (Ackerman 1988; Fox et al. 1996) or if they continue to constrain accomplishments at superior or expert levels of performance (Hambrick and Engle 2002; Wai 2014). Controversies and answers to these questions depend to a large degree on how the type and level of performance necessary to be considered an expert is defined (Ericsson 2014). Whatever the precise perspective on the precursors of expertise, maintaining expertise into later adulthood amounts to a considerable extension of the long-distance race because age changes the nature of effort, motivational, and resource constraints.

Accounts for High Levels of Accomplishment in Older Experts

The primary goal of the experimental study of expert performances is to demonstrate reliable differences between experts and novices in tasks reflecting accomplishment in a specific domain. In the context of aging, the key questions are whether these performance advantages continue

to exist for older experts when compared with age-matched controls. For theoretical reasons such age x expertise studies try to address three other questions: (1) do experts, who excel in their domains also differ from “normal” individuals when it comes to domain-general abilities such as general intelligence (processing speed, working memory) or cognitive control (monitoring and controlling attention, suppressing irrelevant information, updating information in working memory, switching between task sets and plans)? (2) Does domain-specific expertise also convey an advantage in near-transfer domains that are subject to age-related decline in the general population (e.g., are older chess masters also better in reasoning tests)? (3) Does the level of expert performance maintained depend on older experts' investments into certain activities (e.g., practice)? Depending on the answers to these questions, we can distinguish four different accounts of expert or exceptional performance in later adulthood in the literature.

The *preserved differentiation* or a priori *disposition* account maintains that (experts) have always been superior in skill-relevant abilities, such that their advantages at any age could be attributed to interindividual differences with long-term stability that already existed prior to expertise acquisition. For example, a predisposition for visual imagery might nurture interest in and a professional choice for graphic design or architecture. The second position, *expertise-driven general ability account* emphasizes transfer to broader cognitive abilities. The idea is that acquiring expertise involves gradual improvements in some, though not necessarily all, domain-general functions. For example, daily professional challenges to keep complex facts in memory might foster increases in working memory span. *Differential preservation* or *selective maintenance* accounts emphasize the role of specific over broad abilities. Accordingly, expertise at any age rests on specific mechanisms, which age more gracefully than general mechanisms, presumably because experts actively maintain them through continued use or deliberate practice. Finally, the *compensation* account posits that older experts actively acquire specific mechanisms when

experiencing age-related decline of those mechanisms supporting their expertise.

Experimental Studies of Expert Performance in Young and Older Adults

Expert performance has been studied under laboratory conditions with age-comparative samples for such diverse domains as typewriting, games (chess, bridge, GO, mastermind), piloting, and air traffic control, management skills, visual search in medical assistants, fine motor control in mechanics, memory for numerical information in accountants, auditory processing in musicians, and musical performance (for a review, see Krampe and Charness 2006). Across studies experts in their late 50s and 60s typically perform at levels comparable to or slightly below those of experts in their late 20s. Even for experts of more advanced ages, studies have reported at least reduced age-related decline compared with age-matched novices. At the same time, older experts showed the typical reductions in measures of domain-general processing, which were similar to those observed in age-matched controls. This pattern of results strongly suggests that older experts rely on domain-specific mechanisms to circumvent the processing constraints of domain-general functions just like young experts do. In line with this assumption, benefits are the highest in the most complex skill-related tasks, where experts can bring their most adapted specific processes to bear. As an example, professional pianists have a higher single-finger tapping rate compared with novices and amateur musicians; however, their advantages are magnified when complex sequencing of multiple fingers is required. In turn, age effects in the novice group are the largest in the most complex conditions because they related tasks require increased engagement of domain-general functions like working memory or cognitive control. These functions are known to be most affected by age-related decline (West 1996).

It is hardly feasible that such highly specific adaptations reflect a priori (e.g., innate) dispositions. Instead, the pattern agrees best with the selective maintenance account. Studies

investigating experts' activities revealed a clear relation between levels of expert performance and the amount of practice that went into acquisition (Ericsson et al. 1993). Deliberate practice seems to be as important when it comes to maintaining expertise into later adulthood (Charness et al. 1996; Krampe and Ericsson 1996). In particular, the study by Krampe and Ericsson suggests that it is not years of experience, starting age, or practice during young ages, but the amount of practice invested during recent years, which determines the degree of maintenance.

The specificity of the expertise advantage in older experts is in line with the assumptions of limited transfer to other skills or to general dimensions of cognitive abilities (Hambrick et al. 1999; Owen et al. 2010). Individual differences in cognitive abilities (Ackerman 1988) correlate with learning rates in early stages of skill acquisition, but these correlations weaken once learning proceeds to expert levels. These findings are at odds with the expertise-driven general ability account, which posits that the acquisition of a specific skill leads to improvements at the level of general abilities. One specific version of this account continues to enjoy enormous popularity in science and the media, namely, the assumption that music lessons boost intelligence in children. Two intervention studies indeed found small but reliable benefits of music training for broader intellectual abilities in preschool children and 6-year-olds. Surprisingly, these advantages are smaller in adults and absent in professional musicians. Some authors argued for medium transfer of skills such that cognitive control (executive functions) or language processing rather than broad mental abilities benefit from musical training in adults. In the aging context, it is next to impossible to distinguish whether group differences in general abilities reflect expertise-driven mitigation or preserved differences, which existed prior to skill acquisition. For example, two studies found superior performances on tests of broad visuospatial abilities in architects (Salthouse et al. 1990) or graphic designers (Lindenberger et al. 1992). At the same time, age-related differences were similar in experts and novices ruling out experience-related mitigation. The authors argued that the

preserved difference account provided the best explanation for these findings.

Evidence for the compensation account remained suggestive. Charness (1981) proposed that older chess experts compensate for slower search rates by relying on refined, knowledge-based processes of move selection. Other authors (Bosman 1993; Salthouse 1984) have speculated that older expert typists compensate for slower reaction time and reduced dexterity by increasing their eye-hand span (the amount of text they look ahead during transcription typing). An inherent problem of the compensation account is that it is difficult to determine whether older experts indeed acquired specific mechanisms in reaction to (as compensation for) age-related declines they experienced or whether these mechanisms were better preserved than other component functions found in young experts.

Limitations on Selective Maintenance of Expertise

A key factor determining experience-related mitigation is how closely experimental tasks relate to the expertise under investigation. However, even if tasks are closely related to the expertise under investigation, skill maintenance is typically not perfect if young expert performance is taken as a benchmark. Studies on highly demanding professions like piloting or air traffic control (Nunes and Kramer 2009; Taylor et al. 2007) found that sparing from age-related decline is frequently limited in scope. In particular, these studies showed that some component skills are more easily maintained than others with speed or working memory demands marking those components more sensitive to aging even in experts. Obviously domains of expertise differ with respect to how many of such components they comprise, how sensitive they are to aging, and whether compensatory mechanisms are effective to prolong high levels of performance into late adulthood.

Several studies also suggested that solid reductions of age-related declines in specific skills require a certain level of expertise or accomplishment. For example, amateur musicians (Krampe

et al. 2001; Meinz and Salthouse 1998) or private-licensed pilots (Morrow et al. 1993) were found to show “normal” age-related declines even in tasks related to their hobbies. On the other hand, even top performers in their domain, who are highly motivated to maintain their levels of performance, are not immune to the effects of aging. In his longitudinal analyses, Simonton (Simonton 2012) showed that creative experts in their 60s and 70s were more productive than young experts starting their careers; however, peak productivities were at younger ages (late 30s and early 40s, depending on domains).

Summary and Implications

Expertise denotes domain-specific skills the development of which can be described as a gradual decoupling of expert mechanisms from domain-general functions. The available evidence gives reasons for cautious optimism that specific skills can be maintained at high levels into late middle adulthood or even old age. Naturally the typical cross-sectional studies in the age \times expertise domain are subject to cohort and selection effects. Arguably, older experts in these studies could represent the survivors of an age-graded winnowing process by which individuals with pronounced age-related declines in relevant capacities or insufficient motivation to maintain their skills have dropped from the field (or have been promoted to positions where more social skills matter). A second methodological constraint is that all evidence related to capacities assumed to moderate age-related changes in expert performance is correlational, and this is equally true for estimates of practice intensity.

Decoupling of expert from domain-general mechanisms goes a long way, and experts, who continue to strive for their best performances, show remarkably little age-related decline. However, expertise is not immune to aging. When experimental tasks cover a broad range of component skills, maintenance in older experts is rarely perfect, and some component skills are more difficult to maintain than others. This has important implications for certain professions as the studies

of air traffic controllers and pilots illustrate. The degree of decoupling of expert mechanisms from domain-general mechanisms might itself change with age. Theories of life span intellectual development refer to this phenomenon as differentiation-dedifferentiation (Li et al. 2004). Dedifferentiation means that at advanced ages acquired specific skills and their neural underpinnings become vulnerable, and we have to default to domain-general processes again. The implication is that expertise can certainly buffer age-related decline, but this effect does not extend endlessly into very old age.

Expertise does not rest on mere experience lest it fades away in the ruts of routine. An important implication for aging is that the maintenance of expertise does not come for free, but it requires continued efforts in the sense of deliberate practice. This is particularly true as most domains nowadays undergo rapid changes in component skills and standards. Meeting these challenges in terms of time, energy, and motivation becomes increasingly difficult considering physical and mental changes in later adulthood. The type of activities experienced as gratifying and the goals pursued differ between young and older adults (Ebner et al. 2006). There is no reason to assume that this typical adult development should be totally different in experts. From these perspectives the question whether young adult levels of performance could be maintained in principle becomes an academic one.

Synonyms

Family caregiving; Family intervention

Definition

Therapeutic interventions that change interpersonal processes among family members alter the structure or functioning of families with the goal of improving the family's abilities to meet the developmental needs of all members; aging family therapy focuses specifically on the "needs of families in which the key concerns center around the well-being of elderly members of the family" (Qualls 1995, p. 475).

Background

Families are a key social context for older adults, with family members making up more of the social network in later life than at any other time in adulthood. The salience of families makes them particularly influential to the well-being of older adults, and vice versa. The instrumental (aid with

tasks) and emotional support flow in multiple directions within the family across the lifespan. As older adults develop illness, disability, or frailty, family support often increases in intensity, frequency, or style in a pattern termed family caregiving. Transitions in family life can disrupt familiar patterns in ways that disrupt the well-being of older adults or other family members as well as in families with long-term deficits. Family therapy focuses on relationships within which older adults live and make their meaning as key opportunities for improving their well-being.

Conceptual Foundations

Family development and family systems theories posit that families engage a variety of processes to support the development of members (Walsh 2011), and those processes are influenced by structural characteristics of families (McGoldrick et al. 2008). Age-related changes in biological, psychological, or social functioning can alter family structures or processes in ways that lead families to seek assistance.

Basic family structures include marriage, partnership, and parenting that are often depicted in a diagram of a family tree called a genogram (McGoldrick et al. 2008). Intragenerational structures include marriage or partnership, siblings, and cousins. Intergenerational relationships are represented in vertical lines that illustrate parent-child relationships across multiple generations.

The entry and exit of members are defining characteristics of stages of the family life cycle because they represent structural changes that influence functioning. Ambiguity in family structures is particularly stressful on families (Boss 2007). An example of ambiguous structure in later life occurs when a member has dementia that renders him or her incapable of independent participation in family interaction.

Basic family processes include child-rearing, parent care, and partnership for pleasure and economic sustenance among many other functions family members perform for each other. Processes involve communication, verbal and behavioral, that cues family members to act, feel, or think in ways that become highly predictable circular cycles of prompts and responses. The recursive cycles of behavior among members of a family can be articulated as rules of the family system. Anticipation of the familiar sequence shapes the timing and selection of behaviors in particular relationships in ways that appear rule driven. Observers can name the rules that describe the sequences and interrupt the automatic pattern in order to open the opportunity for novel responses that meet members' needs far better.

Life stressors may alter family structures or processes in ways that interrupt support patterns for one or more members. Stressors may result from historical events such as war or economic depression; from normative life events such as employment, the onset or termination, or relationships; or from nonnormative events such as house fire. The individuals' coping responses to stressors are communicated in behaviors that impact other family members, sometimes altering structural or functional characteristics of the family system.

The chronological aging of members in a family may impact family structures or processes, primarily through changes in functional abilities to participate in family activities or self-care. In addition, cultural rules about roles for aging family members also influence family structures and processes if elders are imbued with particular roles or values within the culture. Illnesses or deaths that alter or remove members from the structures often provoke shifts in roles related to instrumental or emotional support. By later life,

older adults are likely to live as singles, with men more likely to live in partnership or marriage than women, especially in advanced age (Davey and Takagi 2013). Historical cohorts vary in number of children, leading to variation in the number and complexity of intragenerational as well as intergenerational relationships. When plotted in a genogram, or family tree, the older adults' families clearly have more intergenerational relationships than within-generation relationships.

The diversity of structures in aging families is great, especially when compared with younger families. In child-rearing families, the parent and child roles have relatively prescribed definitions, with variations across cultures in the timing of transitions, contexts of development, and rules about specific aspects of family roles. Child-rearing families experience role ambiguity primarily during periods of significant transition from one status to another (e.g., child to adult) or when membership status is ambiguous such as occurs when someone is missing in action in war and thus is not dead, but not participating in the family roles (Boss 2007). Aging families, however, are composed of primarily adult members, with no clear role definitions supplied by the culture for the important distinctions between adults as children of independently aging versus very frail or cognitively compromised aging parents. Similarly, there is no clear signal point when a marital or intimate partnership shifts from mutually autonomous to one defined by caregiving and care receiving. Structural ambiguities add stress to the family, especially in times of intensive role demands (Boss 2007).

Age-related chronic illnesses can alter family relationships by shifting roles, with long-term shifts into caregiver and care recipient as being one variation. Families may adapt roles, communication patterns, and decision-making structures from those used in the early adult phases. Later-life family challenges and adaptations occur within the context of many decades of interaction patterns, cultural norms, and expectations and particular intergenerational structures that offer strength, resilience, and challenges (Walsh 2011; Davey and Takagi 2013). Although most families adapt well to aging-induced transitions, some fail

to adapt effectively or experience stress during the period of adaptation; intense or protracted stress can undermine the well-being of one or more members. Perhaps the best-documented example is the impact of the transition to care for a member with dementia on the primary caregiver (see entry on caregiving/carer burden).

Families may enter later life with little preparation for the challenges or the contexts of aging. In recent centuries, each generation must learn the health, housing, social, and legal service structures for their own aging experience, because what was observed in the previous generations offers little guidance due to rapid rates of cultural change. Family therapy often includes education about aging processes or age-related diseases or difficulties, as well as about the formal service systems available to support older family members.

Problems Addressed by Family Therapy

In later life, family therapy can assist families with life stresses, health transitions, or relationship problems in the older or younger generations. The biopsychosocial model that has been embraced by healthcare points to the multiple domains of human well-being that have reverberating effects in others, so interventions with families may be key to supporting health interventions (e.g., changes in diet or activity patterns), psychological interventions (e.g., dementia or depression), or other social interventions (e.g., increasing the rate of social contact or addressing a conflicted relationship with another family member).

Social transitions in later life can disrupt long-term patterns of family life in ways that alter support to members (old and young) and impact other domains of functioning. Retirement generally is experienced as a positive transition, but when the retiree lacks control over the timing or conditions of the retirement, or loses significant resources with the retirement, other members of the family may be impacted. Remarriages and other intimate partnerships in later life can bring great joy and meaning to the couple, even as they may disrupt other aspects of family function (e.g., blending family holiday activities, assets, and

decision-making structures). Disruptions in the life of the mid-life generation can challenge the older members of the family system. Transitions in the lives of mid-life family members that can affect the older generation include divorce, incarceration, geographic relocation, or significant changes in lifestyle. Although these transitions can be navigated with minimal disruption to family patterns, they often require some shifts in communication style and frequency, nurturance, or problem-solving style, ultimately affecting the regular structures or processes of family life.

Chronic disease, sensory impairment, functional disabilities, and/or cognitive impairments in later life intrude upon families, often altering structure, function, and meaning. Families play key roles in delivering health services to older family members, partner with them in management of daily life when illness or disability constrains independence, and negotiate transitions across the healthcare system repeatedly (e.g., from home to hospital to rehabilitation to home with home health to family support to complete independence). Not surprisingly, some transitions are accomplished poorly, with disruptions in needed care (emotional or instrumental). Although current models of health service delivery increasingly recognize the importance of empowering older adults and their families as key participants in the service delivery model, very few health systems can accommodate family members' participation on health teams.

Models of Family Therapy Applied to Geropsychology

Among the earliest adaptations of family intervention approaches for aging families was the application of family systems approaches to later life families by Herr and Weakland in what they described as a "counseling approach" (Herr and Weakland 1979). Grounded in family systems theory, they advocated the use of problem-solving techniques with aging family challenges as conceptualized by systems theory. The contextual approach to family therapy was applied to aging families by Hargrave and Anderson (1992) who

emphasized the importance of addressing obligations and expectations that require forgiveness in order to repair family functioning from the effects of previously painful experiences. Structural family therapy (Minuchin 1974) informs the approach to family therapy for caregiving families who are experiencing significant role shifts by Qualls (1995) and Qualls and Williams (2013).

Medical family therapy has evolved in the past two decades to offer substantial guidance to geropsychologists whose work with later-life families often involves illness-related challenges and transitions (McDaniel et al. 2013). Medical family therapy applies the principles of family development and family systems to families in which one or more members have significant health challenges. This approach addresses the changes in structure and function that illness can impose on families as well as the meaning of illness in the family system (McDaniel et al. 1997) and thus is directly applicable to work with later-life families who are most likely to seek help for health-related challenges.

Family Therapy Research

The research literature on family therapy with aging families is limited. Reviews of the literature show a stable pattern of approximately 3% of articles in the major marriage and family journals that focus on aging over recent decades (Lambert-Shute and Fruhauf 2011), a rate far lower than expected if research productivity matched the demographic representation. Low rates of curriculum content on aging within marital and family therapy programs offer little opportunity for marriage and family therapy trainees to learn about practice with aging families (Barber and Lyness 2001).

Outcome research on interventions with aging families has focused heavily on families in caregiving situations. Family-level counseling was a key component of successful intervention for dementia caregivers in two programs that have a substantial evidence base: the New York University (NYU) Caregiver Intervention (Mittelman et al. 2004) and the multisite REACH (Schulz et al. 2003) (Resources for Enhancing

Alzheimer's Caregiver Health) study and its extension, REACH II (Belle et al. 2006). Although intervention research with family caregivers has been conducted around the world, family-level interventions have not been the focus outside the USA.

Reviews of the literature on interventions with dementia caregivers found that education and support groups alone produce poorer outcomes than more intensive interventions, including family counseling interventions (Coon et al. 2012). Interventions often include training in specific strategies for communicating with persons with dementia, problem-solving approaches to addressing behavior problems, and strategies for enhancing social support for the primary caregiver(s).

General models for intervention with family caregivers can be applied to a wide range of situations. A strong assessment is key to planning interventions for caregiving families (Zarit and Heid 2015). As with any family faced with significant health problems, aging families require assessment of the care recipient and caregiver and the broader context for care (Zarit and Heid 2015).

Family interventions may also be helpful for problems other than dementia, including elder abuse within families and challenges experienced by grandparents rearing grandchildren. Families of persons within other populations who require family support also benefit from variations on these interventions (e.g., traumatic brain injury, developmental disabilities, or serious mental illness).

Culturally diverse populations require strategies that are aligned with cultural frameworks on the roles of families and the acceptability of nonfamily members understanding the inner workings of the family system (Knight and Sayegh 2010). Furthermore, deliberate outreach approaches are needed in order to reduce disparities in access to services.

Future Directions

Today, family therapy for aging families is based on the limited conceptual scholarship, with very little empirical data, primarily from the USA. Looking forward, conceptual scholarship needs to

elaborate the foundational constructs for adapting family therapy interventions into strategies and protocols for particular problems faced by diverse family constellations. The elaboration of the conceptual frameworks provides the foundation upon which fidelity of interventions in outcome research can be investigated. Randomized clinical trials are challenging to conduct with aging families due to the heterogeneity in family structures, processes, and problems, yet rigorous empirical investigations need to inform providers about which interventions work for which populations in which settings to achieve which outcomes.

Descriptive research on help seeking by aging families is also needed. Aging families are often geographically dispersed, with highly varied membership and member participation in interventions. When not recruited for research studies, exactly who seeks intervention, in what family constellations, for which problems, and from what sources? Feasibility questions are also key: how are families engaged in intervention, by whom, for what purposes, with what value, to what members of the family, and the service delivery network. How does integrated care offer opportunities for engaging families?

Cultural variation in the processes of engagement (which families seek services in which settings, and accept services from which types of providers) is critical to reduce the disparities in access, services, and outcomes. Careful mapping of the types of problems that families bring to service settings and the interpersonal dynamics within which those problems are embedded would lead the field far toward understanding where interventions can be targeted effectively. Variations in families due to the nature of the stressors being experienced, communication styles and processes, and cultural contexts all need far more investigation. The field knows little about the cost to family members, older adults, or society of the failure to support families with interventions.

Research is needed on training strategies for building skill in geropsychologists to assess and intervene with aging families and with marriage and family therapists to address the distinctive challenges presented by aging families. Training

professionals in family therapy approaches to work with older adults will add to the demand for policy shifts in reimbursement structures for family-level interventions in countries where health and social service reimbursement regulations constrain payments to particular family constellations (e.g., care recipient must be present).

Synonyms

Filial norms; Filial obligation; Filial piety; Filial responsibility expectations

Definition

Filial obligation is the obligation of children to defer to parental wishes and meet a parent's needs. This role not only includes contact with parents, having shared living arrangements, and providing routine care, but also involves providing physical, informational, and emotional support and financial help, especially when parents reach old age. This responsibility also includes more comprehensive efforts to ensure a parent's safety, health, emotional well-being, sociability, and continued integration in society through contact with the outside world (Schorr 1960; Caro 2014; Whyte 2004).

What Is Filial Responsibility?

Families provide psychological, social, and physical resources to family members throughout their lives, and family is especially important in an older adult's later life. When physical, cognitive, or mental functions decline, family can provide assistance with ADL (activities of daily living) and IADL (instrumental activities of daily living); medical and long-term care information; emotional, affective, and psychological support; and financial aid.

The terms filial responsibility, filial norm, filial piety, and filial obligations are often used interchangeably. Some studies use the term filial responsibility expectations to reflect what parents expect from their offspring instead of the adult children's perspective or normative obligation beliefs.

Different theoretical approaches, including societal, familial, attitudinal, and psychological perspectives, shed light on the development and maintenance of filial responsibility (Donorfio and Sheehan 2001). From the societal perspective, cultural expectations and values influence the nature and expectations of parental care, and filial obligations are culturally regulated duties based on kinship. Familial perspectives refer to the family norms that ensure that certain functions are performed to maintain and protect the health and safety of older family members. These norms and expectations vary across families, races, ethnicities, socioeconomic statuses, and geographic locations. Attitudinal perspectives refer to the

attitudes assumed by adult children toward intergenerational support, interaction with parents, visiting, and caregiving. Psychological perspectives posit filial responsibility as a developmental stage or task confronting middle-aged children. Filial responsibility is also viewed as a process in which children face a developmental crisis called “filial maturity” (Marcoen 1995). Filial maturity requires adult children to accept that their aging parents are becoming weaker and more vulnerable and are no longer reliable support resources. Adult children must renegotiate their relationship with their parents during this crisis before coming to accept their responsibilities for parents.

Previous studies have universally sought to establish the rationale and motive for filial obligation (Ganong and Coleman 1999). For instance, filial responsibility has been explained as a form of altruism based on kinship ties, involving a genetic predisposition to care for those to whom one is genetically related. A norm of intergenerational transmission of reverence has also been used to explain filial responsibility; when children support their parents, they will likewise receive support when they reach old age. A feeling of gratitude also explains why children reciprocate their parents’ help; parents raised their children or helped their children establish their own families, and so children help their parents in return when needs arise. Filial attitudes may also be influenced by moral duty if one believes that good people show filial responsibility. Children may also be motivated by emotional attachments to their aging parents. Intergenerational solidarity is another model that explains filial responsibility, and this model proposes that children support their aging parents because of “familistic norms, affection for parents, an opportunity structure that facilitates interactions, and perceptions that exchanges between generations have been reciprocal” (Ganong and Coleman 1999).

Personal Feelings of Obligation and Normative Obligations

Filial responsibility includes an individual’s sense of obligation to assist parents and

normative obligations or societal beliefs (Ganong and Coleman 1999). Norms of filial responsibility refer to the recognized duties and obligations that define the social role of adult children with respect to their aging parents. These norms have been described as “more than an expectation of one’s own behavior” (Gans and Silverstein 2006). They are socially defined norms with regard to family obligations and are also described as “rights and duties that specify the ways in which any pair of kin-related persons is expected to behave toward each other” (Rossi and Rossi 1990). From this perspective, filial obligations or filial responsibility expectations are used to label normative beliefs on adult children’s obligations to their aging parents. Personal feelings or attitudes of obligation, however, are defined as the individual’s self-perceived responsibilities. In this perspective, personal obligations are changeable beliefs, and they may change as the relationship and the contexts shift. Hence, a sense of filial responsibility may represent internalized norms of the society or may arise from personal affection for the parent and hence a genuine concern for the parent’s welfare. In most cases, children’s filial responsibility has both elements.

A close examination of the general literature on filial responsibility, including filial obligation, filial piety, filial norms, and filial responsibility expectations, may reveal that authors face difficulty conceptualizing filial responsibility and even simply understanding the expansive idea of that responsibility. The value has been defined in various ways depending on the authors’ interests and the purposes of the studies, resulting in a variety of measurements of filial responsibility (Sung 1995). The measurements include individual feelings, attitudes toward specific behaviors such as coresidence, and the frequency of supportive behaviors toward aging parents. Some are limited to care-related behaviors toward parents with disability, and others include more comprehensive support for protecting aging parents and deferring to them. Consequently, systematic development of measurement for the different components of filial obligation is needed.

Life Course, Age, Gender, Race, and Cohort Variations in Filial Responsibility

Research has shown that filial obligations may be subject to change throughout the course of a lifetime. In general, younger generations show relatively stronger sense of filial obligation than older generations (Gans and Silverstein 2006), suggesting a weakening of normative beliefs with increasing age. One explanation is that the younger generation, because of inexperience, tend to hold idealistic views about caregiving without considering its practical implications and consequences. In contrast, older generations may have already been exposed to these situations, either as caregivers to their parents or because they have needed help, and may also have observed these situations among their family or friends. Exposure to these experiences may change individuals' perceptions of filial piety (Gans and Silverstein 2006).

A lower expectation reduces the likelihood of "filial discrepancy" (i.e., seeing children's filial behaviors as less than desirable), thus enhancing satisfaction with children's support and avoiding strain in the relationship (Cheng and Chan 2006). As excessive demands may discourage children from offering support when future needs arise, lowering filial expectation is adaptive in the long run.

From a sociological perspective, modernization and aging theory has attempted to explain the decline of status and family support for older parents in developing as well as industrialized countries. Modernization and aging theory explains the decline as a result of extended families giving way to the modern nuclear family, which is related to urbanization and industrialization. The emphasis on the bonds between young parents (i.e., adult children) and their dependent children within the reduced family structure, ultimately, causes a decreased willingness on the part of adult children to provide for their aging parents (Aboderin 2004). The role of material constraints, however, provides an alternative explanation, which emphasizes the incapacity of adult children, rather than unwillingness, to provide

support to their aging parents due to the rising cost of living, especially in urban areas. The growing financial pressure in many economies worldwide put families in a difficult situation if they have to provide support to older family members and younger children at the same time (Aboderin 2004).

On the other hand, an opposite cohort effect has been found in previous studies in that those born in the 1950s and 1960s showed stronger filial beliefs at midlife than their parents' generation (i.e., the later-born generation reported stronger filial obligation than the earlier-born generation). This seemingly confusing may be explained by the fact that the pro-familism trend, which existed simultaneously with a historical trend of weakening filial responsibility, peaked in 1970s and 1980s but diminished subsequently (Gans and Silverstein 2006).

Previous research has identified several personal and family characteristics that explain variations in filial responsibility (Burr and Mutchler 1999). Gender differences have been found, with women consistently showing stronger beliefs of filial obligation than men across cultures. Gender also affects how responsibilities to aging parents are realized. Women tend to provide more housework and personal care for family members than men do. However, in Asian countries, it has been observed that older parents tend to prefer children of the same sex to perform care activities that involve personal privacy such as bathing (Cheng et al. 2015). Moreover, financial assistance to older parents is generally believed to be the responsibility of adult sons.

Economic class is another factor that determines how filial piety is manifested. Middle-class families prefer the transfer of money and goods rather than the provision of actual support, whereas the latter is preferred by the working class. Consequently, working- and lower-class families show stronger beliefs of filial obligation.

Geographical area is another factor. Family ties are stronger among those living in rural areas, who report a greater sense of filial responsibility than those in more urbanized areas (Lee et al. 1994a). This may be a reflection of geographical location; family members usually need to

cooperate with each other in economic production, such as on farm, in rural areas. When actual in-kind help is needed, geographical proximity becomes an important consideration, with distance between parents and children found to be associated with the amount and type of help children provide (Rossi and Rossi 1990). Coresidence or geographical proximity increases help exchange. However, no type of help increases compensatory as the result of fewer in-kind help due to the greater distance.

Filial responsibility also varies by cultural background. In the United States, attachment to the norm of filial responsibility is generally stronger among minority families, including African-Americans, Hispanics, and Asian-Americans than among non-Hispanic whites. African-Americans, for example, who have long struggled for economic and social equality, may have developed extensive generational support networks among family and friends (Burr and Mutchler 1999). Hispanics and Asian-Americans may experience similar circumstances as the African-Americans, and their traditional filial attitudes may be maintained by strong family ties, even though impacts of immigration and acculturation, which likely undermine traditional values, cannot be overlooked. Yet, results were not always consistent. A lower sense of filial obligation among African-Americans, compared with Caucasians, has also been reported (Hanson et al. 1983). Future research should recruit larger and more representative samples of different ethnic groups and examine the longer- and short-term impacts of immigration and acculturation on filial responsibility, in order to reach more definitive conclusions about cultural influences and variations in filial attitudes.

Filial Responsibility for Caregiving Behavior

As parents age, filial responsibility increasingly emphasizes physical assistance, emotional support, and financial support to address parents' needs. In particular, once parents are perceived to have dependency needs, adult children

mobilize their resources to meet the needs. How adult children fulfill their roles as caregivers in the family is contingent on the family situation.

Studying the whole family that includes all the adult children, their interrelationships, and their relationships with aging parents (instead of just one parent-child dyad removed from the family context) is needed to understand the behaviors that help parents. For example, when a family has multiple children, each sibling expects support to parents from the others. While siblings may not provide care in exactly the same ways, the distribution of filial responsibility is partly determined by family structure, family history, and affective ties (Matthews and Rosner 1988). Gender also determines the type of care adult children provide to their parents. Female siblings are more likely to be involved in providing care than male siblings when there are both male and female siblings in a family, although sons do help when asked. Sons may feel obliged to provide care, as daughters do; however, some types of caregiving tasks are more traditionally provided by females. As a result, female children are more likely to engage in routine care (e.g., housework and personal care) than male children. When male children are the caretakers, their wives are also usually involved, either in an assisting or a principal capacity, although fewer and fewer daughters-in-law are willing to assume the primary caregiving role (Zhang et al. 2014; Cheng et al. 2013). In families with multiple children, siblings share caregiving roles; some siblings coordinate routine care, whereas others are involved sporadically or help financially. The birth order of siblings is an important factor in care provision decisions in Asia and sometimes in Western countries; for example, the oldest sibling may be expected to be involved in routine care (Cheng and Chan 2006).

The effects of filial responsibility on family caregiving have been examined in several studies. On the one hand, filial responsibility may reduce the negative impacts of caregiving. Several studies have reported that filial piety is related to a lower level of the caregiving burden (Khalaila and Litwin 2011). On the other hand, a strong sense of filial obligation may place undue pressure on the

caregiver, leading to feelings of guilt when one seems to perform below self-expectations (Cheng et al. 2014). The benefits of filial responsibility may also differ according to culture (Funk et al. 2013), and more studies are required to elucidate how cultural values moderate the relationship between filial piety and caregiving burden. It also has to be mentioned that the relationship between the attitude of filial responsibility and actual caregiving behavior is not clear. Attitudes of filial responsibility are not necessarily translated into enacted social support (e.g., personal care) (Chappell and Funk 2012). Unfortunately, research on the impact of filial responsibility on caregiving is limited by inconsistent definitions and measurements of filial responsibility. Thus, future research should clarify the relationships between feelings of filial responsibility, adult children's helping behaviors, the selection and usage of public long-term care service, and caregivers' mental health outcomes.

Filial Responsibility Expectations

Although the foregoing discussion has focused on children's filial attitude and its relationships with caregiving behaviors, the role of older parents' filial responsibility expectations should not be ignored. The concept of intergenerational solidarity suggests that caregiving behaviors are more likely to be executed in an appropriate manner when the two generations share similar filial responsibility norms and make decisions collectively (Bengtson and Roberts 1991). Otherwise, there may be negative impacts on older adults' personal well-being when their expectations are unrealistic or are not met by their children (Cheng and Chan 2006; Seelbach and Sauer 1977).

Some studies have focused on the perspective of the older parents on filial responsibility expectations. These studies measure filial responsibility expectations as the extent of support to which aging parents feel entitled to receive from children. Women, unmarried, those in poorer health, and those of lower economic class and education are more likely to hold stronger filial responsibility expectations (Lee et al. 1994a). This may

simply reflect that those who need help expect more from adult children. Although parental expectations of filial responsibility appear to vary by race, the findings are far from being conclusive. For example, whereas a study has reported stronger filial responsibility expectations among African-Americans than among Caucasians, even when sociodemographic, health, and support factors were statistically controlled for (Lee et al. 1998), others have found the reverse or a lack of difference between the two ethnic groups (Lee et al. 1994b). Moreover, parents' expectations of filial obligation do not determine the actual amount of support received from adult children, although parents' aid to children does positively affect the amount of aid adult children provide to their parents (Lee et al. 1994b).

Filial Responsibility in the West and the East

In the United States and some other Western countries, filial responsibility has become a growing issue in view of the number of older adults with different degrees of dependency. Actual help from offspring is typically provided only after the parents have ceased struggling to maintain their independence and self-sufficiency, as individuals taking responsibility for themselves are culturally valued in these countries (Cheng and Chan 2006; Silverstein et al. 1996). An ideology that people are responsible for themselves and their dependents is the result of a long history of autonomy orientation or individual rights in the United States and elsewhere. Yet, ideas about individualism have existed alongside the assumption that women will be available, able, and willing to assist and support family dependents in the household. However, this assumption is increasingly challenged due to changing family structure, including the downsizing of the family, women working outside the home, or the reconstruction of families through divorce or remarriage, uniformly closed relationships, or the unavailability of family members to provide services for aging parents. How such changes in the family affect the provision of care to aging parents in the context of

the traditional emphasis on personal autonomy remains to be seen.

In Asian societies, the concept of filial responsibility is commonly believed to derive from Confucianism. Filial piety is a dominant idea in Confucian teachings and guides the relationship between children and parents. This belief system prescribes such behaviors as showing respect, being obedient, and honoring or promoting the public prestige of one's parents and ancestors. Filial piety, in the traditional sense, also emphasizes the value of producing an heir, carrying on the family line, and caring for the parent, whether healthy or sick (Cheng and Chan 2006). Children in Asian countries are taught from an early age to show courtesy and respect to older adults (Bengtson et al. 2000). Having filial children is a source of pride and major support resource, so much so that childlessness poses a risk for ill-being in Asian older adults (Cheng 2014). However, it has been argued that the value of filial piety has been changing in Asian countries such as China, Korea, and Japan because of industrialization and urbanization. Nevertheless, filial piety has remained a core value, and rapidly aging societies have continued to rely on family support with fewer children to provide it. In this context, formal social services and long-term care programs are expanding to meet the needs that families cannot provide. Thus, the unavailability of family support has led to modifications of the methods used to support older adults.

Filial Responsibility and Aging Policy

One major issue in societies with aging populations and declining fertility is how to provide care for the elderly. The reduction in the number of potential caregivers vis-à-vis the increasing number of frail older adults places strain on the state's health care and support resources. The combined effects of increased longevity, fewer kin ties, and women's social advancement in rapidly aging societies lend greater importance to the balance between family and state responsibility in care provision for the aged (Cheng et al. 2015). However, weakened

marital relations or reconstructed family networks erode familial responsibility and make family members unavailable as a future resource for supporting aging parents.

The traditionally important role of the family in supporting aging parents has been well documented, and even societies that have introduced long-term care programs retain this fundamental assumption. It is generally recognized that the role of the state in care provision will become increasingly indispensable, along with the rapid increase of the older adult population, but whether that will diminish family responsibility in providing for the needs of older family members is debatable. Nevertheless, the state can never replace the family's support functions entirely, as certain support functions, such as confiding and affectionate exchanges, cannot be reliably replicated by formal care services, though some of the traditional family caregiving tasks could be replaced by the expansion of public services.

However, current aging policies in most countries face the limitation of the competing roles between family and states. Most studies support the idea of complementarity rather than substituting family with the state (Bengtson and Lowenstein 2003). Complementarity is based on the idea that the family would provide care by using services when the service reduces the family's burden. In this way, public services could contribute toward practical and material support so that the family can focus more on emotional support. Additionally, the generous pension system in some countries allow older adults to reciprocate via financial support to the younger generation, thus sustaining adult children's in-kind support to parents (Bengtson and Lowenstein 2003). How state involvement changes concepts of filial piety and adult children's responsibility to parents remains to be seen.

Conclusion

Filial piety is a multidimensional concept. It includes normative expectations, actual expectations at the personal level, and enacted behaviors. When it comes to expectations and normative

beliefs, there could be intergenerational differences and conflicts that produce tension between adult children and their aging parents. Understanding filial responsibility and behaviors within the family context becomes more and more important in aging societies. As we embrace the challenges of our rapidly aging societies, both family support and formal care provided by the state are necessary to meet the needs of an aging population. However, with the reduction in the number of children per family, the possibility of relying on the family is reduced. Balancing reliance on formal services and reliance on informal support networks becomes a crucial issue. Although it is often said that state involvement will erode traditional family values and responsibilities, we opine that the proper provision of formal services and social welfare may be necessary to preserve the values of filial piety and family responsibility because these values will only break down more quickly if families cannot cope.

Some studies conclude that filial piety is still strong even in the face of changes to traditional family structures and have introduced public long-term care programs in modern society. However, ambiguities with regard to the way the concept is defined and measured across different studies have sometimes clouded conclusions. Different researchers may talk about filial piety at the same time; yet one may be referring to normative expectations, another to self-expectations, and still another to filial behaviors. However, these constructs are not identical. For instance, a strong belief in filial responsibility does not necessarily imply enacted supportive behaviors to aging parents in times of need. Thus, researchers need to define the concept more clearly in the future and preferably assess the different aspects of filial piety simultaneously so that we can have a more thorough understanding of this important topic as we embrace rapidly aging societies.

Synonyms

Financial planning; Financial security; Life savings; Pensions; Retirement planning; Retirement savings

Definition

Financial planning for retirement refers to the process that an individual undertakes to safeguard his/her financial security post retirement, most often in the form of voluntary financial contributions to pension plans and personal savings accounts while still in employment.

Introduction

Aging has been identified as one of the four key “megatrends” that will shape the world in over the next 15 years. People are living longer and it is estimated that the typical worker today is likely to have approximately 15–20 years of retirement (Adams and Rau 2011). Acknowledging distinct variations in national social security and pension provisions across countries, the OECD in 2012 highlighted that recent reforms in many developed countries will lead to lower public pensions for future generations of retirees, to the extent that future retirees will have to rely less on social security schemes and more on voluntary pension plans to finance their own retirement. When one considers that most people tend to wait until the age of about 48 years before they start planning for their retirement (Hershey and Mowen 2000), the suggestion is that many workers will leave employment with insufficient resources to maintain their financial independence during

retirement. The absence of adequate retirement preparation poses a real concern (at the individual as well as at the policy level) about individuals' ability to adequately finance their retirement, with the concomitant risk of falling into poverty in later life. Calls for concerted national efforts to foster long-term investments in income and old-age pension systems are being made amid concerns that retirees across the globe run the risk of becoming poorer relative to the rest of society.

Importance of Financial Planning for Retirement

Our understanding of retirement has been informed by a well-developed body of research evidence that has described retirement as an identifiable stage during an individual's life cycle. Much of the early research on retirement focused on the experience of transitioning out of the workforce and in particular on the loss of job role. This literature evolved to consider factors associated with the physical and psychological effects of no longer being "employed" and the attendant loss of structure, focus, purpose, and social connection that many retirees wrestle with. More recent research has focused attention on unearthing a range of antecedent factors that may help predict positive adjustment to retirement, and here, financial planning is recognized as one critical activity which may facilitate both a successful transition into retirement and satisfaction with one's retirement lifestyle, and consequently, an activity that facilitates successful aging in retirement.

While research has shown that higher income promotes better retirement adjustment, and that inadequate income and financial stress are associated with dissatisfaction and more negative retirement experiences (Heraty and McCarthy 2015), it is almost a certainty that many retirees could have set aside savings while they were working but failed to do so. Given the centrality of financial planning for adjustment and well-being in retirement, there is a growing debate that the stumbling block for many people is a widespread uncertainty about how to go about financial planning for the future.

Theoretical Frameworks

Research on retirement has adopted varying approaches to understanding the dynamics of when and why people retire, how they approach preparing for their retirement, and how they adjust to life in retirement. A recent review (Wang and Shi 2014) depicts three particular psychological models for understanding retirement: the temporal process model encapsulating retirement planning, retirement decision-making, and retirement transition and adjustment; the multilevel model of retirement which institutionally embeds retirement and individual decisions and plans into a social, cultural, and organizational milieu; and the resource model which focuses on retirement adjustment as a fluctuating process dependent on a range of individual resources. Resources here are understood to include an individual's total capability required to fulfill a valued need, and therefore comprise a combination of income, health, and social support resources (Kim and Moen 2002; Donaldson et al. 2010). A more recent six-factor resource model (Wang and Shultz 2010) extends beyond the resource categories of physical (health), financial (income), social resources (relationships and activities) to include emotional resources (positive emotions), cognitive resources (including self-esteem, mastery, and optimism), and motivational resources (goal clarity and tenacity). Together, this resource perspective suggests that resources determine retirement well-being in terms of retirement adjustment and retirement satisfaction. It is suggested (Heraty and McCarthy 2015) that this resource perspective could also be used to explain preretirement behavior. Since the accumulation (and depletion) of resources occurs across the life span, it is likely that the valence of particular resource types (at critical points in time) will be associated with certain preretirement behaviors, including financial planning for retirement.

Focusing on financial preparation for retirement here, we can trace the use of a range of perspectives to understand the dynamics of individual financial planning behavior. Early work (Ando and Modigliani 1963) used life cycle economic theory to explain individuals as rational

economic maximizers who make decisions that will afford them the highest net benefit, and so will make investment decisions that will yield higher returns over the longer run. The theory of planned behavior (Ajzen 1991), based on earlier work on reasoned action, has emerged as one of the most influential frameworks for the study of human action. This theory suggests that human behavior is guided by three particular kinds of considerations: attitudes about the likely consequences or other attributes of the behavior (*behavioral beliefs*), attitudes about the normative expectations of other people (*normative beliefs*), and attitudes about the presence of factors that may further or hinder performance of the behavior (*control beliefs*). In consort, behavioral beliefs produce a favorable or unfavorable attitude toward the behavior; normative beliefs result in perceived social pressure or subjective norm; and control beliefs give rise to perceived behavioral control, which is the perceived ease or difficulty of performing the behavior. In general, the more favorable the attitude and subjective norm is toward a certain behavior and the greater the perceived behavioral control over that behavior, the stronger an individual's intention to perform the behavior under consideration (Ajzen 1991). The relative importance of these three determinants is expected to vary across behaviors and situations. This suggests that financial planning for retirement is a function of the degree to which people feel they need to make adequate provision and have the capability to make such provision now. A number of additional features have been identified in this regard and are explored next.

Predictors of Financial Planning for Retirement

The possibility of being able to predict who will most likely engage in financial planning behaviors is intuitively appealing at several different levels and remains an area of considerable research interest, especially in terms of retirement planning. To date, research has unearthed a combination of demographic, dispositional, and psychological variables that have some

explanatory power in helping to predict financial planning behavior generally and financial planning for retirement specifically. These will be considered in turn.

Turning first to demographic predictor variables, it has been shown that the nature and amount of preparation people engage in changes (i.e., increases) as they draw nearer to the retirement event (Hershey et al. 2007; Phua and McNally 2008). This *life stage* view of planning can be understood through the Life Course Perspective (Elder 1995), which presents our lives as a series of key transition events, during which individuals reflect on their own development and interpret their aging as they move across the life span. The closer one gets to retirement age, the more readily individuals can conceptualize themselves as being retirees, and the more likely they are to plan for that more immediate life stage.

There is also some evidence (Moen et al. 2001) to suggest that those with higher overall levels of *education* are more likely to engage in financial planning behavior. This may be related to better financial literacy or higher incomes linked with better job opportunities overall.

Gender appears to have some explanatory power when it comes to predicting financial planning. Specifically, men are more likely than women to engage in financial planning (Moen et al. 2001; Glass and Kilpatrick 1998). Women appear to have lower occupational pension coverage and lower pension income than men, due at least partially to interrupted work histories because of occupational segregation, childbirth, child-rearing, and other caring responsibilities. Given that women have a higher life expectancy than men and so are more likely to have longer life in retirement, they may run a higher risk of income poverty in retirement.

Financial literacy has been consistently found to be a strong predictor of financial planning for retirement (Lusardi and Mitchell 2011). Although financial knowledge and financial literacy in general populations is considered to be low (Lusardi and Mitchell 2011; Babiarz and Robb 2013), it becomes a key concern as individuals consider when and how to plan for their retirement. In particular, a working knowledge of the basic

fundamentals of finance and economics, including understanding compound interest, inflation risk, and risk diversification, provides individuals with some objective knowledge of what may be required for pension purposes. Evidence (Lusardi and Mitchell 2011) suggests those who actively plan for their retirement tend to arrive close to retirement with much higher wealth levels and display higher financial literacy than those who fail to plan.

The *temporal perspective* explores how individuals adopt a long or short time perspective when considering finances. The ability to engage in and commit to planning over a longer time perspective has been shown to explain variations in individual savings patterns (Van Dalen et al. 2010), such that those who adopt a longer time horizon are more likely to engage in active planning for their retirement.

Risk tolerance has been found to partially explain financial planning behavior. In this context risk tolerance provides an indication of the amount of financial uncertainty someone is willing to accept. Risk propensity is thus an individual's attitude and behavioral tendency toward taking or avoiding risks. Financial risk tolerance has been described as an individual's willingness to engage in financial behaviors in which the outcomes remain uncertain and possibly even negative (Grable et al. 2009); it has been shown that those with a higher propensity to plan for their retirement are more risk tolerant. Those who have a tendency to avoid risk have been found to have more conservative investment patterns in retirement savings and therefore lower income replacement in retirement. There is also some indication of a lower preference for risk taking among women when compared with men.

Self-efficacy is a well-established construct in the psychological literature that describes an individual's perception of his or her ability to perform a certain behavior in response to a particular threat or challenge (Bandura 1977). In terms of financial planning, self-efficacy influences the perceived amount of control and ability one feels when considering and dealing with financial plans – the extent to which one feels capable of developing plans and following through with them.

There is some evidence to suggest that individuals with higher levels of self-efficacy when it comes to saving for retirement are more likely to participate in pension plans and for this to be reinforcing (Lusardi and Mitchell 2011; Wiener and Doescher 2008).

A link between individuals' *self-perceptions* or self-concept and financial planning behavior has also been established (Hira and Mugenda 1999) suggesting that financial behaviors are as likely to be influenced by sociopsychological needs as practical and financial ones. A recent study of self-perceptions of aging as psychological predictors of financial planning behavior (Heraty and McCarthy 2015) among older workers (aged 50 year +) found that, after controlling for age, gender, employment contract type, and industry sector, self-perceptions of aging significantly predict the likelihood of financial planning behavior. Specifically, older workers with more positive beliefs about their ability to control aspects of their aging were more likely to financially plan for retirement, while those with a less consistent awareness of their own aging were less likely to plan for their retirement.

Future Directions

In the last 20 years, people all over the world have, on average, gained 6 years of life expectancy. This increasing longevity means that people can expect to live for longer in retirement, and therefore, the pressure escalates to ensure that individuals can create and maintain the means to ensure their financial independence as they enter into retirement. This is particularly important where the evidence shows that inadequate income predicts dissatisfaction and maladjustment in retirement.

However, while recent work demonstrates the significance of a combination of demographic, dispositional, and psychological predictors of financial planning behavior, there is still much to be learned about the particular mechanisms that underlie financial planning for retirement. Indeed, since aging itself is characterized by large interindividual variability, planning for retirement is likely to vary as a function of many

contextual and psychological predispositions. The recognition that dispositional and psychological factors may be more salient than several demographic variables should facilitate a more nuanced understanding of how retirement itself may be internalized by the individual and allow for different strategies to be employed to cater for individual needs. In particular, they may help to identify those at more risk of failing to adequately prepare for retirement and who consequently run the risk of pensioner or retiree poverty. This suggests a key role for career counselors, organizational psychologists, those who are responsible for managing the transition into retirement, and those involved in designing training and development programs on career planning, pensions, and retirement planning in the workplace. While research continues to explore variations in financial planning behaviors, there is an interest in exploring patterns of behavior over time and on a longitudinal basis. Such a dataset would allow for a more patterned exploration of individual differences in financial planning over time. It is suggested that our understanding of successful aging generally would benefit considerably from the use of multiple data sets from longitudinal research studies (Zacher 2015).

Echoing recent policy-level discourse in both the European Union and in the United States on how to reform and restructure pension systems to facilitate retirement planning, it is suggested that research that makes comparisons across national contexts may be particularly helpful, with the potential to advance theory on financial planning for retirement, especially where different national pension systems are in operation.

Five-COOP Study

Jean-Marie Robine
INSERM & EPHE, Paris and Montpellier, France

Synonyms

100 years old people; People having reached the age of 100 years; Studies of centenarian people

Definition

The 5 Country Oldest Old Project (5-COOP) is the first study which analyzes the relationship between the level of mortality selection, the speed of accumulation of oldest old, and their functional health status. The 5-COOP project will provide the prevalence of the main functional limitations and geriatric conditions, at the age of 100 years, in the five geographic settings (Denmark, France, Japan, Sweden, and Switzerland) as well as the level of independence in activities of daily living.

The number of oldest old is increasing dramatically. However, the health status of nonagenarians and centenarians remains controversial: some studies show that they are healthy, while others suggest relatively poor health. Few studies have been able to explore how the mortality selection and the rate of increase of the oldest old are associated with cognitive and physical status

among very old people. The 5 Country Oldest Old Project (5-COOP) aims to study these questions by pooling and comparing representative samples of subjects aged 100 years in Denmark, France, Japan (including Okinawa), Sweden, and Switzerland. A theoretical sample size of 1250 (5* 250) subjects has been initially set. In the first phase, each sample is analyzed at the country level. In the second phase, comparisons among countries will be performed by merging the five standardized data sets. The 5-COOP project will increase knowledge about the age trajectory of several functional and geriatric conditions (mobility, difficulty in activities of daily living, cognitive disorders) and about the relationships between longevity and health (i.e., risk of dependence as well as medical and social needs). This understanding of mortality selection and health status will help us to plan care resources and make better population forecasts.

Background

One of the most important changes in modern societies is the (slow at first and then rapid) emergence of a new age group of population, the oldest-old people, beyond the usual elderly people. Actually, very little is known about the nonagenarians and the centenarians. Their numbers and their speed of accumulation greatly vary between developed countries even if life expectancies at birth are quite close. Even less is known about their health status. Data from Denmark suggest that the functional health of the Danish centenarians improved, especially for females, between 1995 and 2005, while data from Japan suggest a significant decline in the functional health status of the Japanese centenarians since 1973. In Denmark life expectancy at age 65 for females increased from 17.8 in 1985 to 19.0 in 2005 (1.3 years increase), while the number of females aged 100 years increased from 66 to 233 (250% relative increase). In Japan, life expectancy at age 65 for females increased from 19.0 in 1985 to 23.2 in 2005 (4.1 years increase), while the number of females aged 100 years increased from 536 in 1985 to 7892 in 2005

Five-COOP Study, Fig. 1 Centenarian rate in 26 European countries in 2006 (for females)

(1300% relative increase). This discrepancy in longevity increase suggests the existence of a trade-off between the level of mortality selection, the speed of accumulation of oldest old (centenarians or nonagenarians), and their functional health status.

In the mid-1990s, James Vaupel and Bernard Jeune demonstrated that the number of centenarians had doubled on average every 10 years since 1950 in half a dozen Western and Nordic European countries (Vaupel and Jeune 1995), however, starting with very small numbers. Since that time, the increase in the number of centenarians has been meticulously described in Japan (Robine et al. 2003) and in a handful of European countries such as Denmark (Jeune and Skytthe 2001), England and Wales (Thatcher 2001), Belgium (Poulain et al. 2001), France (Vallin and Meslé 2001), and Switzerland (Robine and Paccaud 2005). More recently, Robine and Saito analyzed the emergence of the centenarians in 27 European countries (Robine and Saito 2009), disclosing significant differences in the probability of becoming centenarian: For instance, French females, born in 1906, had an about ten times higher chance to reach 100 years alive than Bulgarian females (see Fig. 1).

On the other hand, little is known on the health status of the oldest old, nonagenarians or centenarians. Most published nonagenarian and centenarian studies consist of small convenient samples

of people being interested and who volunteer to participate in scientific studies exploring their “extreme longevity.” This often leads to the perception that centenarians are healthy people, free of most of the aging-related impairments, especially of cognitive disorders. In reality, the few representative or quasi-representative studies of nonagenarians and centenarians have demonstrated that they are in relatively poor health with a significant proportion being bedridden and/or demented (Andersen-Ranberg et al. 2001). According to Gondo and colleagues, less than 2% of the Japanese centenarians are in perfect health, defined as having no sensory problem, no cognitive deficit, and being fully independent in basic activities. Most of them should be considered as frail or fragile people (Gondo et al. 2006), confirming a previous study showing that only 1% of Italian centenarians were fully independent (Motta et al. 2005).

Relationships Between the Mortality Selection and the Health Status of Centenarians

However, studies have also suggested that these extremely old people were in relatively good health 5 or 10 years before reaching age 100. For instance, among the 1905 Danish cohort, the great majority of those who became centenarians in

2005 were physically independent when they were 92 years old. As only a modest decline in the proportion of independent individuals has been observed within this cohort between the ages of 92 and 100 (Christensen et al. 2008), differential mortality risk must have eliminated the frailer and more dependent nonagenarians. Indeed, nonagenarians and centenarians are strongly selected people, and the current spectacular increase in their numbers in many countries creates new concerns. For instance, in Japan the number of centenarians increased from 154 people in 1963 to more than 50,000 in 2013. This phenomenal increase is mainly due to a reduction in mortality above the age of 80 years. Are older people more likely to become centenarians because they are in better health or because they are better cared for or, more generally, because it is much easier to survive today than before? In Denmark, where the number of oldest-old people increased relatively slowly compared to most of the Western European countries, over the recent decades, the functional health status of female nonagenarians and centenarians significantly improved (Christensen et al. 2013; Engberg et al. 2008). On the other hand, in Japan, where the number of centenarians has increased more than threefold every decade since the 1970s, occasional centenarian surveys demonstrated significant declines in the functional health status of Japanese centenarians. For instance, the prevalence of female centenarians being bedridden increased from 21.9% in 1973 to 41.1% in 2000 (Gondo 2008). The first objective of the 5-COOP project is to clarify the existence of a possible trade-off between the speed of increase in numbers of oldest-old individuals and their functional health status.

The Cognitive Status of the Centenarian People

Besides specifying the prevalence of the main functional limitations and geriatric conditions in the five geographic settings as well as the level of independence in activities of daily living, the second important objective of the 5-COOP project is

to better characterize the cognitive status of centenarians. Indeed, the literature provides a very large range of prevalence of dementia among centenarians, from 50% to 100% (Calvert et al. 2006). The 5-COOP project has made an important effort in collecting comparable data on the cognitive functional status of the centenarians, and the merging of the five samples should help to better understand the dementia development in the very old. Combining information on health and cognition, the 5-COOP project will not only estimate how many centenarians suffer from dementia or are dependent in the five studied countries but will also estimate how many can be considered as frail or as successful according to various definitions of frailty and successful aging (Nosraty et al. 2012). For all these objectives it is of the utmost importance to get representative, or at least unbiased, samples of centenarians. This methodological issue was central since the beginning of this study, and the 5-COOP project did the maximum of what was possible in each country to maximize the representativeness of the samples. Data collection shows that not only it is more and more difficult for the researchers to contact the oldest-old people and their families because of the newly established privacy and ethical rules, but even when the families are contacted the rate of participation in social surveys tends to decrease. For these reasons, the participation rates in 5-COOP are much lower, except in Sweden, than expected or experienced in previous surveys in Denmark and in France.

The 5-COOP Consortium

The 5-COOP Study is a joint effort of the Institute of Public Health, University of Southern Denmark, in Odense in Denmark (<http://www.sdu.dk>); the research team “Biodemography of Longevity and Vitality” (INSERM U1198) of the French National Institute of Health and Medical Research in Montpellier in France (<http://www.inserm.fr>); several Japanese research groups in Keio University, Nihon University, Osaka University, and Okinawa International University

coordinated by the Advanced Research Institute for the Sciences and Humanities of Nihon University in Tokyo (<http://www.nihon-u.ac.jp/intldiv/en/academics/graduates/arish.html>) and the School of Human Sciences of Osaka University (<http://www.hus.osaka-u.ac.jp>); the Aging Research Center (ARC) of the Karolinska Institute at the Stockholm University (<http://ki-su-arc.se>); and the Department of Internal Medicine, Rehabilitation and Geriatrics, Geneva University Hospital (<http://www.hug-ge.ch>) as well as the Institute of Social and Preventive Medicine of University Hospital of Lausanne (<http://www.iumsp.ch/>) in Switzerland. All together, these five economically advanced countries present three levels of mortality selection among the oldest-old people which will allow the various research questions to be explored (Robine et al. 2010).

The 5-COOP Timeline

The 5-COOP project has been prepared through three international workshops held in Geneva/Archamps in November 2008, August 2009, and August 2010. At least two researchers per country participated in each workshop. The first workshop examined and discussed (i) the data availability (including ethical and privacy issues) in each country, (ii) the historical background (i.e., health events and transitions, diet, tobacco consumption, etc.), (iii) the more general sociodemographic background, (iv) the functioning and disability data, and (v) the usefulness of the clinical exam and biomarkers. The opportunity of a common study design were also discussed and working groups prepared proposals for the second workshop, as well as an Internet discussion on the general study design. The working groups examined four main issues (i) functioning (mobility, difficulty in activities of daily living – ADL, vision and hearing, physical tests), (ii) geriatrics (symptoms, fatigue, sleep, pain, mood; clinical assessment; cognitive functioning and biomarkers), (iii) health care consumption (health care and social services uses), and (iv) demography and background (sociology, economy, anthropology and

quality of life). The second workshop focused on the general study design and broadly discussed sample characteristics, questionnaires, physical tests, clinical and cognitive assessment, blood samples, data management, statistical analysis, and ethical issues. New working groups related to these issues were set up. Eventually, the study protocol and the various questionnaires were fine tuned during the third workshop in the summer of 2010.

The data collection, funded by AXA Research Fund, started in the different countries as soon as each national team got the legal permission to start the 5-COOP project. This phase took a few months in Denmark which was the first country starting to collect the data in May 2011, but it took more than 2 years in Switzerland which started to collect the data only in August 2013. The three other countries started to collect the data in fall 2010. Getting legal permission involves up to three kinds of committees as in France (privacy committee, ethical committee, scientific committee) and may have to be obtained from several regional or local committees as in Switzerland. In Denmark, the 5-COOP survey benefited from the staff of the Danish oldest-old surveys, and several specially trained interviewers collected the data throughout Denmark in a little bit more than 1 year. In Sweden, the 5-COOP survey was embedded in the SWEOLD survey, and the data was nationally collected by lay interviewers in about 8 months. In Japan, the data was collected in five prefectures evenly distributed from the north to the south of the archipelago: Aomori, Tokyo, Hyogo, Fukuoka, and Okinawa. The data collection lasted about one year and a half in Japan. In France, the data was collected in only one region, namely, the Languedoc-Roussillon, by the same interviewer who visited during two years and a half each new centenarian who accepted to participate in the 5-COOP project. In Switzerland, the data was collected in Western French-speaking cantons by trained nurses between August 2013 and December 2014.

The response rates in the 5-COOP project were lower than expected, except in Sweden where the participation was exceptionally high for a centenarian survey with a participation rate of 85.6%. The response rate reached only 30.4% and 31.6%

Five-COOP Study, Table 1 The 5-COOP project: Summary of the data collection

	Denmark	France	Japan	Sweden	Switzerland	Together
Starting date	05/05/2011	01/09/2011	20/02/2012	24/10/2011	21/08/2013	05/05/2011
Ending date	05/07/2012	31/03/2014	26/09/2013	27/06/2012	31/12/2014	31/12/2014
Sample size	504	756	1067	360	428	3115
Interviews	251	211	337	274	168	1241
Deceased before interviewed		63		40	13	116
Males	56 (22.3%)	36 (17.0%)	58 (17.2%)	75 (18.2%)	23 (13.7%)	248 (20.0%)
Females	195 (77.7%)	175 (83.0%)	279 (82.8%)	199 (81.8%)	145 (86.3%)	993 (80.0%)
Response rate*	49.8%	30.4%	31.6%	85.6%	40.5%	41.4%

*The response rate, in percentage, is obtained by dividing the number of conducted interviews by the number of centenarians contacted minus the number of centenarians who deceased before the date of the interview

in France and Japan, respectively, 39.8% in Switzerland, and 49.8% in Denmark. The impact of these low response rates on the representativeness of the samples will be carefully studied (see Table 1).

National and Common Analyses

The 5-COOP samples are first analyzed at the national level before being merged in the common 5-COOP database at the Geneva University under the responsibility of François Herrmann.

Data cleaning and national analyses started in 2013 for Denmark and Sweden. Various results have been already presented in several national conferences. The 5-COOP project organized a first symposium at the annual scientific meeting of the Gerontological Society of America in Washington in November 2014 (Robine and Saito 2014). Data cleaning is under way in France, Japan, and Switzerland. All data will be merged in 2015 and the first common analyses will follow. A theoretical sample size of 1250 subjects had been initially set for allowing the simultaneous analysis of up to 125 variables in multiple regression models. The final sample size of 1241 subjects will not reduce the statistical potential of the common analyses, which will be weighted according to the survey sampling schemes used in each country. Comparison among countries will be performed with usual statistics (i.e., chi square,

Kruskal-Wallis nonparametric tests, ANOVAs and multiple regression). The first elements to be compared are the participation rates, the reasons why data could not be collected, and the prevalence of geriatric conditions, including dementia and cognitive disorders. The results of the 5-COOP project will be publically available through scientific publications in several disciplines: anthropology, demography, epidemiology, geriatrics/gerontology, sociology, and public health.

Flexible Work Arrangements

Judith Davey
Institute for Governance and Policy Studies,
Victoria University of Wellington, Wellington,
New Zealand

Synonyms

Employers' attitudes; Employment of older people; Part-time work; Phased retirement; Prolonged workforce participation

Definition

Paid work arrangements that may be desirable for older workers, including flexible working hours, part-time work, working at home, part-year work, and casual work

Introduction

Longer lives and better health in later life provide an opportunity for prolonging participation in paid work beyond what has been considered a normal or sometimes compulsory, retirement age (often 65 years). The social, economic, and individual benefits of encouraging older people to

remain longer in paid work are increasingly recognized in academic literature and in policy statements (Carnegie Trust 1993; OECD 2006). There is considerable evidence that meaningful and appropriate work is beneficial to the well-being of older people. Remaining in or reentering the workforce has been shown to have a positive psychological impact for older people; the habits of work routine are beneficial to a sense of well-being and accomplishment and are linked to self-worth as opposed to retirement, which may be viewed as a non-role (Jaworski 2005; Hinterlong et al. 2007). Remaining in paid work provides people with social contact and mental stimulation. "Productive engagement" can lead to improved health and functioning for older people (Humphreys et al. 2003). Participation in paid work will also increase the incomes of older people, improving their material well-being in later life.

There are potential disbenefits to individuals. Retirement is now seen as a legitimate phase of life, a right that has been earned by a lifetime of paid work and something to look forward to (Phillipson 1998). Low levels of job satisfaction and low morale resulting from unsatisfactory working conditions can lead to a deterioration of both physical and psychological well-being, at a time when age-related health problems may be beginning to affect some people. The quality of work in later life is therefore important.

There are also social benefits. Society would be worse off if older people are not given the opportunity to contribute their skills and experience as role models and mentors in workplaces, helping to break down ageism and negative stereotypes. This will also contribute to intergenerational solidarity. A World Economic Forum report expresses this in terms of releasing accrued social capital among the older population and facilitating the process of adaptation to an aging population (Biggs et al. 2012).

Demographic trends suggest that labor and skill shortages will become more pressing in the future as younger people entering the workforce do not balance the numbers retiring. The economy therefore benefits from having an economically active older population, which will contribute to growth and the maintenance of living standards

and also, through taxation, help to meet the costs of an aging population. Older workers represent a valuable and often untapped source of increased productivity. Retaining older workers provides important benefits to employers in meeting skill shortages; retaining the valuable skills, experience, and the accumulated knowledge of older workers; and encouraging them to act as mentors to younger staff. Firms which understand the implications of aging will be better placed to address its challenges. Population aging itself can be a significant source of innovation and business opportunity.

If these benefits are to be realized and potential disbenefits are to be avoided, older people will require appropriate and acceptable working arrangements. Working conditions and experiences can be very influential in decisions about retirement from the paid workforce. These factors include the availability or otherwise of flexible conditions, access to training to keep up and prevent obsolescence of skills, the quality of working conditions, feeling valued by employers and colleagues, and having a sense of control and of purpose in their job (McNair et al. 2004; Smeaton and McKay 2005).

Elements of Flexible Working Arrangements

Alternative work options for older people are varied. They include permanent or semipermanent part-time work, sometimes linked to phased retirement with reduced work schedules, prorated salary, and benefits; adjustment of responsibilities and time at work (variations to starting and finishing times, number of hours worked per day, and part-week, -month, or -year arrangements); contract work – on a fee for service basis; relieving pools (for temporary full-time or part-time assignments); temporary or seasonal work, telecommuting, or home-based work (working a portion of usual hours regularly at home or working from home or an emergency or casual basis); and extended leave and the flexible use of annual leave and long service leave (Morrison 1986; Government of Western

Australia 2010). Self employment will provide the opportunity for flexible work arrangements as these can be set by the people themselves.

Such measures, which seek to enhance the functional capacity of older workers, have been brought together in a process called “reciprocal adaptation,” in which the individual seeks to establish a “fit” with the job, and the job is modified to suit the needs, values, and interests of the older worker (Yeatts et al. 2000). This aims to produce job modifications acceptable to both workers and employers in a “win-win” situation. Work Ability, a concept developed in Finland, aims to establish a proactive, preventative, and holistic approach to working lives, through better age management at the enterprise level (Maltby 2011). It balances personal factors – health, skills, motivation – with the job and how it is managed and aims to encourage employers to tailor work to individuals as they age.

At the same time, the human resource approach needs to shift from a “depreciation model,” where a worker’s value to the organization peaks early in their career, reaches a plateau mid-career, and then steadily declines (Yeatts et al. 2000). Instead, there is benefit in fostering a “conservation model” in which all employees, regardless of age, are viewed as renewable assets that can continue to yield a high rate of return if they are adequately managed, educated, and trained and given appropriate working conditions. The similar “age management” approach aims to ensure that workforce aging is managed well and that age does not become a barrier to employment (Naegele and Walker 2006; Brooke and Taylor 2005).

The Value and Importance of Flexible Work Arrangements

Flexible work arrangements are the means whereby older people can achieve their preferences and aspirations in the paid labor force and retain levels of participation which provide job satisfaction, income to supplement pensions and superannuation, and time to pursue recreational and family activities, including caring, and voluntary work, which are seen as part of a healthy

retirement and positive aging (Hegewisch 2009; Lissenburgh and Smeaton 2003; Australian Institute of Management 2013). They allow older people to exercise a preference to sacrifice income for more control over their time without giving up paid employment entirely. If older workers are unable to balance their chosen activities, capabilities, and responsibilities with the demands of their paid work, and employers are unwilling to provide flexibility, then many older workers may be forced out of the workforce, removing valuable skills and significantly impacting on their future financial and personal well-being.

Deteriorating physical and mental health among older people may be a barrier to continuing workforce participation. Flexible work arrangements will be helpful to people with declining physical stamina and sensory impediments, especially when accompanied by ergonomic and other forms of job adaptation.

Flexibility in work arrangements may also be required to accommodate caring responsibilities, especially eldercare. As life expectancy increases, many working people in their 50s, 60s, and even 70s have living parents in their 80s and 90s, often in need of care and support. At the same time as governments are intensifying their efforts to delay retirement, many are also pursuing policies to support aging at home with reliance on informal care. Middle-aged women are frequently expected and frequently do take on eldercare responsibilities and also caring for grandchildren and other dependent relatives. Yet this group has increased its level of participation in paid work and this is likely to continue. As a result they may experience difficulties in juggling caring responsibilities with paid work. Lack of flexibility in the workplace may lead to their withdrawal as work becomes incompatible with the service they wish to offer their families (Johnson 2011). Considerable attention has been focused on family-friendly working arrangements with respect to child rearing, but less has been given to workers in midlife with other family responsibilities, ranging from social contact to personal care. Combining paid employment with eldercare is an emerging issue in New Zealand and internationally (Phillips et al. 2002).

Flexible working conditions also provide a means of phasing into retirement. Many older people switch to part-time work for a few years before full withdrawal from the paid labor force. While most people still expect to retire, an abrupt break between working full time and not working at all is becoming much less likely. Rather than seeing retirement as a “one-off” concept, it would be more productive to see people negotiating moves in and out of work, not related to chronological age, but based on their skills, abilities, and life experiences (Allen et al. 2004). This might develop into a transitional decade, during which people select how and when they wish to retire, with the option of gradually winding down by adopting more flexible work practices.

International research suggests that the majority of workers would prefer a gradual transition to retirement and that there are benefits for both workers and employers (Department of Labour 2011). For workers, reduced participation in paid work allows them time to pursue leisure and family activities and adjust and prepare for the financial changes which retirement brings. For employers, retaining older workers allows valued knowledge and experience to remain with the firm and be used to mentor and train less-experienced workers.

Policy Initiatives on Flexible Work Arrangements

Facilitating participation in the labor market by people with caring responsibilities has been a focus of policies relating to flexible work, but other considerations include providing opportunities for employees to pursue education and training, assisting older workers to transition to retirement, and increasing labor force participation through part-time work.

Several countries, including New Zealand, Australia, the UK, and Northern Ireland, have legislation providing the “right to request” flexible work arrangements. This legislation may confine the right to employees with caring responsibilities, although some countries are

extending these provisions to all workers. In New Zealand, the Employment Relations (Flexible Working Arrangements) Amendment Act came into effect in 2008. This provides employees, who have worked for the same employer for at least 6 months and are responsible for the care of any person, with the right to request flexible working arrangements (i.e., a variation to their hours of work, days of work, or place of work). After a review, these provisions are being extended to all employees. Employers can refuse a request on reasonable business grounds, which include inability to reorganize work among existing staff or to recruit additional staff, the burden of additional costs, and/or a detrimental effect on ability to meet customer demand.

Reviews of flexible working arrangements in Australia and New Zealand found that the provisions were working effectively and were being taken seriously by employers and employees, and the vast majority of requests were being granted (Department of Labour 2011). In New Zealand the majority of employee-reported requests were accepted by employers without recourse to the formal legislative process, but only 56% of requests related to caring responsibilities; a significant proportion were for other reasons. The conclusion was that employers and employees have been independently developing formal and informal flexible work arrangements that suit their particular needs. However, even where legislation exists, many workers are not aware of their rights to request flexible work arrangements and employers also are often not well informed. Awareness appears to be higher in larger businesses and among higher-income employees.

The Availability of Flexible Work Arrangements

Flexible work practices are already widespread in many countries and also are very popular with older workers. As already noted, a high proportion of organizations, in New Zealand and elsewhere, provide flexible work arrangements in some form for all employees (Hudson 2004). Such practices are more likely to be offered in large businesses

than smaller firms. In New Zealand, they are most prevalent in government agencies, professional services, and IT firms, and manufacturing, construction, property, engineering, and wholesale distribution firms are the least likely to offer flexibility. It is more common for employees working in highly skilled occupations to have flexible hours than those working in other types of occupations and employees with no qualifications.

Research shows that flexible working arrangements are being taken up by both men and women, and a significant proportion of these employees have no caring responsibilities. Benefits to employees arising from better work-life balance include higher levels of motivation and commitment to their jobs, lower levels of stress and higher productivity, better relationships with their families, and better health outcomes (Heathrose Research 2010).

Assessment of Flexible Working Arrangements

A gradual reduction in hours over a number of years leading up to retirement is the most preferred flexible work arrangement among older workers, and one of the most common barriers to working beyond the age of eligibility for superannuation/pensions is the inability to access greater flexibility in work arrangements. But despite these demonstrated benefits, there are barriers to their extension. Some groups of workers may have little or no access to flexible work due to limited bargaining power, the culture of the workplace, and operational constraints within some workplaces (EEO Trust 2006; Department of Labour 2006). There may also be attitudinal barriers to accessing flexible working arrangements on the part of workers themselves. These include perceptions that using flexible work will hamper career progression and involve a reduction in income; that flexibility is only available to highly valued employees in particular occupations or industries; and that workplace cultures were not supportive, including the attitudes of managers or employers and the views of colleagues and

coworkers, leading to guilt about reducing working time.

Recent surveys in New Zealand, the UK, and Northern Ireland show that employers widely perceive flexibility as delivering positive business benefits (Heathrose Research 2010). Their experience in this area has been largely unproblematic; few have encountered the costs, increased litigation, or flood of requests anticipated prior to the introduction of flexible working legislation. Benefits include better employee retention, reduced turnover, improved recruitment through widening the talent pool, increased employee motivation and loyalty, and improved productivity and profitability.

Support for flexible work arrangements was also expressed in recent research among New Zealand employers and representatives of public and private sector organizations involved with workforce issues (Davey 2015). The unanimous opinion was that flexibility could be consistent with business efficiency and could pay a dividend in employee engagement and loyalty and being seen as an employer of choice. There was acknowledgment, however, that flexibility might not be appropriate in all jobs, such as assembly line, retail, reception, and hospital work. Part-time work may not be easy to fit in to schedules that require fieldwork and teamwork. In some cases, respondents reported that senior management may resist moves toward flexibility, at least on a formalized basis. If greater flexibility was extended only to senior workers, this could bring accusations of unfairness from other staff who do not have such freedom.

Some managers may fear that flexible working conditions which suit the preferences of older people may not be consistent with business efficiency. For example, part-time workers can increase administration costs and flexible working can be harder to manage. Nevertheless, problems with flexibility can be tackled; increased overheads related to part-time workers can be overcome with creative thought – using “hot” desks or off-site work. Work from home can save the cost of office space. One respondent commented: “Having the best person 80% of time is often better than having another 100%.”

Conclusions

The social, economic, and individual benefits of extended participation in the paid workforce among older people are now widely accepted, and in many countries policies are being promulgated to encourage this trend. There are a wide range of work arrangements which can be applied to facilitate older people's working arrangements while taking into account the possibility of reduced physical or sensory capacity and allowing them to participate and contribute in other areas of life, including voluntary work, family activities (and informal care), recreation, and leisure. Flexible work arrangements can facilitate the transition to retirement and the adjustments – social and financial – which this entails.

Initiatives to encourage and facilitate flexible working conditions may come from government policies. These include legislation on access to flexible work, employment regulations and agreements, antidiscrimination law, and provisions around retirement income support (e.g., whether a work test is applied for pension entitlement). However, the main decisions about allowing flexible work arrangements are made at the individual business level. Therefore the attitudes of managers and employers and the prevailing business culture are of fundamental importance in whether or not flexible work arrangements for older people are offered and supported.

Definition

The Fordham Centenarian Study is a population-based study which aims at describing life circumstances in very advanced age and characteristics of near-centenarians and centenarians. A mixed-methods designed was used to investigate individuals aged 95–107 years old with respect to person characteristics (e.g., health, cognition, well-being, psychological strengths), their immediate social network (e.g., family and friends, informal support, relationship to advanced age children), and societal-cultural features that may play a role for successful aging in these very old individuals. Findings confirm poor health conditions and limited social networks, while maintaining rather high levels of mental health and well-being. Future analysis comparing the Fordham Centenarian Study data with data from the Second Heidelberg Centenarian Study and the Oporto Centenarian Study will help to better understand specific vs. global mechanisms of successful aging.

Introduction

Living an exceptionally long life is wished for by many individuals, and this wish is likely to become reality for more and more people. The older adult population is growing rapidly in industrialized countries around the world, as life expectancy increases due to advances in medicine and healthier lifestyle, as well as the aging of large cohorts such as the “baby boomers” (Christensen et al. 2009; Ortman et al. 2014; Robine et al. 2010). The group of the population that shows the strongest increase is very old individuals. In the USA, for example, the number of centenarians increased by 66% between 1980 and 2010, resulting in a total of 53,364 individuals aged 100 or older, as documented by the 2010 CENSUS (Meyer 2012). This trend will continue and is likely to accelerate, resulting in population projections of between 600,000 and 1 million centenarians in the USA by 2050. Given that half of all children born after the year 2000 are expected to reach their 100th birthday

(Christensen et al. 2009), this global trend will change the life perspectives in many countries and poses various challenges at the individual, family, and societal levels. To better evaluate the challenges to be expected and to plan for the future, it is important to learn more about what characterizes life at age 100.

Despite currently increasing numbers and future projections, centenarians represent an understudied and underserved group to date. As most centenarian studies have concentrated on demographic, medical, and genetic research questions, with the overarching aim of enhancing the understanding of what may be responsible for increase in life expectancy and what contributes to exceptional longevity, only few studies have addressed what it actually means to live to age 100 (Jopp et al. *in press a, b*). As a consequence, views on very old age described in the media are rarely realistic but polarizing: individuals of very advanced age are either depicted very positively, by showing for example outstanding centenarian and supercentenarian individuals who are aging extremely well, or they are depicted very negatively, for instance by describing a “tsunami” of very old people who, bedridden and plagued by dementia, endanger our social welfare systems. In the absence of a solid empirical knowledge base, life in very old age is still poorly understood in terms of its unique characteristics and challenges. Moreover, as reaching very old age becomes a topic of personal interest for more and more individuals, questions about quality of life at this age urgently need to be addressed. Also, as those demographic changes do not only affect the individual, but their families and societies, additional challenges arise. To handle these successfully, information about care needs is important in order to develop support structures that could enable the very old to maintain their independence for as long as possible.

The Fordham Centenarian Study has three key goals: (a) to create a realistic, more balanced, and more differentiated picture of very old age. Following a population-based recruitment approach, it aimed at gaining representative information about the limitations to be faced in very old age, as well as the strengths possessed by the very long

lived; (b) to determine support needs of the very old and create a knowledge base that will help to develop well-suited care and service structures. As very old age comes with unique challenges and service needs, identifying those is essential for the individual, the family, and society in planning for the future; (c) to determine individual, societal, and cultural characteristics that contribute to successful aging and enhance and foster those in current and future generations.

The Fordham Centenarian Study has a key interest in identifying personal factors that may enable successful aging and a specific focus on psychological characteristics such as psychological strengths (e.g., self-efficacy, optimistic outlook, meaning in life, and will to live). At the same time, expanding on classic approaches of successful aging and in line with lay perspectives on successful aging (e.g., Jopp et al. 2015), the Fordham Centenarian Study considers the immediate social context (e.g., social network and informal support system) as well as the wider societal and cultural context (e.g., laws and regulations as well as attitudes towards aging) as important features that shape life in younger years but particularly in very old age. It is our long-term goal to ascertain the person factors, social network characteristics, and cultural aspects that are of key importance for quality of life in very advanced age and to examine their interplay to better understand mechanisms of successful aging. This will be a major step toward developing prevention and intervention programs that enable more very old individuals and their families to age successfully.

Methodology

Participants. Participants included individuals aged 95 years and older from the three most diverse boroughs of New York City (i.e., Manhattan, Brooklyn, the Bronx). Participants did not need to be fully cognitively intact to be eligible for the study, but they had to be able to reliably respond to questions about themselves, as the study’s goal was to capture the very olds’ experience of their very advanced age, well-being, and

depressive symptoms, as well as other psychological constructs. In order to ensure a population basis of the study, recruitment was primarily accomplished by inviting individuals aged 95 years and older for study participation who were listed in the New York Voter's Registry. The recruitment approach resulted in 103 interviews, of which 95 were included in the study (80% of the total sample). As this main recruitment approach made it slightly more difficult to reach individuals living in nursing homes, we recruited an additional 23 participants via five collaborating health care providers. Finally, one additional centenarian was recruited by word of mouth. The final sample consisted of 119 adults aged 95–107 years ($M_{\text{age}} = 99.25$ years; 78% females), including 57 near-centenarians (95–99 years old; $M_{\text{Age}} = 97.11$; 71.9% females) and 62 centenarians (100–107 years old; $M_{\text{Age}} = 101.22$; 83.9% females). Of these, 92 (77.3%) were White, 23 (19.3%) were Black, and 4 (3.4%) were Hispanic. Thus, the Fordham Centenarian Study included similar proportions of both gender and ethnic groups as documented within the US CEN-SUS for the city of New York (Meyer 2012).

Measures. The assessment included a comprehensive interview, for which a mixed methods approach was used, combining qualitative and quantitative data collection techniques. Specifically, both standard questionnaires with a Likert-type answering format and questions with an open answering format were applied; the former allowing to compare the centenarians with younger age groups and the latter allowing the very old to describe less investigated aspects in their own words. In line with our experience in prior studies and during the study's pilot phase, we adjusted the measures to reduce their cognitive load as much as possible. Due to age-related reduction in sensory capacity and potential restriction in cognitive function, all centenarians were interviewed in person at their home by well-trained interviewers. To facilitate the interview procedures, we reformulated statement items often used in self-report questionnaires ("I feel satisfied with my life") into questions ("Do you feel satisfied with your life?") to ensure that the centenarian understood right away that an item was meant as a

question for him/her when read by the interviewer. We also checked items for double negations and other complicated formulations were replaced. We furthermore reduced the answering options to a maximum of 5, as more options caused difficulty to the centenarians. The open answers were later coded using clustering or open coding techniques usually applied in qualitative research.

In line with our key research questions, the following areas of functioning were investigated: basic demographic aspects (including life achievement such as education and work history, marital status), health (including common diseases, subjective health, sensory impairment, pain, activities of daily living, walking speed, and grip strength), cognitive status (including a shortened version of the Mini-Mental State Examination, Folstein et al. 1975; and the Global Deterioration Scale; Reisberg et al. 1982), social network and living arrangements (including social contact, informal support, loneliness, living in a private household, living with whom), well-being aspects (including life satisfaction, happiness, depressive symptoms), and psychological strengths (including self-efficacy, optimistic outlook, meaning in life, will to live, self-determination, coping, and life management strategies). Key constructs that were assessed with open coding procedures were everyday challenges, relationship between centenarians and their advanced age children, and centenarians' views about what had contributed to their successful aging.

Procedures. Participants were interviewed in person at their residence (private home or institution). Specifically, interviews were divided into two sessions of 1.5 h each to minimize fatigue. Study procedures were approved by three institutional review boards. Data collection was conducted between 2010 and 2012.

Results

Health and Physical Functioning

Whether centenarians are prime examples of successful aging has been long discussed, given that they have outlived almost all their peers. Yet, life

at age 100 seems nevertheless characterized by illness. In line with findings from prior studies on health in very old age, many Fordham centenarians were affected by multimorbidity, reporting an average of 4.85 (SD = 2.32) medical conditions (Jopp and Hicks 2016). The health issue reported most often, mentioned by over 80% of the sample, was sensory (vision, hearing) conditions. This was also the top one condition mentioned in the Second Heidelberg Centenarian Study (Jopp et al. 2016d), which is notable as sensory issues can be expected to have a high prevalence at this age, but they have received limited attention in prior studies on health in centenarians. Heart/circulation conditions and muscular-skeletal conditions were both mentioned by about two thirds of the sample, representing the second highest prevalence. Mobility issues were on rank 4 with a slightly lower prevalence. In the Second Heidelberg Centenarian Study, we had, however, found mobility issues to be the condition mentioned second most often (Jopp et al. 2016d). Possibly, the slightly younger age of the Fordham Centenarian sample is responsible for this finding. Another notable difference was the nearly doubled prevalence of conditions related to the respiratory system in the Fordham sample compared to the Second Heidelberg Centenarian sample, which was particularly due to reports of pneumonia (Jopp and Hicks 2016).

Despite high multimorbidity, self-rated health was fairly high, with 67% reporting their health as good or excellent. Centenarians also showed good functional health, as indicated by low levels of restriction in personal activities of daily living. Functional health was assessed with reported difficulty in seven personal activities of daily living (PADL) and seven instrumental activities of daily living (IADL) as measured within the Older Americans Resources and Services Multidimensional Functional Assessment Questionnaire (Fillenbaum 1988). Specifically, findings indicate that functional capacity was high for PADLs, with an average of 10.41 (SD = 3.67) out of 14 from the PADL scale. Twenty-eight percent of the sample had the highest score of 14, 21% had difficulty with only 1 activity, and 19% had difficulty with only two activities.

Nevertheless, regarding specific PADL activities, about half of the sample mentioned having difficulty in taking a bath (55%), getting dressed (52%), and moving in and out of bed (48%). Centenarians had increased levels of impairment in instrumental activities of daily living, which were slightly more impaired, with an average score of 8.89 (SD = 4.05) from the IADL scale; however, 17% of the sample reported no difficulty. The instrumental activities causing difficulty most often were light housework (77%), shopping (76%), preparing meals (65%), and getting around/traveling (64%; Jopp et al. 2016c). Compared to prior studies, levels of PADL and IADL in our sample were higher than previously reported.

Sensory impairments were assessed via self-rated vision and hearing capacity. Participants rated each on a 5-point scale ranging from 1 (Poor) to 5 (Excellent). Many centenarians reported impairments in vision and hearing: specifically, 17% indicated to have only poor or fair ability for vision and 18% had poor or fair ability for hearing, while 38% had poor or fair function in both vision and hearing concurrently (Cimarolli and Jopp 2014). Thus, while vision and hearing impairment only were reported at similar rates as in younger samples, prevalence of dual sensory impairment was particularly high in this age group and substantially higher than in younger ages (compared to, for example, 20% of a sample with average age of 78 years, Brennan et al. 2005). At the same time, it is notable that more than a quarter of the sample reported no sensory impairments, which was an unexpected finding that deserves future attention. Confirming the importance of vision and hearing for everyday functioning, vision impairment only and dual sensory impairment were found to be strong predictors of functional disability and these effects remained significant when controlling for depressive symptomatology, health limiting desired activities, and living in a nursing home. Explaining independent amounts of variance in functional ability, namely, 6.6% (vision impairment only) and 4.8% (dual sensory impairment), indicates that these impairments have a substantial role in determining the extent to which a person is able to live independently. Notably, these

impairments had about the same size effects as other factors (e.g., living in an institution or depressive symptoms), yet, the importance of sensory impairment is often overlooked. Findings further suggest that individuals with dual sensory impairment had the highest level of depressive symptoms, compared to the other impairment groups.

An additional set of analyses revealed which specific basic or instrumental activities of daily living were influenced by vision or hearing impairment. Specifically, vision impairment had a significant influence on taking care of one's appearance, eating, taking medications, writing checks, and using a telephone, while hearing impairment had a significant influence on traveling only (controlling for age, gender, minority status, cognitive function, depression, and the other [vision or auditory] impairment; Cimarolli et al. 2016). Thus, vision impairment seems to have an effect on more specific activities compared to hearing, which is likely to be related to the nature of these activities and the extent to which visual and auditory senses are involved in accomplishing them successfully.

Education and Cognitive Functioning

Participants of the Fordham Centenarian Study were relatively well educated, with one third ($n = 40$, 34%) having a bachelor's or higher degree and another third having a high school diploma or some college ($n = 38$, 32%). Another third had middle school education or completed some high school ($n = 36$, 30%). Very few ($n = 3$, 3%) had received only primary school education. Participants also exhibited relatively high levels of cognitive functioning. To assess cognitive functioning, we used the following subscales from the Mini-Mental State Examination (MMSE; Folstein et al. 1975): Orientation (range: 0–10 points), Registration (range: 0–3 points), Attention (0–5 points), and Recall (0–3 points), resulting in a maximum total of 21 points. Doing so, we followed the recommendations by Holtsberg et al. (1995), who proposed using items that were unlikely to be biased by the poor sensory functioning highly prevalent in centenarians. Our findings indicate an average shortened MMSE score of

16.45 ($SD = 4.04$) out of 21, indicating high levels of functioning. Although study participation had not been possible with a shortened MMSE score of 4 or less, in order to ensure that centenarians were able to reliably talk about their lives and inform about subjective well-being and psychological strengths, there was still substantial variability as indicated by a range of 5–21. Based on the observer rating of the Global Deterioration Scale (1 = no memory deficit evident from interview, to 7 = very severe cognitive decline; Reisberg et al. 1982), participants had a mean score of 1.44 ($SD = .9$, range: 3–7), denoting only little memory impairment. Ninety-three individuals (93%) had no or little cognitive limitations (scores of 1 to 3), and seven individuals (7%) had moderate limitations (scores of 4 and 5), which indicates that the sample was somewhat more positively selected, but in line with our study goal of assessing reliable self-reports among this age group.

Living Arrangements, Marital Status, and Social Network and Support

Despite the substantial health issues mentioned above, a large majority of the Fordham centenarian study participants lived in the community (74%), while only 26% lived in an institution (i.e., 6% assisted living, 19% nursing home, and 1% other). Of those living in the community, 66% lived alone, 3% lived with their spouse, 19% with children, and 3% with other family. The proportion of near-centenarians and centenarians living alone was substantially larger than in other studies, and comparing both age groups, centenarians were even more likely to live alone than near-centenarians (Jopp et al. 2016b). One could speculate that this is due to the fact that living in a city like New York comes with more services, ranging from a doorman, food delivery services to various levels of professional care supports, which could allow for residing in the community longer. Furthermore, considering marital status, we found that most of the sample (75%) was widowed, but 7% were still married. Eight percent were divorced/separated and 9% had never married.

In comparison to studies with younger individuals, social functioning of the near-centenarians

and centenarians was poor: Participants reported having an average of three relatives to talk to at least once a month, two relatives as confidants, and two relatives as emergency contacts. In comparison to family contacts, the number of friends available to talk to at least once a month was smaller, namely, about two, and the number of friends being confidants and emergency contacts were between one and two on average. A combination of these indicators of social contact and support (as measured by the six-item Social Network Scale (Lubben 1988)) underscored the impression that the very old had substantially smaller social resources than individuals of younger old age. Although most participants had at least one person for communication/social support, their overall support score of 12 was substantially lower than that of young-olds (70–80 years old), who scored between 16 and 18 (Lubben 1988; Lubben et al. 2006). Using 11 or less as a cutoff for the total score and 5 or less for the family and friends score (Lubben 1988; Lubben et al. 2006), we found that, when considering their total network, half of the sample (51%) was at risk for social isolation. Considering family support, the percentage at risk was smaller (34%), but for friendship support, the risk was double (58%), indicating that a large proportion of near-centenarians and centenarians were at risk for social isolation (Jopp et al. 2016).

Given our particular interest in social factors enabling very old individuals to age successfully, one focus of the Fordham Centenarian Study was to examine more closely the nature and quality of the relationship between the centenarians and their children, who themselves have reached advanced age. Study participants had a mean number of living children of 1.36 ($SD = 1.31$). It is notable that about 39% had lost one or more children, which represents one of the most difficult life experiences of centenarians. The average age of the living children was 66 years. The range of the children's ages was 42–83, and about one fourth of the children were older than 70 years old and 10% were older than 75 years old, highlighting a new phenomenon associated with the current

demographic development, namely, that for the first time, two generations within one family reach old and very old age together. Of those who had children, 76% reported having a child living close.

In-depth assessment of the quality of the relationship was delivered by a subgroup of very old and their children ($n = 29$). Qualitative coding of the relationship description indicated that most centenarians and their children experienced their relationship as positive (90% of the very old and 70% of the children). It was, however, notable that the very old gave much more positive reports and rarely mentioned issues, while the children were somewhat less positive and were more open to talk about difficult aspects of their relationship. Positive features mentioned were feeling a close bond, sharing activities, and having important conversations. Negative features included having day-to-day frictions and having different views. Only few mentioned serious frictions. Children, however, also mentioned old wounds that made the relationship difficult (Jopp et al. 2016a).

Considering the amount of informal support that near-centenarians and centenarians receive in everyday life (e.g., help with care, household, but also socializing), the children had a particularly important role. In most cases, the child was the main go-to person: they were the primary contact involved in providing day-to-day help mentioned by 31% of the sample (Jopp et al. 2016b). We were furthermore surprised to find that individuals other than immediate family played a much smaller a role: friends were mentioned as providing help by 15% and other relatives by 9% of the participants. Furthermore, those with a living child had substantially more help than those without children, indicating that having a child does apparently not only come with help from the child him/herself but also seems to facilitate help from other individuals. Nevertheless, it is of note that only 51% of the near-centenarians and 40% of the centenarians indicated receiving any help at all. Although study participants residing in the community received more help (52%), only one fourth of

those living in an elder facility indicated receiving any informal help.

Well-Being and Mental Health

Participants of the Fordham Centenarian Study had relatively high levels of mental health (Jopp et al. 2016c). Using the Geriatric Depression Scale (GDS; Sheikh and Yesavage 1986), with higher scores indicating more depressive symptomology (theoretical range = 0–15), mean depression score was 4.10 (SD = 3.41), and 72% of participants had few or no depressive symptoms (i.e., GDS scores 0–4). Over 80% of the sample did not meet the criteria for clinical depression (GDS scores 8 and higher). Life satisfaction, measured by the Satisfaction with Life Scale (Pavot and Diener 1993), was moderate considering the mean level (M = 2.07, SD = 1.14). About 66% reported moderate to very high life satisfaction. About 25% were “a little” satisfied and only 9% were not satisfied with their lives. Regression analysis indicated that individual differences in depression were related to subjective health and IADL functioning, as well as support from the family. For life satisfaction, subjective health as well as PADL functioning and number of children were significant predictors (Jopp et al. 2016c). In a second set of analyses, in which we considered not only basic personal resources but also psychological strengths, we found that optimistic outlook and will to live were the strongest predictors of life satisfaction, besides ADL functioning and number of living children (Jopp 2016), suggesting that psychological aspects play an important role in the well-being of the very old.

Common Challenges and Beliefs about Successful Aging

Centenarians’ reported everyday challenges were assessed with two open-ended questions. The first was, “Please think now for a moment about the things that you find challenging. Are there things that you find challenging or difficult?” Participants were then asked how the difficult instance

was challenging for them. Responses were coded using open coding and clustering methods in order to identify common challenges among these centenarians.

Allowing the very old to indicate in their own words what they found challenging in their everyday life revealed a multidimensional concept of challenges at this very advanced age. Although near-centenarians and centenarians most commonly reported functional challenges (76%), such as restrictions in activities of daily living, disability, health, and sensory impairment, they also indicated other types of challenges, including psychological and social. Psychological challenges (40%) were commonly mentioned, including loss of independence and loss of enjoyable activities. Social challenges (20%) were also commonly reported, involving, for example, social loss and leaving loved ones behind. It should also be noted that a small proportion of centenarians mentioned having no challenges at all. Regression analysis further revealed that differences in aging satisfaction were predicted by functional and psychological challenges, with functional challenges being negatively associated and psychological challenges being positively associated. The latter, somewhat unexpected, effect could indicate that those very old reporting psychological challenges are more sensitive to age-associated challenges and see the potential of these to grow and develop. A regression predicting loneliness furthermore revealed that functional challenges were related to higher levels of loneliness. In addition, more social challenges were marginally related to higher levels of loneliness. Interestingly, none of the specific challenge types was associated with depressive symptoms. In sum, findings suggest that perceptions of challenges are not only specific and varied but that they are also differentially associated with mental health outcomes.

To assess centenarians’ views on successful aging, participants were asked two open-ended questions. The first was, “A lot of people are very fascinated that one can reach a very old age and wonder how this comes about. Since you are

one of the few people who have reached their 100th birthday, or are close to it, what do you think are the reasons for it?" The second question was, "And if you think about your life, did you have a certain theme, a guideline, after which you lived and maybe still live?" Responses were coded using open coding or content-based clustering to identify recurrent themes. Findings indicate that most centenarians believed that psychological aspects (e.g., taking good care of yourself, letting others help you) had helped them reach age 100. The two most commonly mentioned themes after psychological aspects were social aspects (e.g., family background, children, friends) and lifestyle (e.g., living life in moderation, healthy diet). Other themes mentioned include faith, health, luck, work, leisure (having hobbies), and aging experience (e.g., forget about aging). Thus, results suggest that, in line with more recent findings on laypeople's views on successful aging, near-centenarians and centenarians have a multidimensional view of aging and that psychological aspects are quite important, maybe even more important than in other age groups.

Conclusion

In line with the main goals of the Fordham Centenarian Study, its findings to date give important insights about what characterizes life in very old age and help to increase our understanding of the common challenges at this age, as well as levels of functioning and strengths of near-centenarians and centenarians. Findings indicate that all study participants had health challenges, yet they perceived their health as good. The cognitive status of the sample was high, which was in line with the goal of the study to talk directly to individuals of that age, rather than gaining information by proxy informants. Findings also demonstrate that the social resources of the sample were low and many of them were at risk for isolation. Despite reduced levels of physical functioning and social resources, very old participants were in good mental health suggesting high resilience and the

ability to adapt to age-associated challenges. Findings further indicated that perceived challenges were related to mental health outcomes, which indicates that centenarians are not ignoring their issues but apparently have ways of dealing with these in a positive way. Future analysis will further highlight the role of psychological factors that seem to be responsible for this successful adaptation.

Findings further highlight the importance of social partners. The Fordham Centenarian Study is the first to provide information about the relationship of centenarian parents and their advanced age children, a dyad that is the result of recent demographic changes. How old children and very old parents experience their relationship will be further investigated, also taking into account how the nature of the relationship may influence physical and mental health outcomes in both dyad partners. So far, it is already clear that the children become the most important go-to people and that the relationship is mostly experienced positively, but that difficult interactions with substantial burden do occur. More research is necessary to identify the unique care needs and to provide guidance for the development of well-suited services for this very old population.

That a large proportion of the sample lived in the community, and that this proportion was much higher than in other studies, seems to be in line with the very old's desire for leading an autonomous life, which may have been facilitated by New York service culture. The impact of the wider societal and cultural environment will be further investigated by considering data from the Second Heidelberg Centenarian Study (Jopp et al. 2013) and the Oporto Centenarian Study (Ribeiro et al. *in press*), which were designed in large parts as parallel studies to the Fordham Centenarian Study (Jopp et al. *in press b*). The comparison of person, social, and societal-cultural factors among the parallel studies will help to identify which factors are responsible for successful aging in specific cultures and which are responsible across countries, in order to shoulder the global challenge of very old age at individual, family, and societal levels.

Synonyms for Frailty

Fragility; Vulnerability to stressors

Definition of Frailty

An age-associated syndrome linked to diminished physiological reserves and lower resistance to stressors. This syndrome is associated with increased risk for negative health outcomes, such as immobility, hospitalization, and death.

Introduction

Definitions and Models of Frailty

In recent decades, the frailty syndrome has received different definitions. Earlier studies equaled frailty to multiple comorbidities, dependency, mobility limitations, institutionalization, failure to thrive, and predeath (Hogan et al. 2003). In the past 15 years, the concept has gained more precise definitions. Frailty can be considered a biologic age-associated syndrome linked to diminished physiological reserves and lower resistance to stressors (Fried et al. 2001). It results from cumulative declines across multiple physiologic systems due to age and diseases. Frailty increases the risk for negative health outcomes, such as immobility, falls, hospitalization, and death.

An international consensus has defined physical frailty as “a medical syndrome with multiple causes and contributors that is characterized by diminished strength, endurance, and reduced physiologic function that increases an individual’s vulnerability for developing increased dependency and/or death” (Morley et al. 2013).

This consensus has also stated that the syndrome can be prevented and treated by interventions which include exercise, protein-calorie supplementation, vitamin D supplementation, and reduction of polypharmacy; it can be identified with rapid screening instruments, and that individuals 70 and older or with significant weight loss due to disease should be screened for frailty.

An influential model (Walston et al. 2006) has proposed that frailty is related to oxidative stress, mitochondrial dysfunction, DNA damage, genetic factors, and inflammation. These processes may lead to decrease in key hormone levels, such as estrogen, testosterone, and dehydroepiandrosterone (DHEA) and increase in cortisol levels, increase in inflammatory markers (TNF-alpha, IL-6), and loss of lean muscle mass.

According to Rodriguez-Mañas and Fried (2015), the prevalence of frailty in people older than 65 years is high, ranging from 7% to 16.3% in most studies. The prevalence increases with age and it is greater in women than in men. In older samples, 85 years and older, it may reach 28% (Collard et al. 2012). Prevalence estimates depend on sample origin and may be higher in clinical samples.

There is a productive debate about the best approach and criteria to identify frailty in clinical and research settings. Three recent strategies have been most frequently used for that purpose.

Fried et al. (2001) have proposed a frailty phenotype which emerged from the Cardiovascular Health Study (CHS) including data from 5,317 men and women 65 years and older. The phenotype associated with negative health outcomes in this study comprised three or more of the following characteristics: unintentional weight loss (10 pounds in the past year), self-reported exhaustion, weakness (assessed by grip strength), slow walking speed, and low physical activity. Reaching frailty criteria at baseline was associated 3 or more years later with incident falls, worsening mobility or ADL disability, hospitalization, and death. Presenting one or two of such characteristics was regarded as pre-frailty, and it was associated with intermediate risk for the conditions described above.

The frailty phenotype has generated a very significant body of research, spanning several aspects of the syndrome from epidemiology and early diagnosis to treatment and prevention strategies (Rodriguez-Mañas and Fried 2015). The phenotype has been helpful to identify a high-risk subgroup of seniors for negative outcomes with higher predictive value than chronic disease.

Researchers from the Study of Osteoporotic Fractures (SOF) have proposed the use of a simplified strategy to identify the frailty syndrome – the SOF index. This index includes weight loss, inability to rise from a chair five times without using arms, and reduced energy level assessed with one question from the Geriatric Depression Scale. One criterion should indicate pre-frailty status and/or two frailty status. Studies from this group (Ensrud et al. 2009) have shown that the SOF index predicts risk of falls, disability, fracture, and mortality as well as the CHS criteria.

Alternatively, the Canadian Study of Health and Aging has defined frailty as a risk index. According to this group, frailty can be evaluated by the number of health deficits that individuals accumulate. Therefore, the frailty index is calculated as the ratio of the deficits present in a person to the total number of potential deficits evaluated. In many epidemiological and clinical studies, the FI has successfully graded the degree of risk of adverse outcomes, such as mortality, health service use, hospital-acquired complications, worsening health, and loss of independence (Mitnitski et al. 2015).

In addition to the phenotype and the risk index perspectives, several different instruments and questionnaires have been proposed to detect frailty. Such instruments might capture some of the core aspects of frailty maintaining predictive validity for adverse outcomes (Pialoux et al. 2012). However, this approach has been questioned, as the use of frailty screening instruments may only identify the presence or absence of frailty. Such instruments most likely cannot identify the level of risk or gradients of frailty in order to predict specific outcomes accurately, and they may be limited in their contribution to the device of individualized care plans (Rockwood et al. 2015).

Several issues remain open to debate regarding frailty. It has been challenging to reach consensus regarding the essential characteristics of the syndrome and ways to operationalize its assessment. In addition, there has been prolonged debate whether cognitive impairment should be included in frailty criteria. Some research groups (Fried et al. 2001) have excluded older adults with cognitive impairment from study samples justifying the need to study frailty in general and not frailty associated to dementia. In the risk index perspective, the inclusion of cognitive problems has been recommended as it may represent an important deficit that accumulates with others to determine frailty thresholds (Mitnitski et al. 2015). In the next sections, the evidence linking frailty and cognition will be revisited with the aim to support the view that frailty and cognitive impairment are associated phenomena and may be subsided by similar biological processes.

Frailty and Cognition: Evidence from Cross-Sectional and Longitudinal Studies

Cross-sectional studies from different regions of the world have reported that frail and pre-frail older individuals tend to have lower scores in global and domain-specific cognitive tests compared to non-frail seniors (Chen et al. 2015). In addition, cross-sectional studies have reported that individual markers of frailty are associated to cognition. As an example, one previous study tested the association of the five CHS frailty criteria individually with cognitive scores and found that grip strength and gait speed were significantly correlated to cognitive performance (Yassuda et al. 2012).

Longitudinal investigations have reported that frailty is a significant predictor of future cognitive decline. Samper-Ternent et al. (2008) followed up 1,370 older Mexican Americans for 10 years, without cognitive impairment at baseline. They reported that frailty was an independent predictor of cognitive decline assessed by the Mini-Mental Status Examination (MSSE). In another longitudinal study, Ávila-Funes et al. (2008) classified a community-based sample into seniors who were

frail, pre-frail, and robust according to the phenotype model and further classified all participants into those who were cognitively impaired and those who were intact. They reported that cognitively impaired frail elderly had higher risk for functional impairment, mobility limitations, and hospitalization than those frail individuals who were cognitively intact. These findings suggest that the presence of cognitive impairment among frail elderly may increase the predictive value of frailty to determine negative outcomes.

Other studies have suggested that changes in individual frailty criterion may predict cognitive decline. Alfaro-Acha et al. (2006) reported that older Mexican Americans with reduced grip strength at baseline, after 7 years, demonstrated significant decline in the MMSE, whereas seniors with high grip strength tended to maintain cognitive performance. Mild physical impairment has also been associated with greater risk for cognitive decline and dementia (Wilkins et al. 2013).

Frailty Increases the Risk for MCI and AD

Most importantly, previous studies have revealed that physical frailty is associated with higher risk for mild cognitive impairment (MCI) and Alzheimer's disease (AD). Buchman et al. (2007), in a 3-year follow-up study of 823 seniors, found that baseline frailty scores and annual rate of change in frailty were associated with an increased risk of incident Alzheimer's disease (AD). In a recent study of this group, Buchman et al. (2014) reported that in 6 years, frailty and cognition declined in similar proportions. Most individuals showed worsening frailty and cognition (82.8%). In addition, rates of change in frailty and cognitive scores were strongly correlated. Brain tissue analyses revealed that AD pathology, macroinfarcts, and nigral neuronal loss showed independent associations with the rate of change in both frailty and cognition. These results strongly support the hypothesis that frailty and cognition may be caused by the same biological mechanisms.

Using data from 7,239 cognitively healthy, community-dwelling older adults from the Canadian Study of Health and Aging, who had 5- and 10-year follow-up data, Song et al. (2011)

calculated a frailty index based on 19 deficits not known to predict dementia. Their results indicated that dementia and AD incidence increased exponentially with the increase in this frailty index. These results suggest that frailty and general health are associated with the risk for dementia.

In a longitudinal study, including 750 seniors without cognitive impairment, with follow-up assessments of up to 12 years, Boyle et al. (2010) showed that frailty was associated with a higher MCI incidence risk and a faster rate of cognitive decline.

A previous study in Japan (Shimada et al. 2013), which included 5,104 community-dwelling seniors, investigated the prevalence of frailty, MCI, and both conditions concomitantly. Results indicated that 11.3% of participants were frail, 18.8% were diagnosed as having MCI, and 2.7% had both conditions. More importantly, there was a significant relationship between frailty and MCI.

Few studies have investigated the frailty syndrome among patients with MCI. McGough et al. (2013) assessed a sample of 201 sedentary seniors previously identified as having amnesic MCI for three frailty criteria (gait speed, grip strength, and physical activity level) and cognitive performance in the ADAS-Cog, Trail Making A and B, and WMS-R Logical Memory I. Among participants, the majority reached criteria for frailty, 57.3 for low gait speed, 64.2 for low grip strength, and 58.2 for low physical activity. In a linear regression model, gait speed was significantly associated with all cognitive measures, whereas activity level was associated with Trail Making B and ADAS-Cog Word Recall, and grip strength was associated with scores for the Trail Making A. These results lend support to the notion that there is a significant relationship between frailty dimensions and cognitive performance in a sample of older adults with cognitive deficits. Most importantly, MCI patients who reach certain frailty criteria, particularly gait speed, may be at a higher risk for conversion to dementia and may require more assistance.

In a longitudinal study of 12 months, Alencar et al. (2013) followed up 207 cognitively intact seniors. After 1 year, there was an incidence of

4.9% of cognitive impairment among the physically robust participants, 8.9% among the pre-frail, and 13.3% among the frail seniors. The latter group had lower scores in the MMSE in both evaluation points. This study suggests that even in a short-time period, an association between frailty and cognitive decline can be observed.

Frailty among the oldest old has been less frequently studied. Using data from 840 community-dwelling seniors 85 years and older from the Jerusalem Longitudinal Cohort Study, with 5-year follow-up assessment, Jacobs et al. (2011) reported that frailty and cognitive impairment were significantly associated. Mortality rates were higher for frail and pre-frail than for robust participants. However, mortality among frail subjects with or without cognitive impairment was equivalent. Also, frailty alone was more predictive of mortality than cognitive impairment alone.

Taken together, cross-sectional and longitudinal studies have provided support for the hypothesis that frailty is a clinical condition associated with worse cognitive performance, faster cognitive decline, and higher risk for MCI and dementia. The initial implication for these findings is that frail seniors should be screened for cognitive impairment in order to improve early dementia detection. In addition, individualized care plans for frail elders may need to include cognitive stimulation and/or cognitive training programs. Considering that frailty and cognitive deficits may be subsided by similar biological processes, seniors with MCI or dementia might also benefit from frailty screening and interventions aiming to minor or delay frailty. It is plausible that frail seniors with MCI might be at a greater risk for conversion to dementia and may benefit from multimodal interventions targeting both physical and cognitive impairments.

The Concept of Cognitive Frailty

The evidence linking frailty and cognitive impairment has compelled a panel of specialists to propose a condition called cognitive frailty (Kelaiditi et al. 2013). This condition should describe the deleterious effects of frailty on cognition in the absence of dementia. The tentative criteria proposed by this panel for cognitive frailty are the

presence of frailty, presence of MCI (CDR = 0.5), and absence of AD or other dementias. In other words, the condition should describe cognitive decline not associated with neurodegeneration.

The cognitive frailty concept has faced some challenges, such as ruling out the presence of neurodegenerative processes. It is known that healthy seniors may also present a significant degree of atrophy and AD markers, in the presence of intact cognition. Therefore, the criteria for cognitive frailty might need to include a temporal aspect; that is, the presence of frailty may need to precede the onset of cognitive deficits (Canevelli and Cesari 2015). According to these authors, the concept of cognitive frailty needs to be further investigated in epidemiological and clinical studies so that its operational definition may be improved as well as the understanding of its biological mechanisms.

Interventions Geared Toward Improving Frailty

Currently, there is considerable interest in identifying interventions that might prevent or delay frailty; yet there is a lack of well-designed frailty trials. Cesari et al. (2015) reported findings from the Lifestyle Interventions and Independence for Elders Pilot (LIFE-P) study. In all, 424 community-dwelling persons (mean age = 76.8 years) with sedentary lifestyle and at risk of mobility disability were randomized into the 12-month physical activity or successful aging interventions. The CHS frailty syndrome criteria were assessed at baseline, 6 and 12 months. At 12 months, there was a reduction in frailty prevalence in the physical activity group compared to the active control group. However, when individual frailty criteria were analyzed, the authors observed that low physical activity was the criterion most affected by the key intervention. The other criteria, such as gait speed and grip strength, were not altered by the physical activity intervention. The authors hypothesized that to alter other frailty dimensions, multimodal interventions may be needed. In other words, physical activity may need to be offered along with nutritional supplementation, for instance.

A recent review with a focus on studies which offered physical activities to frail elders has

documented the large methodological variability among the studies (de Labra et al. 2015). Among other findings, the authors documented that five out of seven studies reported significant increases in muscle strength in frail seniors.

The literature on interventions to improve or delay frailty is diverse, and several studies have investigated specific outcomes, such as falls, or instead included in their sample seniors with certain clinical characteristics, such as cardiologic diseases. So far, most clinical trials have not used well-established models to assess frailty at baseline and follow-up, and they have failed to show convincing evidence of effectiveness (Rodríguez-Mañas and Fried 2015). Well-designed intervention studies addressing frailty and cognition simultaneously have not been identified in recent searches.

Future Directions

Frailty is now widely regarded as a relevant medical condition associated with adverse health outcomes. There is debate regarding the ideal criteria to define this condition and the best strategy to operationalize its assessment. There is agreement that frailty and cognitive deficits may co-occur, and that the presence of frailty increases the risk of MCI and dementia. Larger and well-designed intervention studies are needed to offer insights regarding the best strategies to delay or prevent frailty. Such interventions may play an important role in dementia prevention as well.

Definition

In the US' Department of Health, Education, and Welfare, Office of Human Development Services, the Federal Council on [the] Aging defined frail older people as: "persons, usually but not always, over the age of 75, who because of an accumulation of various continuing problems often require one or several supportive services in order to cope with daily live."

An Aging in Place Population

In our modern society, the older population is growing rapidly. The World Health Organisation estimates in their fact sheet 404 that between 2015 and 2050, the proportion of the world's population over 60 years will nearly double from 12% to 22%. This aging process is unprecedented, universal, sustainable, and far-reaching. Several explanations for this aging process are proposed. First, a continuous increase in life expectancy over the last decades results in a situation where more people attain very old ages. Mainly due to initiatives in the domain of public health and supported by enhanced nursing and medical care for older people, mortality rates are declining. Moreover, as birth rates are declining, an additional increase of the proportion of older people will take place (Grundy 2006).

In order to cope with the challenges of an aging population and to meet the preferences of older people themselves with regard to the place where they age, in Europe, governments have changed their vision towards health care provision (de Gooijer 2007). This policy mainly reflects a deinstitutionalization of long-term care services in order to provide opportunities for older people to stay in their own environment for as long as possible, also known as "Aging in place." Several studies demonstrated that this is the most preferred way of aging by older people themselves and addressed the impact of it on an individual's quality of life (Mitzner et al. 2014). It is more than a symbol of quality of life as it covers a basic need (accommodation) and has benefits on both physical and psychological health. It is also the place where intimate relationships with family members, relationships with friends/relatives, and leisure take place (Rojo Perez et al. 2001).

Clearly, aging in place creates opportunities to bind people. Indeed, older people are often reluctant to leave their community dwellings, even when it is difficult for them to manage the household chores, mostly because the familiar home environment provides them with a strong sense of meaning and belonging (Costa-Font et al. 2009). Older people's experience with their neighborhood and neighbors may be just as important

as their home itself. As a consequence, the residential area is not restricted to the home itself but also to the environment where the home is situated and to the people who live in the neighborhood (Satariano et al. 2012). This shift of mind is prompted by the prevailing belief among policymakers that an aging population inevitably means increasing demands on health care resources, social support, informal networks, etc. (Bond and Cabrero 2007). Moreover, aging in place is considered to be less expensive than institutionalization (Marek et al. 2012).

Conceptualization of Frailty

A major challenge for European governments with regard to this aging in place policy lays in the early detection of frail or vulnerable older people so that appropriate and often preventive support can be provided as early as possible and unnecessary adverse outcomes may be prevented. Indeed, when aging in place, older people are confronted with the limits of their own resources, their informal and formal care framework, and of their living environment. If there is an imbalance between resources and demands, people can become frail or vulnerable (Grundy 2006). In order to identify these limits and to ensure that adequate care is provided to the right persons in time, detection of these limits seems essential, but not straightforward.

Although recognized as a syndrome for some time (Weindruch et al. 1991), frailty is now a fast growing research area in gerontology and geriatric medicine focusing on its causes, risk factors, and adverse outcomes (Gobbens et al. 2010). Within Western welfare policy and practice, frailty is increasingly used for classification of older people (Nicholson et al. 2012). The term "frailty" is derived from the Latin word "Fragilitatem" which means "being weak or flaw." The Federal Council on Aging (USA) proposed the first definition of frailty (see "Definition"), and since 1991, frailty is also a Mesh term (Medical Subject Heading) and defined as: "Older adults or aged individuals who are lacking in general strength and are unusually susceptible to disease or to other

infirmity.” The initial purpose of the Federal Council on Aging was to make an inventory about the care needs, but later on, frailty was recognized as an interventionist concept (Weindruch et al. 1991; Hertogh 2010) not in the least because the aging process is stereotyped as a period of losses and decline in physical and mental functioning. Some researchers consider frailty as a clinical syndrome, a pure biomedical problem.

Fried, one of the leading scholars regarding frailty, developed the phenotype approach (Fried 2001), which has received international attention and has been extensively validated in research literature. Criteria used by Fried to define frailty are: weight loss, endurance, inactivity, gait speed, and hand grip strength. Over the years, a wide range of other physical problems have been linked to frailty: gait speed, a 3 m walk test, a stand-up test, endurance, weakness, reduced physical activity, weight loss, mobility, exhaustion, cardiac functioning, grip strength, balance, strength, slowness, neuromotor performance, sarcopenia, etc. Thus, in this respect, frailty is considered as a medical/clinical syndrome in which the underlying physiological and biological processes result in multiple clinical manifestations.

However, other scholars recommend giving more attention to the psychological aspects of frailty. Conceptualizing frailty as a pure medical problem is neglecting both the capacities of older people themselves to withstand stress and their experiences (Hertogh 2010). As a consequence, psychological indicators (cognition, mastery, depression, anxiety, sadness, and management capacities) were introduced in frailty assessments in addition to biomedical indicators. This bio-psychological approach was criticized for neglecting the interplay of bio-psycho-social factors in frailty (Nicholson et al. 2012). As a consequence, social indicators like social support or social network were also introduced in frailty assessment.

Although a consensus about an operational definition of frailty is still lacking, one aspect is gaining consensus: frailty is an entity that can be distinguished from disability or comorbidity (Gobbens et al. 2010) and is associated with excess of healthcare costs ranging from medical

consultations to institutionalization. As a consequence, prevention becomes very meaningful.

Frailty: Paradigm Shift

In literature, new debates are going on about the frailty concept. One debate explores the multidimensionality of frailty. According to (Hertogh 2010), psychological and social factors are overlooked in frailty. Additionally some researchers also point to environmental factors associated with frailty (Markle-Reid and Brown 2003).

According to (Romero-Ortuno et al. 2010, p. 1) frailty is

loss of independence, vulnerability and impairs the quality of life and psychological well-being of many older people; it also poses an enormous challenge on families, carers and other structures of social care and social support. In the face of the rapid population ageing occurring in Western Societies, frailty is set to reach epidemic proportions over the next few decades.

As the number of older persons increases in society, the prevalence of frailty in the population will consequently also increase. The interest in frailty lies in postponing the decline in health and quality of life of frail older persons in order to improve their chances of living a longer and healthy life. Frailty is therefore frequently conceptualized as an antonym for successful aging, and some researchers state that frailty can be prevented, delayed, and eventually reversed (Lang et al. 2009). Because of the shift in focus towards prevention and risk reduction, some frailty conceptualizations neglect other critical aspects of aging (Hertogh 2010).

A second debate is about the way frailty is conceptualized. When older women were asked how they perceive frailty, most of the answers were not only linked to physical descriptions, but also to contextual, social, and emotional problems, suggesting that older people themselves have other definitions about frailty than clinicians (Grenier 2007). Gustafsson and colleagues investigated frailty from a health care professional's perspective. Seven dimensions were consistent with frailty: *being bodily weak and ill, being*

negatively influenced by personal qualities, lacking balance in everyday activities, being dependent in everyday life, not being considered important, being hindered by the physical milieu and defective community service, and having an inadequate social network. These results point to the fact that health care professionals' view of frailty in older persons differed from the current state of knowledge on frailty (Gustafsson et al. 2012). As a consequence, a paradigm shift regarding frailty is needed.

Measuring Frailty in the Community

In most Western societies, frailty has been recognized as a major challenge the world is facing today for both formal health services and informal caregiving (Ceci and Purkis 2011). As a consequence, detecting frailty in primary care is a major challenge for primary care physicians. The I.A.G.G. (International Association of Gerontology and Geriatrics) and the G.A.R.N. (IAGG Global Aging Research Network) have already taken initiative in this domain and pointed to the need to concentrate on aging in place in order to prevent premature nursing home placement. According to Romero-Ortuno and colleagues (2010), the problem with the extant frailty instruments is that they are not readily applicable in primary care practice. The aforementioned phenotype of frailty has the advantage that it only requires the measurement of five variables, but while this is affordable from a primary care point of view, the problem arises with the construction of the measure as it requires considerable statistical expertise to dichotomize criteria measured on a continuous scale (e.g., grip strength) (Romero-Ortuno et al. 2010). Other scholars, however, state that using the extant screening instruments in community-dwelling frail people is impractical, because the assessment methods are complex and time-consuming and the results are difficult to report.

Altogether, if primary care providers need to screen for frailty, user-friendly instruments are required (De Lepeleire et al. 2008), but comprehensive tools to identify multidimensional aspects

of frailty in the primary care setting are still in the preliminary stages of development.

Moreover, different existing approaches of frailty are criticized because they are often based on a negative and stereotypical view of aging associated with becoming disabled (Markle-Reid and Brown 2003) and loss or declining abilities (Kaufman 1994). These instruments neglect the lived experiences of each individual (Grenier 2007), assuming that aging is a uniform process (Kaufman 1994). According to Gobbens and colleagues (2010), addressing frailty exclusively on physical components jeopardizes the attention for the individual as a whole. Markle-Reid points to the fact that frailty is a multidimensional non-age-related concept that must consider the interplay of various physical, psychological, social, and environmental factors. The fact that much biomedical research on frailty demonstrates great variations in frailty according to gender, socio-economic status, education, etc., points to the social production of frailty (Markle-Reid and Brown 2003).

While some authors have developed a measurement instrument for frailty aiming to meet the aforementioned critiques (e.g., Groningen Frailty indicator, Tilburg Frailty Indicator), they ignore the environmental aspects of frailty. In such an approach, however, frailty shifts from a microlevel analysis focusing on the individual only to a macrolevel analysis, where frailty is seen as a result of numerous intersecting factors, many of which are external to the individual. Additionally, some scholars (Grenier 2007) suggest to take the subjective perceptions of an individual into account, the so called lived experience. For example, social isolation, inadequate care and support, and living arrangements are risks associated with aging, but all these factors can have both mutual and individual antecedents and are experienced in different ways.

Beside the criticism on the operational definition of frailty, some scholars like Robertson (1997) expressed their concerns about the medicalization of aging due to the use of frailty measurements. For Robertson, the biomedicalization and gerontologization of old age are being reconceptualized as a new medical space requiring new supporting ideologies which protect the

new created space, with over servicing as a consequence, and requiring new customers. As a consequence, the socially constructed dependency of older adults serves those structural interests. Using functional and ill-health variables tends to a medical construction where older people are placed into classes (e.g., nonfrail, pre frail, frail, severely frail), and the distinction between normal and not normal is made. Those assigned with the status of frail become eligible for public and home-care services (Grenier 2007).

Not only does this approach overlook the social and emotional experiences, it also places older people in competition with each other for the scarce resources. In 1994, scholars like Kaufman already argued that frailty, constructed from within a health care context, transforms the older people's lived and experienced problems to diagnosis, then to treatment plans and rules about what ought to be done, leading to negotiated compliance. This view ignores the role of the broader environment and neglects the cumulative disadvantages build up during the lifespan (Grenier 2007). The implementation of frailty has no preventive aims but corresponds with an increased professionalism and efforts to ration care and thereby neglecting government initiatives to include older people in the society. Problems of aging are reduced to an individual level, moving responsibility from the government to the individual. As a consequence, the problem of frailty is depoliticized.

Some scholars point to the social construction of frailty (Lustbader 2000). In order to remain in the community, older individuals also rely on aspects in their social, psychological, and physical resources. Consequently adjusting the frailty measures for home-care clients to a biopsychosocial or more integrative approach may prove valuable. Furthermore, although social science literature acknowledges the merits of the frailty measurements in order to identify patient problems, it also points at a conflict between the biomedical conceptualization and the older people's experiences. On the other hand, it was found that when clinicians were asked to rate the different factors related to frailty, they rated mobility, stamina, and activities of daily living as most important and social and psycho-emotional factors as least important.

Development of the Comprehensive Frailty Assessment Instrument

In order to answer the aforementioned critiques, the Comprehensive Frailty Assessment Instrument (CFAI), which assesses the physical, social, psychological, and environmental domain of frailty, was developed and validated (De Witte et al. 2013a, b). Each domain received equal attention. This self-administer instrument (CFAI) contains 23 indicators and demonstrates a high overall internal consistency and high consistency of its scales, thus supporting the validity and reliability of the instrument and highlighting the multidimensionality of frailty as described by Markle-Reid and Browne (2003). Indeed, in a sample of 33,629 community-dwelling older people, the CFAI has been proven to be internally consistent, with a Cronbach's α of 0.812, explaining 63.6% of the variance in frailty (De Witte et al. 2013b). In a second study (N = 181), the CFAI was cross-validated with the Tilburg Frailty indicator. The internal consistency of the CFAI was 0.759. The correlation between the CFAI and TFI was 0.590. Correlations between the physical, psychological, and social domains of both scales were good, and the environmental domain showed weak correlations with all other domains, pointing to convergent and divergent validity (De Witte et al. 2013a).

The CFAI assesses frailty on four domains and all contribute to frailty, confirming the results of several studies have already addressed that frailty is more than just a purely physical phenomenon. Environmental indicators include the bad condition of the house, the house being uncomfortable, problems with heating the house, and aversion against the neighborhood. These factors are in line with scholars like Costa-Font and Wahl (Costa-Font et al. 2009; Wahl et al. 2009), who all highlighted the importance of the spatial context and environmental resources on which an individual depends when aging. As expected, social support also contributed to frailty.

The psychological domain added the most to the respondents overall frailty score. This is a new insight, which, to the best of our notion, has not

been addressed in earlier research. Therefore, literature was screened for possible indirect explanations. Although much research needs to be done to untangle this, psychological frailty seems to be very complex. Several theoretical explanations can be proposed, which all guide future research directions. A first topic could be mental health problems, the interdynamics between frailty and depression and the exploration of psychological risk factors like stress and ageism. Second, emotional well-being could be investigated where the differentiation between being frail and feeling frail could be made. A third research topic could be the relationship between psychological frailty and dependence. Finally, the study of individual's lifespan development could give more insight into the problem. Besides these topics attention to protective factors must be given. Here possible research topics could be psychological and existential well-being, having a purpose in life, environmental mastery, resilience, self-efficacy wisdom, and aging attitudes could be investigated.

Conclusion

Frailty is a broad concept which is often assessed from a biomedical point of view. Considering population aging and aging in place constructs, biomedical assessments are too narrow to tackle the multidimensionality and complexity of frailty in community-dwelling older people. With the development and use of the Comprehensive Frailty Assessment Instrument, the multidimensionality of the frailty concept is confirmed. Moreover, frailty seems to be a very relevant psychological problem, as this domain contributed most to frailty. Due to the changing policy towards aging in place, the demographic challenges and scarce resources, focusing on the frailty balance between being frail and feeling frail is fundamental. This suggests a paradigm shift regarding frailty in community-dwelling older people and offers new opportunities for research, not in the least regarding the prevention of frailty.

Synonyms

Behavioural variant frontotemporal dementia; Frontal dementia; Semantic Dementia; Progressive non-fluent aphasia; Pick disease

Definition

Frontotemporal dementia is an insidious neurodegenerative disease characterised by progressive deficits in behaviour and cognition. Three main clinical entities as well as overlapping syndromes affecting the young subject (< 65 years old) are described here on a clinical, neuropsychological and imaging point of view.

Introduction

Frontotemporal dementia (FTD) is an insidious neurodegenerative disease characterised by progressive deficits in behaviour and cognition. FTD is a common type of dementia, particularly in patients younger than 65 years. It is the second most common form of younger-onset dementia after Alzheimer’s disease (AD) (Ratnavalli et al. 2002). Despite such prevalence, FTD has received far less recognition compared to other dementias. This is surprising considering the overlap FTD shares clinically and pathologically with many other dementias, making it a challenging condition in terms of diagnosis and treatment. Currently, three different FTD subtypes are clinically recognized: behavioral variant FTD (bvFTD) and two FTD subtypes with progressive aphasia (PPA) – semantic variant primary progressive aphasia (sv-PPA) and nonfluent variant PPA (nfv-PPA) (Hodges 2011). All three subtypes have specific but overlapping clinical, pathological, and neuroimaging features which will be discussed in detail shortly. First, we will give a brief historical and general introduction to FTD before discussing the main subtypes as well as the most prominent overlap syndromes.

FTD was first described by Arnold Pick in 1892 (Pick 1892). Pick published a series of patient cases which all showed significant behavioral and language changes. Importantly, postmortem examinations of the patients showed atrophy macroscopically in the temporal and frontal lobes and microscopically ballooned cells, called Pick bodies. The disease has been historically known as Pick’s disease, however was renamed frontotemporal dementia in the 1980s by

researchers in Lund and Manchester (Neary et al. 1986), according to the prominent macroscopic atrophy seen in these patients. Diagnostic criteria for FTD were first published in the 1980s with revisions in the 1990s (Neary et al. 1998). The most recent diagnostic criteria split the behavioral variant (Rascovsky et al. 2011) from the aphasic (Gorno-Tempini et al. 2011) subtypes to allow more detailed phenotyping of the variants.

Over the years, FTD has moved from being considered a condition that only occurred occasionally to a more prominent role. In particular, the genetic connection of amyotrophic lateral sclerosis (ALS) and FTD has highlighted that FTD pathology and associated symptomology are more common than previously assumed. The following book chapter will allow the reader to gain an insight into the FTD spectrum which will hopefully trigger further clinical and research interest in the FTD field.

Behavioral Variant Frontotemporal Dementia (bvFTD)

Clinical Symptoms

bvFTD is the most frequent subtype of FTD. The median survival (from first assessment) is about 3.0–4.5 years (Piguet et al. 2011a), with a disease onset usually around 60 years old, although younger and older cases have been frequently described. The clinical symptomatology of bvFTD is dominated by progressive and dramatic changes in patients' social behavior and personality that become gradually evident to their relatives, often to great distress. Apathy, behavioral disinhibition, inappropriate social conduct, lack of empathy, stereotyped and rigid behaviors, as well as changes in eating behavior are the clinical hallmarks of bvFTD (Piguet et al. 2011a; Rascovsky et al. 2011). Patients also exhibit a loss of insight that complicates their engagement and referral to the clinic (Hornberger et al. 2014; Eslinger et al. 2005), as they do not recognize either their deficits or the relevance of a medical consultation. These insight problems make a

comprehensive interview with informants crucial to establish symptoms. In that perspective, the use of carer questionnaires (such as the Cambridge Behavioural Inventory – CBI, Bozeat et al. 2000) to identify and quantify behavioral changes is particularly useful.

Apathy is observed in many, if not all, bvFTD patients. A striking reduction of motivation and interest in others, work, hobbies, and hygiene may be observed, resulting in social withdrawal and a significant reduction of premorbid activities (Chow et al. 2009) that could be mistaken for depression (Woolley et al. 2011). Importantly, although loss of libido may be commonly observed, patients generally do not report the other key symptoms that characterize depression, such as feeling of worthlessness or guilt, sleep disturbances, and recurrent sad thoughts. **Behavioral disinhibition** is also an early symptom of bvFTD and usually coexists with apathy (Le Ber et al. 2006; Seelaar et al. 2011). Patients can act impulsively without taking into account the consequences of their actions and thus make poor financial decisions and reckless purchases, or engage in pathological gambling (Manes et al. 2010). Another key symptom of bvFTD is **inappropriate social conduct**, manifesting as abnormal intimacy with strangers, loss of manners, and embarrassing or tactless personal remarks (Lu et al. 2006). Such socially awkward behaviors are further aggravated by a **lack of empathy** and a decreased ability to decode others' thoughts and beliefs. This leads to decreased interest and concern for others, including closest relatives, which is a major cause of carer and family distress (Baez et al. 2014; Lough et al. 2006). **Stereotyped behaviors** are commonly observed, with simple repetitive movements such as grunting, humming, food tapping, or lip smacking being frequent as well as the repetitive verbalization of words or phrases (Snowden et al. 1996, 2001). **Mental rigidity** is also habitually observed, manifesting as a rigid adherence to everyday routine, a lack of creativity, and, sometimes, compulsive ritualistic behaviors (Snowdmeeen et al. 2001; de Souza et al. 2010). **Change in eating behavior** is also an early symptom of bvFTD. Patients can be

gluttonous, which can cause significant weight gain. A deterioration of table manners, impulsivity to start eating before everyone else, snatching food from others and stuffing it into the mouth all at once are frequently observed symptoms (Ahmed et al. 2014; Piguët et al. 2011b; Woolley et al. 2007).

It should be noted that some patients differ in their progression, showing hardly any change over a decade (Davies et al. 2006) while still exhibiting the behavioral symptoms of bvFTD. Comparative investigations between these “phenocopy” patients and the patients who progress suggest that an absence of brain atrophy, normal or sub-normal executive functioning, and preservation of everyday living activities allow for accurate identification of these nonprogressors (Hornberger et al. 2009).

Neuropsychology

Apart from the neuropsychiatric symptoms, the neuropsychological profile of bvFTD is dominated by deficits in all aspects of **social cognition**, including empathy, theory of mind, and emotion recognition (Lavenex et al. 1999; Gregory et al. 2002; Bertoux et al. 2013). Carer questionnaires such as the Interpersonal Reactivity Index (IRI – Davis 1983) can be useful to measure a decrease in empathic concern. Faux pas and sarcasm detection are among the most sensitive assessments to capture theory of mind impairments in bvFTD (Bora et al. 2015; Henry et al. 2014). Finally, emotion recognition tests show difficulties in identifying negative emotions (Bertoux et al. 2015a).

Dysexecutive symptoms, such as impaired organization and planning, decreased verbal fluency, difficulties in verbal and nonverbal conceptualization, inhibition dysfunctions, and working memory deficits are commonly observed, although they can be absent or subtle in the earliest stages of the disease (Lindau et al. 2000; Gregory and Hodges 1996; Rahman et al. 1999; Harciarek and Jodzio 2005; Perry and Hodges 2000; Hornberger et al. 2011). It should be noted that these symptoms have a poor discriminative value between bvFTD and AD or depression (Libon et al. 2007; Stopford et al. 2012).

Impairments in **decision-making** and **reward processing** have also been documented in bvFTD (Rahman et al. 1999). Patients exhibit a decreased sensitivity to reward (Fletcher et al. 2015), reduced aversion to losses (Chiong et al. 2016), an increased discounting of future reward (Bertoux et al. 2015c), and striking difficulties in reversing the selection of a previously rewarding item that becomes punishing (Bertoux et al. 2013).

Poor **episodic memory** has only recently been recognized as a possible cognitive symptom of bvFTD (Hornberger et al. 2010) and can be observed in 50% of bvFTD patients (Bertoux et al. 2014) although spatial orientation appears to remain relatively preserved (Tu et al. 2015).

The **language** profile of bvFTD is characterized by diminished spontaneous speech and deficits in noun and verb naming as well as impaired single word comprehension, but to a lesser extent than in sv-PPA (Snowden et al. 1996; Hardy et al. 2015).

Praxis disturbances can be observed after the earliest stages of the disease, particularly difficulties imitating face postures (Johnen et al. 2015).

Neuroimaging

Structural imaging such as magnetic resonance imaging (MRI) scans show a typical pattern of atrophy that is ideally seen in coronal orientation. It is characterized by predominant frontal, fronto-insular and/or anterior temporal atrophy, which is sometimes asymmetrical (Agosta et al. 2012). Because atrophy can be very subtle in the early stages of the disease, a normal MRI should not exclude the diagnosis of bvFTD. Regions that are more likely to be atrophied in the earliest stages are the medial prefrontal and orbitofrontal cortices, as well as the anterior insula (Perry et al. 2006; Seeley et al. 2008). In the temporal lobe, the amygdala and hippocampus are also affected (Seeley et al. 2008; de Souza et al. 2013). Subcortical structures such as the striatum (Bertoux et al. 2015b), thalamus (Hornberger et al. 2012), and hypothalamus (Piguët et al. 2011b) are also involved, as well as white matter tracts such as the paracallosal cingulum bundle, corpus callosum, uncinate fasciculus, and fornix (Hornberger et al. 2012; Mahoney et al. 2015).

Functional imaging such as single photon-emission computed tomography (SPECT) shows important hypoperfusion in the fronto-insular and polar tempolar regions (Le Ber et al. 2006; Jeong et al. 2005). As amyloid deposition is not a neuropathological feature of FTD, amyloid tracer can efficiently distinguish bvFTD from AD (Rabinovici et al. 2011).

Semantic Variant Primary Progressive Aphasia (sv-PPA)

Clinical Symptoms

Sv-PPA, also called semantic dementia (Snowden et al. 1989; Hodges et al. 1992), is a progressive disorder of language. It is a presenile disease with onset commonly ranging between 66 and 70 years. Anomia and single-word comprehension deficits are the core features of the disease. Although these symptoms, particularly anomia, may be observed in other FTD variants or neurodegenerative conditions such as AD, these disturbances are especially severe in sv-PPA. The disease involves a gradual degradation of conceptual knowledge (thus affecting all modalities), which impairs object knowledge and object use after the earliest stages. Behavioral changes similar to those observed in bvFTD are also common symptoms of sv-PPA (Hodges and Patterson 2007; Bang et al. 2015; Gorno-Tempini et al. 2011). Finally, prosopagnosia can be observed, most commonly in sv-PPA with right predominant atrophy, which accounts for one third of sv-PPA cases and shares many behavioral similarities with bvFTD (Thompson et al. 2003; Evans et al. 1995; Kamminga et al. 2015).

Anomia is a key symptom of sv-PPA, occurring in the spontaneous speech that, by contrast with other PPA variants, is not marked by phonological or grammar difficulties. This symptom is obvious during language assessment (e.g., picture naming test) but less noticeable in spontaneous speech, as patients compensate for their difficulties with the use of circumlocutions (Hodges and Patterson 2007). A **single-word comprehension deficit** is also a hallmark of the disease. It is also

less obvious in conversation than during testing because of the critical importance that contextual cues have in a discussion. Similarly to what is observed with anomia, factors such as familiarity and prototypicality (e.g., “dog” for the category “animal”) influence performance (Rogers et al. 2015). The progressive **deterioration of conceptual knowledge** leads to an impairment of object knowledge and use, although patients should function normally with everyday objects at home (also reflecting an effect of familiarity for objects). **Surface dyslexia and dysgraphia** are also observed, where irregular words (e.g., “pint”) are pronounced or written as if they were regular (e.g., “mint”). Although symptoms and complaints preferentially focus on language impairment with less emphasis on behavior, **behavioral symptoms** are common and can mimic the changes observed in bvFTD (Kamminga et al. 2015; Seeley et al. 2005), particularly for sv-PPA with predominant right-sided atrophy. Therefore, apathy, behavioral disinhibition, changes in eating behavior (e.g., restriction of food preferences and bizarre food choices), and emotional withdrawal are commonly observed. Patients also often present with an abnormal egocentric behavior (Snowden et al. 2001; Belliard et al. 2007), extreme rigidity, and compulsions such as repetitive playing of puzzles (Hodges and Patterson 2007). Finally, newfound religiosity, collectionism, and eccentricity of dress are also reported (Edwards-Lee et al. 1997; Snowden et al. 2001). Insight abilities in sv-PPA are mostly impaired for behavioral changes but, by contrast, patients show only a mild anosognosia regarding language deficits (Hornberger et al. 2014; Savage et al. 2015).

Neuropsychology

Alterations of language are the main causes of complaint and functional impairment in sv-PPA, as well as being the core features for its diagnosis. **Anomia** is especially salient during picture-naming tests, where specific terms tend to be replaced by more prototypical words or by the superordinate category name (e.g., “dog” or “animal” instead of “wolf”) or, in latest stages, by no

answer (Hodges and Patterson 2007; Belliard et al. 2007; Savage et al. 2013). Phonological cues such as pronouncing the first letter or the first phoneme of the word to help its production have little or no effect (Jefferies et al. 2008). **Semantic fluency** is dramatically impaired, reflecting a severe difficulty to generate words in a particular category, while phonemic/letter fluency is relatively preserved during the early stages (Hodges and Patterson 1996; 2007). After the earliest stages, **identification of objects** in any modality is also impaired and reflects a central semantic deficit (Golden et al. 2015; Luzzi et al. 2015; Hodges and Patterson 2007; Savage et al. 2013). Consequently, **object use** may also be altered (Hodges and Patterson 2007). Similarly to anomia, patients with sv-PPA invariably have an impaired **comprehension of single words**, which is strongly modulated by word familiarity (Hodges and Patterson 1996, 2007; Savage et al. 2013). Therefore, while patients may be able to repeat words without errors, difficulties arise when they have to provide **definitions**: definitions lack in detail at first and, in the most severe stages, can be impossible. When the patient is asked to read or write, “typicalization” errors are observed: irregular words are pronounced or written as if they were regular, including verbs (e.g., “drinked” instead of “drank”), which is typical of **surface dyslexia and dysgraphia** (Hodges and Patterson 2007; Savage et al. 2013).

Executive functions in sv-PPA are overall relatively preserved in left-sided presentations of sv-PPA and impaired in right-sided sv-PPA. Digit or visuospatial spans are well preserved, and semantic deficits may explain day-to-day working memory impairment as well as verbal fluency deficits (Laisney et al. 2009; Jefferies et al. 2008; Desgranges et al. 2007; Hodges et al. 1999). While alteration of cognitive flexibility may be observed in left-sided sv-PPA, it is more often seen in right-sided sv-PPA as part of a more general dysexecutive syndrome (Desgranges et al. 2007; Kamminga et al. 2015).

Although many patients complain of memory problems, this does not reflect a true amnesia. **Memory deficits** in sv-PPA are modality-specific,

occurring mostly on verbal tasks, with a relative preservation of day-to-day memory (Irish et al. 2016; Hodges and Patterson 2007) and autobiographical memory (Irish et al. 2011) as well as spatial navigation (Pengas et al. 2010).

Visuospatial abilities are well preserved (Desgranges et al. 2007; Perry and Hodges 2000) with normal copy of complex figures (Hodges and Patterson 2007). **Prosopagnosia** appears predominantly in right-sided sv-PPA and can be its principal symptom at presentation, helping to differentiate these cases from bvFTD. By contrast, it is rarely observed in cases with left-side predominant atrophy (Thompson et al. 2003; Kamminga et al. 2015).

Social cognition deficits can be seen in both left- and right-sided sv-PPA. Facial and musical emotion recognition is altered (Hsieh et al. 2012) as well as empathy and theory of mind. In particular, nonverbal sarcasm detection has been shown to be impaired (Rankin et al. 2009) as well as false-belief, mental-state inference, and attribution of intention (Irish et al. 2014; Duval et al. 2012).

Neuroimaging

Structural imaging examinations show characteristic focal and bilateral, though asymmetric, atrophy of the temporal lobe, involving the polar, lateral, and inferior surface (including fusiform gyrus) with relative preservation of the superior temporal gyrus (Chan et al. 2001; Galton et al. 2001). This atrophy is typically left-sided (the right-sided atrophy is observed in one third of cases) and ideally appreciated in coronal orientation. Medial temporal structures are also involved, with the amygdala and hippocampus being severely atrophied as well, particularly anteriorly (Galton et al. 2001; La Joie et al. 2013). Involvement of the ventromedial frontal cortex and insula is also frequently observed (Agosta et al. 2012; Gorno-Tempini et al. 2004; Rosen et al. 2002).

Functional imaging shows hypoperfusion/hypometabolism in anterior temporal regions as well as in the hippocampus and orbitofrontal cortex, which is more marked on the left side (Rabinovici et al. 2008; Agosta et al. 2012).

Nonfluent/Agrammatic Variant Primary Progressive Aphasia (nfv-PPA)

Clinical Profile

Consistent with other syndromes on the FTD spectrum, nfv-PPA is a younger-onset condition with an average age of 60 years and equal prevalence in male and female patients (Johnson et al. 2005). Survival is approximately 7 years after symptom onset (Hodges et al. 2003; Kertesz et al. 2005). According to current diagnostic criteria, hallmark features of nfv-PPA are **agrammatism** and **slow, effortful speech**, typically with accompanying deficits in **syntax comprehension** in the context of spared single-word comprehension and object knowledge (Gorno-Tempini et al. 2011). Speech production in nfv-PPA contrasts with the fluid, syntactically correct, but meaningless speech production seen in sv-PPA, and patients are usually aware of their speech output deficits (Hodges and Patterson 1996). Speech becomes increasingly effortful over the disease course and typically ends in mutism. Communication via writing has been anecdotally reported as better preserved compared to speech output; however, formal assessment can reveal equivalent impairments in both domains (Graham et al. 2004). Prominent behavioral disturbance is uncommon early in the course of nfv-PPA; however, apathy, agitation, and depression have been documented (Rohrer and Warren 2010) and more profound personality changes and deficits in social functioning can emerge with disease progression (Grossman 2012). Neurological examination in nfv-PPA patients is often unremarkable, although the presence of extrapyramidal features is suggestive of an FTD overlap syndrome such as ALS or corticobasal degeneration (CBD).

Neuropsychology

Slow, effortful speech in nfv-PPA is marked by errors, with abnormal prosody and a slowed rate of speech (Gorno-Tempini et al. 2004, 2011; Ogar et al. 2007). Errors can include distortions (lack of accurate articulation), deletions, substitutions, insertions, or transpositions of speech sounds. Changes in prosody can reflect the incorrect placement of stress or intonation on syllables or

words within a sentence (Leyton et al. 2011). Trial and error processes often accompany this speech output where the patient “grope” for the correct sound or mouth formation. Apraxia of speech (AOS), which refers to disordered articulatory planning and speech sound coordination, is a prominent mechanism underlying the labored speech in nfv-PPA (Josephs et al. 2006). Slowed rate and effortful speech are apparent in spontaneous speech output. On more standardized assessment, when nfv-PPA patients are asked to provide a description of a series of pictures or a visual scene, their rate of speech is less than one-third the speech rate of healthy control subjects and slower than other FTD variants (Ash et al. 2009; Wilson et al. 2010b; Grossman 2012). Formal assessment tools for this include describing the “Picnic Scene” from the Western Aphasia Battery (Kertesz 1982) or the “Cookie Theft” picture from the Boston Diagnostic Aphasia Examination (Goodglass and Kaplan 1983). These tools can also be used to quantify the frequency of agrammatic errors. **Severely reduced fluency** in nfv-PPA is also evident on classical tests of phonemic and semantic fluency (Nestor et al. 2003; Wilson et al. 2010b).

Agrammatism in nfv-PPA is reflected in the reliance on short, simplified phrases; omissions of grammatical morphemes such as function words or inflections; and errors in word arrangement (i.e., syntax) (Gorno-Tempini et al. 2011; Leyton et al. 2011). Frequency of grammatical errors also contributes to the reduced rate of speech production (Gunawardena et al. 2010). Related to this are deficits in **syntax comprehension**, where patients have difficulty understanding the syntactic aspects of speech (Hodges and Patterson 1996; Thompson et al. 1997). Agrammatism can be observed in spontaneous speech or tested informally by asking the patient to follow sequential commands that increase in their syntactic complexity (e.g., “put the pen on the watch before giving me the scissors”). Standardized assessment of complex sequential commands reveals impairments relative to healthy controls (Gorno-Tempini et al. 2004). Tasks that assess syntactic comprehension, such as responding to questions about a complex sentence (e.g., “The friendly boy that the

girl chased was nice.” versus a simple sentence, “The nice, tall girl chased the friendly boy.”) show pronounced deficits relative to controls, sv-PPA, and bvFTD (Peelle et al. 2008). Matching syntactically complex sentences with the correct line drawing using the Test for Reception of Grammar (Bishop 2003) also reveals significant impairment in nfv-PPA patients (Nestor et al. 2003).

Repetition of multisyllabic words (e.g., stethoscope) is particularly sensitive to nfv-PPA, and impaired repetition seen in the context of spared naming and comprehension supports a breakdown in grammatical processing or articulatory planning (Leyton et al. 2014). Testing of repetition can be done informally or using standardized repetition tests contained in language assessment batteries such as the Sydney Language Battery (SYDBAT) (Savage et al. 2013) and the Western Aphasia Battery.

In contrast to the striking language deficits, performance is better preserved in other cognitive domains, such as episodic memory, visuospatial skills, and nonverbal reasoning (Graham et al. 2004). However, measures of **working memory** (e.g., digit span) are reliably impaired in nfv-PPA (Nestor et al. 2003; Wilson et al. 2010b) consistent with a deficit in phonological rehearsal abilities (Leyton et al. 2014). Impairments in attentional set-shifting are also observed on the trail making test (Savage et al. 2013; Brambati et al. 2015).

Neuroimaging

Structural MRI in nfv-PPA reveals gray matter atrophy in the inferior frontal region of the left hemisphere, which can extend to the anterior insula, frontal operculum, dorsal prefrontal cortex, and superior left anterior temporal lobe (Gorno-Tempini et al. 2004; Peelle et al. 2008; Rogalski et al. 2011; Grossman 2012). Progression of gray matter loss in the left frontal regions is evident in longitudinal studies, accompanied by involvement of subcortical regions (Brambati et al. 2015).

Metabolic abnormalities in left hemispheric regions are also documented by PET imaging (Grossman et al. 1996; Nestor et al. 2003). Local white matter abnormalities in the dorsal language network (e.g., superior longitudinal fasciculus)

are documented, as well as more diffuse white matter changes outside the language network (Galantucci et al. 2011; Schwindt et al. 2013). Fluency impairment has been directly related to gray matter volume in the left inferior frontal regions, insula, and superior temporal area (Ash et al. 2009), whereas apraxia of speech is associated with changes in the premotor and supplemental motor cortices (Josephs et al. 2006). Posterior regions of the inferior frontal cortex show functional abnormalities related to processing of syntactically complex sentences during fMRI (Wilson et al. 2010a).

Neuropathology of FTD Variants

Neuronal loss, gliosis, and microvacuolar changes characterize frontotemporal lobar degeneration (FTLD). Specific patterns of abnormal protein deposition are observed in FTLD, such as microtubule-associated protein tau (MAPT), TAR DNA-binding protein with molecular weight 43 kDa (TDP-43), and fused-in-sarcoma protein (FUS). Ubiquitin-only, p62-only positive inclusions, or no inclusions are sometimes observed, but in many fewer cases (Mackenzie et al. 2010; Bang et al. 2015).

FTLD-MAPT or tau accounts for 36–50% of all FTLD cases, almost equally distributed between Pick’s disease, CBD, and PSP cases (Josephs et al. 2011; Sieben et al. 2012; Dickson et al. 2011). FTLD-TDP accounts for about 50% of all FTLD cases, with three major subtypes (A, B, and C) accounting for about half of the nfv-PPA cases (FTLD-TDP-A), two-thirds of FTD-MND cases (FTLD-TDP-B), and the majority of sv-PPA cases (FTLD-TDP-C) (Josephs et al. 2011; Sieben et al. 2012; Mackenzie et al. 2011; Le Ber 2013). Deposition of TDP-43 pathology in the hypoglossal nucleus and in the anterior cingulate cortex has been found to have high value to respectively identify MND and bvFTD patients (Tan et al. 2015). FTLD-FUS accounts for about 10% of all FTLD cases and is characterized by early-onset FTD with severe behavioral and psychiatric abnormalities without linguistic and motor impairments (Mackenzie et al. 2011).

Finally, AD pathology is observed at autopsy in 15–30% of patients with a diagnosis of FTD (Hodges et al. 2004; Grossman et al. 2007; Alladi et al. 2007), mostly in bvFTD and nfv-PPA.

Overlap Syndromes (ALS, AD, Logopenic, PSP, CBD)

A number of syndromes overlap with the classical FTD spectrum, with shared clinical, pathological, and genetic characteristics. Overlap syndromes include ALS, progressive supranuclear palsy (PSP), CBD, AD, and logopenic aphasia.

Amyotrophic Lateral Sclerosis (ALS)

ALS is dominated by motor symptoms caused by lower and upper motor neuron dysfunction. These symptoms include weakness, spasticity, muscle wasting, dysarthria, and swallowing difficulties (Mitchell and Borasio 2007; Kiernan et al. 2011). Cognitive and psychiatric changes are increasingly recognized in ALS and 20–50% of patients meet diagnostic criteria for FTD (Ringholz et al. 2005). A proportion of FTD patients also go on to develop ALS motor features (Lomen-Hoerth et al. 2002). Cognitive dysfunction in ALS is characterized by executive impairment, personality changes, poor insight, and behavioral changes that include disinhibition and apathy (Flaherty-Craig et al. 2006; Phukan et al. 2007). Clinically, this presentation overlaps considerably with bvFTD (Lillo et al. 2012b). Neuroimaging in ALS patients with cognitive and behavioral dysfunction reveals frontotemporal atrophy (Lillo et al. 2012a; Mioshi et al. 2013). Consistent with the clinical overlap, FTD and ALS also share overlapping pathology and genetic susceptibility. TDP-43-positive inclusions are present in half of the patients with FTD and in the majority of ALS patients (Neumann et al. 2006) and expansions in the C9 or f72 gene are a common cause of both familial FTD and ALS (DeJesus-Hernandez et al. 2011; Renton et al. 2011).

Progressive Supranuclear Palsy (PSP)

PSP is characterized by vertical gaze palsy, postural instability, and cognitive decline (Litvan

et al. 1996a). Cognitive impairment occurs in the majority of patients and is characteristically “fronto-subcortical,” with mental slowing and executive dysfunction (especially attention and verbal fluency) and inefficient memory recall (Brown et al. 2010). PSP patients also exhibit significant levels of apathy and disinhibition (Litvan et al. 1996b; Aarsland et al. 2001). The combination of executive dysfunction and neuropsychiatric features supports a clinical overlap with FTD, and one case series identified over 30% of pathologically confirmed PSP cases met clinical criteria for possible bvFTD (Kobylecki et al. 2015). Pathologically, PSP is characterized by accumulation of tau protein and neuropil threads primarily in the basal ganglia and brainstem (Hauw et al. 1994; Williams and Lees 2009). Tau pathology represents a common substrate underlying PSP, which is also present in nearly half of FTD cases (Josephs et al. 2011). A PSP-FTD subtype has been proposed to identify those patients with a prominent FTD cognitive/behavioral syndrome. Those patients show more extensive cortical pathology compared to PSP without prominent cognitive/behavioral changes (Dickson et al. 2010).

Corticobasal Degeneration (CBD)

CBD is characterized by tau pathology and a combination of motor and cognitive/behavioral features related to frontoparietal neuronal loss and basal ganglia degeneration. Numerous diagnostic criteria and terminologies have been proposed (Riley et al. 1990; Boeve et al. 2003; Bak and Hodges 2008; Armstrong et al. 2013). The clinical motor syndrome commonly associated with CBD is parkinsonism, asymmetric rigidity, and corticobasal dysfunction evidenced by limb or oculomotor apraxia, cortical sensory deficits, and alien limb or dystonic limb posturing (Kouri et al. 2011). The cognitive/behavioral syndrome is characterized by language and visuospatial dysfunction and changes in behavior and personality (Burrell et al. 2014). Visuospatial dysfunction is typically striking and may include Balint’s syndrome (simultanagnosia, oculomotor apraxia, and optic ataxia) (Graham et al. 2003). Language features overlap with nfv-PPA (Kertesz et al. 2000;

McMonagle et al. 2006) and behavioral symptoms mirror those seen in bvFTD, particularly apathy and disinhibition (Kertesz and McMonagle 2010; Bruns and Josephs 2013).

Alzheimer's Disease (AD)

AD is pathologically distinct from FTD; however, shared clinical features can make these diseases difficult to distinguish. AD is characterized by impaired ability to retain newly learnt information (anterograde episodic memory) (Kopelman 1985; Butters et al. 1987; Perry et al. 2000). Progression sees decline in other aspects of memory (i.e., semantic knowledge and remote memory), accompanied by attentional, executive, and visuospatial deficits (Hodges 2006). Cognitive decline in AD is associated with early hippocampal and medial temporal pathological changes and later frontal and parietal changes, which are apparent on structural, functional, and metabolic imaging (Jack 2012). Episodic memory impairment was previously considered a distinguishing feature to separate AD from FTD as it was presumed to be intact in FTD (Neary et al. 1998). However, memory impairment in FTD, in particularly bvFTD, can be equally severe as seen in AD (Hornberger et al. 2010; Bertoux et al. 2014). Atypically presenting AD may also manifest a “frontal” behavioral syndrome characterized by behavioral abnormalities and executive dysfunction (Warren et al. 2012). The potential overlap between memory impairment and behavioral change means in certain cases AD and bvFTD might only be distinguished postmortem. AD pathology involves the accumulation of beta-amyloid plaques and neurofibrillary tangles beginning in the transentorhinal cortex and hippocampus, before progressing to adjacent medial temporal regions and later neocortical association regions (Braak and Braak 1991).

Logopenic Aphasia

Sv-PPA and nfv-PPA were the prototypical primary progressive aphasias prior to identification of a third variant known as logopenic aphasia (Gorno-Tempini et al. 2004). Word retrieval and sentence repetition deficits, accompanied by slowed speech with frequent word-finding pauses, are hallmark features of logopenic aphasia and

linked to a core phonologic short-term memory deficit (Gorno-Tempini et al. 2008, 2011). Although the slowed speech overlaps with the nfv-PPA presentation, logopenic aphasics do not exhibit the same degree of motor speech errors or agrammatism (Grossman et al. 1996). The confrontation naming impairment is typically less severe than in sv-PPA and characterized by phonological errors as opposed to semantic errors (Gorno-Tempini et al. 2004). Compared with the two other progressive aphasias, logopenic aphasia is associated with a more rapid progression toward a global dementia that encompasses non-verbal domains (Leyton et al. 2013). Imaging abnormalities in the left temporoparietal junction and dorsal language network are found in logopenic aphasia (Rohrer et al. 2010; Leyton et al. 2012). Amyloid imaging and neuropathological studies confirm that Alzheimer pathology is the most common underlying cause of logopenic aphasia (Mesulam et al. 2008; Rabinovici et al. 2008; Rohrer et al. 2012).

Conclusion and Outlook

The current chapter gave an overview of the FTD spectrums as well as the most prominent overlap syndromes. As evident from the chapter, FTD is a complex and multifaceted disease, which covers different cognitive, neuroimaging, and pathological domains. More specifically, FTD patients can not only present with behavioral and language problems but can also show social cognition and memory deficits as well as motor symptoms. Similarly, brain regions affected by structural and functional changes can be widely distributed or focal. Finally, the admixture of tau and TDP-43 pathology adds the last level of complexity for this disease spectrum.

Such multifaceted complexity might at first seem daunting for any clinician or researcher. However, FTD is therefore emerging often as a critical disease to determine pathological specificity. More specifically, comparisons between FTD and other dementias allow to delineate cognitive, neuropsychiatric, and neuroimaging biomarkers specific to each conditions. This is particularly

relevant for phenotypological variability across dementias, i.e., where patients can show overlapping cognitive symptoms.

Taken together, our overview shows the importance of FTD as a syndrome within the dementias, especially for early-onset cases. Despite its lower prevalence than AD, FTD emerges as important syndrome to delineate different dementia pathologies on a cognitive and neuropsychiatric level. Clearly future investigations are needed to explore this further via novel cognitive biomarkers that can be then also used as outcome measures in disease modifying trials. Finally, the longitudinal trajectories of cognitive and neuropsychiatric changes are still virtually unknown in FTD, which are important to explore as to allow better symptom management in patients in the future.

Synonyms

Ageing and retirement in Europe (SHARE); Cohort effects; Gender differences; Longitudinal assessment; Mathematics; Memory: episodic; Verbal ability; Visuospatial ability

Age and gender are variables that have been found to influence cognitive performance. In the following entry, findings of gender differences in cognitive functions will be reviewed, with a specific focus on examining to what extent the pattern and magnitude of these differences change over the adult life span. First, results on gender differences found in memory and cognition tasks in childhood and young adulthood are presented. This is followed by a discussion of the extent to which these differences change over the life span and/or over geographical regions. Lastly,

somewhat contradictory findings reported in cross-sectional and longitudinal studies will be highlighted.

In this review, the following main conclusions are drawn: There is little evidence to suggest that the rate of decline in cognitive performance over the life span is different for men and women. However, cross-sectional studies, comparing individuals of different ages, suggest that the magnitude of gender differences may change over time. Improvements in living conditions and better educational opportunities are factors that may lead to increased gender differences favoring women in some cognitive functions and decreased or eliminated differences in other cognitive abilities. These changes in gender differences seem to take place due to a general increase in cognitive performance over time, associated with societal improvements, where women improve more than men.

Gender Differences in Cognitive Abilities

Not all cognitive tasks give rise to differences in test scores between men and women, but some do and have consistently been shown to do so. The focus in this entry will be on tasks assessing visuospatial, verbal, numerical, and episodic memory abilities – cognitive abilities that typically yield differences between men and women.

Visuospatial ability. Most research indicates that men perform at a higher level than women

when it comes to visuospatial ability. The most recent meta-analysis on the topic (Voyer et al. 1995) concluded that men perform at a substantially higher level than women on most visuospatial tasks, with the overall gender difference in visuospatial ability being $d = -.37$ (effect size, $d = (M_{\text{women}} - M_{\text{men}}) / Sd_{\text{total}}$). Although men outperform women, the size of the difference may vary depending on the task being assessed. The largest difference is found in mental rotations ($d = -.56$; the ability to rapidly rotate two or three dimensional figures in mind), while it is somewhat smaller for spatial perception ($d = -.44$; the ability to determine a spatial relation regardless of distracting information) and considerably smaller in spatial visualization ($d = -.19$; the ability to manipulate complex spatial information when several steps are required to arrive at the correct solution).

The differences in visuospatial ability have also been examined in children. For example, studies conducted on 3- to 4-month-old (Quinn and Liben 2008) and 5-month-old babies (Moore and Johnson 2008) have shown that male infants are able to differentiate between rotated (compared to the orientation it had during the encoding phase) familiar figures and novel ones. In both of these studies, male infants displayed a novelty preference for the new figure, indicating that they recognized the familiar figure and therefore spent less time viewing it. This was not found for the female infants, who divided their attention between the two items equally. Others (Levine et al. 1999) have demonstrated that 4.5-year-old boys display the same kind of male advantage when it comes to spatial visualization and mental rotation tasks. The edge that boys have over girls at this age also persists into adolescence, as demonstrated by Herlitz and colleagues (2013) who found that these differences also exist around puberty and that the magnitude of the difference is similar across the examined age groups (12–14 years) (Herlitz et al. 2013).

Verbal ability. When it comes to verbal ability, the prevailing opinion has been that women outperform men. However, the picture is slightly more complicated. A meta-analysis on the existence of gender differences in verbal abilities

(Hyde and Linn 1988) showed an overall modest advantage for women over men ($d = .11$). However, different tasks yielded different effect sizes, with the largest differences found in speech production tasks ($d = .33$). In anagram solving, women's advantage was smaller ($d = .22$), in vocabulary it was nonexistent ($d = .02$), and in verbal analogies men had a slight advantage over women ($d = -.16$). Further, in verbal production tasks, such as category fluency, an advantage favoring women is most often found (Maylor et al. 2007), but depending on the topic that the participants are asked to generate words from, no gender differences are sometimes found (Weber et al. 2014). Similarly to visuospatial abilities, studies examining the development of verbal abilities, specifically concerning verbal production tasks, find gender differences favoring girls as young as 5 years of age (Hyde and Linn 1988). In line with this, another study (Herlitz et al. 2013) has found that the magnitude of the gender differences is similar for 12- to 14-year-olds.

Episodic memory. Episodic memory refers to the conscious recollection of unique personal experiences in terms of their content (what), location (where), and temporal occurrence (when). It is typically assessed by first presenting some information (e.g., episodes, words, objects, or faces) and then asking the person to recall or recognize the earlier-presented material.

Although the first comprehensive review of gender differences in cognition did not find any differences between men and women when it comes to memory (Maccoby and Jacklin 1974), many more recent studies have found gender differences favoring women in episodic memory tasks (see Herlitz and Rehnman 2008 for an overview). Women consistently outperform men on tasks that require remembering items that are verbal in nature or can be verbally labeled. However, women also excel on tasks requiring little or no verbal processing, such as recognition of unfamiliar odors or faces. In contrast, there is a male advantage on episodic memory tasks requiring visuospatial processing. Thus, the pattern of gender differences in episodic memory mirrors the pattern seen in verbal and visuospatial tasks,

with the notable caveat that gender differences favoring women are also found in tasks requiring little or no verbal or visuospatial processing (Lowe et al. 2003). Studies of episodic memory function in children have found the same patterns as in adults, with girls having a slight overall advantage compared to boys as well as girls being better at verbal memory tasks and boys being better at visuospatial memory tasks (e.g., Lowe et al. 2003). Also, the magnitude of the difference in adolescents is similar to the difference found in adults, shown for example in a study examining memory in 12- to 14-year-olds (Herlitz et al. 2013).

Mathematics. Mathematics is an umbrella term that includes several different cognitive abilities concerning quantities, space, and numbers. Performing mathematical tasks therefore involves the recruitment of several cognitive abilities, and as a result, gender differences in mathematics often vary as a function of type of task. Although gender differences exist in school grades in mathematics, with girls having a small advantage over boys ($d = .07$) (Voyer and Voyer 2014), this edge is typically not present on tasks assessing mathematical ability. A meta-analysis taking type of task into consideration showed that boys and men have an advantage over girls in general tasks ($d = -.15$), with differences being larger in cognitively more demanding mathematical tasks such as mathematical complex problem solving. Further, the differences are also more prominent in samples performing in the upper percentiles of the distribution (Hyde et al. 1990). Interestingly, boys have a larger advantage over girls in later school years as compared to earlier (Hyde et al. 1990), indicating that the magnitude of gender difference may increase throughout childhood and adolescence.

Taken together, gender differences exist in some cognitive tasks, with girls and women outperforming boys and men in some of them, whereas the reverse is true in others. With the possible exception of mathematical ability, these differences seem to be present already in childhood and are preserved through adolescence and young adulthood without any change in magnitude.

Gender, Age Decline, and Age Differences

Are there any reasons to expect that men and women decline cognitively at different rates in old age? Biologically, there are some factors that would suggest age-related variation in the magnitude of gender differences. One such factor is accelerated brain aging, or brain atrophy, with some reports suggesting that men show more brain atrophy than women (Raz et al. 2004). Such gender differences in age-related brain atrophy may lead to greater gender differences with increasing age on tasks in which women excel, and smaller differences on tasks in which men perform at a higher level than women. On the other hand, the positive health selection of men with advanced age (i.e., the men who survive into old age may be healthier than the average), together with an increased risk of women being affected by Alzheimer's disease, may lead to a minimization of gender differences in which women excel.

When investigating differences related to age, it is important to differentiate between longitudinal and cross-sectional assessments of gender differences across the life span. With longitudinal studies, it is possible to examine to what extent the same individuals or groups of individuals deteriorate with increasing age, whereas the cross-sectional assessment will show to what degree different age groups, measured at the same time point, vary with regard to performance. Naturally, age groups assessed at the same time differ not only with regard to age, but also with regard to the environment they have been exposed to. For example, later-born generations have typically grown up in societies in which individuals have received more years of education, better nutrition and health care, and more complex and stimulating environments. However, the exposure to these societal improvements may also vary between men and women, with women in many societies and age groups receiving less favorable exposure (Else-Quest and Grabe 2012).

Longitudinal assessment. There have been several longitudinal studies looking at gender differences in cognitive decline. One of these studies

investigated cognition over a 10-year period in a population-based sample (De Frias et al. 2006), with over 600 participants (initially 35–80 years old). Regardless of initial age, it was shown that gender differences remained stable over the examined 10-year period: women performed at a higher level than men on some cognitive tasks (episodic memory, verbal production), whereas men performed at a higher level on a task assessing visuospatial ability. In line with this, results from the Berlin Aging Study, with participants aged between 70 and 100 years of age, showed that men and women declined virtually in parallel, with no evidence of any differences in decay over the 13-year period (Gerstorff et al. 2006). Further, a recent meta-analysis, where altogether 13 studies were included, came to the same conclusion (Ferreira et al. 2014). With very few exceptions, gender was not found to affect the rate of decline in the cognitive tasks assessed.

As is often the case in geropsychological research, studies are only rarely conducted in less affluent regions. This is also the case for studies on gender difference in cognitive decline, with most of them being conducted in Europe or in North America. Since it is possible that societal differences could influence men and women's rate of cognitive decline differently, future research is needed to determine if the same type of patterns are present in less affluent regions of the world where there often also is less gender equity.

Cross-sectional assessment. An issue related to the discussion above is whether the magnitude of cognitive gender differences varies when different age groups are compared at the same point in time. Indeed, cross-sectional studies have found that the magnitude of gender differences may vary depending on the age groups assessed. One such study (Maylor et al. 2007) gathered data on about 200,000 individuals between the ages of 20 and 65. The participants, stemming from 53 countries, completed web-based tasks in English assessing visuospatial ability, verbal production, and episodic memory. As usual, men performed at a higher level than women on the visuospatial tasks, whereas women outperformed men on the

category fluency and episodic memory tasks. However, although performance on all tasks declined with age, gender differences were smaller in the older age groups for the tasks where men outperformed women, and larger for the tasks in which women outperformed men. Although the underlying reasons for this pattern are unclear, it can be speculated that it is related to sample differences; older women around the world who both have access to computers and master English as a second language may have had to pass a higher cognitive threshold to acquire these capabilities, compared to participating men of the same age.

Other cross-sectional studies, however, have reported a different pattern of results (Weber et al. 2014). Data from the Survey of Health, Aging and Retirement in Europe (SHARE) were used to analyze over 30,000 individuals, aged 50 years and older, from 13 European countries. The participants were tested on tasks assessing episodic memory, numeracy, and category fluency. For the data analysis, these 13 countries were merged into three geographical regions: Northern Europe (Denmark, Sweden), Central Europe (Austria, Belgium, Czech Republic, France, Germany, The Netherlands, Poland, Switzerland), and Southern Europe (Greece, Italy, Spain). As expected, younger cohorts performed at a higher level than older cohorts, regardless of gender and geographical region. Further, there was a Northern advantage over Central and Southern regions, and gender differences varied systematically across age groups and regions (see Fig. 1). Using episodic memory as an example, women in Northern Europe performed at a higher level than men across all age groups, whereas women in Central Europe only had an advantage in the younger age groups. In Southern Europe, there was even less of a female advantage, with men in the oldest age group performing at a higher level than women. Similar patterns were found for numeracy and category fluency, with less or no advantage for men in Northern Europe, and more of a male advantage in Central and Southern Europe, especially in older age groups.

Gender Differences in Memory and Cognition, Fig. 1 Mean performances in episodic memory, numeracy, and category fluency across age by gender for Northern, Central, and Southern Europe (Adapted from Weber et al. 2014)

Why would gender differences in cognitive performance be larger in some age groups? As discussed previously, there have been substantial and continuous increases in living condition with regard to, for example, health, economy, family size, nutrition, and education. Such improvements, taking place over time, have been connected to improvements in cognitive performance, called the Flynn effect (Flynn 1987). An example of this comes from a study of Norwegian
