Environmental level barriers include differential opportunities and challenges that may be outside of the control of the individual. These opportunities and challenges can be the result of laws, policies, or expectations by institutions (i.e., government agencies or employers) and communities. As depicted in Fig. 2, there are opportunities for institutional barriers to prevent individuals from either obtaining training (e.g., stereotypical beliefs held by those choosing employees for training programs) or from receiving the benefits of training (e.g., discriminatory promotion practices) in the human capital model of lifelong learning (Sterns and Doverspike 1989). Figure 3 illustrates the influence of barriers within the humanistic model of lifelong learning at the community level. While this model encourages individuals to seize their right to have access to free and equitable education, this is not always feasible when the community is unable to offer those opportunities due to differences in national funding for education, particularly for postsecondary education and informal learning opportunities.

While multiple laws have been put in place to protect workers from discrimination in the workplace (e.g., Age Discrimination in Employment Act, Americans with Disabilities Act, Equal Pay Act), experiences with workplace discrimination are still prevalent (Goldman et al. 2006). A thorough review of the literature on discrimination in the workplace by Goldman and colleagues (2006) discussed the consequences of discrimination on both the individual as well as the organization, a concept not often considered in the literature. The authors noted negative organizational consequences due to the costs associated with fighting legal cases, repairing a damaged reputation, and underutilizing and ineffectively managing a diverse workforce. A meta-analysis of 49 studies on sexual harassment by Chan and

colleagues (2008) found that higher levels of sexual harassment were related to lower levels of job satisfaction, job commitment, job performance, well-being, and health; furthermore, higher levels of sexual harassment were also related to higher levels of job and work withdrawal (e.g., avoiding tasks, resigning), work stress, general distress, and health symptomology. These findings were found to be stronger in workers under 40 years of age compared to those over 40 years old. Thus, it is evident that discriminatory workplace practices have negative outcomes for the individual (e.g., lower well-being) and the institution (e.g., lower worker productivity).

It is difficult to understand the impact of discrimination on workforce participation and outcomes by looking at forms of discrimination in isolation because, in reality, individuals have multiple identities that coexist to influence how they are treated by others. For example, a recent meta-analysis of 59 independent samples by Vanhove and Gordon (2014) analyzed the interaction of weight discrimination with sex, race, and age on employment outcomes (i.e., employment status, income). They found support for sex and age differences in weight-based employment discrimination, such that women experience higher rates of discrimination. Additionally, both young and older workers experienced significantly higher levels of discrimination than middle-aged workers. No difference was found between young and older adult workers. There were no significant differences based on race alone; however, white women experienced significantly higher levels of discrimination than white, black, or Hispanic men but not black or Hispanic women. Further, white men experienced significantly higher levels of discrimination than black and Hispanic men, but not black or Hispanic women. It should be noted that across race, women experienced higher levels of weight-based discrimination than their same-raced male peers. This study illustrates the difficulty in both studying and understanding how multiple identities (e.g., age, race, sex) can intersect to create opportunities for oppression or privilege in the workplace, which is important to

consider given the effects discrimination can have on the lifelong learning opportunities of the individual.

Practical Implications

While an understanding of lifelong learning necessitates an understanding of the context of the learners, a discussion is not complete without mentioning *andragogy*, the art and science of facilitating adult learning (Knowles et al. 2005). This term turns the focus from the learner to the dyadic relationship between the learner and the “teacher.” Specifically, it gives a theoretical, philosophical, and pedagogical framework for determining what approaches to the instruction of older adults are currently supported in the literature. Zepke and Leach (2006) recommend the application of empirically supported pedagogical practice into informal learning opportunities. These practices include: (a) developing a supportive work environment conducive to learning, (b) creating institutionalized peer support and mentoring programs, (c) valuing and utilizing diverse workers, and (d) instructional flexibility and focus on the needs of the worker.

Applying the seven tenants of lifespan development to understand lifelong learning acknowledges the multiple and unique factors that influence learning over the lifecourse (Baltes 1987). The overarching message underlying the application of this theory is that learning can vary depending on the historical and cultural environments individuals develop in, nonnormative influences (e.g., brain trauma), as well as in terms of changes in educational, health, and employment opportunities. The classic text on adult learning with the most recent edition of Knowles and colleagues (2005) classic text on adult learning discussed the contribution of lifespan development theory to adult learning. The authors note that an individual’s motivation for learning, training, or updating is often prompted by life changes. They propose five points for individuals facilitating learning with adults to consider: (a) use developmental theories to help prepare for learning needs associated with particular points in the

lifecourse; (b) anticipating life changes allows instructors the ability to help prepare adults ahead of time; (c) recognize that life events can impact learning in either a positive or negative way; (d) take advantage of in-the-moment opportunities that open the door to learning; and (e) meet the learner where they are by planning meaningful learning opportunities.

As workers are increasingly vulnerable to discrimination based on their age, it is important to break down myths and stereotypes related to older workers as they are commonly used as a justification for discriminatory treatment toward older adults. For example, a recent meta-analysis of 418 studies by Ng and Feldman (2012) investigated six common stereotypes about older adults in the workplace: (a) less motivated, (b) less willing to participate in training and career development activities, (c) less willing to change, (d) less trusting, (e) less healthy, and (f) vulnerable to work-life imbalance. The authors did not look at a seventh stereotype that older workers are worse performers than younger workers, as a previous meta-analysis they conducted found no supporting evidence for that stereotype. Similarly, the authors found insufficient support when analyzing data throughout the literature for stereotypes of older workers as less motivated, less willing to change, less trusting, and more vulnerable to work-life imbalance. They also suggest the stereotypes that older workers are less healthy and less willing to participate in training and career development activities are over exaggerated due to weak correlations and effect sizes in their analyses. Further, the only evidence that supported older workers having poorer health was blood pressure and cholesterol levels; however, the authors noted it was unlikely that cardiovascular disease would present before retirement.

Conclusion

As noted in Fig. 3, the humanistic model positions lifelong learning as a potential source of empowerment by encouraging individuals to take control and become active in social, political, and economic movements. This type of empowerment

can be achieved with the creation of a culture to support lifelong learning that values informal and formal methods of continued education, both within the work context and without. Within the work context, a culture of lifelong learning requires institutions to continuously provide opportunities for all of their employees, regardless of age, to receive additional training rather than simply waiting for a need or decrement in performance as an impetus for training and mentoring programs.

At a macrolevel, there is a need for policy and programs to support lifelong learning and reduce barriers to obtaining lifelong learning opportunities. Support for these programs can come from the government, national organizations, colleges and universities, community organizations, non-profits, public libraries, museums, and trade unions. Legislation to protect individuals by requiring institutions to adhere to practices that can promote lifelong learning differ worldwide (Manheimer 2008). A review by Cascio et al. (2015) notes that leave policies (e.g., maternity leave, paternity leave), subsidized childcare, and formal preschool increase female workforce participation. Increasing female workforce participation across the lifecourse with these types of policies can potentially alleviate the economic impact of taking unpaid and unprotected leave from the workforce. Furthermore, there is a need for nations to adopt laws to protect vulnerable groups from work-based discrimination based on their age, race, ethnicity, gender identification, sexual orientation, weight, and disability status. All of these issues can affect the willingness to engage in maintaining competence, skill updating, and the pursuit of additional education and training. Learning is a lifelong enterprise.

Definition

The effects of lifestyle on mental health, especially depression, in older adults.

Introduction

The global prevalence of depressive disorders in the elderly population at a particular point in time has been reported to be between 10% and 20%, and depression is the third highest burden of disease globally (World Health Organization 2008). Depression in older adults has been associated

with increased risk of cognitive decline, disability, and mortality. The World Health Organization estimates that depression will be the number one leading health concerns by 2030 (World Health Organization 2008), and depression among older adults is a significant and growing public health problem worldwide due to our rapidly aging population.

Late-life depression refers to clinical depression occurring for the first time in an older person aged 60 years or older. Contrary to popular belief, it is not part of normal aging. Depression in older adults often goes undiagnosed or under-reported due to the fear of being stigmatized or the belief that it is a normal response to living with chronic diseases or disabilities, which may delay appropriate treatment and ultimately result in poorer prognosis.

Treatment of depression in older adults is often inadequate due to a number of factors such as poor recognition of depressive symptoms, comorbidity of multiple illnesses, poor adherence to treatment, and adverse effects of polypharmacy. A growing body of evidence supports the notion that lifestyle factors can be potent in determining both physical and mental health and cognition. Lifestyle factors as discussed here include physical activity, dietary patterns and supplements, smoking, sleep, and alcohol consumption. Better understanding of modifiable lifestyle factors may, therefore, contribute to the development of more effective strategies to prevent or reduce depressive symptoms among older adults.

Physical Activity

Physical activity has been regarded as a key modifiable factor for improving physical health, cognitive functioning, and emotional well-being. Physical inactivity has been found to increase the risks of developing depression, while being physically active has been shown to effectively reduce symptoms of depression and improve mood in younger adults (Kwan et al. 2012). Similar beneficial effects of physical activity on depression have also been reported in older adults (Kwan et al. 2012).

Over the past decade, physical activity as an intervention has shown promise in older adults in reducing the risks of depression as well as in treating depressive symptoms (Kwan et al. 2012); however, direct comparison between different studies is fraught with methodological issues due to heterogeneity in sample characteristics (e.g., age, comorbidity, severity of depression, recruitment setting), intervention protocols (e.g., type of exercises, intensity and duration, control group, and length of follow-up), and outcome measures.

In a systematic review of 11 randomized controlled trials with over 500 participants who were over 60 years of age, significant short-term improvement in depressive symptoms was found in most of the studies utilizing aerobic and resistance programs, regardless of the intensity, duration, or the actual form of exercises. However, medium- to long-term effects remain unclear (Blake et al. 2009). If the beneficial effects of exercise diminish with time, physical activity perhaps should be maintained indefinitely to keep depressive symptoms at bay among older adults as a prophylactic measure.

In a meta-analysis of seven randomized controlled trials, Bridle et al. (2012) found that moderate-intensity of mixed exercise including strength and endurance has a comparable effect as antidepressant medication and psychotherapy on depression severity for older people. At a clinical level, they calculated that 63% of exercise participants had a lower severity of depression than the average control participant and approximately 20% reduction in the severity of depressive symptoms. While this may be argued as a relatively small clinical effect, considering the issues of medication compliance and possible side effect of antidepressant medications, as well as issues with stigma and access to psychotherapy, individualized exercise program is a more attractive alternative without those problems but with the additional health benefits, such as reducing the risks of stroke, obesity, and heart disease. Despite emerging evidence, exercise is currently underused as a treatment for depression.

A number of underlying mechanisms have been proposed in order to explain the beneficial impact of physical activity in reducing the

incidence and severity of depression. First, physical activity may prevent the development of serious chronic conditions such as diabetes, osteoporosis, and heart disease, all of which have been shown to be associated with an increased risk of depression and lower health-related quality of life in old age (Craft 2012). Second, increased level of monoamines and endorphins and alterations to central norepinephrine activity after exercise may be responsible for the improved mood and better quality of life associated with physical activity (Craft 2012). Third, physical activity has been shown to decrease stress-induced cortisol responses (Craft 2012). Finally, greater physical activity may promote increased self-esteem and increased feelings of self-efficacy and, in turn, positive psychological outcomes (Craft 2012).

Nutrition and Diet

There is growing evidence that improving the nutritional status in older adults may help improve or maintain emotional status and decrease depressive mood. Studies investigating the association between diet and depression focused primarily on a single nutrient in the past, and such approach is valuable in identifying food supplements that may offer prophylactic and therapeutic benefits for improving depressive mood. However, since meals are consumed as a combination of numerous nutrients that may interact with each other, research in recent years has started considering the effects of dietary patterns, not just individual nutrient, on health outcomes. Hence, the association of depression between supplements and dietary patterns must both be considered in order to understand the impact of nutrition and diet on mood. Due to their involvement in biosynthesis, metabolism, and neuronal membrane stability, the association between depressive symptoms between specific nutrients including omega-3 fatty acids, folate, and vitamin B12 has been examined.

Low levels of omega-3 in the body have been shown to be correlated to depression in older adults, and dietary omega-3 fatty acids have

been suggested to play an important role in the prevention of depression (Payne 2009). Omega-3 fatty acids are involved in brain biochemistry, physiology, and functioning and have vascular and anti-inflammatory properties that could explain their protective effect against depression (Payne 2009). Promising result of fish oils as a treatment for depressive symptoms in older people has been demonstrated in an eight-week randomized, double-blind controlled trial (Rondanelli et al. 2010). The researchers reported a statistical significant difference in depressive symptoms measured by the Geriatric Depression Scale (GDS) between the treatment group and placebo group after 2 months of 2.5 g of fish oil per day versus paraffin oil per day, which is consistent with the positive finding of omega-3 fatty acids in patients with mood disorders in a meta-analysis of ten double-blind, placebo-controlled studies (Lin and Su 2007).

The relationships between depression and vitamin B12 or folate remain controversial. Some studies found no significant association between folate or vitamin B12 status and depression (Eussen et al. 2002; Refsum et al. 2003), while two recent systematic reviews of observational studies concluded that folate and vitamin B12 deficiencies are associated with increased risk of depression (Gilbody et al. 2007; Almeida et al. 2015). Although it has been suggested that depression may lead to inadequate intake of food and consequently lead to vitamin deficiency, older Korean men with lower serum levels of folate and vitamin B12 were found to have an almost two-fold increased risk of developing clinically significant depression over the 2–3-year follow-up period, after controlling for a large number of covariates, including age, sex, education, minimal state examination (MMSE), smoking, alcohol, physical activity, vascular risk, serum creatinine levels, vitamin supplementation, and homocysteine (Kim et al. 2008). The underlying mechanisms have been posited to involve the effects of folate and vitamin B12 on neurotransmitter and myelin synthesis or through vascular pathways by influencing homocysteine metabolism (Payne et al. 2009). A Cochrane review based on three intervention trials concluded that folate

may be useful as an adjunctive treatment for depression, although it is still unclear as to whether supplementation will benefit both those with low and normal levels of folate (Taylor et al. 2004).

In a large cross-sectional study investigating the relationship between past dietary habit and current depressive symptoms among elderly people in Japan, it was found that individuals whose diet consisted of regular consumption of dairy products and well-balanced meals were less likely to report depressive symptoms. Also, avoidance of excess salt and fat in men has been found to be associated with reduced risks of developing depression in old age (Aihara et al. 2011). In a large longitudinal study in Chicago, Skarupski et al. (2013) reported that adherence to a Mediterranean-based diet, a diet comprised of vegetables, fruits, whole grains, fish, and legumes, was associated with a reduced number of newly occurring depressive symptoms at 7-year follow-up. In a population-based study of older adults in France, men who consumed mainly pasta in their diet reported higher level of depressive symptoms when compared to men who consumed mainly fish, whereas women whose diet consisted mainly of fruits and vegetables reported lower levels of depression compared to women who consumed snacks high in fat and sugar (Samieri et al. 2008). Given the cross-sectional analysis of this study, the findings suggest that people who consume more carbohydrates and sugars experience a higher level of depressive symptoms. Alternatively, they also suggest that individuals who are depressed may be more likely to crave for sugars and carbohydrates.

Overall, some evidence is emerging to suggest that certain dietary habits may be more beneficial to protect against depressive symptoms and the protective effects may be gender specific. Although the positive effects of certain dietary patterns and nutrients such as omega-3 on depressive symptoms appear promising, these findings are limited by publication bias (i.e., non-significant findings are rarely published), potential uncontrolled confounders, heterogeneity of sample characteristics, and small sample size in prospective intervention studies. The benefit of

taking dietary supplements and the dosage required are yet to be determined.

Smoking

Smoking is a well-known risk factor for a number of physical illnesses, including coronary heart disease, type 2 diabetes, and stroke. Recent neuroimaging and neuropathological studies have found evidence of significant cerebrovascular disease in older people with depression, suggesting that cerebrovascular disease may be linked to late-life depression (Aizenstein et al. 2011). Although smoking has been extensively studied in numerous studies, few have reported the relationships between smoking and depression. In a retrospective study of community-dwelling women aged 70 years and over, Cassidy et al. reported a nearly three times increased risk of depression in women who smoked more than 20 cigarettes per day for at least a year in their lifetime (Cassidy et al. 2004). In a large population-based study in Hong Kong, smoking was shown to be positively associated with depressive symptoms in older people aged 65 or over (Lam et al. 2004). They found that current female and male smokers who smoked at least one cigarette per day for at least a year increased the risk of having depressive symptoms by 43% and 62%, respectively, when compared to never smokers. For former smokers, the risks of having depressive symptoms increased by about 20% than never smokers. Although the causal relationship of smoking and depression in older adults cannot be formally established based on the cross-sectional designs used to study them, the current evidence of its association is consistent.

Several theories have been proposed to explain the strong association between smoking and depression in general. These include the possibility that smoking and depression may share the same genetic vulnerability and psychosocial factors such as divorce, assault, and job losses that may trigger both the onset of depression and smoking (Mendelsohn 2012). According to the self-medication model of smoking, the central antidepressant properties of nicotine are especially reinforcing for those who experience

depression and promote smoking as a coping strategy to regulate emotions and relieve symptoms of depression (Mendelsohn 2012).

Given the strong association of smoking and depression, change in smoking habits or smoking cessation may play an important role in reducing depressive symptoms or the risks of developing depression in late life. Although the effect of smoking cessation on mental health in older adults specifically has never been examined, research findings in younger adults are contentious. Some research indicate that smoking cessation may result in increased depressive symptoms (Hughes 2007), whereas others report no significant associations (Mathew et al. 2013). Some recent studies have suggested that reducing cigarette consumption or smoking cessation is significantly linked to improved mental health outcomes or increased happiness (Cavazos-Rehg et al. 2014; Taylor et al. 2014; Shahab and West 2012). Discrepancies in these findings could be explained by differences in the design and delivery of the intervention program (e.g., gradual reduction vs. abstinence) as well as participant characteristic (e.g., depressive symptoms vs. depression diagnosis, classification of smoking status, psychosocial factors, and psychological resilience). A deeper understanding of how an individual's personality and coping strategies interact with their social environment in smoking cessation may lead to better psychological outcome in adulthood and reduce subsequent risks of late-life depression.

Alcohol Consumption

Moderate levels of alcohol consumption in older people have been found to be protective against cardiovascular morbidity and mortality, and it has been associated with better cognitive health. A U-shaped or J-shaped relationship has been suggested between alcohol consumption and cognitive function or cardiovascular health, whereby light to moderate drinking is found to be more beneficial to cognition and cardiovascular health than abstinence or heavy drinking (Zacharias 2012).

Although the relationship between depression and alcohol consumption is not well established, comorbidity between hazardous alcohol use and various types of psychiatric conditions has been documented in the literature (Mäkelä et al. 2015; Gilman and Abraham 2001). Depressive symptoms among older adults have been associated with problem drinking (St John et al. 2009), and persistent depression has been shown to be associated with incident excessive alcohol use (van Gool et al. 2007).

Interestingly, older adults who reported moderate alcohol consumptions were found to have fewer depressive symptoms than those who abstained from alcohol or those who drank heavily, suggesting a similar U-shaped or J-shaped relationship observed in alcohol consumption and cognitive function or cardiovascular health (Kim et al. 2015; Lang et al. 2007). A light to moderate level of alcohol consumption may reflect the individual's social network and ability to engage in social interaction, which in turn reduces the risks of social isolation and modulates the level of depression (Lang et al. 2007). In contrast, heavy drinking may reflect maladaptive coping, while abstinence may reflect social isolation which may be a result of and contributor to depressive symptoms.

Using alcohol as a coping mechanism is more common among men than women, and it is not surprising that the effect of alcohol on emotional well-being is gender specific. For example, a large population-based study in the USA has found that frequent drinking and heavy or binge drinking were significantly positively associated with depressive symptoms in older men, but no association was found between drinking and depression in older women (Choi and DiNitto 2011). Likewise, Cassidy et al. (2004) found no significant associations between moderate alcohol consumption, defined as up to 40 g of alcohol (four standard drinks) per day for no more than three days per week, and mood in older Australian women in the community. It is possible that gender differences in relationship between alcohol consumption and depression may stem from the different attitudes men and women have toward alcohol, whereby men tend to use alcohol to numb

their emotional pain while women may cope with psychological distress through other means like religion and emotional release rather alcohol. In contrast, Aihara et al. (2011) has reported that occasional alcohol consumption during middle age was significantly associated with the lack of depressive symptoms in older Japanese women (OR = 10.46, 95% CI = 1.16–94.75), while no significant association was reported between alcohol consumption during middle age and depressive symptoms among older Japanese men. This interesting finding points to another layer of complexity in this area – cultural differences and social interpretation of alcohol use and its associated psychological impact.

Although acute alcohol exposure elevates serotonin levels in the brain and may relieve depressed mood in the short term, the accumulative toxic effects of long-term alcohol exposure interferes with neurotransmitters and tends to lead to worsening mood. Fortunately, the effects of alcohol on depression appear to be somewhat reversible with abstinence. In a large-scale multicenter study of older adult inpatients suffering from clinical depression, significant improvement on depressive symptoms on the Geriatric Depression Scale was reported on discharge when patients abstained from drinking alcohol during their inpatient stay and the improved mood was maintained at 3-month follow-up (Oslin et al. 2000).

In addition to similar methodological shortcomings found in other lifestyle studies, one of the major challenges is the classification of frequency and level of alcohol consumption, which varies significantly from studies to studies. Given the complex U-shaped relationships in alcohol consumption and depression, as well as potential cultural and gender differences, it is important for future research to be more collaborative and consider more standardized classifications and measures.

Sleep

Sleep disturbances, including both insomnia and hypersomnia, have been estimated to be experienced by as many as 90% of patients with

depression (Tsuno et al. 2005). Recently, insomnia and hypersomnia have also been reported to co-occur during a depressive episode for some patients. Hypersomnia is less prevalent in the older population and most research to date has focused mainly on the impact of insomnia on depression.

A number of longitudinal studies across different age groups have demonstrated that insomnia is a risk factor for developing both new and recurrent episodes of major depression, suggesting that insomnia may mediate the development and severity of depression. In a recent meta-analysis, Baglioni et al. (2011) analyzed 21 longitudinal studies of varying age groups on the role of insomnia as a predictor of depression. Taking into consideration of heterogeneity of the study population, design, and measures, nondepressed people with insomnia was found to have a significant twofold risk to develop depression, compared to people with no sleep difficulties.

Insomnia has also been shown to increase the severity and duration of a depression episode and may be a predictor for poorer treatment outcome (Pigeon et al. 2008; Thase et al. 1996). In a case-control study, depressed older adults with sleep abnormalities were found to have poorer responses to cognitive behavior therapy than those without sleep disturbances (Thase et al. 1996). Similarly, in a multisite intervention study, Pigeon et al. (2008) reported that older adults with persistent insomnia were 1.8–3.5 times more likely to remain depressed at 6- and 12-month follow-up, compared with their counterparts. These findings suggested that strategies aiming to improve sleep quality through lifestyle modifications or sleep intervention may reduce incidence and prevalence of depression and potentially boost rates of recovery in older adults.

Although sleep disturbance is a symptom of depression, and that insomnia and depression share a bidirectional relationship, a high degree of residual insomnia has been reported in up to 55% of treatment responders following cognitive behavioral therapy or pharmacotherapy for depression alone (Nierenberg et al. 2010; Carney et al. 2007). A few small-sample intervention studies have looked at the effects of combined

psychotherapy and antidepressant medications on insomnia and depressive symptoms in adults. For example, in their pilot study, Manber et al. (2008) found a 50% remission rate for insomnia in the treatment group receiving combined escitalopram and cognitive behavioral therapy (CBT) compared with just 7.7% in the control group receiving escitalopram and insomnia psychoeducation. Moreover, the combined treatment group also had a greater rate of remission of depression than the control group (61.5% vs. 33.3%). In a recent randomized controlled study comparing therapist-guided CBT with self-help CBT, therapist-guided CBT demonstrated significantly greater decline in the severity of insomnia and depression than the self-help group, both immediately posttreatment and at 3-month follow-up (Ashworth et al. 2015). Although these studies show promising results, further studies are required to provide more evidence for the efficacy of psychotherapy and antidepressant medications in the treatment of comorbid insomnia and depression in the older population.

Summary

Depression is one of the most prevalent mental health conditions and can affect people of all ages. The causes of depression are multifactorial, and lifestyle modification may offer a unique opportunity for safe and low-cost interventions to prevent the risks of developing depression and augment the current treatment regime of depression. Identifying and implementing effective strategies focusing on early prevention of late-life depression and management of depression in older adults are therefore an increasing public health priority for many countries facing the same issue of a growing aging population, both from the individual and societal point of view. Understanding how lifestyle choices impact on depression in older adults is essential in facilitating the establishment of effective therapeutic lifestyle change programs and guidelines for older adults. While the beneficial effect of physical activity on depressive mood in older adults is

well documented, less clear are the potential protective effects of smoking cessation, dietary change, improvement in sleep quality, and reduced alcohol consumption have on the emergence of depressed mood. Further research in this area with greater collaborative effort to standardize measures and classification, taking into consideration the effect of gender, culture, and ethnicity would be advantageous in moving forward.

Loneliness and Social Embeddedness in Old Age

Louise C. Hawkey
Academic Research Centers, NORC at the
University of Chicago, Chicago, IL, USA

Synonyms

Social connectedness; Social isolation

Definition

Loneliness is an unpleasant and distressing experience that accompanies a perceived deficiency in social relationship quantity or quality. Loneliness is not synonymous with objective social isolation. People can be alone without feeling lonely, and, conversely, people can feel lonely even when with many others. The subjective nature of loneliness has given rise to an alternate term for loneliness, namely, “perceived social isolation.” There is no obvious term for the opposite of loneliness, but “social embeddedness,” “belongingness,” and “connectedness” are common surrogates.

Prevalence

Loneliness is a prevalent experience across the lifespan. Available studies conducted in developed countries indicate that as many as 40% of adults over 65 years of age report being lonely at least sometimes. Approximately 5–15% of adults of this age report feeling lonely frequently, but that figure increases to about 50% of adults 80 years and older. Chronic feelings of loneliness are experienced by 15–30% of the general population.

Loneliness Theories

Loneliness has been approached from many perspectives (Peplau and Perlman 1982), but three approaches currently dominate its scientific study. The social needs approach, introduced by Robert S. Weiss in the 1970s, holds that social relationships serve specific functions and that the absence of a reliable attachment figure, poor social integration, few opportunities for nurturance, and other provisions of social relationships contribute to feelings of loneliness. The primary distinction made by Weiss was between social and emotional loneliness, where social loneliness reflects a lack of an engaging broader social network and emotional loneliness reflects the lack of an intimate or close emotional attachment figure.

The cognitive approach, described by Letitia Peplau and Daniel Perlman in the 1980s, holds that loneliness results when subjective evaluations of social relationships are perceived as deficient in meeting personal standards for the number or quality of social relationships. Social comparisons influence the standards for evaluation and the importance and magnitude of perceived discrepancies. From this approach, loneliness intensity can be reduced by, for example, developing new, more satisfying social relationships, altering one’s relationship standards, and developing skills to improve relationship quality in order to reduce the discrepancy between actual and ideal social relationships.

A third approach, described by John Cacioppo and Louise Hawkey in the early 2000s, holds that

loneliness is a biological signal that helps to ensure that people seek out and maintain social connections (Cacioppo and Patrick 2008). In evolutionary time, the pain of loneliness may have deterred selfish actions that would have disconnected one from the group and promoted the social connections needed to increase the likelihood of survival. In contemporary society, evidence suggests that loneliness can have maladaptive effects on cognition and behavior. The threat of isolation, actual or perceived, is sufficient to elicit implicit hypervigilance for social threat (e.g., rejection) and defensive behaviors that include greater anxiety and hostility. Implicit hypervigilance becomes manifest in attentional biases favoring negative social information and self-fulfilling confirmation biases in which negative expectations and distrust adversely affect behavior toward others (e.g., aggression). Negative behavior toward others tends to elicit negative behavior from others, thereby confirming the lonely person's negative expectations and reinforcing feelings of disconnection and loneliness. Behavioral confirmation processes help to explain why lonely individuals tend to believe that they have little control over their social contentment. This "loneliness regulatory loop" (Cacioppo and Hawkey 2009) describes how loneliness can be perpetuated and exacerbated over time. In most cases, however, loneliness functions well in motivating efforts to establish or reestablish social connections, efforts that typically cause feelings of loneliness to dissipate.

From an evolutionary perspective, it is reasonable to expect that loneliness has a heritable component. Indeed, roughly half of the variance in loneliness in the adult population has been attributed to additive genetic components (Peplau and Perlman 1982). The heritable component has been posited to include variability in sensitivity to social isolation that might result in individuals feeling more or less lonely in similar circumstances, whereas the nongenetic component includes a range of individual differences, including social cognitions, emotions, and behaviors that perpetuate loneliness.

Measurement

Large-scale surveys often rely on a single direct question to inquire about people's feelings of loneliness. A typical question is "How often do you feel lonely?" with response options ranging from never to often/always. Such questions have been criticized, however, because societal stigma attached to admitting loneliness may bias reports downward, particularly for some groups. Men, for instance, are less likely to admit loneliness than women (Borys and Perlman 1985). For a similar reason, face-to-face interviews tend to elicit lower intensity and prevalence rates than the more anonymous methods of mailed-back questionnaires or phone interviews (Bowling 2005).

Indirect measures of loneliness avoid the inclusion of terms likely "lonely" and "loneliness" and instead ask questions pertaining to experiences associated with feeling lonely. The most widely used instruments to measure loneliness indirectly are the UCLA Loneliness Scale (Russell 1996), used predominantly in the United States, and the De Jong Gierveld Loneliness Scale (De Jong Gierveld and Kamphuis 1985), used predominantly in Europe. Both were initially developed in the early 1980s and have subsequently been validated in many populations (e.g., scores are highly correlated with self-reported feelings of loneliness). Sample items from the full 20-item UCLA Loneliness Scale include "How often do you feel isolated from others?," "How often do you feel that there are people you can talk to?," and "How often do you feel part of a group of friends?" The four response options are never, rarely, sometimes, and always. Sample items from the full 11-item De Jong Gierveld Loneliness Scale include the statements "I experience a general sense of emptiness" and "I miss having people around." The response options are "yes!," "yes," "more or less," "no," and "no!;" a reduced response scale uses only "yes," "more or less," and "no." Short-form versions of each scale have been developed (i.e., a 3-item UCLA Loneliness Scale and a 6-item De Jong Gierveld Loneliness Scale) for use in large-scale survey research. For both the UCLA and the De Jong Gierveld Loneliness scales, responses are reversed for positively

worded items before summing or averaging across all items to produce a total loneliness score. The result is a continuum of loneliness frequency or intensity. Scores on these scales are typically skewed; most people experience relatively infrequent and low intensity feelings of loneliness, but some people experience frequent and/or intense loneliness.

Loneliness intensity exhibits a U- or J-shaped function across the adult lifespan (Pinquart and Sörensen 2003). Levels are relatively high in young adulthood, diminish through middle adulthood, and increase as old age is approached, but do not surpass young adult levels of intensity until oldest old age (about 80 years and older). Overall, loneliness exhibits fairly high temporal stability, with correlations of loneliness scores ranging from 0.6 to 0.9 for periods of days to weeks and from 0.5 to 0.8 for periods of up to 5 years.

Loneliness Dimensions

Although the UCLA Loneliness Scale was developed as a unidimensional construct and is used as a unidimensional scale, factor analyses of this scale have nevertheless revealed several dimensions. Russell (Russell 1996) confirmed a global bipolar loneliness factor but the direction of item wording (i.e., positively and negatively worded items) resulted in a two-dimensional structure. Large-scale studies incorporating exploratory and confirmatory factor analyses in young and older adults have also confirmed a global loneliness factor but have also revealed a conceptually differentiated three-dimensional structure (Hawkley et al. 2005). These dimensions have been labeled Intimate, Relational, and Collective Connectedness and are highly correlated. Intimate Connectedness reflects a deep sense of connectedness and self-worth and, relative to the other dimensions, is uniquely correlated (i.e., independently of its correlation with the other two Connectedness dimensions) with being married. Relational Connectedness reflects feelings of closeness and support in social relationships and is uniquely correlated with regular contact with close friends. Collective Connectedness reflects

feelings of group identification and a sense of belonging and is uniquely correlated with membership in a voluntary group. These results provide evidence of construct validity, but the dimensions are only partially represented by their constituent items, and subscales representing these dimensions have not been applied in research contexts.

The De Jong Gierveld Loneliness Scale can be and is used as a unidimensional scale, but was developed under the assumption that loneliness is a multidimensional construct with a social and an emotional loneliness component as articulated by Weiss (see Loneliness Theories above). During the development of this scale, items were chosen to capture the absence of an intimate relationship or close emotional attachment (emotional loneliness) and the absence of a broader group of contacts or a fulfilling social network (social loneliness). Subscale scores can be calculated for social loneliness and emotional loneliness, and research has found that these dimensions of loneliness have unique antecedents and consequences (De Jong Gierveld et al. 2006).

Risk Factors

Variability in loneliness between individuals and within individuals over time has been associated with a variety of personality, demographic, and situational factors. *Personal characteristics* that are associated with greater loneliness include poor social skills, shyness, social anxiety, introversion, pessimism, and low self-esteem. Cross-sectional studies have shown that risk factors for loneliness severity in older age encompass several domains (Pinquart and Sörensen 2003; De Jong Gierveld et al. 2006). In the demographic domain, *age* is a weak predictor of loneliness severity and tends to be inversely correlated with loneliness until oldest old age. Longitudinal studies have the advantage of not confounding age and cohort, and results are generally consistent with cross-sectional data. When examined as the prevalence of self-reported loneliness frequency, occasional loneliness shows a U-shaped distribution, but frequent loneliness shows a relatively linear increase from

adolescence to oldest age (Yang and Victor 2011). For both loneliness frequency outcomes, however, prevalence is lowest among adults aged 30–60 years as is found when examining loneliness severity.

Studies of older (and younger) adults have found that *gender* is inconsistently associated with loneliness; some studies find men are lonelier than women, some find women are lonelier than men, and some find no difference. Question wording contributes to the gender inconsistency; as noted above, men tend to underreport when asked direct rather than indirect questions about loneliness, possibly because the stigma of loneliness is greater among men than women. *Socio-economic status* has been associated with loneliness in older adults; better education and higher income predict lower levels of loneliness. Some evidence suggests that in the United States, education and income explain higher levels of loneliness in ethnic minorities. These findings suggest that income and education represent protective resources. For instance, financial means may improve access to social opportunities and activities, and education may improve problem-solving strategies and coping skills. *Health* is consistently associated with loneliness in older adults; poorer self-rated health and more functional limitations, for instance, predict higher levels of loneliness. *Stressful events* (e.g., traumatic events in early or later life) and *perceived stress* have also been associated with greater loneliness in older age.

Individual differences in social roles and behaviors are, not surprisingly, consistently associated with loneliness. For instance, people who are *married or in a cohabiting partnership* have lower levels of loneliness than the unmarried, particularly relative to widowed or divorced individuals. Contact with children alleviates loneliness to a greater degree in formerly married than currently married older adults, and siblings and friends are particularly important in alleviating loneliness among those without a partner or children. Both of these effects suggest that specific relationship types can compensate, at least partially, for the absence of an intimate attachment figure.

The *size of individuals' social networks* is inversely associated with loneliness, as is the *composition of the network*. People with strong and weak ties in their network are less lonely than those with strong ties only, and those with purely kin networks are lonelier than those with more heterogeneous networks. Loneliness is also inversely associated with the *frequency of interactions* with close others, *frequency of attendance at religious services*, and *membership in voluntary groups and associations*. *Relationship quality* surpasses quantitative aspects of people's social behavior in the magnitude of the association with loneliness, such that closeness is inversely associated with loneliness even after adjusting for social network size and frequency of contact. Even among married individuals, marital quality matters for loneliness; people in better-quality marriages have lower levels of loneliness than people in lower-quality marriages.

Cross-sectional studies are limited, however, in that they are unable to address the causal role of risk factors in the onset and perpetuation of loneliness. Longitudinal and prospective studies are superior for causal inference, and of the few such studies, almost all have been conducted in European countries. The findings show that loneliness increases as older people experience various types of losses, including loss of a spouse, especially through widowhood; death or other loss of relatives or friends; changes in living arrangements that entail the loss of cohabitants in the household; loss of independence through institutionalization; deterioration of health; impairment of mobility, vision, and hearing; shrinking social networks; and reduced social activity.

Health Correlates, Consequences, and Mechanisms

Transient feelings of loneliness (e.g., brief periods of perceived social exclusion or rejection) are unpleasant, but associated feelings of sadness and anxiety are typically short-lived and resolved upon recovery of a sense of social embeddedness. More intense and enduring feelings of loneliness contribute to persistent psychosocial problems

and to the gradual development and exacerbation of physiological changes that are associated with disease and death (Hawkey and Cacioppo 2010). Among psychosocial problems, loneliness is associated with greater depressive symptomatology, and increases in loneliness have been shown to predict increases in depressive symptoms over follow-up periods of a year or more. In addition, cognitive functioning is worse in lonelier older adults, and loneliness predicts more rapid cognitive decline and dementia (Cacioppo and Hawkey 2009).

Loneliness has been associated with poorer health behaviors known to affect physical, emotional, and cognitive functioning. Lonelier older adults, and chronically lonely individuals in particular, are less physically active, discontinue physical activity at a faster rate during aging, are more likely to abuse alcohol, and have a greater risk of obesity than their socially embedded peers. Sleep is also influenced by feelings of loneliness. Lonelier older adults suffer from less satisfaction with their sleep quality and greater daytime fatigue than their less lonely counterparts, even though sleep duration is comparable.

Lonelier adults report poorer health and are more likely than their less lonely counterparts to be admitted to a nursing home. Objective indices of poor health that have been associated with chronic loneliness include coronary heart disease incidence, higher rates of age-related increases in blood pressure, and functional limitations. A meta-analytic review found that risk for mortality is significantly greater among adults with impoverished social relationships (Holt-Lunstad et al. 2010). Individual studies have shown that the mortality difference tends to be most marked when contrasting chronically lonely with nonlonely or situationally lonely older adults. Although some health behaviors differ between lonely and nonlonely adults, health behaviors have not to date explained loneliness-related differences in mortality. However, some studies have found that medical status (i.e., more chronic health conditions) accounts for higher rates of mortality in lonelier older adults.

The causal mechanisms for the association between loneliness and health are unclear at present, although physiological mechanisms suggest several possibilities. Indicators of altered physiological functioning in lonelier older adults include impaired blood pressure control, dysregulation of the hypothalamic-pituitary-adrenocortical (HPA) axis, and differential expression of pro- and anti-inflammatory genes. Blood pressure is the end point of two physiological processes: regulation of blood volume (i.e., cardiac output) and resistance to blood flow (i.e., peripheral arterial resistance). In young adults, loneliness is associated with greater peripheral resistance but no significant difference in blood pressure, possibly due to local chemical compensatory processes. To the extent that heightened peripheral resistance persists over time, however, blood pressure would be expected to increase more rapidly in lonelier adults. Evidence consistent with this scenario shows that in middle and older age, blood pressure positively correlates with loneliness and increases more rapidly over time (Hawkey and Cacioppo 2010). An accelerated increase in blood pressure suggests that lonelier older adults are at greater risk for hypertension and associated cardiovascular diseases.

Loneliness has been associated with larger diurnal increases in cortisol upon awakening, possibly signifying the enhanced mobilization of energy resources in anticipation of greater daily stresses and challenges (Hawkey and Cacioppo 2010). Cortisol has anti-inflammatory properties, but only to the extent that the HPA axis is responsive to the cortisol signal. Genome-wide studies (Hawkey and Cacioppo 2010) have found evidence that genes with anti-inflammatory functions are under-expressed in lonely relative to nonlonely individuals, suggesting a deficit in the receptor mechanism that detects the cortisol signal. At the same time, proinflammatory genes are over-expressed in lonely relative to nonlonely individuals, suggesting a possible mechanism for increased rates of morbidity, particularly because the chronic health conditions of older age are known to have an inflammatory component.

Interventions

A meta-analysis (Masi et al. 2011) reviewed the efficacy of a variety of intervention strategies that have been attempted to ameliorate loneliness. Among the 50 eligible interventions published between 1970 and 2009, only 20 used the gold standard randomized control group design. Analyses of these studies showed that the interventions had a beneficial but small effect on average and that effectiveness was moderated by the type of intervention that had been implemented. Interventions that targeted maladaptive cognitions (e.g., cognitive behavioral therapy with a social focus) had the largest effect, larger than providing social support, teaching social skills, or increasing opportunities for social contact. In studies of older age groups, however, the dominant type of intervention implemented was social support provision; only one randomized control group study implemented social cognitive training.

Conclusion: The Future of Loneliness Research

The future of loneliness research is increasingly focused on the one hand and broader in scope on the other hand. Among the focused domains of research, the limited efficacy of extant loneliness interventions indicates that considerably more research is needed to effectively prevent and ameliorate loneliness in older adults. This is an active area of study, in part because of mounting concern about the growing population of older adults. Focused research is also indicated and underway to better understand the mechanisms through which loneliness influences health and well-being. This research may be furthered through the development of an animal model of loneliness (Capitanio et al. 2014), which would permit a greater degree of experimentation in a species with a more rapid developmental trajectory.

In the broader scheme, population-based surveys are increasingly incorporating a loneliness measure, and studies are beginning to examine whether

countries, or regions of countries, differ in mean levels of loneliness. Within Europe, older adults in Eastern European countries (e.g., Bulgaria, Russia, and Hungary) have significantly higher levels of mean loneliness than those in Western European countries (e.g., Germany, Sweden, and the United Kingdom) (Hawkley et al. 2005). Moreover, within Western Europe, older adults are lonelier in southern and central European countries (e.g., Spain, Greece, and Italy) than they are in northern countries (e.g., Switzerland, the Netherlands, and Denmark) (Fokkema et al. 2012). An analysis of World Values Survey data from 17 countries (Stack 1998) found that across the adult age range, people in Italy and Japan report more frequent intense loneliness than those in the United States and Canada, for instance. Explanations for national differences in loneliness are theorized to include differences in cultural norms; societal wealth, inequities, and welfare; health; and social engagement. Research in this area will foster an understanding of contextual factors that may serve as effective intervention targets to prevent or reduce loneliness and improve quality of life.

Finally, as panel data accumulate in population-based surveys, it will be possible to trace loneliness trajectories across the lifespan and whether these trajectories differ among cohorts. This information will be useful in distinguishing among subgroups whose loneliness onset is early versus later in life and who do or do not recover from loneliness once it is triggered. These subgroups may benefit from different types of interventions. The relevance of loneliness for physical and mental health, and well-being for the individual, and for the financial cost to society of caring for a growing number of lonely older adults highlights the importance of understanding how to alleviate loneliness.

Definition

This entry describes the general outline of the Longitudinal Aging Study Amsterdam (LASA) and highlights some recent outcomes. LASA is the first ongoing longitudinal study in the Netherlands specifically designed to study determinants of the autonomy and well-being of older persons. In LASA, four domains of functioning are distinguished: cognitive, social, emotional, and physical. The study focuses on predictors of change in these domains, on trajectories of functioning, on the interrelationship between the four domains of functioning, and on the consequences of change in functioning for the use of formal and informal care and well-being.

Introduction

One of the biggest triumphs of mankind is the increased longevity of human beings. The life expectancy doubled since 1850, while fertility rates decreased. Consequently the population of the Netherlands is aging, just like that of many

other developed countries. A worrisome outcome, however, is a misbalanced dependency ratio. It is predicted that for every person who is not working, only two will be working in 2030 (Statistics Netherlands 2013). This undeniably puts the sustainability of pensions systems, social security systems, and health care provision under pressure. In the late 1980s of the last century, policy makers in the Netherlands became increasingly aware that maintaining independent functioning, a high quality of life, and participation in society were one of the major strategies to combat these threats. In order to develop policies for older people who are in need of support and care, scientific insight into the aging process was needed. In 1991 the Longitudinal Aging Study Amsterdam was initiated to fulfill this need.

Aim of LASA

In line with Havighurst's notion that "one of the major aims of gerontology is to provide society and individuals with advice on the making of societal and individual choices . . ." (Havighurst 1961), LASA is essentially a scientific study aiming to collect scientific insights on the multidimensional nature of the aging process, but with a very practical purpose. While LASA is feasible for thorough and in-depth mono-disciplinary research, it stands out among many longitudinal studies on aging for its potential to conduct multidisciplinary research, which facilitates cross-fertilization between scientific disciplines, the combination of methods, and the integration of divergent perspectives. Interdisciplinary research enables a holistic approach and is an important means to a life course perspective on aging.

LASA was funded in 1991, originally as a 10-year prospective longitudinal study. Participants aged between 55 and 85 years old were invited to participate in LASA for three measurement cycles. Additional funding in the following years allowed for continuation of the study until today, with a follow-up measure being conducted about every 3 years. Moreover, the sample was enriched with additional cohorts of

respondents aged 55–65 years old in 2002 and 2012. Recently, a cohort of Turkish and Moroccan older people (LASA Wave 3 M, $n \approx 478$; at the time of writing, data collection is still to be finalized) was recruited for the study. Currently, the eighth measurement cycle is in preparation and will be conducted in 2015/2016.

At the outset of LASA, the following central research questions were formulated:

1. Which changes over time take place in the physical, cognitive, emotional, and social components of functioning in older persons?
2. Which predictors of change can be recognized in these components of functioning?
3. How are changes in the four components of functioning interrelated?
4. What are the consequences of changes in functioning in terms of contributions to society, the necessity of adjustment, and the need of care?

These questions are based on the assumptions that aging is a process, involving multiple aspects of cognitive, social, emotional, and physical functioning important to maintain individual autonomy and self-evaluations of functioning. The consequences of improvements and declines in functioning and the resulting (in)dependence can be expressed in terms of autonomy and well-being, contributions to society, and the need for health and social services (Deeg and Westendorp-de Serière 1994).

The LASA Sample and Data Collections

The LASA participants were initially recruited for the "Living arrangements and Social Networks of older adults (LSN)" study (Knipscheer et al. 1995). LSN utilized a nationally representative sample ($N = 3,805$) stratified according to year of birth and sex and consisted of people born between 1908 and 1937. The LSN sample was randomly taken from the registers of 11 municipalities in 1991 in the West (Amsterdam and surroundings), North East (Zwolle and surroundings), and South (Oss and surroundings) of the Netherlands (Fig. 1). These areas are culturally distinct

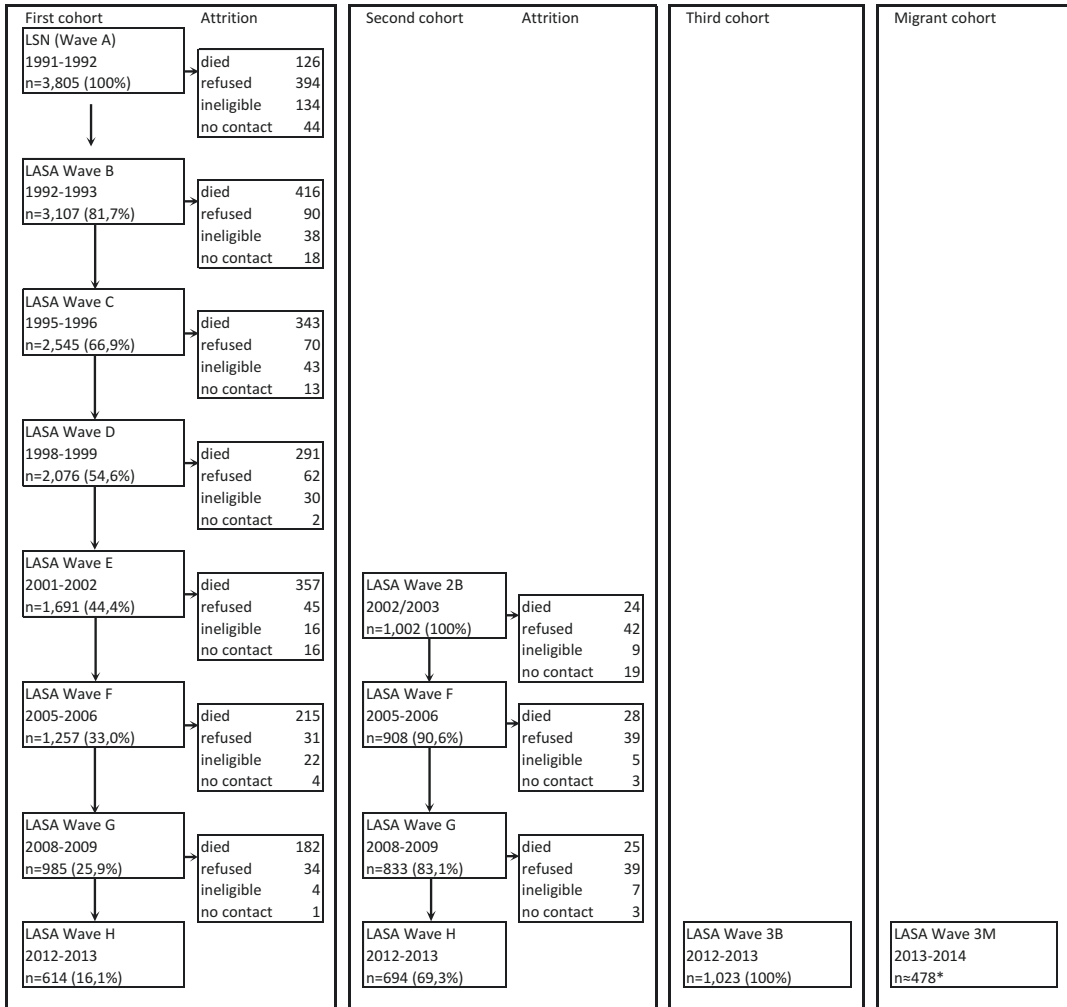

Longitudinal Aging Study Amsterdam, Fig. 1 Map of the Netherlands, with black dots representing the 11 municipalities from which the initial LASA samples are drawn

and consist of one medium to large size city and two or more rural municipalities that border on the city. The initial response rate was 60% and the cooperation rate 62%. The response rate is calculated according to guidelines of the American Association for Public Opinion Research (2015) and reflects the number of complete and partial interviews with persons divided by the total number of eligible persons in the sample, plus a fraction of those persons who were in the sample but of whom eligibility could not be determined. The cooperation rate is defined as the proportion of completed interviews in the number of contacted eligible persons. On average, 11 months after the LSN interview, the participants were approached to participate in the first LASA cycle, with a response rate of 85% and a cooperation rate of 89%.

The first LASA data collection (Wave B) took place in 1992/1993 ($N = 3,107$), and there were follow-up measures in 1995/1996 (Wave C), 1998/1999 (Wave D), 2002/2003 (Wave E), 2005/2006 (Wave F), 2008/2009 (Wave G), and 2012/2013 (Wave H). The mean cooperation rate for the follow-up observations since LASA

baseline was 95%. Additional cohorts of respondents aged 55–65 were added to the LASA sample in 2002/2003 and 2012/2013 to study age-period-cohort effects. The first additional cohort (years of birth 1938–1947; $N = 1,002$) was recruited 10 years after the first LASA cycle (Wave 2B), and roughly the same measurement instruments were applied so that cohort differences in physical, cognitive, emotional, and social components of functioning can be studied. In the subsequent waves, respondents from this second cohort were combined with those from the original one (Fig. 2). A third cohort of 1,023 respondents was added in 2012/2013 (Wave 3B) and consists of respondents born between 1948 and 1957. These respondents will be added to respondents from previous cohorts in subsequent measurement waves. Attrition between Wave A and Wave H for the first cohort is mainly due to death ($n = 1,930$, 62%), followed by refusal ($n = 726$, 9%), ineligibility ($n = 287$, 9%), and no contact ($n = 98$, 3%). Attrition between Wave 3B and Wave H for the second cohort is due to refusal ($n = 120$, 12%), death ($n = 77$, 8%), no contact ($n = 25$, 3%), and refusal ($n = 21$, 2%) (for more information on the cohort profile, see (Huisman et al. 2011)).

Data are collected in the homes of the participants in three different data collection modes. In the main face-to-face interview, various sociological, psychological, and demographic variables are assessed. At the end of the interview, respondents are invited for a medical interview, and if consent is provided, the interview takes place within a few weeks after the main interview. In this medical interview, several medical and cognitive tests are conducted, among which measures of physical performance, such as a walking test, tandem stand test, a test of upper extremity performance, and a chair-stand test, and cognitive performance, such as memory, problem solving, and processing speed. Occasionally blood samples are taken. After the main face-to-face interview, respondents are also asked to fill in a written questionnaire with additional questions on aspects such as quality of life, norms, values, sleeping habits, and questions about the partner.

* at the time of writing of this chapter, data collection is still to be finalized

Longitudinal Aging Study Amsterdam, Fig. 2 Survival and participation in the LASA study

The face-to-face and the medical interviews take about 90–110 min each. If participants are too frail to sustain a full regular interview or refuse to do so, they are invited for a telephone interview. Telephone interviews take considerably less time (about 15 min) than regular interviews. If a telephone interview with the LASA participant is not possible, a proxy of the participant, for example, a family member or caregiver, is asked for a telephone interview. Participants who are interviewed by telephone are not asked to participate in the medical interview,

nor are they asked to complete the self-administered questionnaire in that particular measurement wave.

Next to the regular LASA-cycles, more than 25 side studies have been completed with additional data collections among a selection of LASA participants, all with high response rates.

For example, approximately 300 LASA participants have filled in a questionnaire on depressive symptoms every 5th month during 6 years, to capture the potential fluctuating course of depression. Other side studies with additional data

collections focused on the structure and function of the social network and loneliness; adaptation to widowhood; precursors and consequences of (recurrent) falling; religiousness and mood; life-style factors such as physical activity, sports, and diet; and end of life.

Data Quality

Of crucial importance for all longitudinal surveys are a high-quality data infrastructure, reliable data, a fixed set of validated measurement instruments, and a low nonresponse rate. Several strategies are applied in LASA to optimize the circumstances for a high data quality. With respect to the collection of data, special attention is paid to the registration of the interviews and the selection and training of the interviewers of LASA. The interviews are computer assisted (CAPI on notebooks) to facilitate the interview and reduce data entry errors. Interviews are tape recorded for later inspection. Interviewers who live in or near the municipalities in the study are recruited, since they can understand or speak the dialect spoken in the region. Furthermore, interviewers are thoroughly trained to be sensitive to the needs and wishes of respondents, especially with regard to monitoring signs of fatigue and responsiveness and changes in mood. Responding adequately to such signs is crucial for minimizing respondent burden (Robins et al. 1981), which in turn is crucial for participation in the study. To increase control over the data collection and to enhance data quality, the staff has organized the data collection and data storage since 1991 under their own management. Issues of reliability and validity are further addressed by using a large set of validated measurement scales. Equivalent interviews are applied during the seven measurement cycles so that observed within-person change can be related to changes in the intended construct. A specific concern for longitudinal studies on aging is that attrition is considerable. Therefore, men and the oldest participants were oversampled at the start of the study to ensure that there would be reasonable numbers of very old men, even after long periods of follow-up.

The quality of the data, the data collections, and the studies conducted with LASA data are further enhanced by means of regular meetings with an external and independent advisory board, consisting of high-profile international experts in the scientific disciplines and on subtopics that LASA set out to study. This advisory board assists LASA in fulfilling its purposes by providing advice on the research agenda, the quality of data collection and data infrastructure, and the quality of its research by examining indicators of output, including scientific publications, research grants, (inter)national collaborative networks, and knowledge valorization. The long-term viability of the data has been judged to be of good quality, based on an assessment of Data Archiving and Networked Systems (DANS), which resulted in a DANS Data Seal of Approval in 2013.

Measurements

Detailed information of the measurements used in the LASA can be found on the LASA website (www.lasa-vu.nl) and elsewhere (Huisman et al. 2011). In short, the following domains are assessed: physical, emotional, cognitive, and social functioning and the use of health care services. Measures of physical functioning include self-reported chronic diseases, functional limitations, indicators of physical performance based on performance tests (e.g., walking speed, chair stand, balance test, cardigan test), lung functioning, grip strength, anthropometry, pain and perception (hearing, vision), and lifestyle (diet, physical exercises, alcohol use, and smoking). Emotional functioning is assessed by means of diagnostic tests (DIS (Samelson et al. 2008), CIDI (Wittchen 1994)) and screening instruments including level of depressive symptoms (CES-D (Radloff 1977)), symptoms of anxiety (HADS-A (Zigmond and Snaith 1993)), evaluation of life, sleep problems, and aspects of personality, such as mastery (Pearlin Mastery Scale (Pearlin and Schooler 1978)), self-esteem (Rosenberg Self Esteem Scale (Rosenberg 1965)), and neuroticism (Dutch Personality Questionnaire (Luteijn et al. 1975)). Cognitive functioning is evaluated

by means of general cognitive functioning (MMSE (Folstein et al. 1975)), information processing speed (letter-letter coding task (Savage 1984)), episodic memory (15-words task (Saan and Deelman 1986)), memory complaints, and problem solving (Raven's colored progressive matrices (Raven 1995)). Measures of social functioning include among others social network (Van Tilburg 1998) (e.g., size, composition, social support obtained from and given to network members), intergenerational relationships, loneliness (De Jong Gierveld loneliness scale (De Jong Gierveld and Kamphuis 1985)) aspects of participation in productive and cultural activities, and in more recent waves the use of Internet. Demographic information comprises among others year of birth, gender, level of education, work history, age of retirement, level of urbanization, and housing history. In more recent waves, detailed information is collected about the use of curative and long-term care and characteristics of the partner.

Output and Highlights

Since the beginning of LASA 56 PhD dissertations, 16 reports to the ministry and more than 750 scientific papers have been published, the majority in peer-reviewed scientific international journals (<http://www.lasa-vu.nl/publications/publications.htm>). LASA staff members have regular meetings with representatives of the Ministry of Health, Welfare and Sports. The purpose of these meetings – usually about four times a year – is to develop research questions to address current policy concerns. The large number of respondents, the long follow-up information on a broad range of indicators, the multidisciplinary approach, and the cohort-sequential design allows LASA to answer many policy-relevant and fundamental questions on aging. Below, some recent publications are highlighted that are of particular interest to geropsychologists to illustrate LASA's many potentials.

Cognitive functioning has been assessed on all waves of LASA with a variety of neuropsychological tests on fluid intelligence (Horn and Cattell

1967) such as memory, learning, information processing speed, and problem solving. In contrast with crystallized intelligence, these functions show increasing inter- and intraindividual differences in functioning over time. Thirteen-year changes in processing speed, memory, nonverbal reasoning, and general cognitive functioning found support for the processing speed hypothesis (Salthouse 1996), indicating that age-related reduction in information processing speed accounts for impairments in other cognitive functions (Robitaille et al. 2013).

Although processing speed plays a central role in many age-related cognitive differences, multidisciplinary studies of LASA found that other domains of functioning and factors earlier in life also relates to age-related decreases in cognitive functioning. For example, mental health predicts both decline of general cognitive functioning and information processing speed, independent of relevant covariates (Van den Kommer et al. 2013). Emotional support, operationalized as talking with someone about personal thoughts and feelings, is related to better cognitive functioning (Ellwardt et al. 2013) and a complex network that consists of relations with a variety of contacts, such as family members, neighbors, and friends, and helps delay the onset of cognitive decline (Ellwardt et al. 2015). This fits to the idea that a stronger engagement of older adults in social activities and greater embeddedness in networks buffer cognitive decline and lower risks of dementia. Korten and colleagues examined whether childhood adversity might cause biological or psychological vulnerability, which is associated with both depressive symptoms and cognitive decline in later life. Their study showed that persons who experienced adverse childhood events had a faster 10-year decline in processing speed but only when depressive symptoms were experienced. Persons with more recent negative life events showed slower processing speed at baseline but no faster decline (Korten et al. 2014).

Studies on depressive symptoms are another central theme in LASA. One study recently investigated the relation between depression and physical health, in particular the risk of stroke. The authors argue that the mixed findings on the risk

of depression on incident stroke may be explained by differences in vascular disease and neuroticism, as only in persons with low levels of neuroticism depression is predictive for future stroke (Marijnissen et al. 2014). Studies on associations between depressive symptoms and a variety of demographics, social network, and personality characteristics found that a high need for affiliation is associated with depression in women but not in men. Lack of a partner in the household and having a small network predicted onset of depression in men but not in women. In respondents with high affiliation need and low social support, depression rates were higher, with men being more often depressed than women (Sonnenberg et al. 2013).

Recently, LASA has entered a new field of study in older adults, that is, the study of attention deficit hyperactivity disorder (ADHD) in older adults. Despite the abundance of studies on ADHD in younger adults and children, there is virtually no knowledge of the prevalence and correlates of ADHD in older adults. Studies by the LASA team found a prevalence of 2.8% in the general population of older adults, which demonstrates that ADHD does not fade or disappear in adulthood and that it is a topic very much worthy of further study (Michielsen et al. 2012). The association between ADHD and depression, and the potential mediating role of personality characteristics was further examined in a series of studies. It was revealed that associations between ADHD and depressive symptoms exist, which is partly due to the accumulation of adverse life events (Semeijn et al. 2015) and differences in mastery and self-esteem (Michielsen et al. 2013)

The study on aging is an enduring and challenging puzzle on the interrelations between changes at the cell level, the individual level, the group level, and even the societal level (Bengtson and Allen 1993) and the cumulative advantages and disadvantages (Dannefer 2003) of events and behaviors during the life course. Thanks to the addition of new cohorts of people aged 55–65 years 10 and 20 years after the beginning of LASA it will be possible to study also consequences of changes in the societal context of LASA. One study on the social-emotional domain in

LASA lends support to the notion that the societal level may exert important influence on individuals. This study revealed that divorcees in 2002 are less socially lonely than in 1992, with a smaller and nonsignificant further decrease in loneliness in 2012 (Van Tilburg et al. 2014).

The recent addition of a cohort of older Turkish and Moroccan immigrants will further add to our understanding of the sociocultural context of aging, as well as of the generalizability of results of studies on physical, mental, cognitive, and social functioning of older adults. LASA possesses a gold mine of data that has enabled – and continues to do so – the investigation of the consequences of improvements and declines in functioning and the related and consequent levels of autonomy and well-being, contributions to society, and the need for health and social services.

Funding

LASA has been financially supported by the Ministry of Health, Welfare and Sports. The ministry has funded the regular measurement cycles since 1992, as well as the inclusion of the new cohort of respondents in 2002. The ministry's funding covers costs of interviewers, data management, data collection management and fieldwork coordination, secretarial support, and overall management, with some additional funding for research to investigate specific topics of interest to the ministry. In 2011, additional funding was obtained from the Netherlands Organisation for Scientific Research (NWO), which allowed LASA to include again a new cohort of respondents aged 55–64 years in 2012 and a cohort with respondents from Turkish and Moroccan migrant groups for the first time. Researchers and PhD students working with LASA data are usually hired on the basis of additionally acquired research grants.

Intimate relationship; Later adulthood; Legal separation; Marital relationship; Older adults; Spouse

Definition

Marriage is defined as the legally recognized union of two people as partners of each other in an intimate relationship, while divorce is defined as the legal dissolution of a marriage. Marriage is one of the important relationships in human adulthood. Spouses in long-term marriages have accompanied each other for decades and have a strong influence on each other's lives. This entry considers changes in marital quality across adulthood, the characteristics and special challenges for marriage in later life, and the influence of divorce on the lives of older adults.

Change of Marital Quality Across Adulthood

Marriage is a process. A first step to understand marriage in later life is to understand its history. Many studies have investigated how marital quality changes across adulthood. The family life cycle theory (Duvall 1957) divides the whole course of marriage into eight stages mainly based on the age of the eldest children in the family. The eight stages are beginning families, families with infants, families with preschool children, families with school-age children, families with teenagers, launching families (i.e., families that start to have grown-up children leaving the household), empty nest families, and families after retirement. Research has shown that marital quality varies across different stages in the family life cycle, largely following a U-shaped curve (Rollins and Cannon 1974). Marital quality is the highest in the first stage followed by a deep drop after the first child's birth, and starts to bounce back in later life when the children are leaving the household.

Critics on the family life cycle theory argue that the theory relies too much on childrearing, which is only one of the tasks for a marriage. The theory also cannot be applied to a growing population of couples who choose not to have children in modern societies. Thus, later studies have examined changes in marital quality over the duration of marriage instead of focusing on the

family life cycle. These too find a similar U-shaped pattern (Glenn 1990). Marital quality drops from the beginning to middle adulthood and levels out in later adulthood. Parents and nonparents show a comparable decline in marital quality in the early years of marriage (Kurdek 1993), suggesting that the change of marital quality is not solely due to the presence of children.

However, the increase in marital quality in later life is mostly identified in cross-sectional studies and is challenged by longitudinal findings. For example, Van Laningham and colleagues (2001) found that marital quality continued to decline in later life over a 17-year period, suggesting that the previously identified bouncing back of marital quality in later life may just be an artifact due to natural attrition and cohort effects. When seven different cohorts of couples were examined separately, they all reported a steady deterioration in marital quality over the 17-year period (VanLaningham et al. 2001).

More recent studies shed new light on this debate about the developmental trajectory of marital quality. This emerged when researchers started to explore categorical differences in how marital quality changes across adulthood among different types of couples. Using 20-year longitudinal data, Kamp Dush and colleagues (2008) found that couples can be divided into three categories based on their overall marital satisfaction. For couples who were high in overall level of satisfaction, their satisfaction level remained largely stable across the 20-year period. For those with a medium or low level of satisfaction, the developmental trajectory of their marital satisfaction did demonstrate a U-shaped curve with increasing marital quality in later life. A similar but reversed pattern was identified for marital conflict. Couples with relatively high or medium levels of marital conflicts demonstrated a longitudinal steady decline in marital conflict in later life (Kamp Dush and Taylor 2012). Moreover, initial life happiness, shared decision-making, and greater involvement of husband in housework were important factors that determined couples' membership in these three latent groups.

Thus, the current conclusion is that couples may differ qualitatively from each other in their initial level of marital quality and the trajectory of marital

quality changes. Nonetheless, most couples experience relatively stable or slightly enhanced marital quality in later life compared with middle adulthood. Some possible reasons for the sustained, if not improved, marital quality in later life are introduced in the next section, together with the special challenges faced by older couples.

Characteristics and Special Challenges for Marriage in Later Life

According to the socioemotional selectivity theory (Carstensen 2006), older adults face a limited future, so they do not need to suffer for now to prepare for the future. Instead, older adults tend to focus on, and enjoy, the present. Thus, emotional meaningful goals and maximizing enjoyable affective experiences in the present are prioritized by older adults. As one of the key close social relationships, marital relationship represents a major source of emotional meaningfulness. Research suggests that older adults experience a more positive pattern of marital interactions in general.

For example, Lang and Carstensen (2002) have found that a limited future time perspective was related to higher emphasis on emotion-regulatory goals, which was in turn related to better social satisfaction and less interpersonal stress. In another study, researchers have asked younger and older adults to report their interpersonal experience on a daily basis, including how much interpersonal tension they encounter daily and how much stress these tensions bring (Birditt et al. 2005). Results indicated that older adults reported a similar amount of daily interpersonal tension as did younger adults. However, older adults felt less stressed and were less likely to experience arguments as the result of interpersonal tension. This suggests that older adults' better social satisfaction is not due to fewer problems in their relationships but due to more efficient management of interpersonal problems.

In dealing with relationship-related problems, older adults tend to adopt a mixture of active and passive strategies (Blanchard-Fields 2007). On the one hand, they use primary control strategies (e.g., discussion) to actively solve problems just as

younger adults do; on the other, older adults engage in more secondary control strategies (e.g., emotional regulation) compared with younger adults. These emotion-regulatory strategies do not tackle the interpersonal problems directly but help people to maintain more positive affect facing these problems. Such passive strategies can be an effective compromise for older adults when the problem is very difficult, if not impossible, to solve in a limited time frame. With greater flexibility in strategy choice and more adoption of passive strategies, older adults appear to be more effective in dealing with interpersonal problems and keeping a relatively positive emotional state at the same time.

Older adults' emphasis on emotional meaningful goals and effectiveness in handling interpersonal problems lay the foundation for more positive marital interactions in later life. Several studies have compared older and middle-aged couples' behaviors and physiological responses while discussing marriage disagreements. Compared with their middle-aged counterparts, older couples felt less negative affect during the discussion and gave more positive evaluations for their partner after the discussion (Smith et al. 2009a). Their cardiovascular system was also less aroused during the conflict discussion (Smith et al. 2009b). This is not due to decreased sensitivity of the older adults' physiological system as older couples were found to be more physiologically responsive than middle-aged couples while discussing a collaborative topic. Rather, reduced physiological arousal during conflict discussion may reflect older couples' greater acceptance of existing marital problems and better management of affect in the presence of conflicts. When couples' dialogue of the conflict discussion were analyzed, older couples were found to use more pronouns that were inclusive of the couple (e.g., *we*), and this was related to better emotional experiences and reduced physiological responding during the discussion (Seider et al. 2009).

To conclude, dyadic interaction between older couples appears to be more positive and constructive than that between middle-aged couples, which can be one of the reasons that explains the sustained or enhanced marital satisfaction in later life.

Nonetheless, marriage in later life also faces some specific challenges. For example, older couples need to adjust to one or two spouses' retirement together. In general, retirement does not bring substantial changes in marital satisfaction. Couples may experience an initial drop in marital satisfaction after retirement but will usually recover after a few years. However, detailed dynamics in couples' interactions do change after retirement (Trudel et al. 2008). Older couples with two spouses both working or both retired report higher satisfaction than those with one spouse retired and the other one still being employed. The mismatch of couples' working status may cause the husband and wife to have different priorities in life and this, in turn, creates tensions and marital conflicts in regard to time management, division of labor, and so on. When both spouses in a couple retire, they tend to spend more time together and engage in more housework or other tasks that used to be the responsibility of their partner. Thus, there is less gender differentiation in marriage after retirement (Szinovacz 2000). Another factor identified as influencing marital satisfaction after retirement is the shift in power balance between the couple. If one spouse becomes less influential in marital decision-making after retirement, their marital satisfaction will be impaired (Szinovacz and Davey 2005). Moreover, as marital relationship usually becomes the major interpersonal relationship in people's lives after retirement, a well-functioning marriage can actually provide the necessary social support and help that individuals need to better adjust to retirement (Wang et al. 2011).

Besides adjustment to retirement, many older couples also face the deterioration of one's own or the partner's health. Older age is inevitably related to higher risks of different types of chronic diseases and other health-related problems. Spouse usually becomes the primary caregiver of their partner. The addition of caregiving demand places a significant stressor for marriages in later life, and marital quality may suffer as a consequence. In fact, one's marital satisfaction is affected more by the spouse's health than one's own health (Yorgason et al. 2008). It is the caregiver who takes up most of the challenges brought by

chronic illnesses. Research has shown that caregiving demand is related to a heightened risk for the caregivers' own physical health. In a 4-year longitudinal study, the mortality rate of older adults who reported to be stressful caregivers was 63% higher than that of those who were not caregivers (Schulz and Beach 1999).

Nonetheless, older couples tend to cope with the caregiving situation better than their younger counterparts. Older couples' marital satisfaction was less affected by spouse's general health decline compared with younger couples (Yorgason et al. 2008). One possible reason for such age differences may be that younger couples have more life tasks to deal with in addition to the health problem, such as working and childrearing. The cumulative stress can be more detrimental to their marital relationship. Meanwhile, older couples may be more accepting of the illness and use more emotion-regulatory strategies to cope with the adversity. For example, compared with younger couples, older couples with one spouse diagnosed with Parkinson's disease demonstrated more mutuality in their interactions and reported finding more meaning in the coping process (Carter et al. 2010). Many older couples also report sharing the responsibility to manage the illness and trying to focus on the positive side of life despite the illness (Yorgason et al. 2010).

More importantly, other than being susceptible to the detrimental influence of health deterioration, marital quality can be an important resource that helps older couples stay healthy and survive under the stress of chronic diseases. For example, more negative marital experience was related to faster longitudinal subjective health decline, especially for older couples (Umberson et al. 2006). High marital quality also helps to attenuate the association between disability and loneliness for older adults (Warner and Kelley-Moore 2012). Thus, older adults' better marital interactions can also support them to handle chronic health problems more effectively.

To conclude, because of older adults' focus on emotional meaningful goals and close relationships, older couples demonstrate a generally positive pattern of marital interaction. While being threatened by some specific difficulties in later

life, such as transition to retirement and decline of physical health, a well-functioning marriage helps older couples to survive these challenges. However, not all marriages last over a lifetime, even for long-term marriages. The next section introduces the rising trend of divorce in later life and how it influences the divorced older adults' lives.

Divorce in Later Life and the Influences

Duration of marriage is negatively related to the probability of divorce (Arland and Rodgers 1987; Brown and Lin 2012). Most divorces happen in the early years of marriage. Divorce is less likely in later life partly because older couples have more positive dyadic interactions as reviewed above. On top of that, older adults usually face greater barriers to leave their marriage. The spouses may be more interdependent socially, financially, and emotionally after being in a long-term marriage. Older adults may also face a more limited pool of available alternatives for a potential future relationship. According to the Investment Model of Commitment (Rusbult et al. 1998), greater barriers to leave and limited alternatives both lead to higher commitment to the current relationship and lower possibility of marital dissolution.

Despite these protecting factors of older adults' marriage, recent statistics show that there is a rapid increase in divorce for individuals aged 50 years and above (i.e., "gray divorce"). Based on nationwide samples of the United States, Brown and Lin (2012) reported that the divorce rate for people aged 50 years and above has doubled from 1990 to 2010. The "gray divorces" constitute about one quarter of all the divorces in 2010. The unprecedented population aging is one of the reasons for the increased number of divorces in later life. As the proportion of older adults in the population increases, older adults are also taking up a growing share of the divorce population. Moreover, improved education and better working opportunities for women grant more independence and freedom for wives to end a marriage and stay financially viable after the divorce. Most societies also become more tolerant of divorce. Marriage is considered less as a lifelong institution but more as

one of the relationship statuses. As a result, a larger number of older couples are in remarriages rather than first marriages. All these changes in recent years make divorce a more plausible choice for older adults (Brown and Lin 2012).

Compared with younger couples, marital happiness is found to be a stronger predictor of older couples' divorce (White and Booth 1991). Given the greater barriers and limited alternatives for divorce, older adults rely more on marital happiness to decide whether to end their marriage. This is consistent with the argument of socioemotional selectivity theory that older adults prioritize the emotional meaningfulness of a relationship. A recent qualitative study investigated older couples' divorce based on in-depth interviews (Canham et al. 2014). The reasons of divorce in later life are quite complex. Some older adults thought their marriage was a mistake from the beginning, while others enjoyed the beginning years of the marriage but the relationship stopped working because of change in oneself or their partner. Like younger couples, destructive communication, physical or emotional abuse, and unfair division of household labor led to the deterioration of the marriage, but many older adults reported delaying divorce because of concern for the children. Financial concerns and fear of being alone were also factors that prevented some people from divorcing earlier.

No matter why older couples choose to divorce, it has a substantial impact on their lives. Research has shown that divorced individuals have more health problems and higher mortality rates compared with those in an intact marriage (Dupre et al. 2009). Longer marriage duration is found to be the strongest factor that predicts lower mortality rate for both men and women. Married individuals' survival rate after major surgeries is also higher than those who have divorced (Idler et al. 2012). As divorce is becoming more acceptable in recent decades, studies have examined whether the detrimental impact of divorce on health is ameliorated in recent years. However, results suggest that differences in self-rated health between married and divorced individuals increased from 1972 to 2003 (Liu and Umberson 2008). Whether divorce is socially acceptable or

not, the immediate support offered by a spouse seems to have indispensable effects on health maintenance.

The picture is slightly different when it comes to enduring unhappy marriages. As noted earlier, some divorces in later life are due to long-term unhappiness but have been delayed for various reasons. Staying in a long-term unhappy marriage was found to be even more harmful to health than a divorce (Hawkins and Booth 2005). Contrary to their younger counterparts, individuals who divorce in later life did not experience elevated depressive symptoms after the divorce (Pudrovskaya and Carr 2008), which may be partly due to the feeling of relief and freedom after stepping out of the troublesome marriage.

Another area that is influenced by divorce in later life is the social network of the divorced partners, especially the relationship with their children. While quality of parent-child relationship before the divorce is a significant predictor of the relationship quality after the divorce, different studies consistently find that divorce in later life has a greater influence on fathers' relationships with their adult children than mothers' (Kalmijn 2007; Shapiro 2003). Divorced fathers are less likely to live with an adult child, have reduced contact with their adult children, and receive less support from their adult children. All the impacts are lessened or even reversed for mother-child relationship. In other words, men's social network is more vulnerable after later-life divorce than women's.

Conclusion

This entry considered marriage changes in later life and the general interaction pattern between older couples. Marital quality is sustained in later life. Because of a heightened focus on the emotional meaningfulness in life and more flexible use of effective strategies to deal with interpersonal problems, older couples demonstrate relatively positive dyadic interactions compared with their younger counterparts.

Supportive marital relationship also helps older adults to deal with various challenges in later life, including adjustment to retirement and

taking care of chronic health problems. On the other hand, as the result of population aging and increasing social acceptance of divorce, a growing number of couples choose to divorce in later life. While the detrimental effect of divorce on well-being seems to be alleviated after a long-term unhappy marriage, divorce in later life still impairs older adults' relationship with their adult children, especially for men.

The current entry does not cover remarriage, cohabitation, and bereavement in later life, which are also important issues in regard to older adults' intimate relationship. Moreover, as the legislation of same-sex marriages has been introduced in more and more jurisdictions, whether and how the above findings about older couples, especially those regarding gender differences, can be generalized to homosexual couples needs further investigation. Last but not least, empirical research that specifically focuses on older adults' marriage and divorce, especially longitudinal investigations, is still lacking. While the aging population is growing rapidly across the world, more future research is needed to further understand marriage and divorce in later life, and how they contribute or undermine older adults' well-being.

Definition

‘Medication-related issues in later life’ refers to the safety aspects associated with medication use by older persons. This can be related to individual, medication, health professional and healthcare system factors, with examples of strategies provided to assist older persons in managing their medications safely and effectively.

Introduction

The prevalence of most chronic diseases, such as heart disease, diabetes, and dementia, increases with age. As a result of population aging, the global burden of chronic diseases (see “Definition”) is projected to increase from 47% in 2002 to 60% by the year 2020 (Epping-Jordan et al. 2004). Medications, including prescription, over-the-counter, and complementary preparations, are commonly used for preventing, treating, and managing symptoms and disease states in older people (Simonson and Feinberg 2005; Elliott and Booth 2014).

The availability and use of medications as first-line therapy for many health conditions has led to a significant increase in the number of medications used by older people over recent decades. Seventy five percent of the older people admitted to Australian hospitals use five or more medications, known as polypharmacy, and more than 20% use 10 or more medications, known as hyperpolypharmacy (Elliott and Booth 2014; Hubbard et al. 2015). Similar patterns of medication use have been reported in other developed countries (Feldman et al. 2009; Ellenbecker et al. 2004, 2008). High treatment intensity, having multiple prescribers, and suboptimal integration of care have led to increasing complexity of medication regimens and increased risk of medication-related problems (Elliott and Booth 2014). Medication use is higher in people residing in aged care facilities, who take an average seven

Medication-Related Issues in Later Life, Table 1 Medication-related problems commonly occurring in older Australians^a

Type of medicine-related problems	Prevalence in Australia (%)
Problems associated with prescribing	
Unnecessary and inappropriate prescribing	25–40
Underdosing	21
Overdosing	45–81
Drug interactions	7–67
Under-prescribing	25
Suboptimal monitoring	33
Medicine nonadherence	18–47
Problems associated with poor medication management	
Having poor knowledge about medications	20
Inappropriate storage and repackaging of medications	4–14
Stockpiling and hoarding of medications	20–42
Sharing of medications	13–20
Poor ability to self-administer medications	Up to 34
Adverse drug reactions	19

to ten medications compared with an average of five medications in community-dwelling older people (Elliott and Booth 2014; Lee et al. 2010). This chapter aims to provide insights into a range of medication-related issues in older people.

Medication-Related Problems in Older People

Medication-related problems are defined as an event or circumstance involving a person’s drug treatment that actually or potentially interferes with the achievement of an optimal outcome (Table 1) (Simonson and Feinberg 2005).

Review of individuals’ medication regimens by clinical pharmacists reported that older people who use multiple medications experience, on average, one to three medication-related problems (Elliott and Booth 2014). Medication-related problems contribute to adverse clinical and social

outcomes including falls, cognitive impairment, dehydration, incontinence, and depression. In turn, these outcomes increase older peoples' risk of functional impairment, nursing home placement, hospitalization, and reduced quality of life (Simonson and Feinberg 2005).

Up to 30% of unplanned hospital admissions in older people and 18% of deaths in hospital are due to medication-related problems (Elliott and Booth 2014; Scott and Jayathissa 2010; Easton et al. 2009). Fifty percent of the medication-related problems and up to 75% of adverse drug event-related hospital admissions in older people are potentially preventable. This constitutes a large and potentially avoidable cost to the healthcare system (Simonson and Feinberg 2005; Elliott and Booth 2014; Elliott 2006; Scott and Jayathissa 2010).

In the United States, it has been reported that approximately 20% of older people discharged from hospital to their own homes experience an adverse event and more than 66% of these are medication-related (Lindeman 2010). Almost 20% of hospitalized older people are readmitted within 30 days, 76% of which are considered to be potentially avoidable (Lindeman 2010). Medication nonadherence in the United States is shown to contribute to 33–69% of medication-related hospital admissions and 23% of nursing home admissions (Lindeman 2010, 2011). It is estimated that if medication adherence was improved, this could lead to a saving of approximately US\$290 billion annually (Lindeman 2010, 2011).

Risk Factors for Medication-Related Problems

Older people are at greater risk of experiencing medication-related problems because they have a higher rate of comorbidities, tend to consume multiple medications, and are more sensitive to the effects of medication due to age-related physiological changes in body composition and functioning (Simonson and Feinberg 2005; Scott and Jayathissa 2010). Over 50% of the older people living in the community have at least one risk factor for medication-related problems, and in

Medication-Related Issues in Later Life, Table 2 Risk factors for medication-related problems^a

<i>Medication-related factors</i>
Using ≥ 5 medications ^b
Using ≥ 12 medication doses a day ^b
Using medication(s) with a low therapeutic index or requiring therapeutic drug monitoring ^{b,c}
Using psychotropic medication(s)
Using complex medication regimens
Being recently commenced on a new medication
Having ≥ 4 changes to medication regimen during the previous 12 months ^b
Experiencing symptoms suggestive of an adverse drug reaction
<i>Patient-related factors</i>
Having ≥ 3 concurrent medical conditions ^b
Having a history of nonadherence with medication use ^b
Having poor medication knowledge
Attending multiple doctors or pharmacies to obtain medications
Being discharged from a hospital in the previous 4 weeks
Having a change in health status
Having cognitive impairment
Living alone
Having literacy and/or dexterity problems
High out-of-pocket cost of medication
Attitudes about disease and symptoms
Attitudes about treatment
<i>Healthcare system-related factors</i>
Lack of integrated care
Lack of system for monitoring and improving medication-related problems

^bRisk factors consistently associated with increased risk of medication-related problems or adverse outcomes in older people

^cExamples of medications with a low therapeutic index or requiring drug therapeutic monitoring – carbamazepine, digoxin, lithium, phenytoin, phenobarbital, procainamide, quinidine, theophylline, and warfarin

institutionalized care, this increases to more than 70% of residents (Lee et al. 2010, 2011). While there is a range of factors which can predispose older people to greater risk of medication-related problems (Table 2), six factors are consistently associated with increased risk of medication-related problems in older people (shown with superscript “a” in Table 2). When assessing older

Medication-Related Issues in Later Life, Table 3 Commonly used medications associated with increased risk of adverse medication events in older people^a

Examples of medications associated with increased risk of adverse drug reactions (also sometimes referred to as potentially inappropriate medications)

Anticholinergic antidepressants, muscle relaxants, and antispasmodics (e.g., amitriptyline, doxepin, oxybutynin)

Amiodarone

Long-acting benzodiazepines (e.g., diazepam, nitrazepam)

Long-acting oral hypoglycemics (e.g., chlorpropamide, glyburide)

Dextropropoxyphene and propoxyphene

Digoxin (>125 micrograms per day)

Dipyridamole

Methyl dopa

Nonsteroidal anti-inflammatory drugs (NSAIDs [e.g., diclofenac, naproxen])

Psychotropic medications (≥ 2 used concurrently)

Examples of medications associated with medication-related hospitalizations in older people

Antithrombotic and anticoagulant agents (e.g., aspirin, warfarin)

Anti-inflammatory drugs (corticosteroids, NSAIDs)

Antineoplastic or cytotoxic drugs

Disease-modifying antirheumatic agents (e.g., azathioprine, cyclosporin)

Cardiovascular medications (e.g., antihypertensives, digoxin, diuretics)

Central nervous system drugs (e.g., anticholinergics, anticonvulsants, antidepressants, antiparkinsonian agents, benzodiazepines, hypnotics, psychotropic agents, sedatives)

Insulin

Opioid analgesics

Oral hypoglycemic agents

^aReferences: Simonson and Feinberg (2005), Elliott and Booth (2014), Lee et al. (2010, 2011), Elliott (2006), Scott and Jayathissa (2010), and Easton et al. (2009)

people's risk of experiencing medication-related problems, these six factors should be considered.

Certain medications are associated with increased risk of adverse drug reactions or medication-related hospitalizations in older people (Table 3) (Simonson and Feinberg 2005; Elliott and Booth 2014; Lee et al. 2010, 2011; Elliott 2006; Scott and Jayathissa 2010; Easton et al. 2009; Goeman et al. 2015). One example is

psychotropic medications, including antidepressants, antipsychotics, benzodiazepines, and cholinesterase inhibitors (Goeman et al. 2015). These medications should be used with caution in older people due to greater risk of neurological side effects. A recent study reported 61% of older people with cognitive impairment, living in the community, were using at least one psychotropic medication (Goeman et al. 2015). Use of psychotropic medications has been linked to poor health outcomes in older people (Goeman et al. 2015). Although these medications are recommended for limited short-term use for specific issues such as short-term alleviation of behavioral and psychological symptoms of dementia, older people are more likely to be prescribed psychotropic medications for extended periods, and there is a need for greater focus on measures to limit inappropriate usage (Goeman et al. 2015).

Poor adherence to medications is a significant problem in older people (Elliott and Booth 2014). This occurs when a person does not follow the agreed directions for using their medication(s) (Simonson and Feinberg 2005). The rate of adherence for a person is measured as the percentage of the prescribed doses of the medication actually taken by the person over a specified period (Osterberg and Blaschke 2005). There is no agreed standard that defines an acceptable rate of adherence as it varies by disease. Some studies considered rates of greater than 80% to be acceptable, whereas others consider rates of greater than 95% to be mandatory for adequate adherence, especially among people with serious conditions such as infection with the human immunodeficiency virus (HIV) (Osterberg and Blaschke 2005). In older people, the prevalence of poor adherence ranges from 44% to 95% and may be unintentional or deliberate (Elliott 2006). There are many reasons for poor adherence in older people (Simonson and Feinberg 2005; Elliott 2006; Lindeman 2010). Poor memory or recall about consumption of medications can lead to problems such as missed doses or double-dosing (Simonson and Feinberg 2005; Elliott and Booth 2014; Elliott et al. 2015; While et al. 2013). Nonadherence may be due to persons' attitudes or behaviors, real or perceived side effects or risks

of adverse events, cost of medication(s), difficulty with swallowing, and tolerating or administering medication(s) correctly (Simonson and Feinberg 2005; Elliott 2006). When assessing a person's adherence to medication use, identifying the main barrier(s) to medication adherence and understanding the person's needs can help reduce the risk of nonadherence and medication errors and establish an effective medication regimen for the person.

Medication Management in Older People and Associated Issues

The processes of obtaining and managing multiple prescriptions and receiving, storing, and administering multiple medications can be complex and challenging for some older people (Elliott and Booth 2014; Ellenbecker et al. 2004). Up to one-third of older people living in the community have difficulty managing their medications (Elliott and Booth 2014). The interaction between health professionals has an important impact on medication management. This process often involves multiple healthcare personnel, including general practitioners (GPs), specialist medical practitioners, other prescribers, pharmacists, nurses, professional or non-professional caregivers, and other members of the healthcare team such as case managers and insurance companies. Healthcare system issues, including poor communication, inadequate teamwork, or insufficient sharing of information between healthcare team, can contribute to poor medication management processes and increased risk of medication-related problems. For example, poor interdisciplinary care can lead to polypharmacy and complex medication regimens, resulting in potentially inappropriate prescription and thereby raising the risk of harmful drug interactions (Easton et al. 2009; Elliott et al. 2015). Transitions of care, including discharge from hospital to the community or residential care, lack of integrated, shared health records, poor understanding of different health professional's roles in medication support, and the complex and onerous process of navigating access to services such as medication reviews, all

contribute to increased risk of error or misadventure (Ellenbecker et al. 2004; Easton et al. 2009). Substitution of different brands of medications by prescribers or pharmacists, without sufficient counseling, can cause confusion that may lead to omissions or overdosing of prescribed medications (Elliott and Booth 2014; Ellenbecker et al. 2004).

Those who are unable to independently manage their medications because of functional or cognitive decline may require support from their family members or other informal caregivers (Elliott et al. 2015; While et al. 2013). If these are not able to assist, medication management support can be provided via community healthcare workers, such as community nursing home care services. Community healthcare workers, depending on their level of training, qualification, and competence, can provide support, ranging from prompting the person to take their medications to administering the medications to the person (Elliott et al. 2015; While et al. 2013).

Assessment of Medication Management

A comprehensive assessment can be undertaken by a health professional to determine the risk of medication-related problems and type of medication support required by the older person (Elliott et al. 2015; Lee et al. 2015). The assessment should take a holistic approach and consider all domains related to medication management, including capacity to self-manage medications, the stability of the person's medical condition, the number and type of medications used, the complexity of the medication regimen, cultural beliefs, knowledge and understanding of their medications, social and economic status, participation of family or other caregivers in medication support, and medication affordability (Elliott et al. 2015; Lee et al. 2015). All of these factors will inform care planning and provision of care that facilitates the older person's participation in managing their medications safely and effectively. Understanding the person's health goals, capabilities, and support needs is central to safe and effective medicine care, and clear and regular communication between all members of the medication management

team supporting the person is required (Elliott et al. 2015; Lee et al. 2015).

Instruments to Assist Health Professionals with Guidance on Medication Management

Several instruments have been developed to assist health professionals with planning medication management for people. These include person-centered assessment tools that can help a health professional to determine a person’s ability to self-administer their medications, likelihood of their adherence to their medication regimen, their risk of experiencing medication-related problems, and complexity and appropriateness of their medication regimen (Table 4). These instruments may be useful for identifying barriers to self-management and assist health professionals to identify older people in need of education, regimen modification such as simplification of medication regimen, and other medication management assistances or medication management aids.

Strategies to Support Safe and Effective Medication Management for Older People

Ensuring safe use of medications and optimal adherence are critical aspects of medication management for older people. There is a range of interventions available to improve medication use and reduce medication-related problems, errors, and incidents in older people (Elliott and Booth 2014; Feldman et al. 2009; Ellenbecker et al. 2008; Easton et al. 2009; Lindeman 2010, 2011; Elliott et al. 2015, 2016; Towers and Tyler 2014). They may be used alone or in combination. These interventions are summarized below.

Medication Management Aids

There is an increasing range of medication management aids available to assist older people in managing their medications. Tools such as medication alarms, calendars, medication prompting cards, and software applications for smartphones and mobile devices may help the person

Medication-Related Issues in Later Life, Table 4 Medication management-related assessment instruments and tools

Type of medication management-related assessments	Examples of tools
Assessment of ability or capacity in medication self-management	<p><i>Drug Regimen Unassisted Grading Scale (DRUGS)^a</i> A performance-based measure to assess a person’s ability to identify, access, select, and take their medications. The tool takes about 15 min to administer</p> <p><i>Medication Management Ability Assessment (MMAA)^b</i> A performance-based assessment tool similar to DRUGS, but utilizes a standardized simulated medication regimen instead of the person’s own medications</p>
Assessment of adherence to medication-taking	<p><i>Morisky Medication Adherence Scale^c</i> A four-item self-reported questionnaire that assesses a person’s adherence to medications</p>
Assessment of risk for medication-related problems	<p><i>Medication Risk Questionnaire (MRQ)^d</i> A 10-item self-administered questionnaire to assess a person’s risk of experiencing a medication-related problem</p> <p><i>Drug Burden Index (DBI)^e</i> A measure that calculates a person’s total exposure to anticholinergic and sedative medications (a measure of risk of physical and cognitive functional decline)</p>
Assessment of complexity of medication regimen	<p><i>Medication Regimen Complexity Index (MRCI)^f</i> A 65-item tool that quantifies the complexity of prescribed medication regimen</p>

remember to take their medications (Lindeman 2011; Elliott et al. 2015). Most studies investigating the effectiveness of these types of strategy have involved relatively young population on few medications. There is little high-quality evidence about the effectiveness of these strategies for older people who use multiple medications.

The most common medication management aids used by older people in developed countries are dose administration aids (DAAs). These are devices or systems that organize multiple medication doses into secondary storage sorted by date and time. Some types of DAA can be packed by those administering the medications. Others are provided through pharmacies. Some older people, especially those with complex medication regimens or who are prone to double-dosing as a result of difficulty remembering whether they have taken their medications, may benefit from using a DAA (Elliott et al. 2015). DAAs can also help family members or other caregivers to assist in medication support (Feldman et al. 2009; Elliott et al. 2015). Automated (or smart) DAAs can be linked to remote devices such as mobile phones to automatically record the person's medication-taking or send an alert when medications are not taken (Lindeman 2011; Elliott et al. 2015). This information may assist health professionals and caregivers in remote monitoring of a person's medication-taking and help to inform clinical decision-making.

DAAs do have limitations. They are only suitable for oral medications that retain their efficacy when repacked into a DAA. They are not suitable for medications with frequent changes to timing or dose or for medications used occasionally. Use of a DAA may increase the cost of medication management, and some older people may have physical or cognitive difficulty managing a DAA. Introducing DAAs too early, that is, prior to other strategies such as providing education, a medication list, a calendar, or reminder application, can lead to disempowerment and de-skilling of the person. Therefore, these devices need to be used judiciously (Elliott et al. 2015).

Interdisciplinary Care in Medication Management

Medication reconciliation involves obtaining a best-possible medication history using multiple information sources. The medication history is then compared to the person's current medication orders to identify and resolve any discrepancies.

Medication reconciliation has been shown to reduce medication errors such as inadvertent omission of therapy, prescribing a ceased medication, or duplication of therapy (Feldman et al. 2009; Scott and Jayathissa 2010; Easton et al. 2009; Lindeman 2011).

During the process of transitioning to or from hospital, residential care, or community care, the risk of experiencing medication discrepancies and errors is increased. This is often due to poor communication and information sharing between the interdisciplinary team during the clinical hand-over process. There is evidence that 52–88% of documents used in transition of care processes contain an error (Ellenbecker et al. 2004; Easton et al. 2009). Medication reconciliation should be performed as part of medication review and whenever there is a transition of care between healthcare settings or healthcare providers to reduce the risk of errors (Feldman et al. 2009; Scott and Jayathissa 2010; Easton et al. 2009; Lindeman 2011).

Medication review involves a structured evaluation of a person's medications by a health professional, usually a pharmacist, in collaboration with the person's medical practitioner(s). The primary goals are to optimize the impact of medications and minimize the number of medication-related problems (Easton et al. 2009). This approach is used either alone or in combination with strategies such as person-centered education. There is evidence supporting the use of such approach to improve medication use in older people (Feldman et al. 2009; Easton et al. 2009). It is the most common strategy globally recognized and used to improve medication use and reduce the risk of adverse drug events (Feldman et al. 2009; Easton et al. 2009).

There is evidence for the effectiveness of medication reviews in identifying and resolving medication-related problems (Elliott and Booth 2014) and reducing the risk of unplanned hospital admissions in older people at high risk of experiencing adverse medication events (Roughead et al. 2011). A study reported that in a cohort of older people using warfarin who were at risk of hospitalization due to bleeding, those

who had received a medication review had a 79% reduced likelihood of hospitalization between 2 and 6 months post-review compared to their unexposed counterparts (Roughead et al. 2011). There is also evidence that medication reviews and collaboration with other members of the healthcare team, especially pharmacists, prevent adverse events associated with poor medication management (Ellenbecker et al. 2008). This evidence suggests that older people, especially those assessed at risk of experiencing medication-related problems, should have their medications reviewed regularly, at least every 6 months (Roughead et al. 2011).

Person-Centered Education Interventions

Structured education focusing on person-centered medication management can help to improve awareness, knowledge, and adherence to medications and empower older people and caregivers to be more independent with managing their medications (Epping-Jordan et al. 2004; Ellenbecker et al. 2008). Effective education programs include information about encouraging older people and caregivers to keep an up-to-date list of their medications and share it with their family members and health professionals. They should also assist people to identify and access support services in their community such as medication review and medication management aids. To enhance the effectiveness of education programs, the content and delivery must be tailored to the person's needs, including their preferred language, level of literacy, and learning style. Repeating education may be necessary (Ellenbecker et al. 2008).

Electronic Health Interventions and Assistive Technology

Over recent years there has been an increased focus on the development of innovative electronic health interventions and assistive technology products to support medication management (Feldman et al. 2009; Easton et al. 2009; Lindeman 2010, 2011; Towers and Tyler 2014; Elliott et al. 2016). Some examples include electronic prescribing and electronic transmission of medication orders (Elliott et al. 2016). This can

streamline communication between doctors, nurses, and pharmacists and allow health professionals to have real-time access to the person's medication information. Assistive technologies include use of videoconferencing to enable remote monitoring, prompting, and supervision of a person's medication-taking at home; use of smartphone or wearable devices that enable automated monitoring, recording, tracking, and reporting of a person's disease progression; and use of automated dispensing devices that assist the person to self-administer their medications (Lindeman 2010, 2011; Towers and Tyler 2014). Another example includes technology that uses an integrated care management platform to connect the person and their healthcare providers in real time and to improve medication adherence of the person (REMIND TECH™). The platform is designed to track key aspects of care management, medication adherence, and clinical assessments of the person while utilizing data points and interactive tools such as adherence score per medication, side-effect reporting, and a provider-person-caregiver messaging board, allowing healthcare providers and caregivers to be alerted if the person is not adherent to their medication regimen (REMIND TECH™).

Despite some evidence suggesting that using electronic health interventions or assistive technologies has the potential to improve medication safety and medication management (Towers and Tyler 2014; Elliott et al. 2016), to date there has been limited research evaluating their effectiveness, especially in older people. Further studies are required to explore their utility and provide more robust evidence regarding effectiveness and safety in older people.

The Chronic Care Model Framework Approach

A multidisciplinary group including the older person, their caregivers and/or family members, prescribers, community pharmacists, and healthcare providers are all part of the medication support team. In supporting older people to manage their medications safely and effectively, a multifaceted approach is required. The approach should consider a range of interventions that focus on

integrating collaborative and person-centered care, as illustrated by the framework of the Chronic Care Model (Epping-Jordan et al. 2004). This model recommends that interventions used to improve chronic disease care for older people require several essential elements to achieve the best-possible outcomes. These elements are self-management support, delivery system design, decision support, and clinical information systems (Epping-Jordan et al. 2004). This approach encourages older people and their caregivers to actively work in partnerships and participate in medication self-management and decision-making. Building a medication support team around the older person and their informal caregivers, for example, by advocating for the person to attend one general practice and have one pharmacy, preferably in communication with one another, creates a network that can be valuable if or when cognitive and functional capabilities decline (While et al. 2013). Furthermore, encouraging older people to keep a list of their medications and have their medications reviewed regularly can help keep older people safe and independent and defer the need to resort to high-intensity and high-cost interventions such as community nursing home care services.

Conclusions

Medication management in older people is complex. Older people are at a greater risk of experiencing medication-related problems compared to younger adults. Pragmatic screening can identify older people at greatest risk of adverse events and can assist in identifying those who may benefit from assessment and intervention. Knowing the type of medication-related issues and risk factors that affect older people may help to inform assessment, care planning, and development of strategies to minimize the risk of experiencing medication-related problems, errors, or incidents and thereby reduce the incidence of adverse medication events. Multifaceted approaches that integrate different strategies such as interdisciplinary care, person-centered education and support, and,

where appropriate, medication management aids or assistive technologies are likely to be most effective in maintaining safety, effectiveness, independence, and well-being.

Definition

This entry describes an Australian longitudinal cohort study, the Melbourne Studies on Healthy Ageing (MELSHA) program, which has followed a relatively healthy cohort of older people aged 65 years and older across the latter part of their life span from 1994 to the present.

Background

The Melbourne Longitudinal Studies on Healthy Ageing (MELSHA) Program is an ongoing population-based longitudinal cohort study of 1000 people aged 65 years and over living in noninstitutional settings in Melbourne, Australia.

MELSHA was conceived in the 1990s as a way of establishing an evidence base to inform health promotion programs for older people, a relatively novel idea at a time when most research on aging in Australia focused on the “burden of aging” and the fear that population aging would result in a highly dependent cohort who would drain the health budget. While maximizing health and quality of life was seen as a way of reducing dependency and hence health costs, we have argued that good health in old age is a basic human right

(Kendig and Browning 2010). In contrast to paradigms of aging as a process of inevitable decline, we aimed to identify individual actions and public health measures that could be taken to maintain and in some instances recover good health and well-being through later life.

MELSHA has contributed to healthy aging policy in Australia through various federal and state forums and has contributed to the debate about the importance of including older people in health promotion programs (Browning and Kendig 2004; Kendig et al. 1998a). Collaborations with MELSHA and other Australian longitudinal studies through the Dynamic Analyses to Optimize Ageing (DYNOPTA) project where MELSHA is one of the contributing studies (Anstey et al. 2010) have contributed to national analyses of topics including depression, aging policy, medical conditions, and driving (Burns et al. 2013; Anstey et al. 2011; Bielak et al. 2012; Ross et al. 2009, 2011).

The baseline survey for the MELSHA program began in 1994 at a time when concepts such as healthy and active aging were rarely seen on policy agendas for older people. Our focus in 1994 was to identify avenues for changing individual actions and social environments that influence the health and well-being of older people. The Victorian Health Promotion Foundation (1994–1997) and the Australian National Health and Medical Research Council (1998–2000, 2003–2005, 2008–2010) funded the research. The following investigators have contributed to MELSHA: Hal Kendig, Colette Browning, Maria Fiatarone Singh, Leon Flicker, Robert Helme, Birgitta Lundgren Lindquist, Meg Morris, Daniel O’Connor, Susan Quine, Jane Sims, Shane Thomas, Carolyn Unsworth, Karen Teshuva and Yvonne Wells. We continue to monitor the sample through death checks and informant follow-up where possible. The cohort profile was described in Browning and Kendig (2010).

Participants and Procedures

The study is situated in Melbourne, the second largest city in Australia. The baseline survey

sampled older people using a sampling frame based on the Victorian Electoral Roll. The clustered sample consisted of 1865 potentially eligible participants across 40 inner Melbourne postcodes. The sample yielded 1422 eligible participants. People aged 65 years and over residing in private dwellings were included in the sample. Those living in non-private accommodation, including residential aged care, those who could not speak English, and those with health conditions that impacted on communication were excluded. The final baseline sample was 1000 participants yielding a 70% response rate.

The demographic and health characteristics of the participants at baseline are described in Kendig et al. (1996). Fifty three percent of the participants were women, 58% were married, and 82% rated their health as good, very good, or excellent. The sample was somewhat healthier than the population from which it was drawn.

The baseline survey (1994) included face-to-face interviews with participants in their own home, a self-completion questionnaire, and brief physical tests. This protocol was repeated in 2004, 2008, and 2010. Participants answered questions focusing on the following domains: health-related actions, perceptions and health histories; functional health and prevalence of health conditions; quality of life; social support and interaction; and service use and transport and neighborhood. In 1996, 1998, 2000, and 2002, participants completed a computer-assisted telephone interview (CATI) using a shortened form of the original face-to-face interview schedule. In the intervening years, a short mail-out questionnaire was used to collect some key outcome variables and to help track the participants. Loss to sample has been relatively low as we have been able to track the participants through informants and death checks and identify specific outcomes that have precluded survey completion at each data collection such as death, entry to residential aged care, and severe health conditions such as cognitive impairment. For the first 10 years of the study, loss to follow-up was less than 10% at each biennial wave.

Findings from MELSHA

Early cross-sectional analyses focused on particular domains such as social disadvantage, caregiving, driving, falls, urinary incontinence, oral health, functional impairment, and social and physical activity, while later time-based analyses focused on predicting particular outcomes such as entry to residential aged care, aging well and the relationships between illness and depression, and widowhood and well-being.

Physical Activity

MELSHA included a number of measures of physical activity as well as questions about the perceived adequacy of physical activity levels, encouragers of and barriers to physical activity, and the importance of physical activity to health. Browning and colleagues (2009) found that most participants had engaged in light activity in the last 2 weeks and around 45% had engaged in energetic activity that made them puff or pant (Browning et al. 2009). Almost all participants believed that physical activity was important to health and about two thirds judged their current levels of physical activity to be about right. Perceived adequacy of physical activity and positive beliefs about being able to influence health were associated with physical activity behavior. Spouse and family members were common encouragers of physical activity. In addition Kendig et al. (1998b) showed a relationship between former occupation and current income and physical activity behavior (Kendig et al. 1998b). These social class effects underline the importance of the continuing disadvantage that can accrue across the life span and impact on health later in life.

Falls and Functional Health

Falls and functional capacity have been another focus for MELSHA. An early analysis sought to understand the factors that differentiate between frequent and occasional fallers (Morris et al. 2004). Twenty percent of MELSHA baseline participants fell once in the last year and 9% fell

more than once. Women, those with back pain and those with multiple medical conditions, were more likely to be occasional fallers than non-fallers, while female gender predicted multiple falling. Multiple fallers were more likely to be afraid of falling than occasional fallers, but there is limited knowledge about the temporal relationship between fear of falling, falling, and psychosocial risk factors mainly because most of the studies are cross-sectional. Clemson and colleagues (2015) therefore examined the predictors of fear of falling and falls requiring medical attention across 11 years and found that having a serious fall does not predict fear of falling and fear of falling did not predict future falls (Clemson et al. 2015). Depression was a predictor of injurious falls, supporting the need for screening for depression in older people who fall. This study was the first to show that reduced social activities predicted fear of falling. It also has strengthened the knowledge base behind fall prevention programs that have proven efficacy through targeted physical activity programs and home improvements that reduce environmental risks.

Gender differences have also been a focus for MELSHA, and we have argued that it is important to understand the different experiences of aging for men and women, as well as examine potential differences in predictors of health outcomes in order to design programs and services that are targeted correctly. An analysis of gender effects on falls was conducted by Browning et al. (1998) who found that women were more likely than men to fall in the previous year, women were more afraid of falling, and women were more likely to fall in the home than men, while both men and women fell most outside their home (Browning et al. 1998). Predictors of falling for women were taking more than five prescription medications and for men poor eyesight. These findings highlight the need to take into account gender when designing fall prevention programs.

Foot and leg problems are potential markers of functional health in older people. Barr et al. (2005) found that 36% of the MELSHA baseline sample reported foot and leg problems

(Barr et al. 2005). Foot and leg problems were associated with impaired timed “Up and Go” measures, difficulty walking and climbing stairs, and a history of falling independent of sociodemographic factors and medical conditions. The findings underscore the importance of self-care foot education and access to podiatry and related health services.

Impacts of Medical Conditions

MELSHA has provided insights into the various medical conditions of older people and their impacts. Sims et al. (2011) found that 28% of MELSHA baseline participants reported urge incontinence and 21% reported stress incontinence (Sims et al. 2011). The impacts on well-being were different for urge and stress incontinence and for men and women. “Occasional” urge incontinence impacted negatively on depressive symptomology, negative affect, and IADL. Positive affect and self-rated health were impacted negatively if urge incontinence was experienced “often.” Stress incontinence impacted on depressive symptomology, positive affect, IADL dependence, and self-rated health. Women with any form of incontinence had higher negative affect scores than men. The findings reinforce the importance of continence control for self-esteem and for willingness to keep socially involved in community life.

Kendig et al. (2000) examined how activity limitations mediated the impact of illness and pain on psychological well-being (Kendig et al. 2000). They found that major illnesses and pain impacted on psychological well-being (lower positive affect, increased negative affect, and depressive symptoms) by limiting usual activities. This finding highlights the importance of health and independence in old age as a resource to continue with a “usual” life.

Oral health impacts on older people’s physical, emotional, and social functioning including good eating patterns and balanced nutrition. MELSHA was one of the first studies to examine oral health and use of oral health services in Australia in older people. Mariño et al. (2007) found that 34% of

MELSHA baseline participants had visited a dentist in the last year and that 40% had not visited a dentist for over 5 years (Mariño et al. 2007). Those who were younger and had higher income and levels of education were more likely to visit a dentist in the last year, again demonstrating the impact of social disadvantage on health and access to health care. Visiting a dentist in the last year was associated with higher social support and positive affect scores.

MELSHA data has been used to examine the relationship between chronic medical conditions, mortality, and depression over a 10-year period. Depression has been associated with various chronic illnesses including diabetes and cardiovascular disease in cross-sectional studies. Atlantis et al. (2010) found that older people with baseline depressive symptomology were twice as likely to develop diabetes as compared to those without depressive symptomology, and this relationship was independent of antidepressant use (Atlantis et al. 2010). In contrast, Atlantis et al. (2011) found that depressive symptomology or antidepressant use at baseline were not associated with cardiovascular disease or premature death (Atlantis et al. 2011). Analyses of longitudinal data can help untangle the cause and effect relationships between variables. Screening for and providing the appropriate treatment for depression early in old age may impact on the subsequent onset of diabetes.

Medication use and polypharmacy have significant impacts on the health and well-being of older adults. Thomson et al. (2010) investigated medication use and risk factors for side effects at baseline in MELSHA (Thomson et al. 2010). They found that 8.5% of participants on medications reported side effects, which was comparable to those found in older adults attending primary care settings in Australia. Risk factors for side effects included how recently the person visited a pharmacist, younger doctor age, and doctors' awareness of their medications.

Life Transitions

Another focus of MELSHA has been on life transitions. Wells and Kendig (1997) investigated and

compared the consequences of spouse caregiving and widowhood using the baseline data from MELSHA (Wells and Kendig 1997). Interesting interaction effects were found. Former spouse caregivers adjusted better to widowhood in terms of depressive symptomology, but sleeping problems were worse in widowers who had previous spouse caregiving responsibilities. Widowhood was associated with more pervasive negative health and well-being outcomes, while spouse caregiving was associated with both negative and positive outcomes indicating that caregiving should not be just categorized as a stressor. In a later paper, Burns et al. (2015) examined the trajectories of mental health as measured by positive and negative affect and depressive symptomology in those who were widowed compared with those who were not (Burns et al. 2015). At initial partner loss, both men and women showed diminished positive affect, while women showed higher negative affect and depressive symptomology. In the years following partner loss, neither men nor women returned to the levels of positive affect pre-widowhood.

Modeling Key Outcomes

Our longitudinal modeling has also allowed us to examine predictors of entry into residential aged care, predictors of aging well, driving status and trajectories and predictors, of hearing difficulties. Such analytic approaches allow a more fine-tuned understanding of opportunities for intervention both to promote healthy aging and prevent adverse events. They also suggest avenues for recovering capacities after experiencing health and social "shocks" such as acute illness.

Kendig et al. (2014) investigated the threats to aging well over a 12-year period using a model of health and well-being based on older peoples' views of aging well (Kendig et al. 2014). The model includes hierarchical goals for aging: staying alive, living in the community (as opposed to residential aged care), and continuing to live independently with good physical and psychological health. They found that the threats

to aging well were different between men and women. For men, the threats were low stress, perceived inadequate social activity, and smoking. For women, the threats were urinary incontinence, low physical activity, and being under weight. Examining aging well from a gender perspective provides the evidence for more targeted approaches for health promotion in older people. Kendig et al. (2010) examined predictors of entry to residential aged care and found different predictors for men and women (Kendig et al. 2010). For women being dependent in IADL, never being married and low weight were risk factors (indicating social and functional vulnerabilities) for entry, while for men the number of medical conditions and poor nutrition were risk factors.

The transition to limiting or ceasing driving has significant impacts for the older person in terms of independence and access to services, especially in Australia where car use is very high. Unsworth et al. (2007) investigated the predictors of the driving transition over a 6-year period and found that older drivers self-regulate their driving by driving in familiar areas and limiting driving to daytime (Unsworth et al. 2007). The predictors of modifying driving were older age, poor eyesight, and IADL dependence. Women were three times more likely to cease driving than men, adjusting for health and disability, and those on higher incomes were more likely to cease driving.

Heine et al. (2013) examined self-reported hearing difficulties over a 10-year period and the influence of health behaviors and social activity on these trajectories (Heine et al. 2013). As expected, hearing difficulties increased over time. Factors that predicted a more rapid increase in hearing difficulties included health behaviors such as smoking and poor nutrition and older age. Surprisingly, increased social activity predicted increasing hearing difficulties. This finding could be explained by a greater awareness of hearing difficulties in social situations leading to greater reporting of hearing difficulties. The importance of health-promoting actions in old age was once again demonstrated.

Issues in Longitudinal Research

Over the long duration of the MELSHA study, a number of key issues have required adaptations from its planning in the early 1990s, through to analyses that are continuing. The cohort is now largely completed given that few of the original samples are surviving. This enables us to turn to analyses of the full course of later life, for example, trajectories of the final years of life and analyses of late-life issues such as cognitive impairment, dual sensory loss, and frailty.

A fundamental concern has been the shifting funding bases and related changes in the substantive foci and applications of the findings. The baseline survey, funded in 1994 as a cross-sectional effort by the Victorian Health Promotion Foundation, was extended to a second round in 1996 when the Foundation determined that the topic of depression along with behavioral change were priorities. Several subsequent rounds were funded by the Australia National Health and Medical Research Council as 3-year project grants, the first focused on behavioral change and the second on functional capacities and accumulated outcomes. The 2010 data collection and subsequent analyses have been funded by the Healthy and Productive Ageing project in the ARC Centre of Excellence in Population Ageing Research (CEPAR). Each of these project rounds has had a range of investigators and project staff, with continuity provided by ourselves as lead investigators.

Methodological challenges have been considerable. Measures considered to be state-of-the-art at baseline needed to be streamlined and in some cases augmented or replaced by better measures in later rounds while maintaining a core of essential variables. Exhaustive follow-up strategies were devised to minimize loss to follow-up, while analytical strategies employed “survival analysis” and related techniques that took account of missing respondents and variables in survey rounds.

Policy applications and research translation have been priorities for ourselves and our colleagues as well as the funding bodies. A preliminary report on the baseline survey

brought priority findings to the attention of policymakers and program planners at a relatively early date while academic articles went through the lengthy peer review process before publication. We have written for broad “public affairs” audiences, for example, through the Academy of Social Sciences in Australia (Kendig and Browning 2011), as well as ongoing press releases and submissions to various inquiries and hearings concerning health promotion and related policies of national and state governments. Overall, these efforts to influence policy have had modest impacts directly, as governments have largely continued to set younger people and specific diseases as their priorities for action. MELSHA findings have contributed evidence on aging well in interpretive chapters for a number of national and international books, including a textbook on ageing (O’Loughlin et al. 2016), and another for policy and public affairs audiences (Kendig and Browning 2016).

Arguably the greatest impact of MELSHA has been part of broader efforts influencing public and policy thinking to encompass positive and improvable dimensions of aging. After a review by the Australian Prime Minister’s influential PMSEIC Scientific Committee, a number of initiatives were launched including the “Ageing Well, Ageing Productively” research funding programs for the ARC and NHMRC (Kendig and Browning 2010).

Definition

Memory training programs are cognitive interventions that aim to enhance or maintain memory performance via methods such as strategy instruction or engagement; training benefits may be evidenced immediately following training or over time and include improvements for trainees, relative to controls, in performance on tasks targeted in training (e.g., episodic memory), beliefs, or untrained memory or cognitive tasks or other broad outcomes (e.g., indicators of well-being).

As a practical matter, one of the most important questions facing geropsychologists is this one: Are memory training programs effective in

optimizing the memory performance of older adults? The simple answer is yes: *memory training results in immediate improvement in the tasks that are trained* (Gross et al. 2012; Hertzog et al. 2009; West and Strickland-Hughes 2015). However, excitement about this definitive response is tempered by concerns regarding the practical impact of these programs. When older adults ask if memory training is effective, they are really asking about more than immediate improvement on the trained tasks. They want to know if the impact of training is lasting and how challenging it might be to improve “memory in general,” so that training will help them to succeed over time on most practical memory tasks. These more complicated questions about the impact of training are addressed in this overview, which focuses on behavioral memory interventions.

This article documents the extent to which memory training improves memory for healthy older individuals, with a focus on episodic memory and memory strategies. This review excludes physical and pharmaceutical interventions for memory gain as well as interventions designed to improve particular cognitive skills (e.g., reasoning). Issues of practical impact are considered, specifically the long-term maintenance of training gains and transfer of benefit to non-trained tasks. The paper also addresses nonability factors that may moderate gains from training (e.g., beliefs about ability, chronological age) and novel methods for intervention that show promise.

Approaches to Training

A primary aim of cognitive interventions for the aged is memory improvement. This section reviews the types of memory training programs that are typically offered, starting with a general overview, and then describes three exemplar interventions that reflect the variance in focus, duration, and scope among training paradigms.

Memory training programs for older adults range from intensive practice of core processes to extensive interventions aimed at enhancing overall cognitive engagement, and they vary

from training single memory techniques to comprehensive, multifactorial programs, which employ varied activities, including relaxation, attentional exercises, or basic education on aging or memory (Charness 2007; Schubert et al. 2014; Zehnder et al. 2009).

Training gains are typically assessed with a comparison of performance at pretest with performance at posttest (following the intervention), but it is also critical to include a control group. Control groups may be inactive/waitlist groups or active groups (placebo or non-placebo). Comparison to inactive/waitlist groups (who complete only the memory assessments) controls for the effects of practice from repeated testing (Stine-Morrow and Basak 2011). Some investigators use active control groups that serve a placebo function. Such groups are matched to the intervention in terms of meeting frequency, duration of activity, and degree of social engagement, but participate in activities which should not change the outcomes of interest. That is, the placebo controls for the level or type of activity, social experience, expectations, motivation, and other aspects of participation. Other active control groups are non-placebo: such groups may be utilized to compare different versions of training programs, such as group classes versus self-help via a workbook (Bailey et al. 2010; Hastings and West 2009) or novel versus traditional approaches (Rebok 2010; Stine-Morrow et al. 2014). Random assignment of participants to training or control conditions, such as in randomized control trials, establishes comparable groups representing the population of interest. Whether waitlist or active, an appropriate control group must be included for the results of a cognitive intervention to be credible. Thus, intervention programs lacking an appropriate control group are not considered in the present review, and the three exemplar programs, described next, each utilized appropriate control groups.

Everyday Memory Clinic (EMC)

The Everyday Memory Clinic (EMC) was a 5-week-long, multifactorial program which supplemented strategy training with activities and lessons on other topics, such as attention and

normal aging. In addition to training multiple strategies, EMC focused on improvement in memory beliefs. Three episodic memory tasks (name, list, and story recall) as well as related beliefs (locus of control, self-efficacy, and memory anxiety) were assessed at pretest, immediately after training, and 1 month following training.

EMC trainees (aged 50+ years) showed improved name and story recall performance and used strategies more effectively than the control group (West et al. 2008). In addition, active trainees (e.g., high attendance, homework completion, and strong in-class participation) had higher memory scores than inactive trainees, and trainees using a self-help workbook demonstrated greater pretest-to-posttest gains in recall and locus of control, relative to a non-active control group (see Stine-Morrow and Basak 2011).

Advanced Cognitive Training for Independent and Vital Elderly (ACTIVE)

The ACTIVE study is the largest randomized clinical trial for memory intervention conducted with older adults. Participants (ages 65–94 at enrollment) were randomly assigned to one of three different training conditions (memory, reasoning, or speed of processing) or to an inactive control group. Memory trainees completed ten weekly sessions focused on multiple strategies designed to improve verbal episodic memory (e.g., mental association, visual imagery). Directly trained abilities, as well as a large number of cognitive tasks and other measures, were assessed repeatedly, up to 10 years following initial training (Rebok et al. 2013).

Overall, the ACTIVE trial enhanced verbal memory and locus of control for memory. At least one quarter of the memory trainees improved their performance by more than one standard error (see Stine-Morrow and Basak 2011). Verbatim recall of stories was also higher for trainees immediately following training, but not 1 year later (Sisco et al. 2013). One and two years after training, the memory trainees outperformed the other groups on a composite score for verbal episodic memory (Rebok et al. 2013).

Cohen-Mansfield and colleagues (2014) replicated the ACTIVE program using a smaller sample

of older adults with memory complaints (ages 65–87). More particularly, they compared ACTIVE memory training to a health promotion program and to a memory “book club.” All three programs were of equivalent duration and intensity. All groups improved pretest-to-posttest cognitive functioning on a comprehensive test battery that included tests of verbal and nonverbal episodic memory, but only the ACTIVE training group showed reduced memory complaints. Collectively, the large-scale ACTIVE trial and replication showed success in enhancing episodic memory and self-perceptions regarding ability and performance.

Theatric Arts Intervention

A collection of studies by Noice, Noice, and colleagues (Noice and Noice 2011) evaluated the efficacy of a theatric arts intervention for memory and cognition. The authors proposed that acting is a unique leisure activity for promoting cognitive gains because it is multimodal (i.e., involving emotional, social, cognitive, and physiological processes) and fosters engagement through novel experiences. Participants received 80-min acting lessons twice a week for 4 weeks. Lessons were focused on acting techniques and not memorization. The exercises increased in challenge and demand over the 4 weeks.

Across several studies, with participants ranging from 60 to 95 years old, the episodic memory gains for theatric arts trainees exceeded that of non-active control groups and groups trained in other arts programs (i.e., art appreciation or singing). The program demonstrated effectiveness in community-dwelling older adults, residents of long-term care facilities, and low-income seniors (Noice and Noice 2011). Memory gains were even replicated when the intervention was administered by an activity director and an acting teacher outside of the research team (see West and Strickland-Hughes 2015).

Clearly, memory interventions are conducted using many different approaches and techniques, and the data presented thus far has indicated that some programs are quite effective. The next two sections address the overall evidence for training-related changes in memory test performance and beliefs about memory.

Strategy Training: Impact on Memory

Episodic memory performance is a key focus of interventions because memory ability is perceived as highly important and is necessary for everyday activities, yet declines normatively with increasing age. Thus, the primary indication of success for a memory training intervention is memory gain. Importantly, a long-accepted body of work establishes that older adults can benefit from memory training programs, as indicated by pretest-to-posttest improvement in episodic memory performance, over and above any observed practice-related gains in a control group.

A meta-analysis by Gross and colleagues (2012) evaluated training gains in objective memory performance for cognitively intact older adults (60+ years old at time of training) across 35 studies in which memory trainees were compared to appropriate control groups. This report replicated an earlier meta-analysis in that training-related gains in memory were greater for trainees than controls, and training gains were not directly linked to any specific trained strategy. Whereas the earlier review suggested that programs that included pretraining, such as relaxation training or other non-mnemonic instruction, showed higher gains than those without pretraining, this report suggested that programs training multiple strategies may be more effective than those training only one strategy. In effect, both meta-analyses showed that trainees benefit from interventions that go beyond training a single strategy. There is also evidence that group training is more effective than individual training, possibly due to social effects or due to the fact that group training programs tend to be longer (Berry et al. 2010).

In contrast to these promising findings, a review of cognitive intervention programs for both healthy older adults and adults with mild cognitive impairment found improved verbal recall and paired associate memory for trainees compared to inactive control groups, but not when compared to active control groups (Zehnder et al. 2009). These results might suggest that some training-related memory gains may not be specific to the intervention type or content; however, the authors very broadly defined active

control groups (e.g., including exercise interventions). Thus, when comparing memory intervention results to active control group data, the authors may have been comparing multiple interventions expected to yield memory change.

To summarize, meta-analyses have systematically evaluated over 50 years of cognitive interventions for older adults' episodic memory performance. The primary findings of the reports on mnemonic training suggest that older individuals do benefit from memory training, particularly when compared to individuals from inactive control groups. The collective data suggest a relatively greater benefit for training programs which are more comprehensive (e.g., those including pretraining and those training multiple rather than single strategies) and those with group-based exercises. Further, the data show that many different types of strategy training are effective, and no differences have been reported when comparing particular strategies. This suggests that episodic memory may benefit from some qualities of interventions unrelated to the specific strategies trained (e.g., changes in attentional factors). The meta-analyses reviewed here focused primarily on strategy training. Notable evidence on other approaches suggests that adults may also benefit from computerized and video game interventions, higher levels of daily cognitive activity, and repeated practice with attentional or working memory skills (Rebok 2010; Schubert et al. 2014; West and Strickland-Hughes 2015).

Strategy Training: Impact on Beliefs

In addition to actual gains in memory test scores, researchers in the memory intervention area have long been interested in whether training has an impact on beliefs about memory. Self-evaluative beliefs correlate positively with memory performance. This association strengthens with age and is affected by the way in which beliefs are assessed (Beaudoin and Desrichard 2011; Berry et al. 2010). Beliefs also predict performance over short-term goal and feedback manipulations and predict long-term change (West and Strickland-Hughes 2015). Thus, beliefs might influence the

maintenance of intervention effects (Hastings and West 2009). One complicating factor in reviewing the literature on beliefs and intervention is that the assessments of beliefs vary dramatically from study to study (Beaudoin and Desrichard 2011). Nevertheless, there are some reasonable conclusions that can be drawn.

Floyd and Scogin (1997) systemically reviewed the memory training literature on subjective measures, including a wide variety of assessments for beliefs. Their meta-analysis of 27 studies revealed a significant effect size for the impact of training on subjective beliefs, but the effect was smaller than the magnitude of gains for memory performance. Not surprisingly, the greatest changes in beliefs appeared to be related to studies focused on improving aging attitudes. More recent evidence from experimental studies suggests that self-evaluative beliefs might not only be influenced by memory training, but may also predict performance gains through moderation or mediation of intervention effects.

Specifically, the ACTIVE study assessed personal control or the belief that performance outcomes can be determined by one's own influence. Five years after the ACTIVE program, participants who trained in reasoning and speed of processing were considerably more likely to improve their sense of personal control than was the no-contact control group (see West and Strickland-Hughes 2015), even though the ACTIVE training program did not emphasize self-evaluative beliefs. Unfortunately, ACTIVE *memory* trainees did not demonstrate this training benefit. As mentioned earlier, however, ACTIVE memory trainees did show reduced subjective memory complaints in a replication study (Cohen-Mansfield et al. 2014).

The EMC project was designed to enhance memory self-efficacy or confidence in one's memory ability. It did so by fostering enactive mastery (e.g., easier exercises first) and reducing anxiety (e.g., emphasis on self-set goals rather than high performance for all), among other techniques (West et al. 2008). In contrast to the minimal changes in beliefs observed for ACTIVE memory trainees, EMC trainees reported increased personal control and enhanced memory self-efficacy

1 month following the intervention, while the control group experienced some declines in these beliefs. Self-taught trainees showed significant improvements in personal control, but not in self-efficacy (Hastings and West 2009).

Thus, modest evidence suggests that intervention may promote enhanced self-evaluative beliefs. More interestingly, in an inductive reasoning intervention, trainees with higher initial levels of memory self-efficacy allocated more time to training and benefited more from the intervention (see West and Strickland-Hughes 2015). Do self-evaluative beliefs lead to more effort or greater benefit from training? In the EMC study, the initial level of memory self-efficacy, along with education and self-reported health, predicted the degree of active effort by trainees, which in turn predicted training-related gains. Further, memory self-efficacy was a significant predictor of episodic memory performance at follow-up, and training-related change in memory self-efficacy was a mediator of memory gains from the intervention (West and Strickland-Hughes 2015). Considering this collective evidence, beliefs may be related in important ways to the benefits that come from memory intervention.

Strategy Training: Impact over Time

Given what we know about gains in performance and subjective memory, training clearly holds great promise for episodic memory. This promise will be realized if and when it is established that post-training episodic memory gains are lasting. Unfortunately, the majority of intervention studies examine gains cross-sectionally, immediately after training, and do not assess training effects over time (Gross et al. 2012). Consequently, there are no available systematic meta-analyses on long-term maintenance of benefits from training interventions, and relatively little is known about this topic. When training gains are significant, maintenance can still vary (Rebok et al. 2013). Evidence from past research suggests that maintenance is possible over a period of 1–6 months. However, when looking at maintenance for periods longer than 6 months, regression to

baseline performance is commonly found (Berry et al. 2010), or maintenance is limited (Rebok 2010).

In promising studies of multifactorial memory training (focused on encoding strategies, attention, and relaxation), 6-month maintenance was reported, and over 3 years later, maintenance or improvement of performance was still evident for the multifactorial trainees (see Berry et al. 2010). The ACTIVE trial was the first to assess long-term outcomes with a large sample. ACTIVE trainees were assessed immediately 1, 2, 3, 5, and 10 years following training. A subset of trainees completed four booster sessions about a year after training. Participants from all training conditions (with and without booster sessions), but not inactive controls, demonstrated improved memory when comparing performance at pretest with performance 5 years following the study. For memory trainees, these results were not affected by booster session participation (Rebok et al. 2013). However, no training or booster effects were significant for memory trainees 10 years following the program (see West and Strickland-Hughes 2015).

Hertzog and colleagues (2009) propose that our view of cognitive interventions may need to change. Interventions probably do not function like vaccines, that is, providing immediate protection against decline and requiring periodic boosters. Instead, perhaps memory interventions should be viewed like physical activity interventions, wherein continuing exercise is necessary for maintenance of performance. If so, maintenance of specific training lessons may be less of an issue. The focus, instead, should be on ways to encourage and motivate older adults to continue working on their memory. While the evidence thus far is hopeful, additional longitudinal analyses are needed to better understand the long-term benefits of cognitive activity.

Strategy Training: Impact on Transfer and Generalization

Researchers agree that it is desirable for intervention programs to have broad practical impact. This might include transfer of performance gains to

new, untrained memory tasks or extension of learned memory strategies to tasks not targeted in training. These outcomes would increase the value of training and possibly even stave off age-related attenuation in cognition (Hertzog et al. 2009; Rebok 2010). One could also look for broader generalization effects: if training improved social-emotional functioning, promoted neural activation, or encouraged a more engaged physical or mental lifestyle (Hertzog et al. 2009; Rebok 2010; Schubert et al. 2014), it would enhance the daily lives of trainees. Although everyone agrees that transfer and/or generalization represent a value added from memory interventions, there is considerable controversy about how to define transfer and about what kind of transfer should be expected in conjunction with a memory intervention (Fisher 2012; Schubert et al. 2014). If transfer is defined strictly as a change in performance on memory tasks that are not part of training, past research clearly shows that transfer rarely happens (Berry et al. 2010; Fisher 2012; Hertzog et al. 2009; Rebok 2010). Thus, clarifying the *how* and *when* of transfer is imperative, especially for those target skills that are most relevant for everyday experience. Alternatively, researchers could focus on the generalization of training effects to better strategy usage overall, neurogenesis, reduced depression, improved activities of daily living, or more mental or physical activity, and these results are more promising (Hertzog et al. 2009; Rebok 2010; Schubert et al. 2014; West and Strickland-Hughes 2015). Some of these topics are considered here.

Strategy Usage

Older adults are less likely than younger adults to spontaneously employ memory strategies, and they may overly rely on external aids or familiar mnemonics (Fisher 2012). Thus, strategy training is a common focus of intervention programs, and this approach has been quite successful overall (Rebok 2010; Stine-Morrow and Basak 2011). Increased strategy use is often assumed to explain training-related performance gains. Yet, this effect is often unexamined as strategy use can be difficult to assess directly.

More often, strategy use is assessed subjectively, via open-ended or multiple-choice self-report questionnaires after testing. Gross and Rebok (2011) compared the standardized pretest to posttest gain in use of strategies between training and control participants from twelve reports of cognitive interventions. They found that nearly all trainees exceeded control participants in strategy improvement and that this improvement was larger than the improvement in scores, *per se* (Gross and Rebok 2011). For example, strategy checklists completed in the EMC intervention showed that trainees and control participants both reported increased strategy usage over time. Although trainees often chose to use simpler versions of the complex techniques they were taught, trainees clearly shifted to using more effective strategies than the control group over time (West et al. 2008).

Evaluation of clustering techniques, using categorizable lists, is a more objective method of assessing strategy use because it does not require post hoc reporting of strategic behavior (Gross and Rebok 2011). Researchers can report items recalled in the order of the study list (serial clustering, suggesting use of association), items recalled contiguously from one category (semantic clustering or use of categorization), or other signs of item grouping. In the ACTIVE intervention, trainees showed immediate gains on several types of clustering and maintained these gains over 5 years (Gross and Rebok 2011).

Self-Monitoring

A self-monitoring approach to memory training involves guiding trainees to evaluate their learning (i.e., test their memory), identify what needs additional study, and adapt attention and strategy usage accordingly. A focus on self-monitoring techniques in training could be quite valuable because it allows older adults to make use of techniques – such as self-testing and allocating additional study time to unlearned items – which are relatively easy for them to apply (see Charness 2007). Also, successful self-monitoring may guide adults to allocate more learning resources to difficult items or discontinue study of well-learned items, thus helping them to meet their learning goals (see Fisher 2012).

If self-monitoring can be successfully taught, it could easily be included in any kind of strategy training, and the technique can be generalized to other, more practical learning situations (see Charness 2007).

Results are currently mixed for interventions based on self-monitoring. In an early study, gains were significantly greater for trainees in a program focused on strategies plus self-monitoring as compared to a strategies-only group. In addition, the effectiveness of this training approach was promising when administered via self-help workbooks (Bailey et al. 2010). However, two similar intervention programs failed to demonstrate greater gains for the self-monitoring groups above-and-beyond the benefits from traditional strategy training (see Charness 2007). Further intervention-based research is warranted to explore the benefits from self-monitoring approaches to memory training, as well as their potential for generalization in real-world settings.

Engagement

One alternative approach to training is to set up an environment for older adults that leads to broad engagement in cognitive activities (Charness 2007; Hertzog et al. 2009; Stine-Morrow et al. 2014). In essence, this approach builds generalization into the training regimen itself because individuals are practicing cognition and memory in the context of real-world activities. While these approaches may have great potential for improving memory, this potential has been realized in only some cases.

For example, the Experience Corps (Carlson et al. 2008) aimed to improve cognitive and health outcomes for older adults through intensive volunteer training and participation. Participants had approximately 32 h of volunteer training followed by a full year of literacy-related volunteer service in schools (e.g., reading to children). Later, Experience Corps volunteers, and not waitlist control participants, demonstrated improved working memory and executive functioning (see Rebok 2010). Although there were also social and physical gains, the improvements in episodic memory were marginal. The Senior Odyssey program, which encouraged complex problem solving in a

social, intellectual, and competitive context, seems to have led to gains in fluid reasoning and problem solving, but not in episodic memory, at least thus far (Stine-Morrow et al. 2014). More promising is evidence from the theateric arts intervention, described earlier, which showed clear episodic memory benefits, even though the overall focus was on acting rather than specific memory strategies (Noice and Noice 2011). Similarly, Park and colleagues (2014) found that involvement with everyday activities that have high cognitive demands (quilting and digital photography) led to episodic memory change that was not evident in more passive social activities or less demanding mental activities.

The evidence thus far suggests that an engagement-focused intervention may need to include particular kinds of cognitive activities in order to successfully enhance memory, but the exact nature of these cognitive activities remains to be clarified in future investigations.

Strategy Training: Individual Differences in Outcomes

The final issue to address is who benefits from training. Individual differences are person-level factors, such as age or baseline cognitive capacity, which may explain variance in the gains made by trainees. The current review focuses on cognitively intact older adults, who may have experienced normative aging-related memory loss but are free from dementia. However, diagnosis of dementia and level or stage of cognitive impairment are likely individual differences which influence one's ability to benefit from cognitive training. Cognitively impaired individuals may be able to profit from training, if to a lesser extent (e.g., for simple but not complex tasks) than healthy older adults (Zehnder et al. 2009). Further, specific mnemonics (e.g., spaced retrieval) or intervention techniques might be relatively more effective for certain populations (Berry et al. 2010).

Aligned with the idea of muted training gains for cognitively impaired individuals, some research evidence suggests a *Matthew effect*

(i.e., the rich get richer) for training benefit (Stine-Morrow et al. 2014). In the ACTIVE trial, gains immediately following training were greater for trainees with higher levels of education and better self-reported health (Rebok et al. 2013). However, other training programs demonstrated greater improvement for those who had the most to gain (i.e., individuals with lower baseline cognitive performance). For example, Experience Corps volunteers with impaired executive functioning at pretest demonstrated the greatest gains in memory and executive functioning following the program (Carlson et al. 2008). For the theateric arts training program developed by Noice and Noice (2011), training benefits were demonstrated across diverse populations with no indication that levels of independence, education, or income were a factor controlling the degree of benefit from training.

If there is a *Matthew effect* in cognitive training, it may be explained by a relationship between age and level of plasticity, wherein greater plasticity enables adults to benefit more broadly from the cognitive and social engagement provided in a training program (Stine-Morrow et al. 2014). However, evidence for this is mixed. Meta-analyses of memory training programs for older adults have shown mixed results for the relationship between participant age and training-related gains (Gross et al. 2012). Data from the ACTIVE trial suggested that age is negatively related to memory performance over time, but this effect was independent of training (Rebok et al. 2013). Additionally, younger ACTIVE trainees used more memory strategies at baseline, but age did not predict training-related changes in strategy use (Gross and Rebok 2011).

As an alternative explanation for training responsiveness, individual differences in motivation or other psychological factors may be important (Rebok 2010). For example, training gains from working memory capacity training were greater for individuals who were more engaged and implicitly motivated to train, rather than externally motivated by payment. Further, gains were larger for adults with a growth mindset (i.e., believing gains are possible with effort) than for adults who believed their level of intelligence was

fixed (Jaeggi et al. 2014). Higher levels of openness to new experience and larger social network size were positively related to gains in divergent thinking from an engagement-focused intervention where trainees worked in groups to solve ill-defined problems (Stine-Morrow et al. 2014). However, these factors did not explain the level of training-related gain for a traditional reasoning training group, which served as an active non-placebo control group. Therefore, the influence of different individual difference factors may interact with the specific intervention approach.

Realistically, the *interaction* between cognitive factors (e.g., initial cognitive capacity, degree of plasticity, and years of education) and motivational influences likely predict training gains, rather than any one factor acting alone. For example, in the ACTIVE trial, trainees who were adherent to the training protocols (e.g., attended all sessions) had significantly better baseline memory performance than those who were non-adherent (Rebok et al. 2013). In turn, these adherent trainees benefitted from memory training, whereas the non-adherent ones did not. Similarly, EMC trainees who were relatively more educated and healthy and had higher levels of memory self-efficacy were more likely to be actively engaged in training and more compliant with homework (see Rebok 2010). In turn, more compliant trainees demonstrated more profound recall and self-evaluative beliefs change than less involved trainees (see Berry et al. 2010).

Further explaining individual differences in training benefit, the relationship between baseline ability and training outcomes may be quadratic, rather than linear, whereby persons with either relatively higher or lower initial cognitive performance gain more from interventions than those functioning in the middle (Stine-Morrow et al. 2014). Thus, the impact of individual differences on training gain is not straightforward. Individual benefits from training are likely explained by complex interactions among those factors that affect performance and adherence to training regimens. Considering this evidence, it would be valuable to pursue additional research in this area, particularly studies focused on who is more likely to achieve long-term training benefits.

Conclusions

Memory is an integral process involved in many everyday experiences. Adults of all ages value their memory ability and fear memory loss (West and Strickland-Hughes 2015). Intact memory capacity is a prerequisite for older individuals' ability to live independently and perform other important activities (Berry et al. 2010; Schubert et al. 2014; Stine-Morrow and Basak 2011). Yet, the evidence is clear that declines in episodic encoding and retrieval are pervasive in both cross-sectional and longitudinal research (Berry et al. 2010). Because memory is valued by older adults, essential for independent living and at risk for decline, geropsychologists need to address the key memory concerns of older adults.

As evidenced by half a century of research, memory interventions are effective in enhancing the memory performance of healthy, older adults. Multiple meta-analyses confirm this benefit. Experimental paradigms for memory training programs vary greatly, and several different approaches have been successful. Programs which train multiple strategies seem to be more effective than those which train only one technique, and multifactorial programs may promote more lasting training benefits than traditional programs that train strategies only. Programs which encourage social interaction in group training or focus on beliefs or motivation may yield greater benefits.

Returning to older adult concerns about the practical impact of training, it is clear that training, strategy use, and memory practice can all lead to improvement. Thus, older individuals should be encouraged to practice those memory tasks that they want to improve and to learn more about strategic techniques that will enhance their skills. Whether achieved gains will be lasting likely depends upon the individuals' cognitive capacity and their continued motivated effort to work on everyday memory activities. As scholarship continues in this field, additional intervention-based research should further examine how to promote sustained gains from training, which conditions best lead to direct transfer and/or generalization, and how to maximize the gains of particular individuals during and after training.

Definition of Autobiographical Memory

It is where I meet myself, that I remember myself, everything I have done, the moment and the place where I have done it, the emotional state I have had at this moment.

Saint Augustine (354–403)
Les Confessions, Book X, section VIII,
 14, pp. 990–991

Autobiographical memory corresponds to the ability to mentally go back into the past and remember personal events. Within the human memory system, two main components have been distinguished: an *episodic* component and a *semantic* component (Tulving 1985; Fig. 1). To understand the effect of aging on autobiographical

memory, one has to appreciate the separate contributions of these two components on autobiographical memory.

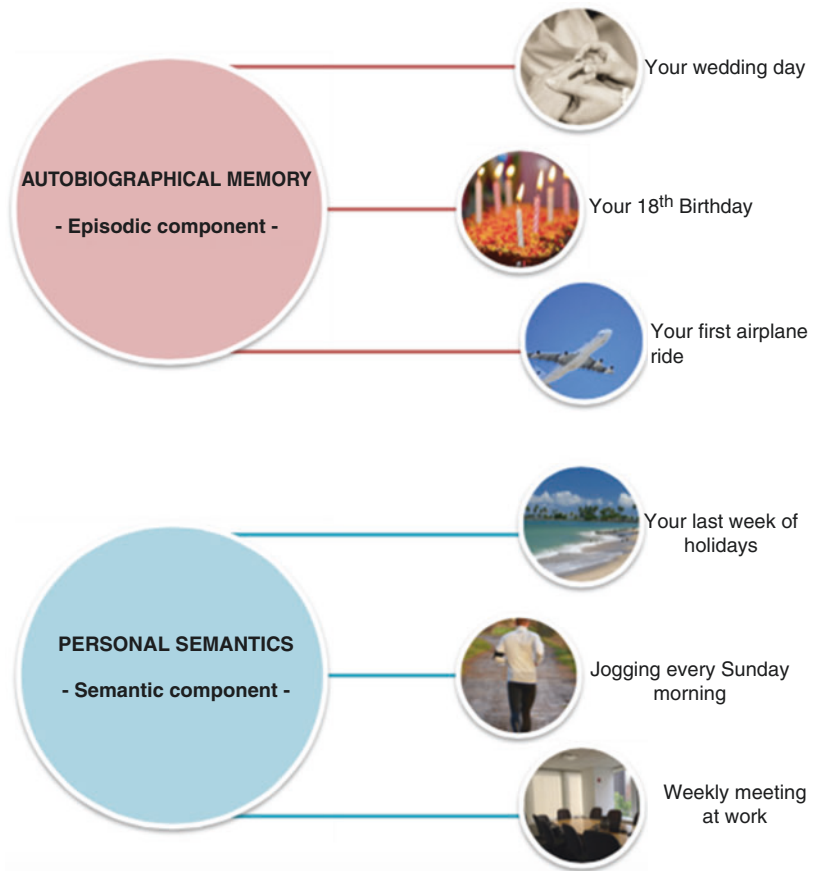

The episodic component corresponds to the ability to retrieve personal detailed events, within a specific spatiotemporal context, with a phenomenal experience of reliving the events as they are remembered. These specific episodes contain perceptual, affective, sensory, space, or time-related details. Conversely, the semantic component corresponds to factual information, such as the day of birth, the name of friends, or general and repeated personal events, such as “Friday nights after work at the Barbarians pub.” For these general and repeated events, a kind of “scaffolding” containing general information is retrieved, like where the events took place, with whom, etc. This relies on stored representations and knowledge not temporally bound to any one event. The differentiating feature of the episodic and semantic components is the level of consciousness associated with the retrieval of information. Specifically, the retrieval of personal episodic memories is associated with auto-noetic consciousness, the recollection of past experiences with the awareness of mentally reliving these events. The retrieval of personal semantics gives rise to noetic consciousness, which describes the retrieval of information without this sense of reliving.

From a theoretical standpoint, the Self-Memory System model (Conway 2005) offers a more nuanced view of autobiographical memory. This model also relies on the distinction between different memory subsystems hierarchically organized, going from life story themes (e.g., work theme, *while I worked in Bristol*) to episodic memories (e.g., *my visit to the Eiffel Tower*). A critical component of Conway’s model is the self, with a distinction between the conceptual self, that encompasses personal semantic representations and the working self, a dynamic system which regulates the encoding and retrieval of autobiographical memories which are relevant for current goals and activities. For the sake of clarity, and based on the theoretical framework used in most of the studies dealing with autobiographical memory and aging, this chapter will refer to Tulving’s

Memory,

Autobiographical,

memory model (Tulving 1985) and the distinction between episodic and semantic components.

Functional Roles and Benefits of Autobiographical Memory

Approximately one third of a waking day is devoted to the generation of self-oriented thoughts, including the recollection of personal memories. This omnipresence is related to the functional roles and benefits that autobiographical memory takes on in everyday life. Three main functions have been attributed to autobiographical memory: (i) A *self*-function, where autobiographical memory participates in the construction of and the sense of continuity of the self and provides material to the emergence of self-concepts. In this context, autobiographical memory contributes to self-coherence but also to self-enhancement, that is, it provides a positive view of the self. (ii) A *social* function, whereby autobiographical

memories aid in the development of new relationships and the nurturing of existing ones. In particular, autobiographical memory enables people to keep memories about significant others, to exchange memories and facilitate social bonding, to elicit empathy or intimacy, or simply to inform people about us. (iii) A *directive* function, where the memories serve as a basis for guiding present and future behaviors, especially for specific past episodes.

As such, from a clinical standpoint, autobiographical memory is of particular importance in conditions where self-changes, self-preservation/enhancement, or self-regulation is required. Indeed a positive association between autobiographical memory performance and quality of life has been found. Conversely, in older adults, autobiographical memory decline could have a deleterious impact on personal identity and well-being (► [Aging and Quality of Life](#) by Chappell,

N. L., this volume; ► [Age, Self, and Identity: Structure, Stability, and Adaptive Function](#) by Lang, F. R., this volume; ► [Aging and Psychological Well-being](#) by Yeung, D., this volume). This underscores the importance of studying autobiographical memory in conditions where major life changes are expected, such as in normal and pathological aging.

Assessing Autobiographical Memory

Various methodologies have been developed to assess autobiographical memory, with differences in terms of tasks, instructions, and scoring procedure. Typically, participants are asked to provide personal events and/or information from their past that happened in particular time frames. In older adults, two methods have been commonly used: the cue-word method (Crovitz and Schiffman 1974) and autobiographical questionnaires.

The cue-word method consists of recalling personal memories elicited by a frequently occurring and imageable word (e.g., car, flower, cat). Participants are asked to recall the first specific event that comes to their mind in relation with the cue-word and date it. Additional instructions are generally given if a nonspecific (i.e., non-episodic) event is provided or if the researcher or clinician is interested in memories from a certain time point. Depending on the focus of the study, varying scoring procedures and methods of analysis have been used: the temporal distribution of memories across lifespan, the ease at which they come to mind and are generated (autobiographical fluency) or their specificity and episodic richness (rated in general on 3-point or 5-point scales, ranging from the absence of memory, generic or repeated events to episodic events).

Several autobiographical questionnaires have been developed in the last decades. The most frequently used in the literature is the Autobiographical Memory Interview (AMI; Kopelman et al. 1989) which encompasses a semantic and an episodic section covering the lifespan. The semantic part tackles semantic facts such as the names of friends and postal addresses from different life periods. These are scored according to the precision of the information. The episodic part

typically consists of the retrieval of personal memories cued by theme such as “your first memory,” scored following their degree of episodicity on a 3-point scale.

To circumvent some methodological issues raised by these two techniques, such as the low sensitivity of the scoring procedure, or an unmatched scoring system for semantic and episodic components, the Autobiographical Interview (Levine et al. 2002) has been developed and widely used in recent studies conducted in healthy and pathological aging. In this, participants are asked to retrieve specific personal events from different lifetime periods and to provide freely as much details as possible about the event. Thus, episodic and semantic details are simultaneously collected, reproducing everyday autobiographical recall for which episodic and semantic components work in tandem. These details are then quantified and classified according to a standardized scoring procedure distinguishing different types of details (e.g., perceptual, emotional, semantic details) but with a matched procedure for episodic and semantic information. This procedure is particularly useful to measure episodic and semantic performance based on a single autobiographical memory and to explore how these two components could be differentially affected in clinical conditions.

Autobiographical Memory and the Brain

During the last decade, a large number of neuroimaging studies have been conducted in healthy participants to explore the functional underpinnings of autobiographical memory. The meta-analysis by Svoboda et al. (2006) proposes that the autobiographical memory network mainly engages left-lateralized and medial brain regions. The recollection of personal memory requires several steps and the involvement of a wide range of cognitive processes that give rise to a stream of cerebral activations within an extensive brain network.

Several brain regions have been identified as pertaining to the “core” and “secondary” autobiographical memory brain network (see Fig. 2). This brain network includes the lateral and medial prefrontal regions, the lateral and medial temporal

Memory,**Autobiographical,**

Fig. 2 Autobiographical memory brain network in healthy adults from the meta-analysis by Svoboda et al. (2006). Activations in the core and secondary autobiographical memory brain network are depicted, as well as infrequent brain activations. Brain activations across right (*left column*) and left (*right column*) hemispheres are illustrated (Reprinted from *Neuropsychologia*, 44, Eva Svoboda, Margaret C. McKinnon, Brian Levine, The functional neuroanatomy of autobiographical memory: A meta-analysis, 2189–2208, Copyright (2006), with permission from Elsevier)

regions, and also the posterior brain areas. In particular, the lateral prefrontal regions are involved in the strategic retrieval of memories, while the medial portion of the frontal lobe, together with the anterior cingulate gyrus, plays a central role in self-referential processes. Concerning the temporal lobe, the lateral region is mostly implicated in the semantic component of autobiographical memory. In addition, a key node of the autobiographical memory brain network is the medial temporal region, and especially the hippocampus, which is associated with the retrieval and binding of disparate details pertaining to a memory. Initial retrieval and

binding phases are followed by the creation of “mental film” of the memory that involves visual imagery processes, sustained by the posterior brain regions, including the retrosplenial cortex and the posterior cingulate gyrus.

Not surprisingly, considering this extensive brain network and the strong interconnections between the involved brain regions, autobiographical memory is particularly sensitive to structural brain changes and brain lesions. The high frequency of autobiographical memory impairment reported in the literature in various conditions has led to the view that damage in any of the key nodes of the autobiographical

memory network will compromise its functioning. This assumption brings us to the core of this chapter, that is, the discussion of the impact of normal and pathological aging on autobiographical memory.

The Impact of Aging on Autobiographical Memory Functioning

In the next sections, an overview of the findings obtained at both behavioral and neuroimaging levels will be given, first in the field of healthy aging and then in pathological aging, especially in dementia.

Healthy Aging

Behavioral Studies

Age-related changes have been described for decades in healthy older adults but with heterogeneous patterns of decline depending on the memory system (see for instance ► [Aging and Semantic Memory](#) by Laver, G., this volume; ► [Memory, Episodic](#) by Shing, Y. L., this volume; ► [Healthy aging](#) by Browning, C). It appears that episodic memory is particularly sensitive to the effect of age, while semantic memory is better preserved. However, this assumption has been mostly based on findings obtained with laboratory tasks, which possibly lack ecological validity and certainly do not represent the whole story with regards to autobiographical memory. An important characteristic of autobiographical memory that is not taken into account in classical laboratory tasks of memory function, such as recalling word lists or recognizing famous faces, is that autobiographical memories are the product of a combination of both personal episodic and semantic information. In this section, the impact of aging will be reviewed on both episodic and semantic components of autobiographical memory, by taking into account the influence of the methods used to address this question.

Overall, it has been posited that the decline of autobiographical memory becomes apparent after the age of 60 years and that older adults tend to produce fewer autobiographical memories than

younger adults. Early studies conducted on this topic hypothesized that autobiographical memory decline in older adults follows Ribot's law. Ribot's law assumes that older memories are better preserved than more recent memories. This view has been quickly challenged by studies reporting a reverse pattern, with a similar recency effect being observed in older and younger adults (a greater number of recent memories relative to older ones). Two other phenomena related to the temporal distribution and organization of memory appear to be preserved in older adults: (i) childhood amnesia, which is the inability to retrieve episodic memories from events that occurred before the age of 3–4 years and (ii) the reminiscence bump, which corresponds to the life period between 10 and 30 years that is associated with an increase in frequency of memory recollection. Taken together, these findings suggest that aging does not affect the relative pattern of temporal distribution of autobiographical memories across lifespan (Fig. 3).

The cue-word method has been widely used to explore the effect of age on autobiographical memory performance. A robust finding is that older adults tend to produce fewer autobiographical memories in general than younger adults, especially episodic personal memories. Autobiographical memory questionnaires have provided insights into the impact of aging on the separate episodic and semantic components of autobiographical memory. Early studies revealed a deleterious effect of aging on both semantic and episodic components, while more recent investigations have highlighted a particular decrease of the episodic score that is possibly compensated by an increase of semantic information.

A line of research also aims to explore the cognitive processes involved in autobiographical memory decline in older adults. In this vein, an association between episodic memory performance in laboratory tasks and the specificity of autobiographical memories has been found. A relationship between executive function and the specificity of memories has also been described in the literature. However, recent studies using the Autobiographical Interview have also highlighted the influence of more general

Memory, Autobiographical,

Fig. 3 Hypothetical curves of autobiographical memory performance across lifespan (episodic component) in healthy aging, Alzheimer's disease, behavioral variant frontotemporal dementia, and semantic dementia

factors on autobiographical memory performance, especially the increased number of semantic content in memories. These general factors include narrative abilities and style or communicative goals (e.g., emphasis on the general meaning and significance of personal events in older adults rather than on its content). Thus, differences between autobiographical memory in older and younger adults may not be wholly cognitive, based on episodic memory impairment.

Research dealing with autobiographical memory in older adults has also explored a particular type of memories named “flashbulb memories.” The distinctive feature of flashbulb memories is that they concern a public event (e.g., the World Trade Center attack in 2001) but with the encoding of the personal context in which people first heard about the event (e.g., I was in the car with my father, going to my grandparents and we heard the news on the radio). A personal significance is thus attributed to this event, with a particular vividness of the event as it is remembered, like a highly detailed and emotionally arousing “snapshot.” As a consequence, flashbulb memories are proposed to be more episodic in nature than autobiographical memories. Mixed results have been obtained regarding the impact of aging on flashbulb memory, with some studies showing a deficit in older adults while other studies reporting that older adults can retrieve flashbulb memories with a similar accuracy to younger adults. In the literature, these findings have been linked to emotional processes related to

memories. In particular, it has been found that emotions could attenuate the deleterious impact of aging on memory specificity.

A specific feature in aging is also the shift from negative information in memory toward more favoring and positive information in older adults (see ► [Emotional Development in Old Age](#) by Kunzman, U., this volume; ► [Positive Emotion Processing, Theoretical Perspectives](#) by Isaacowitz, D., Livingstone, K., this volume). This “positivity effect” (► [Age-Related Positivity Effect and Its Implications for Social and Health Gerontology](#) by Reed, A. E., et al., this volume) is one of the most consistent findings in the literature on autobiographical memory in older adults. Specifically, older adults provide a higher proportion of positive memories than younger adults, a phenomenon that has been explained by older adults’ tendency to reappraise negative memories in a more positive way or to rate emotionally negative events as neutral or positive. According to socioemotional theory (► [Socioemotional Selectivity Theory](#) by Castensen, L., this volume), this positivity effect could stem from changes in the life goals of older adults, with a shift from information acquisition and accurate recollection to an emphasis on emotion regulation.

It has also been demonstrated that memories related to the self or personal concerns are better preserved in healthy older adults. These memories, named self-defining memories, are vivid memories that bring forth strong and intense emotions and are related to other memories that are

Memory, Autobiographical, Table 1 Neural correlates of autobiographical memory impairment in healthy older adults, patients with Alzheimer's disease, behavioral variant frontotemporal, and semantic dementia

Brain regions	Healthy aging	Alzheimer's disease	Behavioral variant frontotemporal dementia	Semantic dementia
Prefrontal regions	++	++	++	++
Medial temporal regions	++	++	--	++
Lateral temporal regions	++	--	--	++
Posterior brain regions (precuneus, posterior cingulate, etc.)	++	++	--	--

++ Brain regions frequently involved in autobiographical memory changes, -- brain regions less frequently involved in autobiographical memory changes

connected to ongoing concern or unresolved conflict. This personal significance and the high frequency of rehearsal that characterized self-defining memories have been put forward to explain their relative preservation with aging.

In sum, age-related changes in autobiographical memory particularly affect the episodic specificity of retrieved personal events but relatively speaking spare the semantic content of such memories. Moreover, the temporal organization of memories across the lifespan appears comparable in younger and older adults. This raises the question of the potential functional cerebral changes that could be associated with these behavioral changes.

Neuroimaging Findings

The study of the neural mechanisms of autobiographical memory decline in older adults necessarily brings into question the neural changes typically associated with aging (► [Cognitive Neuroscience of Aging](#) by Gutchess, A., Paige, L., this volume; ► [Cognitive and Brain Plasticity in Old Age](#) by Li, S., Thurm, F., this volume). Healthy aging is defined here as the result of natural maturational processes in the brain. At the structural level, it is known that the volume of gray matter decreases with age, mostly in relation with lower synaptic densities in older adults. However, discrepancies have been observed in the distribution of these structural changes through the brain. The medial temporal lobe and the prefrontal cortex (especially the lateral portions) appear at the core of age-related changes, while the rest of the brain is relatively unaffected (Hedden and Gabrielli 2004). Structural changes also concern white matter tracts, whose integrity is mostly compromised in the

prefrontal regions, though a decline is observed in all brain regions. This is also accompanied by functional changes in the prefrontal and medial temporal regions, with the observation of both increased and decreased brain activity during the completion of cognitive tasks, in comparison with younger adults. In addition, reduced functional connectivity has been found in the default mode network (i.e., a set of brain regions that are activated in the context of no overt task assignment) in older adults. Most of the studies conducted in this field have interpreted this result as a decrease in the specificity of functional networks with age.

Studies focusing directly on the neural changes associated with autobiographical memory decline in older participants remain scarce. Using functional neuroimaging, it has been demonstrated that older adults mainly engage the same brain network as younger adults during the retrieval of autobiographical memories. However, some age-related subtleties have been observed (Table 1). In particular, relative to younger adults, fewer cerebral activations have been reported in brain regions sustaining the episodic richness of memories, whereas increased cerebral activations were shown in brain regions involved in semantic component. Particular functional changes have also been observed in the hippocampus and in prefrontal regions, which are the core structures of the autobiographical memory network. Neuroimaging studies show the recruitment of contralateral brain areas in healthy elderly participants in these core structures. It has been suggested that this bilateral recruitment is related to the reduced hemispheric asymmetry, or hemispheric specificity, associated with aging.

Overall, it appears that even in the absence of overt brain damage, the functional underpinnings of autobiographical memory are significantly modified in aging, and this is associated with changes at a behavioral level. Beyond the better understanding of cognitive age-related changes, this line of research also paves the way to research exploring autobiographical memory functioning in clinical conditions. The next section will thus mirror the current one, with the aim of giving a comparative view of the changes observed in the case of pathological aging.

Pathological Aging

Pathological aging is associated with nonnormative factors that affect the brain and are independent from modifications typically associated with healthy aging. Pathological aging is commonly associated with dementia (► [Dementia and Neurocognitive Disorders](#) by Krishnan, K., Smith, G.), which is defined as a group of symptoms affecting cognitive functioning, especially memory, with a significant interference with daily life functioning. Most of the dementia conditions are progressive, and different disease courses are observed, depending notably on the brain regions that are damaged. In this chapter, a particular attention will be paid to Alzheimer's disease, behavioral variant frontotemporal dementia, and semantic dementia, which have been the most widely explored in the field of autobiographical memory. Behavioral and neuroimaging findings will be discussed in turn in light of the changes observed in normal aging.

Behavioral Studies

Alzheimer's disease (► [Alzheimer's Disease, Advances in Clinical Diagnosis and Treatment](#) by Welsh-Bohmer, K.) is the most frequent type of dementia, and its deleterious impact on memory has contributed to the particular interest in autobiographical memory in this condition. Alzheimer's disease is characterized by a progressive loss of neurons (relative to healthy older adults), and in the early stages of the disease, this tends to affect disproportionately the medial

temporal lobe. Autobiographical memory impairment in Alzheimer's patients has been consistently reported across studies, even in the early stage of the disease. However, the heterogeneity of the disease course and severity between patients, as well as the varying methodologies used to examine autobiographical memory, have led to some discrepant results in the profile of alteration. Several studies using the method of cue words or autobiographical questionnaires have documented that autobiographical memory deficit in Alzheimer's disease follows Ribot's law, showing less accessibility of recent rather than older memories, whereas other studies revealed a flat gradient that is a similar degree of impairment for all lifetime periods. Research has demonstrated that Alzheimer's disease patients show a temporal distribution of memories, which is comparable to healthy older adults, with a preservation of the reminiscence bump, despite a general impairment in the ability to recall autobiographical memories (Fig. 3). The autobiographical memory impairment also extends to personal semantics, but a marked semantic deficit tends to be observed in the advanced stage of the disease, contrary to the episodic component, which is affected earlier on.

Turning to behavioral variant frontotemporal dementia (► [Frontotemporal Dementia \(FTD\)](#) by Hornberger, M.), this condition is characterized by a predominant deterioration of the medial prefrontal and the lateral temporal regions and is mainly associated with impairment in socio-emotional functions. While research in this field remains scarce, autobiographical memory impairment in the behavioral variant frontotemporal dementia has been consistently described as severe, affecting both episodic and semantic components. In this vein, a robust finding, independent of the testing method, is the flat gradient associated with autobiographical memory deficit in this condition (Fig. 3). This flat gradient corresponds to a consistent impairment irrespective of the lifetime period explored. This pattern of results has been observed for both episodic and semantic components, indicating a global autobiographical memory impairment. Recently, it has been suggested that autobiographical memory

dysfunction in behavioral variant frontotemporal dementia could be related to a more general self-reflective impairment, beyond the involvement of executive functions in memory retrieval difficulties, in association with frontal lobe degeneration (Irish et al. 2012).

Following frontal lobe damage, a particular phenomenon named “confabulation” has been observed in some patients. Confabulation corresponds to actions or verbal statements that are incoherent or implausible in light of patient’s personal history and situation. An important feature is that confabulation is unintentional and is generally observed in patients who are unaware of their memory impairment. For instance, a patient talks about an excellent dinner he had the day before in a restaurant in Paris while he is hospitalized for months in England. Confabulation has been associated with an executive deficit, especially retrieval strategy difficulties that compromise the research and verification of information in memory. As a consequence, automatic and associative processes take over to the more controlled processes and give rise to incongruous associations between information stored in memory. Confabulatory behavior has been observed in both patients with Alzheimer’s disease or behavioral variant frontotemporal dementia, especially in advanced stages of the disease.

Within the spectrum of frontotemporal dementia, semantic dementia (► [Semantic dementia](#) by Bott, N., Hantke, N., Samarina, V.) is a neurodegenerative disorder characterized by the progressive and amodal loss of semantic knowledge, in the context of a relative preservation of general cognitive abilities, including episodic memory. This condition is associated with a primary deterioration of the lateral temporal cortices, which extends from the anterior temporal fusiform gyrus, temporal pole, and anterior hippocampus to the amygdala. Few studies to date have explored autobiographical memory performance in patients with semantic dementia, and most of them have used questionnaires or the Autobiographical Interview. Autobiographical memory impairment in patients with semantic dementia shows a reverse temporal gradient, with better performance for recent than remote memories,

even if some studies also reported a flat temporal gradient in the more advanced stage of the disease (Fig. 3). This reverse temporal gradient observed for the episodic component likely reflects the occurrence of a semanticization process with the repeated rehearsal of episodic memories across time, which makes remote memories more vulnerable. In terms of cognitive mechanisms, it has been suggested that semantic dementia compromises the retrieval of the semantic scaffolding that contributes to the integration of episodic details into a coherent general context. While one would expect a particular impairment of the semantic component of autobiographical memory in semantic dementia, general personal knowledge is relatively preserved in most of the cases.

In a different line of research, but for which only few studies have been carried out, it seems that self-defining memories (i.e., memories strongly related to the self) are better preserved than the other types of personal memories in dementia, reproducing previous findings obtained in normal aging. However, some studies have also suggested that even self-defining memories are compromised in dementia, which could explain the weakened sense of self frequently reported in patients with dementia.

Taking a comparative view, it seems that patients with behavioral variant frontotemporal dementia show the most severe autobiographical memory impairment, followed by Alzheimer’s patients and finally patients with semantic dementia. Interestingly, the use of the Autobiographical Interview enables the distinction between different types of episodic details and provides a fine-grained view of the phenomenological properties of memories. This could be of particular interest to obtain a comprehensive picture of the pattern of memories’ deterioration in pathological aging and explore if some types of detail are more vulnerable than others, depending on the clinical condition. Although it appears that only one study has shed some light on this question (Irish et al. 2011), these findings are of importance to improve the understanding of the cognitive and neural mechanisms underlying autobiographical memory impairment in dementia. Irish et al. found that Alzheimer’s patients demonstrated lower

performance for episodic descriptions of happenings, actions, or people (event details), as well as emotional details. Patients with semantic dementia were particularly impaired for episodic details related to emotion/thoughts and spatiotemporal information. Finally, patients with behavioral variant frontotemporal dementia showed impairments on all categories of detail, including the aforementioned categories plus perceptual details. This last finding brings support to the idea that patients with the behavioral variant frontotemporal dementia are the most severely impaired on autobiographical memory tasks.

Overall, it appears that these three types of dementia compromise autobiographical memory functioning but with distinct clinical features that stem from different neural correlates that will be the focus of the next section.

Neuroimaging Studies

Alzheimer's disease, behavioral variant frontotemporal dementia, and semantic dementia are characterized by different patterns of brain atrophy and disease progression. Different key nodes of the autobiographical memory network are thus affected, leading to specific structural and functional correlates of autobiographical memory deficit in each condition (Table 1).

The neural signature of autobiographical memory impairment in Alzheimer's disease has been explored by means of different neuroimaging techniques. At the structural level, it appears that autobiographical memory performance mostly correlates with brain atrophy in the bilateral medial temporal regions, the bilateral prefrontal regions, and the posterior brain regions, such as the precuneus and the posterior cingulate cortex. Functional cerebral changes have also been reported in the same brain areas, with increased brain activations associated with autobiographical memory deficit in Alzheimer's patients.

In contrast, the autobiographical memory deficit in semantic dementia is mostly related to brain atrophy in the lateral temporal regions, even if some medial temporal structures such as the hippocampus play a particular role in the expression of the deficit. The volume of medial

and lateral prefrontal regions seems also to have an impact on autobiographical memory performance. The reduced volume observed in these brain regions has been associated with upregulated brain activity in patients with semantic dementia. In the case of behavioral variant frontotemporal dementia, the atrophy in the medial prefrontal regions has been identified as the main predictor of autobiographical memory impairment.

Taken together, these findings confirm that a specific neural signature is associated with each profile, with an apparent overlap between structural and functional correlates. However, it is important to note that this kind of investigations remain at a relatively early stage and further studies are necessary to tackle all the changes that could be associated with autobiographical memory decline in dementia.

Autobiographical Memory and Anticipating the Future

Over the past years, there has been growing interest in the ability to mentally project oneself into the future. In the field of healthy and pathological aging, this particular interest is probably related to the central roles that future thinking plays in daily life, such as emotion regulation, problem solving, or goal achievement, but also its association with well-being.

Future thinking is strongly related to autobiographical memory, in that autobiographical memory does not only enable the report of past episodes but also provides the constituent parts for the construction of future personal events. According to the constructive episodic simulation hypothesis (Schacter et al. 2007), past and future events rely on similar information stored in episodic memory, which are flexibly recombined into a novel coherent event, and thus involve similar cognitive processes and cerebral underpinnings to retrieval of the past. However, converging lines of evidence have underlined the higher cognitive and cerebral functional demands for imagining the future compared to remembering the past. In this

context, one could hypothesize that the autobiographical memory deficit would be accompanied by future thinking impairment, with a more severe impairment for future thinking.

Regarding healthy older adults, a clear deficit in future thinking has been consistently reported across studies, with a lower number of episodic details provided by older adults relative to younger adults. In addition to the reduced episodic richness of future simulations, older adults tend to look less far into the future. Importantly, future thinking changes are greater than the change observed for autobiographical memory.

This disproportionate disturbance of future thinking abilities relative to autobiographical memory performance has been replicated in every clinical condition studied to date, including patients with Alzheimer's disease, behavioral variant frontotemporal dementia, or semantic dementia. In every case, the amount of episodic details provided by patients with dementia is significantly lower than in healthy older adults. In contrast with autobiographical memory, for which different profiles and degree of impairment emerge, episodic future thinking performance appears severely and similarly compromised in these three clinical conditions.

Since aging confronts people with major changes in life goals, with social connection and emotion regulation becoming a priority, or with changes associated with the occurrence of a chronic disease, the combined study of autobiographical memory and future thinking is critical to obtain a comprehensive picture of the changes experienced by older people and patients with dementia in their daily life.

Conclusions and Future Directions

Normal and pathological aging have a clear deleterious impact on autobiographical memory functioning. Despite the different profiles of alteration discussed in this chapter, a consistent finding is that the episodic component of autobiographical memory is more sensitive to age-related changes than the semantic component. The cognitive

mechanisms involved in the expression of autobiographical memory impairment are variable. Depending on the etiology, episodic memory, executive functions, or semantic deficit has been suggested as being the main cognitive mechanism involved in autobiographical memory dysfunction. However, as noted in this chapter, the identification of distinct profiles of alteration could be challenged given the varying methodologies used across studies and also because of the progressive nature of dementia and the heterogeneity of disease course between patients.

The underlying brain regions are also differentially affected by normal and pathological aging. As mentioned at the beginning of the chapter, converging results obtained from different conditions support the idea that damage in any key nodes of the autobiographical memory brain network could interfere with autobiographical memory functioning, which makes autobiographical memory particularly sensitive to brain damage.

A recent line of research also aimed to extend the findings of autobiographical memory deficit to future thinking impairment in both normal and pathological aging. This new set of findings significantly contributes to the better understanding of age-related changes faced by older adults in their daily life. From a clinical standpoint, this body of research provides promising avenues to improve the care of people with dementia. In this context, a few studies attempted to improve autobiographical memory in patients suffering from dementia, but only mild improvement has been obtained to date. In contrast, no study has explored the possibility of improving future thinking performance, neither in healthy older adults nor in patients with dementia. Considering the central roles of autobiographical memory and future thinking in everyday life, a priority is further studies that have the potential to promote long-life health and quality of life in older people. In this vein, a topical research interest would be to examine more specifically memories that are particularly relevant to the self, which support personal identity and the sense of continuity across time (► [Self-Theories of the Aging Person](#) by Diehl, M. et al., this volume).

Memory, Episodic

Yee Lee Shing

Center for Lifespan Psychology, Max Planck Institute for Human Development, Berlin, Germany

Synonyms

Declarative memory; Explicit memory; Long-term memory

Definition

Episodic memory refers to memory about events that are bound to particular times and places in the past. It is a type of long-term memory containing information from the past (ranging from minutes to decades ago) that can be recalled explicitly (hence also called explicit or declarative memory). A core part of our identity is rooted in the ability to mentally travel back in time and reexperience past events. For example, to remember what happened on your last birthday is episodic memory.

Episodic remembering is a conscious retrieval process, such that an individual attempts to reconstruct the past personal experience. It can be accompanied by specific contextual details of the episode, generally referred as recollection, or only based on the feeling of remembering without recovering specific details, generally referred as familiarity. While most of the time retrieval of past experience can be achieved reliably, the adaptive nature of the human memory system also renders itself prone to errors and distortions.

Introduction

Most people associate aging with declines in episodic memory. Older adults more often complain

about experiencing memory difficulties, such as learning new information or recalling the name of a familiar face. Empirical evidence lends some support to this common conception. Cross-sectional studies, which involve a study sample consisting of individuals of different chronological age, suggest that individuals who are older show lower memory performance than those who are younger (Kausler 1994). Linear deterioration in episodic memory performance begins as early as in the 20s. Longitudinal and cohort-sequential studies in adulthood, which follow one or a few groups of individuals repeatedly across years, also show that episodic memory declines across time in old age. However, an important divergence in finding emerged such that episodic memory performance seems to remain relatively stable until about 60–65 years of age, after which accelerating decline is observed (Nyberget al. 2012). One source of discrepancy in estimating the onset of decline may be because cross-sectional estimates of age-related difference are potentially biased by cohort effects, with later generations showing higher educational attainment and better memory performance. In any case, it is fair to say that the decline in episodic memory is reliably observed in old age (particularly after age 60) and is steeper than semantic memory, namely declarative information about the world, culture, and one's own environment. This is the case even in individuals who are healthy and show no signs of dementing illness. A number of studies have examined cognitive decline in relation to proximity to death in older individuals (i.e., terminal decline). Accelerated decline in episodic memory has been identified as early as 8.4 years prior to death, with a rate twice that observed as a function of chronological age. At the same time, the structure, function, and neurochemistry of brain circuitries supporting episodic memory also undergo profound reorganization in old age (Buckner 2004). Due to the increased availability of brain-imaging technology, one of the current focuses in the aging research fields is to better understand the links

and dependencies between cognitive and neural changes during late life.

Differential Age-Related Differences in Memory Processes

There are a number of important qualifications to the mean declining trend in episodic memory. The extent of episodic memory decline varies with the type of memory processes entailed. In the laboratory, episodic memory is typically studied by presenting the participants with some to-be-remembered information (e.g., encoding a list of scene pictures or word pairs). After a retention interval (ranging from minutes, days, to weeks), participants' memory on the information is tested or retrieved. One commonly used test format is recognition, in which studied and non-studied items are presented and participants' task is to say "old" to the studied items and "new" to the non-studied items. Another commonly used test format is cued recall or recall, in which participants have to search through their memory actively (or based on a retrieval cue) to remember the studied items, monitor the retrieved information, and judge whether it is the appropriate target given the current retrieval context.

Different aspects of memory performance are disproportionately affected by aging. In general, the extent of age differences in episodic memory depends on the amount of self-initiated processing required by the task. According to Craik (1983), older adults' memory performance is particularly impaired when retrieval depends on self-guided cues and active control processes. This is due to age-related depletion of attentional resources of the mind. On the other end of the continuum, with more task-appropriate cue from the environment, age-related deficits should be reduced (cf. Lindenberger and Mayr 2014). Empirical support for these propositions can be found in the literature. For example, older adults are less effective than younger adults in using memory strategies to aid remembrance. Age differences tend to

be smaller by increasing schematic support afforded by the study material. When memory tasks involve naturalistic information where participants can make use of prior knowledge, age-related differences can be reduced or eliminated. Examples for this include studying grocery items with price information at market value or word pairs comprising words semantically related to each other. The same phenomenon is found for retrieval from episodic memory. Processing demands at retrieval are greater in recall than recognition due to the additional needs to search and monitor the retrieval process. In line with this, age differences found in recall tasks are typically larger than with recognition tasks.

In addition to the central aspects of information, episodic memory heavily involves the encoding and retrieval of contextual information surrounding the episode, such as the modality in which information was presented or spatial location of items. It has been shown that memory for content shows smaller age-related decrease than memory for context (Spencer and Raz 1995). The magnitude of age differences in context memory depends on the relevance of the context to the targeted content. In a more general form of the content-context distinction, Chalfonte and Johnson (1996) proposed that older adults have difficulties binding pieces of information into complex memories. Later on, this was formulated as the associative deficit hypothesis, which postulates that older adults' problems in episodic memory are due to their difficulties in creating and retrieving intra- and inter-item associations. Empirical evidence has been gathered for this hypothesis, indicating a larger effect of age on memory for associative than for item information (Old and Naveh-Benjamin 2008). This was found in memory for source, context, temporal order, spatial location, and item pairings, in both verbal and nonverbal material, and particularly under intentional learning instructions. Additionally, age-related deficits in associative memory, particularly when measured with recognition, are due to higher false-alarm rate in wrongly endorsing rearranged information as original studied material (Shing et al. 2010).

One explanation for such a pattern of results is based on the dual process account of recognition memory (Yonelinas 2002). It is suggested that memory for past events can be based on retrieval accompanied by specific contextual details, that is, recollection, or on the feeling that an event is old without recovering specific details, i.e., familiarity. It is shown that recollection of particular contextual details is more strongly affected by senescent changes than familiarity-based processing (Light et al. 2000). Older adults are also more susceptible to familiarity-based memory illusions, such as ironic effects of repetition, in which repeated lures (unstudied information) during a recognition memory test are mistaken for word originally presented during encoding. Taken together, older adults show a stronger reliance on familiarity feeling during recognition, leading them to be more readily to falsely endorse information that appears familiar without engaging in careful verification through cognitive control.

False Memories in Aging

In older adults, the reduction in memory for context, and the increased reliance on general familiarity, makes them particularly vulnerable for committing false memory (Schacter et al. 1997; Jacoby and Rhodes 2006). It has been shown that older adults, in addition to worse veridical memory, exhibit higher tendency to falsely remember things that in fact did not take place in the past. False memory is commonly studied using the Deese-Roediger-McDermott paradigm. Here, participants study a list of words in which some of them are related to a common theme (e.g., pillow, dream, and rest are related to sleep). Older adults show a more pronounced increase than younger adults in the erroneous endorsing or recall of critical lures (i.e., sleep) after studying the semantically related items in the encoding list. Furthermore, manipulations that reduce false memories in younger adults, such as providing more encoding opportunities or warning about the semantic lures, are only partially effective in older adults. For example, after several repeated

study-test trials in which the same lists were presented, only younger but not older adults showed a decrease in recalling non-presented semantic lures. This showed that older adults have difficulties in building up veridical representations of the actually studied items. At the same time, as both studied and non-studied semantic lures become more familiar across repetitions, older adults are less able to control their decision against the increasing strength of familiarity signals. Research also shows that older adults have difficulties in remembering the source of information, such as whether an event was suggested or perceived, who presented the information, or if the participant asked for, answered, or listened to certain information. Furthermore, older adults' subjective experience of memory (in the form of self-reported confidence judgment) is less well calibrated to their actual level of accuracy. In some cases older adults have been found to be falsely confident about the accuracy of their recognition memory (Shing et al. 2010). This renders older adults more susceptible to falsely endorsing misleading information (the misinformation effect) and scams in real life.

Interindividual Difference in Memory Aging

Despite the general mean trend of memory decline, there are vast amounts of interindividual differences in both level and change of memory performance in late life. This suggests that while some individuals experience massive deterioration in memory functioning, other high-performing individuals display little or no performance decline in memory (Nyberg et al. 2012). These interindividual differences in change of memory increase as a function of advancing adult age.

Basic cognitive resources including perceptual speed, working memory, and inhibition are reported to be important predictors of interindividual differences in memory performance. This was commonly studied by correlational methods testing for mediation, such that the resource factors are

measured independently and their roles in accounting for cross-sectional age-related variance in memory performance are determined statistically. Skepticism is warranted against such approach as it is limited in its ability to explicate within-person longitudinal changes accurately (Lindenberger et al. 2011). To understand interindividual differences in level and change of memory functioning, researchers need to rely on longitudinal investigations of memory development within individuals.

Factors related to lifetime exposures such as educational attainment, socioeconomic status, and occupation have been considered as moderators of the age-memory relationship. This line of work is related to the notion of cognitive reserve, which postulates that cognitive processes are crucial for explaining the differences between someone who is functionally impaired and someone who is not, despite equal brain changes or pathology (Barulli and Stern 2013). These cognitive processes reflect differences in cognitive efficiency presumably shaped by life experiences. Empirically it is often estimated using proxy variables for lifetime exposures and cognitive activity, such as educational attainment. However, existing data suggests that education is associated with level of memory performance in old age, but not with interindividual differences in change, likely reflecting people's differences in cognitive functioning accumulating since early life. On the other hand, data from longitudinal observational studies suggests that having an enriched lifestyle that is intellectually stimulating and physically active predicts better maintenance of cognitive skills and is associated with a reduced risk of developing Alzheimer's disease in late life (Hertzog et al. 2009). Having an occupation of higher complexity in life is related to higher cognitive performance, but this relationship is attenuated after retirement, suggesting that forming as well as maintaining a stimulating lifestyle is important for preserving cognitive functioning in late life (Nyberg et al. 2012). Note that caution is warranted given that causal directionality of the association between enriched experience and cognitive functioning in human is thus far difficult to disentangle.

Plasticity in Memory Aging

It is assumed that aging is not consisting of fixed trajectories but rather a range of possible functioning levels, which reflects person-specific constellations ranging from genetic profile to lifestyle preference. Given the observed memory decline in aging, this begs the question of to what extent (and in which condition) there is remaining memory plasticity in cognitively healthy older adults (Hertzog et al. 2009). Earlier memory training research focused on instructing older adults with memory strategy, as they are less able to spontaneously initiate adequate encoding strategies (Kausler 1994). Instruction and/or practice in a memory encoding technique, for example using imagery strategy, leads to robust performance improvements in healthy older adults. However, thus far the effects of strategy-based training seem to be relatively constrained to the memory task being trained and lack transfer to other cognitive domain or real-life application.

Reducing false memory in older adults can partly be achieved by training retrieval processes. After training in situations that entail facing high levels of interference and being provided by feedback, older adults can increase reliance on recollection and reduce misleading automatic influences of memory, such as the familiarity signal (Jacoby and Rhodes 2006). Such kinds of recollection training show transfer to other classes of memory tasks that are prone to proactive interference and require weighing of competing information.

Aerobic exercise as an intervention paradigm has better documented benefits in improving performance on cognitive tests, including episodic memory (Smith et al. 2010). It has been shown that aerobic exercise training in older adults increased the size of the anterior hippocampus, reversing the amount of loss by 1–2 years. The gain was also related to improvements in spatial memory. The neural mechanisms driving the positive effects of aerobic fitness on brain status and cognitive performance in humans are thus far not well understood. Evidence from animal studies suggests that these effects may be associated with neurogenesis in the hippocampus, and the

dentate gyrus in particular, due to changes in neurotransmitter and growth factor release (Kempermann 2008).

Aging Brain and Memory

In recent years, many studies have used magnetic resonance imaging to examine the neural correlates of episodic memory decline in aging. Age-related differences and in some cases longitudinal decline in the structural and functional integrity of the neural network supporting episodic memory, particularly the prefrontal cortex and medial-temporal lobe, are frequently observed. Prefrontal brain regions are among the areas that undergo the strongest atrophy in old age (Raz 2005). Gray matter changes are especially pronounced in the hippocampus and less so in the surrounding cortex in the medial-temporal lobe. Hippocampal atrophy is particularly visible in those individuals with hypertension, underscoring the importance of vascular health in aging.

Studies assessing age-related differences in functional activation have mostly used the subsequent memory paradigm, in which encoding activity related to subsequently remembered events is contrasted against activity related to subsequently forgotten ones. In a meta-analysis by Maillet and Rajah (2014), age-related decreases in subsequent memory effect in the occipital and fusiform cortex are observed. But older adults tend to over recruit in a set of regions including bilateral middle/superior frontal gyri, anterior medial frontal gyrus, precuneus, and left inferior parietal lobe, which are regions often involved in unsuccessful encoding in younger adults. The implication of this finding is yet to be understood but it underscores a shift in the way older adults encode new information.

Pathological Aging of Memory

Although memory decline is considered a part of normal aging, it can also be a leading indicator of brain pathology, such as dementia of the

Alzheimer's type. Alzheimer's disease is a progressive neurodegenerative disease characterized by loss of function and death of neurons in several brain areas. The medial-temporal cortex, particularly the entorhinal cortex, is vulnerable in the early stages of the disease, hallmarked by manifested deficits in episodic memory (Buckner 2004). It is the most common cause of dementia in pathological aging and symptoms advance to global compromise as the disease progresses, severely hampering life quality of patients and their caregivers. Considerable evidence suggests that individuals who will develop Alzheimer's disease exhibit cognitive deficits (including global cognitive ability, episodic memory, perceptual speed, and executive functioning) several years before a clinical diagnosis of dementia. Furthermore, pathology in the brain exists for at least a decade before clinical diagnosis of Alzheimer's disease is made (Gallagher and Koh 2011). From a clinical perspective, early identification of individuals at risk for developing Alzheimer's disease, combining genetic, biological, and cognitive markers, is imperative for maximizing effectiveness of interventions and is a research area currently under active investigation.

Synonyms

Remembering without awareness; Unconscious remembering

Definition

Among memory researchers it is quite common to conceive of human memory as a collection of different memory systems. For instance, broad agreement exists that working memory must be distinguished from long-term memory (see the chapters in “► [Memory, Autobiographical](#),” “► [Memory, Episodic](#),” “► [Memory, Procedural](#),” and “► [Prospective Memory, New Perspectives for Geropsychological Research](#)”) and that these two memory systems are functionally distinct: They differ in terms of features such as the quantity of information they can hold and the time-span within which information is lost if it is not used.

In contrast, implicit memory is not meant to denote a memory system. Rather, it is merely a descriptive term that represents a particular way of measuring memory – although, as will be discussed further on, certain empirical findings have caused some researchers to suggest that implicit memory represents a memory system

that is separable and functionally distinct from other forms of memory. In order to understand why many people find the implicit way of measuring memory so interesting that even an entry in this handbook was devoted to this topic, it is useful to contrast implicit memory with its counterpart: explicit memory.

A typical explicit memory test is a recognition test in which it has to be judged whether an entity such as a person, an event, or an object has been part of a well-defined past episode. For instance, eyewitnesses may have to judge whether people whose photographed faces are shown as cues in a photo lineup have been present at the crime scene. Free recall is another popular explicit memory test. Here persons have to name entities such as persons, events, or objects from a past episode without any memory cues. The reference to a well-defined learning episode is the defining criterion for an explicit memory test.

Implicit memory measurements, in contrast, lack this reference to a previous learning episode. Instead, aftereffects of prior exposure to entities are measured indirectly. For instance, the perception of an object under difficult viewing conditions is typically somewhat faster and less error prone if that object has been experienced prior to the identification task than if it has not (Buchner and Wippich 2000). As another example, objects that have been repeatedly encountered are often preferred over novel objects merely because of prior exposure (Kunst-Wilson and Zajonc 1980).

For many people it is even more interesting that this improvement in performance or a change in preference can be observed independently of whether the object is recognized or not. This is because, in everyday language, the act of recognition comes with the connotation of being experienced as subjectively conscious. Thus, and in terms of the examples used in the previous paragraph, the performance improvement or the change in preference for previously experienced objects can be observed in the absence of conscious recognition.

It seems reasonable to suspect that the idea of improving a person’s performance or of changing a person’s preferences without the person being aware of it is so fascinating per se that it explains a

substantial part of why the topic of implicit memory is so attractive. For instance, the advertising industry knows that consumers tend to devalue arguments contained in advertisements because consumers (usually correctly) suspect that advertisements are strongly biased in favor of the advantages of the promoted product or brand. Obviously, this form of devaluation depends on the fact that a person is aware of the source of the argument (in this case, the advertisement). However, if a person's preferences could be changed without the person being aware of it, then there would be no basis for such a devaluation. This would obviously open up new ways in which advertisers could try to affect consumer decisions. Indeed, it has been shown that people prefer brands to which they were previously exposed even when they do not remember that they were exposed to those brands (Shapiro and Krishnan 2001).

However, there is more to implicit memory than the mere fascination with the cognitive unconscious. First, and perhaps most obvious, implicit memory tests have greatly expanded, and continue to expand, the available toolbox of memory measures, allowing to assess contents of memory that would not be measurable otherwise and to gain insights into memory processes that would not be possible otherwise. Second, dissociations between implicit and explicit memory measures have been interpreted to show that these measures reflect distinct and functionally dissociable forms of memory systems. As will become clear further on, this interpretation is quite problematic and should be avoided.

Expanded Toolbox of Memory Measures

As Ebbinghaus (1885) has already argued, of all the previous experiences that leave traces in memory and affect current behavior, only a very limited part becomes consciously available and can be assessed with explicit memory measures such as recall and recognition. To overcome this limitation, Ebbinghaus invented the so-called savings method as a way to measure memory for previous experiences independent of whether these

experiences were consciously available or not. In this sense, the savings method can be regarded as the first implicit memory test. The savings method is best illustrated using one of Ebbinghaus' own extensive and heroic self-experiments. For instance, on day 1 of such an experiment, he memorized many long lists of nonsense syllables and noted how many learning trials he needed until he could reproduce each list perfectly. Using the same lists, he repeated the list learning on subsequent days. With every day, fewer relearning trials were needed until the criterion of perfect reproduction was reached. This reduction (or saving) in the number of relearning trials on subsequent days is a measure that represents memory for the nonsense syllables independent of whether those syllables were consciously accessible or not when relearning began on subsequent days.

Memory researchers have been very creative in inventing implicit memory tests as alternatives to the savings method. A whole class of such tests is based on the principle that information that has been processed recently can be accessed more easily than novel information, as a consequence of which the use of this information in a seemingly unrelated task is facilitated. For instance, in the word-stem completion task, participants' task is to complete word stems with the first word that comes to mind. Usually unbeknownst to the participants, some word stems can be completed with words that were encountered just prior to the word-stem completion task in an incidental learning situation in which words may have to be read on some pretext. Usually an attempt is made to conceal the relationship between the prior encounter and the subsequent test, for instance, by pretending that prior encounter and test belong to different experiments. Memory is measured in terms of the proportion of word stems completed with previously encountered words relative to a base-rate condition in which these words were not previously experienced. The same task has also been used with word fragments instead of word stems. Similarly, when category exemplars have to be generated or difficult knowledge questions have to be answered, previously encountered words have a higher probability of being named

as responses than words that have not been encountered previously (Buchner and Wippich 1998, 2000). In all of these measures, performance improves as a function of previous experiences. Therefore, implicit memory tests in which memory is expressed in performance measures (an increase in the number of word stems completed to words that correspond to previously encountered words, an increase of category exemplars named that correspond to previously encountered words, etc.) can be referred to as performance-based memory tests.

Such performance-oriented measures were used in a series of studies published in the 1960s and 1970s that are now considered game changing, but which have received significant attention in the scientific community only one to two decades after they had been published. In one of these studies, memory performance of amnesic patients and control persons was compared using memory measures such as recognition and word-stem completion scores (Warrington and Weiskrantz 1970). The difference between amnesic patients and control persons was large and statistically significant for the recognition measure, but was small and not significant for the word-stem completion measure. Thus, there was a difference in explicit but not in implicit memory between amnesic patients and control persons. Very similar results have also been obtained when younger and older participants were compared. A good example is a series of experiments conducted by Light and Singh (1987). They reported the rather typical result of large and statistically significant differences between younger and older participants with explicit memory measures such as recall and recognition, whereas only small and statistically nonsignificant differences were found using implicit memory measures. Thus, the finding of a memory deficit depends on the way in which memory is measured. With explicit memory measures that imply intentional retrieval processes, it appears that healthy young adults can retrieve more information than amnesic patients or older persons. In contrast, with implicit memory measures that presumably rely mostly on automatic memory processes, this retrieval advantage becomes smaller and sometimes appears

nonexistent. Such an interpretation fits with the assumption that younger adults are much more likely than older adults to store or to retrieve information about the context within which an object or event was experienced. Performance in explicit memory tests such as recognition or recall depends on the availability of context information (i.e., of knowledge about whether or not an object or event was presented in a certain prior episode). Thus, younger adults should outperform older adults in explicit, context-dependent memory tests. In contrast, implicit memory tests such as word-stem completion do not require any context information, thus allowing for equal performance of younger and older adults. Such a pattern of results has been obtained in a number of different studies. However, in general it appears that age-related differences in implicit memory tests are not zero; they are just smaller than age-related differences in explicit memory tests (Zacks et al. 2000).

The same pattern of results has also been obtained when a different class of implicit memory tests was used. These tests are referred to as illusion-based memory measures. A good example of an illusion-based implicit memory test is the fame judgment task that can be used to create the false fame illusion. In that task, participants first read names or see faces of people under some pretext in a study episode. At a later point in time, they are asked to judge whether persons whose names they read or faces they see are famous or not. The typical finding is that previously read names or seen faces are judged to belong to famous persons with a higher probability than new names or faces. This phenomenon was first reported by Neely and Payne (1983) but received little attention at the time. A few years later, Jacoby and colleagues (1989a, b) smartly named it the “false fame effect” and investigated it further. One rather interesting feature of the false fame illusion is that it is moderated by the temporal distance between the study episode and the fame judgment task. With only a few minutes between the study episode and the fame judgment task, participants can easily remember the context in which they had experienced a name or a face. As a consequence, they can correctly attribute the

familiarity of a previously experienced name or face to the study episode rather than to the to-be-judged fame of the person to which the name or face belongs. With a longer delay (e.g., 1 day) between the study episode and the fame judgment task, much of the information about the context in which the name or face was experienced is typically forgotten. That is, participants read a name or see a face, but they often cannot remember that they have seen that name or face the day before. However, previously experienced names or faces still appear more familiar than names or faces that were not experienced in the study episode. In the absence of context information, this increased familiarity is attributed to the current judgment dimension, that is, to the to-be-judged fame of the person, creating the false fame illusion.

Interestingly, when older participants perform a fame judgment task immediately after the study episode, they show basically the same pattern that younger adults show with a 1-day delay between study episode and fame judgment task (Dywan and Jacoby 1990). This is plausible if one assumes that older adults encode or remember less context information than younger adults. With less context information available even immediately after the study episode, older adults tend to attribute the increased familiarity of studied names or faces to the current judgment dimension, that is, to the to-be-judged fame of the person to which the name or face belongs. Note that this pattern of data obtained with an illusion-based implicit memory test nicely fits results obtained with performance-based implicit memory tests: Younger adults outperform older adults in explicit, context-dependent memory tests because younger adults encode or remember more context information than older adults. Implicit memory tests do not require any context information, thus allowing for equal performance of younger and older adults.

The difference between performance-based and illusion-based implicit memory tests is that measures derived from the former – more accurate or faster responses or both – reflect memory performance directly, whereas measures derived from illusion-based implicit memory tests reflect cases in which memory is used as a tool to solve other

judgment tasks. A great variety of such judgment tasks has been explored (Buchner and Brandt 2003). For instance, when spoken sentences are heard against a background of white noise, the noise appears less loud when presented together with a sentence that has been heard before than when presented together with a novel sentence. Presumably, the previously heard sentence is perceived more easily than a novel sentence, as a consequence of which the interference caused by the noise is judged to be lower which is then attributed to the noise being less loud. Similarly, previously experienced problems are judged to be easier than novel problems, presentation times are judged to be longer for previously experienced items than for novel items, previously seen objects are judged to be more aesthetically pleasing than novel objects even when these objects are presented subliminally, and previously heard responses to difficult questions or statements such as product claims are accepted as true with a higher probability than novel statements or responses. It appears a bit scary that the latter is the case even when product claims are unambiguously paired with the note saying that a particular claim is false: Repeated exposure to product claims labeled as false can increase people's judgment that these statements are actually true, and to make matters worse, this false-truth illusion is even more pronounced for older than for younger adults (Skurnik et al. 2005).

Explicit and Implicit Memory as Dissociable Forms of Memory Systems

In the “[Definition](#)” section above, it was pointed out that the term implicit memory is merely descriptive and only represents a particular way of measuring memory. However, dissociations such as those described in the previous paragraph – large age-related differences in explicit memory measures, small to no differences in implicit memory measures – have stimulated researchers to think about explicit and implicit memory as two forms of functionally distinct memory systems (Ward et al. 2013a): an explicit memory system which is impaired as a function of aging and an implicit memory system which is

spared from this impairment. Presumably, this change in theoretical focus has been supported by the fact that similar dissociations were reported for a variety of other comparisons such as those between patients with Alzheimer's disease and healthy older adults, between schizophrenia patients and healthy control persons, or between healthy elderly people who received glucose for peripheral ingestion and those who did not receive glucose (Buchner and Wippich 2000). However, it is more than questionable whether an interpretation of these dissociations in terms of two underlying memory systems is justified.

The main reason for this is a very simple methodological problem. It turns out that the measures derived from implicit memory tests typically have a much lower reliability than the measures derived from explicit memory tests (Buchner and Wippich 2000; Ward et al. 2013b; Buchner and Brandt 2003; LeBel and Paunonen 2011; Meier and Perrig 2000). In any given experiment, the probability of detecting differences between conditions is a function of the reliability of the measure used. In other words, differences such as those between older and younger people are more likely to be detected with the typically more reliable explicit memory measures than with the typically less reliable implicit memory measures (for details, see Buchner and Wippich 2000). Thus, the dissociations between explicit and implicit memory measures reported in the literature may simply reflect the differences in the reliability of the tests that were used rather than differences in underlying memory systems. What is more, Ward et al. (2013a) have recently shown that a single-system memory model can fit typical dissociation data even better than a multiple-system memory model. Thus, it is neither necessary nor justified to conceive of explicit and implicit memory in terms of functionally distinct memory systems.

Conclusions

Measures derived from implicit memory tests have greatly expanded the available toolbox of memory measures. Using these measures,

researchers can explore the characteristics of, and test theories about, human memory in ways that would not be possible otherwise. Illusion-based implicit memory measures may even be considered interesting and relevant per se: The fact that the supposed fame of a person or attractiveness of a brand increases in the absence of explicit memory for having encountered the name or brand is quite fascinating in its own right, with obvious real-world applications.

Another motivation for using implicit memory tests came from the assumption that explicit and implicit memories represent separate memory systems with different developmental trajectories. Specifically, a standard finding in aging research is that younger and older adults usually differ significantly in terms of measures derived from explicit memory tests, but hardly, if at all, in terms of measures derived from implicit memory tests. This dissociation has, in the past, been interpreted as reflecting an explicit memory system that suffers in old age, combined with an implicit memory system that is spared from age-related impairments. This interpretation is not justified. First, the dissociation is likely due to the fact that the reliability of measures derived from implicit memory tests is much lower than that derived from explicit memory tests. Second, it has been shown that a single-system memory model fits such dissociation data even better than a multiple-system model.

It is thus best to use the terms explicit memory and implicit memory in the way in which they have been originally conceived, that is, as descriptive terms for situations in which memory is tested either with reference to a particular study episode (explicit) or without such a reference (implicit).

Synonyms

Non-declarative memory; Procedural learning

Definition

The procedural memory system encompasses the retrieval and the execution of integrated skills, habits, and other procedures such as walking, writing, or riding a bicycle. The procedures are retrieved and performed mostly below the level of conscious awareness and therefore without the need of attentional control. As such the procedural memory is a type of “implicit” memory. It is a memory of “how to do things” and is formed through procedural learning, i.e., repeating an activity over and over again until it is executed automatically. The procedural memory is differentiated from the declarative memory, from the memory of conscious knowledge of facts and events (Schacter and Tulving 1994; Squire and Zola 1996). Together with the declarative memory, the procedural memory forms the long-term memory system.

From a historical perspective, the difference between procedural and declarative memory systems has already been described in the nineteenth century (James 1890). A seminal contribution regarding the experimental evidence for dissociation between procedural and declarative memory is from Milner (1962). She examined a former epilepsy patient, known as patient H.M., who underwent a bilateral medial temporal lobe resection and then suffered from amnesia, i.e., from severe memory impairments. Milner showed that H.M. was nevertheless able to learn and retain a

visuomotor drawing skill, but without explicitly remembering having practiced the task before. Subsequently, there has been extensive research using amnesic patients with brain damages differing in location and degree. Findings showed that amnesic patients, i.e., patients with severely damaged declarative memory, were able to learn and retain a broad spectrum of skills. Thus, the procedural memory system has a distinct underlying neuronal structure from the declarative memory system (Squire 1992).

Today, the underlying neuronal structures of the procedural memory system are well investigated: mainly subcortical regions are involved in procedural memory tasks, in particular the cerebellum and the basal ganglia. The basal ganglia consist of functionally different components whereof the striatum is the most important one for the procedural memory system. Both the striatum and the cerebellum have many interconnections to cortical areas such as to the frontal, parietal, and superior temporal cortex and to the hippocampus (Packard and Knowlton 2002). The subcortical regions are associated with different phases of procedural learning: The cortico-cerebellar and the cortico-striatal system are involved in early phases of motor learning where movements need to be adjusted. The cortico-striatal system stays involved in later phases where the task is executed automatically and consolidation and long-term retention takes place (King et al. 2013).

Age-Related Changes in Procedural Memory Performance

Age effects in procedural memory performance have been studied among individuals with specific skills, such as typists, musicians, or athletes. The main finding in age-related changes in procedural memory skills is the decreased speed of task execution in older adults. However, it is also found that older adults are able to compensate this deficiency using alternative strategies to execute the task. An example is documented in studies by Bosman (1993) and Salthouse (1984). According to their investigations, older typists were slower

than younger typists in tapping a single key. However, older typists were not slower in typing words compared to younger typists, suggesting that older typists were able to compensate for the age-related slowing by beginning to prepare the keystrokes farther in advance as compared to young typists. Furthermore, studies with musicians and athletes showed that age-related changes in procedural memory performance also reflect reduced levels of practice (Ericsson 2000). When older expert pianists maintained a high level of practice, their piano-related task performance was similar to the one of young expert pianists (Krampe and Ericsson 1996).

Studies relying on more experimental settings broadly confirm the results of decreased task execution speed in older adults. Laboratory tasks such as the pursuit rotor task or the serial reaction time task are considered most reliable measures of procedural memory learning. The rotor pursuit task involves learning a sequence of movements by following a moving object with a cursor. In the serial reaction time task, participants are asked to respond as quickly as possible to each stimulus of a series of stimuli which follow a random order or, unbeknown to them, a repeating order (Nissen and Bullemer 1987). Typically, participants become faster at responding to the repeated order than to the random order by practicing the tasks.

Findings from the serial reaction time task show that procedural memory learning and performance is mainly spared from age effects with the exception of the generally decreased speed of task execution. In a study comparing younger and older adults, although older adults showed slower reaction times and a slower learning rate, no age difference was found with regard to the total amount of serial reaction time task learning (Daselaar et al. 2003). The authors also observed similar brain network activations during the serial reaction time task in both age groups. Hence, age differences were found neither at behavioral level nor at brain level in procedural memory.

Further findings indicate that while the learning of simple procedural memory tasks is preserved with age, the learning of more complex procedural tasks is not (Howard and Howard 2012). A first important element triggering

age differences in procedural learning was the predictability of the stimulus. A sequence can either be probabilistic or deterministic; whereas the former describes learning about probabilities in series, the latter describes sequences where each trial is fully determined by the preceding trials. No age differences are reported in the latter, the deterministic serial reaction time task, while there were differences in the probabilistic task (Gaillard et al. 2009). The complexity of the sequence structure was another important factor that mediated age effects in procedural learning (Rieckmann and Bäckman 2009). Age differences increased when the information to be integrated increased from preceding trials, enabling predictions regarding the current trial. This evidence is supported by the finding that cortico-striatal networks subserving motor learning are affected by age although subcortical brain regions are known to show later and slower age-related decline than cortical regions. The fronto-striatal networks are associated with deficits in conditions of increasing task complexity (King et al. 2013).

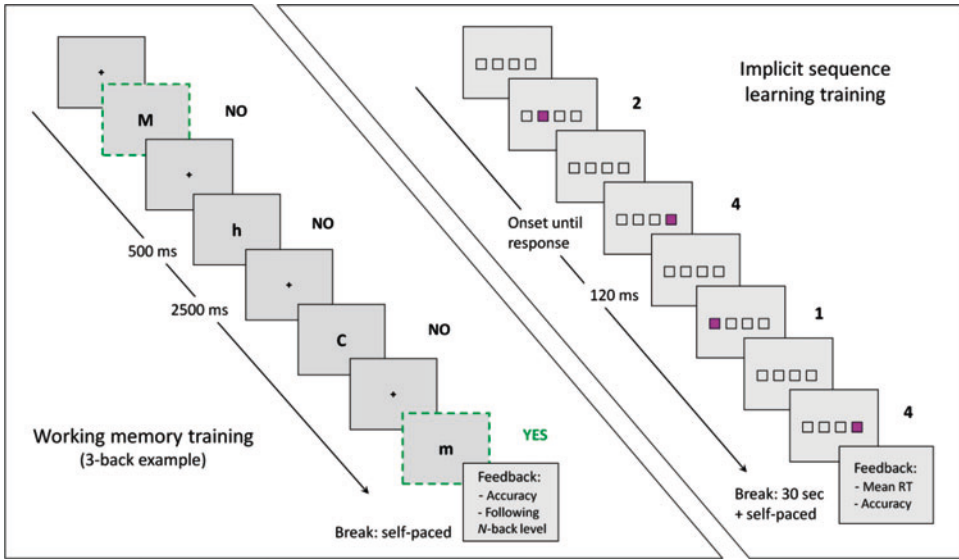

Testing the Limits of Procedural Memory

The literature overviewed in the previous section suggests that no age-related differences in procedural memory occur when tasks are simple. This is also true for extensive procedural memory practice where the participants train over several days and finally perform at their limits. There is still an age-related decrease in speed, but age differences are not increased when participants attain their limits of task performance. This is remarkable, as in the case of working memory, age differences in task performance are substantially increased after several days of practice.

An illustrative example of an extensive practice where the limits of procedural memory and working memory were compared is the following study (Bürki 2012; Bürki et al. 2014). A deterministic lower-order serial reaction time task was implemented in a training procedure over ten training days and compared to the learning curves of a classic working memory training procedure. A sample of younger ($n = 42$; aged

18–38 years) and older ($n = 42$; aged 61–81 years) adults was trained. The goal was to practice a task requiring as little attentional resources as possible as compared to the working memory training. The procedural training group served as an active control group for the working memory training group. The serial reaction time task consisted of four light grey squares presented horizontally aligned in the center of the screen (see Fig. 1, right panel). One stimulus consisted of one pink and three grey squares, each square changing color from grey to pink in turn. The participants were asked to respond as fast and as accurately as possible by pressing the key matching the position of the pink square. The stimuli were presented in a determined second-order sequence where one trial is determined by the two preceding trials. A sequence of 16 trials was presented which was repeated six times without interruption in one block resulting in 96 trials per block. The starting point in the sequence in each block was defined randomly in order to avoid explicit learning of the sequence. Between each block, a rest of a minimum of 30 s was demanded in order to relax the hand. At the same time, the participant received a feedback containing the mean reaction time and the percentage of the correct responses from the preceding block. Fifteen blocks per training session were provided and each session lasted around 20–30 min. The participants trained during ten sessions distributed over 2–4 weeks. For the working memory training, an adaptive verbal N -back task training was used. The task consisted in judging whether the current letter matches the letter N positions back in a sequence of letters presented one by one (see Fig. 1, left panel). The level of difficulty (N -level) was varied by adapting the load in each block to the participant's performance reached in the preceding block. Similar to the procedural memory training, 15 blocks per training session were provided and ten training sessions distributed over 2–4 weeks were performed.

The individual training curves are plotted in Figs. 2 and 3. The interindividual differences are quite large between and within age groups. It is striking that the interindividual differences are larger in the group of older adults in both training

Memory, Procedural, Fig. 1 Illustration of the training tasks. Working memory training (*left panel*): illustration of a 3-back example in the adaptive *N*-back task training.

Memory, Procedural, Fig. 2 Serial reaction time task training. Individual training curves of the averaged correct reaction time as a function of session, the *bold dashed lines* represent the mean of each age group

conditions. Results suggest that in the serial reaction time task training, younger and older adults decreased dramatically in reaction times over the ten training sessions. The age differences remained the same in training sessions one and ten (Fig. 2: note the similar size of the arrow at sessions 1 and 10). However, the analysis of the interaction of age group and training session revealed that younger adults reached the asymptote, i.e., no more reaction time improvement, earlier than older adults (see the increased size of

the arrow at session 5 compared to the arrows at sessions 1 and 10 in Fig. 2). Results of the working memory training revealed that similarly to the serial reaction time task training, younger and older adults increased in task performance and that age differences persisted over training sessions. Contrary to the serial reaction time task, however, the analysis of interaction age group and session shows that older adults attained the asymptote earlier than younger adults and that age differences were larger by the end of the

Memory, Procedural,
Fig. 3 Working memory training. Individual training curves of the averaged *N*-back level as a function of session, the *bold dashed lines* represent the mean of each age group

training compared to the first training session (Fig. 3: note the larger arrow at session 10 than at session 1).

The findings illustrate that the training curves in procedural memory tasks are different from the ones in a working memory task. In particular the age differences in the training curves are not the same between tasks and show that the total amount of learning between groups was similar for the serial reaction time task but not for the working memory task. As regards the asymptote, older adults reached it later in the serial reaction time task training and earlier in the working memory training than younger adults. Based on these results, it can be claimed that in simple procedural memory tasks, the learning rate is slowed down by age but the total amount of learning is preserved in older age, contrary to working memory tasks.

Gait Analysis in the Clinical Setting

Essential everyday skills such as walking are subject of research in the clinical geriatric setting. Gait is a highly automated procedural memory skill, and it is still in older age but to a reduced degree. However, older adults tend to fall more often and walking speed is decreased compared to younger adults. In their seminal study, Lundin-Olsson et al. (1997) found that some older adults stopped walking while answering a simple question. The authors showed that 80% of these older adults fell at least once in the following

6 months, while in the group of older adults who continued walking while talking fell much less. This documents the association of procedural memory, cognition, and fall risks.

In recent years, an electronic gait analysis was developed as a diagnostic tool for fall risk and cognitive impairments (Kressig and Beauchet 2004). Gait analysis measures the degree to which gait is no longer an automatic and purely procedural motor task and therefore requires attentional control. Importantly, gait analysis with walking as a single-task condition alone is often insufficient to reveal deficits. The use of a dual-task paradigm, walking while simultaneously performing a cognitive task, is required to assess the effects of divided attention on motor performance and gait control. When, for instance, a healthy older adult is asked to walk while simultaneously naming animals, walking speed is generally decreased and step-to-step variability is increased as compared to walking without performing an additional task (Springer et al. 2006).

A gait analysis is often employed by using an electronic walkway system which consists of a carpet of approximately ten meters. The carpet is equipped with sensors registering the spatial and temporal parameters of the entire gait pattern. A standardized gait analysis includes usually the assessment of first, a motor single tasks, i.e., walking at normal pace. Then, in order to assess the walking reserve, that is, the difference from the normal walking speed to faster and to slower

walking speed, the participant is asked to walk at a fast and then at a slow pace as compared to his normal pace. Subsequently, cognitive-motor dual tasks, such as walking at normal pace while naming animals or walking at normal pace while counting backward, are employed. Finally, the performance in the cognitive single tasks, that is, naming animals and counting backward while sitting, is assessed. Walking parameters such as gait speed and variability in step length and width are analyzed. The most sensitive marker of the gait analysis is the difference in gait parameters between the single normal walking task and a cognitive-motor dual task, the so-called dual-task costs. The larger the dual-task costs, the more severe the impairment. Larger changes in gait parameters than commonly observed in older adults are associated with mild cognitive impairment, Alzheimer's disease, Parkinson, or with increased falling risk (Bridenbaugh and Kressig 2015). Thus, alterations in procedural memory performance assessed with the cognitive-motor dual-task paradigm are very sensitive for detecting alterations in executive function and attention and provide important diagnostic information.

Explanations from the Lifespan Research Account

The finding that with advancing age procedural memory performance has an increased dependence on attentional resources can be set into the framework of the lifespan research account. In this framework, a generally observed pattern shows a decreasing correlation between different cognitive and sensorimotor variables from childhood to young adulthood and then an increase with advancing age. This phenomenon has been described in the differentiation-dedifferentiation hypothesis (Baltes et al. 1980). It says that the various cognitive, motor, and sensory abilities become more differentiated during child development until young adulthood and then again less differentiated and increasingly explainable by a single factor with advancing age. Observations from the large-scale Berlin Aging Study, for example, showed an increasingly stronger

connection between cognitive, perceptual, and motor variables with advancing older age (Baltes and Mayer 1999). The correlation between sensory and sensorimotor abilities such as vision, hearing, gait, balance, and cognitive abilities was much larger in old adults than in younger adults. The authors claim that there is a dedifferentiation with advancing adult age toward a general factor explaining a large amount of individual variance in brain performance.

Two explanations were proposed which are not mutually exclusive and explain the lifespan differentiation-dedifferentiation process from different perspectives. The first is called the common-cause hypothesis (Lindenberger and Baltes, 1994). The hypothesis suggests that a general neurobiological mechanism regulates the integrity of the brain across a wide range of regions and functional networks. This general mechanism affects all brain functions similarly and is more important during childhood, where the development is in progress, and becomes again more important during older age.

The second approach constitutes the aging-induced permeation of sensorimotor functioning with cognition, the so-called cognitive permeation (Lindenberger et al. 2000). The cognitive permeation hypothesis describes that, with advancing age, more cognitive resources have to be attributed to sensory and sensorimotor functions. In turn, fewer resources are available for intellectual tasks, as the already generally reduced resources in older adults have to be increasingly shared. So the resource overlap and competition between domains increases and compensatory resource allocation trade-offs become more frequent (Li and Lindenberger 2002). Therefore sensory and sensorimotor processes, including procedural memory tasks, are no longer fully automatically executed but require increased cognitive resources and turn into more attentional control demanding tasks in older age.

Conclusions

Overall, procedural memory performance is not as much affected by aging as compared to other memory functions such as working memory. In

simple laboratory tasks, although older adults perform slower than younger adults, there are no substantial age differences in procedural learning and memory. Experts in a particular skill are even able to compensate for the age-related decrease in speed by increased exercise or other strategies. There is nevertheless evidence for qualitative differences in procedural memory performance in more complex tasks, such as dual tasking. Older adults recruit more attentional resources to accomplish a complex procedural task than younger adults. Thus, the nature of task execution is changing and shifting from an implicit to an explicit memory task. This fact is used in clinical geriatric practice in order to detect deficits in attentional processes.

Future research should nevertheless examine the compensatory potential of procedural memory in older adults for deficits in other kinds of memory, since it is less affected by age. Recent research for instance showed the potential of relying on procedural memory to optimize learning of new technologies which may serve as compensatory tools (Bier et al. 2015).

function and higher vulnerability to death (López-Otín et al. 2013). While the United Nations considers a person above the age of 60 years to characterize an “older” or “elderly” person, high-income countries use the chronological age of 65 years as the reference point for older age. Aging is considered a primary risk factor for a number of major human pathologies, including cancer, diabetes, cardiovascular disorders, and neurodegenerative diseases (López-Otín et al. 2013). The process of aging can be characterized by three main features: (1) an exponential increase in mortality with age, (2) physiological changes which typically result in functional decline with advancing age, and (3) an increased susceptibility to age-related diseases.

Mental health is defined as “a state of well-being in which every individual realises his or her own potential, can cope with the normal stresses of life, can work productively and fruitfully, and is able to make a contribution to her or his community” (WHO 2014). It is considered to provide individuals with the vitality needed for active living, to achieve goals and interact with others. Mental health problems are characterized by cognitive, emotional, and behavioral disorders which interfere with the lives and productivity of a person. They can affect the ability of older adults to carry out basic activities of daily living, reducing their independence, autonomy, and quality of life and contributing to their isolation, loss of independence, loneliness, and psychological distress (de Mendoca Lima and Mintzer 2013).

Definition

Aging is the biological process of growing older. It is characterized by the progressive loss of physiological integrity, which leads to impaired

Aging and Mental Health

The World Health Organization (WHO) estimates that the number of adults above the age of 60 years will rise to over two billion people by 2050. Older adults are faced with a number of health challenges, which impact on their ability to live independently (e.g., limited mobility, frailty, physical or mental health problems) and may require long-term care. Social, demographic, physiological, and biological factors all affect the general and mental health status of an individual, especially in older age. Factors include changes to

socioeconomic status resulting from retirement, social isolation, loss of independence, loneliness, death of a spouse or partner, or loss of social networks as a result of decreased mobility, change in residence, or death and negative community attitudes and/or stigma toward aging and mental health issues (Yasamy et al. 2013). The concept of agism is commonly used to refer to stereotypes toward the active process of aging, in which older adults are considered to be frail, “past their sell-by date,” unable to work, physically weak, mentally slow, disabled, or helpless. Such age discrimination has a negative impact on individuals’ well-being (Yasamy et al. 2013).

While the majority of older adults maintain good mental and physical health in older age, approximately 20% experience mental or neurological disorders, including dementia, depression, anxiety, substance use, and self-harm (Yasamy et al. 2013). However, mental health problems in older adults are generally underidentified by both health-care professionals and older adults themselves, in part as a result of the stigma associated with mental health issues and the reluctance of older people to seek help due to this associated stigma (Yasamy et al. 2013). While a number of mental health issues are associated with old age, this entry focuses specifically on dementia and depression.

Dementia

Dementia is one of the most common mental health issues associated with old age. By 2050 it is estimated that over 115 million people worldwide will suffer from dementia. Dementia is a leading cause of disability and death in older adults above the age of 65 and has significant social and financial costs. Dementia is not a normal part of the aging process, and currently there is no cure.

Dementia is an umbrella term used to describe a wide range of symptoms linked to a decline in memory or thinking skills which impact on an individual’s ability to perform everyday activities. According to the *Diagnostic and Statistical Manual of Mental Disorders (DSM) fifth edition*,

dementia is split into major and mild neurocognitive disorders. *Major neurocognitive disorder* involves significant cognitive decline in memory, language, or learning that interferes with independence in activities of daily living. In contrast, *minor neurocognitive disorder* involves modest cognitive decline which does not interfere with activities of daily living, although greater effort is required to complete such activities. Different types of dementia exist, including Alzheimer’s disease, vascular dementia, dementia with Lewy bodies, Frontotemporal lobar degeneration, mixed dementia, and Parkinson’s disease dementia. Each type of dementia is characterized by distinctive symptoms and brain abnormalities.

Alzheimer’s Disease

Alzheimer’s disease is the most common type of dementia, accounting for up to 80% of cases. It is a progressive neurodegenerative disorder of the central nervous system, affecting cognitive function. The American Psychiatric Association defines Alzheimer’s disease as the development of multiple cognitive deficits manifested by memory impairments (in the ability to learn or recall information) and at least one cognitive disturbance, such as aphasia (language disturbance), apraxia (impaired motor activity), agnosia (recognition/identification failure of objects), and executive function disturbance (e.g., planning, judgment). Cognitive abilities are affected selectively and at different stages during the progression of Alzheimer’s disease (e.g., language remains intact for longer, while episodic memory is disrupted early on in the disease). The main cognitive deficit exhibited in Alzheimer’s disease is early failure of episodic memory and the later appearance of semantic memory dysfunction. Further cognitive deficits include attention, awareness (in particular to the impairment itself), and executive function (working memory), while significant impairments are also observed in social and occupational functioning.

The progression of Alzheimer’s disease is classically characterized by a gradual onset and continuous cognitive decline in which the extent of

cognitive loss varies between patients in terms of progression and severity. The early stages of Alzheimer's disease are characterized by progressive cognitive decline and classical clinical features (including amnesic memory impairment, language deterioration, and visuospatial deficits), while later stages are highlighted by motor and sensory abnormalities, gait disturbances, and seizures. Patients with Alzheimer's disease often display symptoms of anosognosia (unawareness of impairment to their memory or cognition) in early disease stages. Functional and behavioral disturbances also typify this disease, with functional impairments being observed in higher-level activities of daily living (e.g., eating, grooming, toileting) and behavioral changes (e.g., depression, anxiety, apathy) appearing in the early stages of the disease and progressing in later stages.

Depression

Depression is a further common mental health issue affecting older adults above the age of 65. It causes significant suffering and impairment to daily life functioning and is not a normal part of the aging process. Late-life depression (i.e., depression first experienced after the age of 60) is commonly associated with aging-related physical health problems. The WHO defines depression as a "common mental disorder, characterized by sadness, loss of interest or pleasure, feelings of guilt or low self-worth, disturbed sleep or appetite, feelings of tiredness, and poor concentration." Notably, the DSM-IV previously excluded a diagnosis of depression for people within 2 months of a bereavement. However this exclusion has been removed in the new DSM-V, recognizing that while grief and depression are distinct, they may also co-occur. The DSM-V classification seeks to clarify that it is normal to feel sadness and loss when grieving but that these feelings are not normal in everyday life and indicate a mental disorder that is treatable.

Depression is widely under-recognized, misdiagnosed, and under-reported in older adults. While global prevalence rates of major depressive disorders in community-dwelling older adults are

quite low (i.e., between 1% and 5%), the inclusion of subthreshold depressive symptoms significantly increases prevalence rates to approximately 12% and 15%, with a tendency to increase with age (Beekman et al. 2001). Notably, depression in older women is more common. Recurrence and persistence levels are also higher in older adults, with one in three older adults with depression developing chronic symptoms and chronic depression being particularly common in institutionalized older adults (Anstey et al. 2007). The presence of depression in older adults with intact cognition is considered a risk factor for cognitive impairment and dementia, eliciting clinical symptoms of cognitive decline and depleting cognitive resources.

The *vascular depression hypothesis* argues that cardiovascular risk factors affecting brain aging also play a key role in the etiology of late-life depression. Depression also occurs with higher frequency after stroke, and there is a bidirectional relationship between depression and cardiovascular disease. It is thought that vascular brain changes may underlie both late-onset depression and vascular cognitive impairment (Alexopoulos et al. 1997). However, a recent autopsy study found that depression in late life was not predictive of dementia-related neuropathology, even among those who developed dementia. The types of neuropathology examined included b-amyloid plaques and tau tangle density in multiple brain regions, neocortical Lewy bodies, hippocampal sclerosis, and gross and microscopic cerebral infarcts (Wilson et al. 2014).

Depression is also more prevalent among adults with eye disease such as macular degeneration and cataract but not necessarily with glaucoma (Eramudugolla et al. 2013). Research has shown that depression in later life is accompanied by cognitive changes such as slower processing speed. It has been difficult to disentangle whether cognitive deficits precede depressive symptoms or vice versa. Statistical modeling of longitudinal data has investigated the temporal associations between depression and cognitive slowing and shown that the best model is one where depressive symptoms precede cognitive slowing (Bielak et al. 2011).

Depression: A Risk Factor for Dementia

In addition to being part of the prodrome of dementia, depressive symptoms are also associated with an increased risk of developing late-life dementia (Barnes et al. 2012). In late life, depressive symptoms increase the risk of mortality, particularly for males (Anstey and Luszcz 2002; Burns et al. 2013). There is a small increase in depressive symptoms in very late life, though most of this increase is attributable to comorbid medical conditions (Burns et al. 2013).

Depression is often considered an initial symptom in Alzheimer's disease, appearing in mild to moderate stages and becoming less prevalent in advanced stages. It is a common neuropsychiatric occurrence in Alzheimer's disease but is considered an atypical form of depression, given motivational symptoms and delusions are experienced more frequently by Alzheimer's disease patients than those non-cognitively impaired. Depression in Alzheimer's disease is characterized by high frequencies of motivational disturbances, symptoms of social isolation, withdrawal, irritability, or emotional distress, and vegetative symptoms of diminished interest, psychomotor retardation, fatigue, hypersomnia, and lack of insight.

Alzheimer's disease-related depression contributes significantly toward impairments in quality of life, activities of daily living, and executive function, while no difference is observed for attention, language, memory, or visuospatial functions when compared to patients with no change in mood. It is associated with an increased likelihood of physical aggression, being discharged from an assisted living facility, earlier entry into a nursing home, higher mortality and suicide, and higher levels of carer depression and burden. Risk factors for depression in Alzheimer's disease include a family history of mood disorders (affective disorders) in first-degree relatives, prior personal depressive history, female gender, and younger age of Alzheimer's disease onset.

With the progression of Alzheimer's disease pathology, the expression of depressive symptoms changes and it becomes more difficult to diagnose. Symptoms of psychomotor slowing, emotional lability, crying spells, insomnia, weight

loss, inability to verbalize affective state, and pessimism are prevalent in both depressed and nondepressed Alzheimer's disease patients. The diagnosis of depression in older adults is further complicated by their tendency to deny the presence of depressed moods and instead report a lack of feeling or emotion, or loss of interest and pleasure in activities. Due to aphasia, many dementia patients lack the ability to express their distress coherently, further complicating the diagnosis and contributing to the under-recognition of late-life depression as a result of clinical and nosological ambiguities.

Behavioral and Psychological Symptoms of Dementia

Progressive cognitive decline and functional disturbances are typical clinical hallmarks of dementia. However, neuropsychiatric symptoms such as agitation, anxiety, irritability, illusion and delusions, apathy, depression, disinhibition, aberrant motor behaviors, and sleep disorders are intrinsic conditions associated with the neurodegenerative process of dementia (Stella et al. 2014). Such symptoms are commonly referred to as Behavioural and Psychological Symptoms of Dementia (BPSD) and form a major aspect of old-age mental health.

BPSD are defined by the International Psychogeriatric Association as "signs and symptoms of disturbed perception, thought content, mood or behaviour that frequently occur in patients with dementia" which may be prominent in some, but not all, phases of Alzheimer's disease – at times occurring prior to the onset of cognitive symptoms (i.e., either in early or late phases). They are a heterogeneous group of noncognitive symptoms which affect up to 90% of people with dementia. BPSD are associated with more functional disabilities, poorer prognosis, more distress, and medication misuse. Presence of BPSD causes a further loss of independence, linked to greater carer distress and burden, reduced quality of life for both the person with dementia and carers, breakdown of community care, earlier institutionalization, and long-term hospitalization. Symptoms can occur individually or in combination, and affect the

ability of people with dementia and their carers to perform everyday activities, thus reducing quality of life and increasing disease burden. While cognitive dysfunction in dementia (e.g., memory, attention, concentration, praxis) declines over time, BPSD symptoms fluctuate.

Mild Behavioral Impairment

Neuropsychiatric symptoms are beginning to be acknowledged as an intrinsic aspect of prodromal stages of dementia and as an early marker of dementia risk which precedes the onset of cognitive symptoms and clinical diagnosis. The concept of “Mild Behavioural Impairment” (MBI) has been proposed as a late-life transitional state between normal aging and dementia (i.e., prodromal stage of dementia), in which the presence of neuropsychiatric symptoms in the absence of cognitive symptoms (i.e., cognitively normal individuals) confers an increased risk of developing dementia (Ismail et al.). This concept has been proposed as a diagnostic construct aimed at identifying individuals at an increased risk of developing dementia who do not exhibit cognitive symptoms and which will enable earlier detection of incipient neurodegenerative illness (Ismail et al.).

MBI is hallmarked by changes in behavior or personality which start in late life (after the age of 50 years) and which persist, at least intermittently, for 6 months. These represent a clear change from the person’s usual behavior or personality and is evidenced by at least one of the following:

- Decreased motivation (e.g., apathy, asponaneity, indifference)
- Affective dysregulation (e.g., anxiety, dysphoria, changeability, euphoria, irritability)
- Impulse dyscontrol (e.g., agitation, disinhibition, gambling, obsessiveness, behavioral perseveration, stimulus bind)
- Social inappropriateness (e.g., lack of empathy, loss of insight, loss of social graces or tact, rigidity, exaggeration of previous personality traits)
- Abnormal perception or thought content (e.g., delusions, hallucinations)

To meet the operationalized criteria for MBI, the behaviors must be of sufficient severity to produce at least minimal impairment to either interpersonal relationships, other aspects of social functioning, or ability to perform in the workplace. Individuals with MBI generally maintain independence of function in daily life and require minimal aids or assistance.

According to the operationalized criteria for MBI, individuals may have comorbid conditions, however behavioral or personality changes may not be attributable to another current psychiatric disorder (e.g., generalized anxiety disorder, major depression, manic or psychotic disorders), traumatic or general medical causes, or the physiological effects of a substance or medication, nor may they meet clinical criteria for a dementia syndrome (e.g., Alzheimer’s disease, frontotemporal dementia, dementia with Lewy bodies, vascular dementia, other dementia) (Ismail et al.). However, Mild Cognitive Impairment (a prodromal stage of dementia) can be concurrently diagnosed with MBI (Ismail et al.).

Behavioral and psychiatric symptoms are universally present in people with dementia. Their presence in prodromal dementia (i.e., Mild Cognitive Impairment) is recognized as an indicator of increased risk of conversion to dementia. The concept of MBI recognizes another population at risk of developing dementia. Acceptance of the syndrome of MBI as a prodromal stage of dementia will have significant implications for improving early detection, prevention, and treatment of dementia by providing a better understanding of the very early consequences of neurodegenerative disease.

Conclusion

A number of factors can affect the mental health of a person. Cognitive, emotional, and behavioral factors are particularly pertinent in affecting mental health in old age. Early identification and treatment of risk factors is vital in order to improve well-being and reduce the prevalence of mental health issues in old age.

Metacognition in Older Adulthood

Sarah (Uma) K. Tauber and Amber E. Witherby
Department of Psychology, Texas Christian
University, Fort Worth, TX, USA

Synonyms

Aging; Control; Metamemory; Monitoring; Older adults

Metacognition can be broadly conceptualized as “thinking about thinking” (Flavell 1979). It is multifaceted and often considered with respect to memory processes – thinking about memory (for a review, see Dunlosky and Metcalfe 2009). For instance, *metacognitive knowledge* refers to a person’s knowledge about his/her own memory. *Metacognitive monitoring* involves assessments of the current status of learning or of retrieval from memory. Finally, *Metacognitive control* involves self-regulatory processes used during learning or retrieval from memory. To illustrate these concepts, consider an older adult (65+ years old) who tends to have more difficulty remembering the name of a newly introduced person compared with other information about that person such as a hobby or occupation. Perhaps this older adult believes that she usually has difficulty remembering names (metacognitive knowledge). Because of this belief, when she meets new people for the first time she makes assessments to

Metacognition in Older Adulthood,

Fig. 1 Metacognitive framework that includes monitoring and control processes (Adapted Nelson and Narens (1990) and taken from Dunlosky and Metcalfe (2009) With permission from John Wiley and Son)

determine whether she will remember their names in the future (metacognitive monitoring). Finally, if she determines that she has not yet learned someone's name, she may decide to spend time using effective strategies to aid in learning it (metacognitive control). Exploring how these metacognitive processes function with aging into adulthood is the primary focus of this entry.

Researchers have increasingly focused on metacognition and in particular on the function of metacognitive processes in older adulthood. The focus of this entry is on healthy aging, but see Ernst et al. (in press) for a review of how neurodegenerative disorders that occur with age, such as Alzheimer's disease, influence metacognition. The normal aging process is associated with decline in most (but not all) types of memory (Hultsch et al. 1992; Salthouse 2010). Even so, older adults (65+ years old) have lived longer than young adults (college-aged) and therefore have more life experiences. Such experiences may preserve metacognitive abilities even though older adults suffer from cognitive deficits. Intact metacognitive abilities could be valuable, because older adults may be able to capitalize on them to enhance actual memory. For instance, if older adults are aware that they generally have poorer episodic memory relative to young adults, then they can make appropriate adjustments (e.g., use more effective strategies like external aids) in an effort to improve their memory in the future. Thus, accurate metacognitive processes can help older adults improve their quality of life, simply because metacognition is intimately related to cognition and mutually they influence each other.

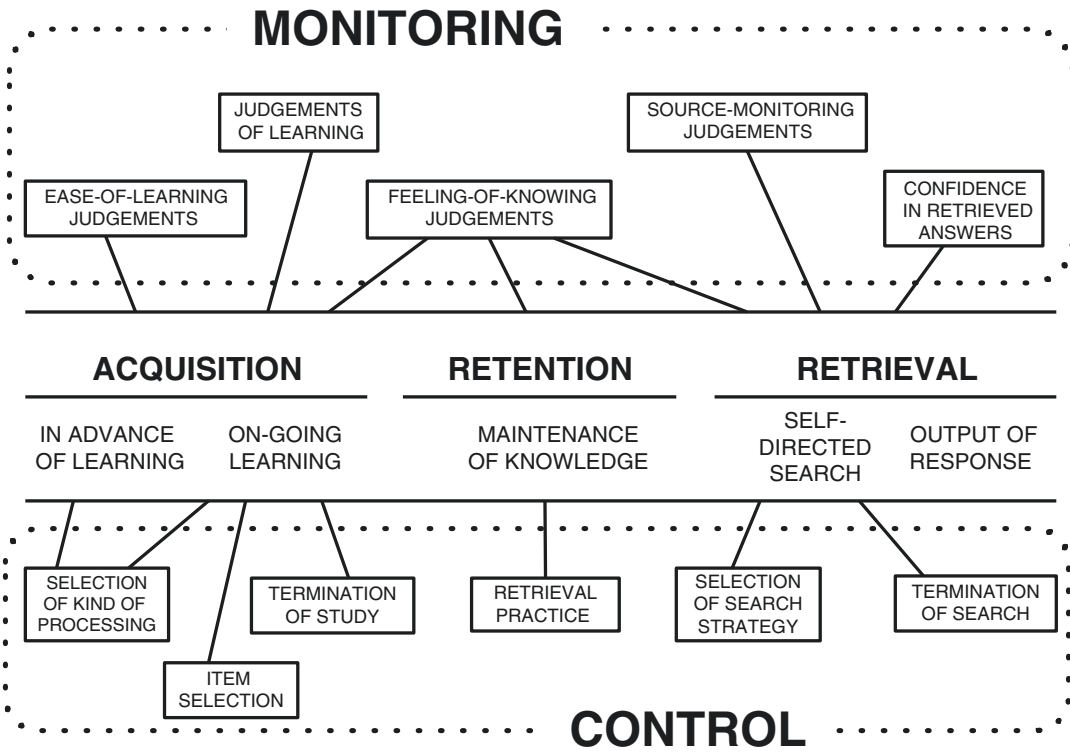

This interrelated nature between metacognition and cognition is illustrated by Nelson and

Narens's (1990) model (Fig. 1). In this model, cognition is represented in the object level and metacognition is represented in the meta level. Information flows from the object level to the meta level via monitoring, and it flows from the meta level back to the object level via control. Nelson and Narens (1990) used their model to produce a methodological framework of measures that can be used to evaluate monitoring and control. The framework (Fig. 2) includes measures of monitoring and control that are organized by the phases of learning: acquisition, retention, and retrieval. As is evident from this framework, several measures can be used to evaluate monitoring and control processes. In this entry, the focus is on the most commonly used measures to evaluate older adults' metacognitive monitoring (i.e., item-by-item judgments of learning and feelings-of-knowing, for reviews of how aging influences other measures, see Castel et al. in press) and of metacognitive control (i.e., item selection and self-paced study, for reviews of how aging influences other measures, see Hertzog in press). Next are discussions of older adults' metacognitive knowledge and of their monitoring and control.

Metacognitive Knowledge

Early metacognitive research focused on beliefs about one's cognition, the importance of which is explained well by Cohen and Faulkner (1984):

...It is important to know what elderly people *believe* about their own memories to find out whether particular aspects of memory are considered to be more affected by age, and what particular problems are encountered in everyday life. (p. 49, italics in original)

Metacognition in Older Adulthood, Fig. 2 Metacognitive framework organized by the phases of learning adapted from Nelson and Narens (1990) and taken from

Dunlosky et al. (2007b). Reprinted from *Psychology of Learning and Motivation*, Thomas O. Nelson, 125–173. Copyright (1990), with permission from Elsevier

One way to illustrate metacognitive knowledge is by considering cognitive complaints made by older adults. Research using checklists (e.g., Schweich et al. 1992) and questionnaires (e.g., Cargin et al. 2008; Cohen and Faulkner 1984) has revealed some consistency in older adults’ cognitive complaints. For instance, Cargin et al. (2008) evaluated the cognitive complaints of older adults with normal memory abilities and older adults with declines in their memory. Participants in both groups reported their memory and cognitive complaints on the Cognitive Failures Questionnaire (CFQ), which was completed twice over 2 years. Difficulty remembering names was the top complaint for both groups, and concerns about concentration and distractibility were next on the list. Given that names can be more challenging for older adults to remember relative to other information about an individual (James 2004; James et al. 2008, 2012), this

suggests that older adults’ metacognitive knowledge reflects actual memory performance.

To more closely evaluate the relationship between older adults’ metacognitive knowledge and cognition, researchers have used questionnaires about cognition and compared them with actual memory performance. To do so, two questionnaires have been frequently used: the metamemory in adulthood questionnaire (MIA) and the memory functioning questionnaire (MFQ). The MIA includes eight factors to evaluate the multifaceted nature of metacognition: understanding of memory tasks, knowledge of memory capacity, perception of changes in memory, knowledge of memory in anxious states, memory motivation and achievement, activities supportive of memory, use of memory strategies, and locus of control in memory (Dixon and Hultsch 1983b; Dixon et al. 1988). The MFQ was designed to evaluate people’s awareness of

daily cognitive experiences, and it includes four factors: general frequency of forgetting, seriousness of forgetting, retrospective evaluation of memory functioning, and use of mnemonics (Gilewski et al. 1990).

The psychometric properties of these questionnaires have been evaluated, and they (as well as others) have been used extensively to evaluate older adults' metacognitive knowledge (e.g., Dixon and Hultsch 1983a; Hertzog et al. 1989; Johansson et al. 1997) and the relationship between it and actual memory (Dixon et al. 1986; Gilewski and Zelinski 1986). The relationship tends to be modest (Hermann 1982). Indeed, a recent meta-analysis including 20,319 older adults established an effect size of $r = 0.062$ (Crumley et al. 2014). Why might this be? There are a number of possible explanations (Pearman and Storandt 2004). For example, older adults' metacognitive knowledge can be influenced by cues that may not influence actual memory. One possible (and misleading) cue may be older adults' self-efficacy in their memory.

Memory self-efficacy (MSE) refers to beliefs about the ability to use your memory in various situations. If older adults' MSE is high, they may feel confident in their memory abilities and therefore take on more cognitively challenging tasks. If older adults' MSE is low, they may feel like they are doomed to fail and avoid learning and memory tasks altogether. Further, when engaged in a memory task, they may be less strategic when completing problems (Lachman and Andreoletti 2006). To evaluate MSE, researchers use a number of measures including subscales of the MIA or MFQ as well as the memory self-efficacy questionnaire (Berry et al. 1989). Unfortunately, older adults tend to have lower MSE relative to young adults (Berry et al. 2013; Hultsch et al. 1987; West and Berry 1994). Further, MSE tends to be weakly related to actual memory performance (McDonald-Miszczak et al. 1995; Valentijn et al. 2006). This suggests that older adults hold some beliefs about their cognition that are not evident on actual cognition – that is, they have inaccurate metacognitive knowledge. Thus, training to improve metacognitive knowledge and MSE is an important focus for intervention studies

(for a review, see Floyd and Scogin 1997). Critically, by improving older adults' MSE, subsequent improvements in quality of life have been observed (e.g., Aben et al. 2014).

Metacognitive Monitoring

As previously noted, metacognitive monitoring refers to assessments of the current status of learning or of retrieval. Current theoretical perspectives on monitoring suggest that it is an inferential process that is based on available cues (Koriat 1997). According to this framework, monitoring judgments will be accurate when they are based on cues that similarly influence (or are related to) actual memory, and they will be inaccurate when they are based on cues that do not influence (or are unrelated to) memory. The focus of this entry is first on monitoring of learning that occurs during encoding followed by monitoring of retrieval processes.

Monitoring During Encoding

Rabinowitz et al. (1982) were among the first to evaluate older adults' monitoring during encoding. To do so, young and older adults were instructed to study word pairs for an upcoming test. The word pairs were highly related (e.g., grass-cow), moderately related (e.g., wallet-cow), or unrelated (e.g., airplane-cow). Half of the participants were additionally instructed to use an effective study strategy by forming a mental image of the word pairs interacting (imagery group) and the other half did not receive additional instructions (learn group). Immediately following study, participants made a judgment of learning (JOL) predicting the likelihood of remembering the target (e.g., cow) when given the cue (e.g., grass – ?) on a future test. JOLs were made on a scale from 1 to 10, with 1 indicating certainty that the cue would not be remembered and 10 indicating certainty that the cue would be remembered. Finally, participants received a cued-recall test on which each cue (e.g., grass-?) was presented and participants attempted to recall the target word (e.g., cow) associated with each. Rabinowitz et al. evaluated

judgment sensitivity, which can be defined as the degree to which the magnitude of judgments varies based on available cues – in this case, item relatedness. Young and older adults' JOLs were sensitive to item relatedness in both the imagery and learn groups: JOLs were highest for highly related word pairs, were moderately high for moderately related word pairs, and were lowest for unrelated word pairs. Thus, young and older adults' JOLs were similarly sensitive to item relatedness. This pattern was also evident on young and older adults' memory: Recall was best for highly related word pairs, followed by moderately related word pairs, and unrelated word pairs.

Recently, Tauber and Dunlosky (2012) evaluated the degree to which older adults' JOLs are sensitive to the emotional valence of to-be-learned information. To do so, young and older adults studied words that were positive (e.g., bunny), negative (e.g., cancer), or neutral (e.g., fabric). Participants made an immediate JOL for each word and received a free recall test. Young and older adults' JOLs were sensitive to emotional valence: JOLs were higher for emotional words than for neutral words. However, older adults' JOLs did not discriminate between positive and neutral items. This may suggest that older adults have impairments when monitoring their learning for positive information. However, follow-up research suggests that older adults' insensitivity was attributable to the type of materials to-be-remembered (Tauber et al. submitted). In particular, when older adults make JOLs for emotional images, their JOLs are sensitive to positive emotion. Thus, older adults' JOLs are largely sensitive to emotional valence. Relatedly, young and older adults' JOLs are similarly sensitive to memories of past test experiences and can be influenced by multiples cues (Hines et al. 2015; Tauber and Rhodes 2012).

An alternative method to evaluate the accuracy of JOLs is to estimate *monitoring resolution*. Monitoring resolution provides an index of the degree to which participants' JOLs discriminate between what will and will not be later remembered (Nelson 1984). To illustrate, consider research conducted by Hertzog et al. (2010b). Young adults, middle-aged adults, and older

adults studied related and unrelated word pairs. They also received information about effective study strategies such as creating interactive mental images for each word pair. Immediately following study, participants made a JOL for each pair and received a final cued-recall test. To estimate monitoring resolution, JOLs were correlated with cued-recall performance for each participant and the substantial correlations (0.4–0.62) did not decrease with age. Indeed, a wealth of research has established minimal age-related differences in monitoring resolution (Hertzog and Hulstsch 2000; Hertzog et al. 2002, 2010; Robinson et al. 2006; Tauber and Rhodes 2012; but see Daniels et al. 2009).

Although there are no age differences in monitoring resolution, accuracy can be rather low (albeit above chance); hence, there are methods to improve upon young and older adults' accuracy. The primary question is whether such methods improve the accuracy of older adults' JOLs to the same degree as that of young adults. Connor et al. (1997) investigated this issue by manipulating the timing of the JOL and the cues available when JOLs were made. Specifically, young and older adults studied word pairs, made a JOL for each, and received a cued-recall test. JOLs either immediately followed study (i.e., immediate JOL) or were made after a delay (i.e., delayed JOL). Further, JOLs were either cued by the entire word pair (i.e., cue + target) or by the cue alone. Young and older adults' correlations were higher for delayed JOLs than for immediate JOLs and were higher for cue alone JOLs than for cue + target JOLs (Fig. 3). Monitoring accuracy improved with delayed JOLs and with cue only JOLs most likely because participants relied on retrieval from long-term memory rather than short-term memory (see Rhodes and Tauber 2011 for a review). As is evident from Fig. 3, correlations did not differ between the age groups. Thus, the accuracy of older adults' JOLs increased to the same degree as for young adults when they were delayed and when prompted by the cue only.

Another method to improve JOL accuracy is to allow participants to learn from task experience. In a typical knowledge updating paradigm,

Metacognition in Older Adulthood, Fig. 3

JOL accuracy as measured via within-participant correlations between JOLs and final test performance (Data estimated from Connor, Dunlosky and Hertzog (1997, Table 7))

participants experience one study-JOL-test cycle. During this cycle, participants gain information about how a cue might influence their memory. The critical question is whether they update their knowledge about that cue and adjust their JOLs accordingly on a second study-JOL-test cycle (for a review, see Mueller et al. 2015). For example, Matvey et al. (2002) had young and older adults learn word pairs, make an immediate JOL for each, and take a cued-recall test. The targets of the word pairs were cued with letters (e.g., ic – ice), a rhyming word (e.g., hurt – dirt), or the category label (e.g., a diagram – chart). Then, participants completed a second complete trial with new word pairs that were cued in the same ways. The cues influenced actual memory performance: Young and older adults' memory was best for the category cued word pairs. To evaluate knowledge updating about this cue, difference scores were calculated and relative accuracy was estimated. Difference scores were calculated by subtracting average recall performance from average JOLs so that positive scores indicated overconfidence and negative scores indicated underconfidence. Improvements in JOL accuracy occurred across trials for both young and older adults. As important, relative accuracy improved across trials, and older adults' correlations were not lower than those of young adults. Thus, older adults updated their knowledge to the same degree as young adults (Dunlosky and Hertzog 2000; Price et al. 2008). Even so, knowledge updating is

often incomplete (for both young and older adults), and in some instances, older adults demonstrated less updating than did young adults (Bieman-Copland and Charness 1994; Hertzog et al. 2012). Thus, discovering why (and when) age differences arise in knowledge updating is an important avenue for future research.

In sum, the literature on older adults' monitoring during encoding converges on the conclusion that young and older adults tend to use similar cues as a basis for their JOLs. Further, monitoring resolution tends to remain stable with age. Such evidence supports the conclusion that monitoring of learning is spared with age.

Monitoring During Retrieval

Monitoring retrieval processes comes in many forms (see Fig. 2). Monitoring retrieval occurs when estimating how confident one is in the accuracy of a retrieved memory, and it occurs during the frustrating experience of not currently being able to recall something but believing that the information is known (tip-of-the-tongue experience, Brown and McNeill 1966). The current focus is on monitoring retrieval during the subjective state of believing that something can be recognized in the future, even if it cannot be currently recalled. This is referred to as a feeling of knowing; it is commonly measured with feeling of knowing (FOK) judgments, and the field of metacognition began with its investigation (Hart 1965, for a historical review, see Tauber and Dunlosky in press). Accurate feeling of knowing states are

important because feeling as though something will be recognized correctly can contribute to strategic choices to search for additional information, whereas the feeling that the answer is not known and will not be recognized later will lead to terminating search strategies.

Lachman et al. (1979) were among the first to evaluate the accuracy of older adults' feelings of knowing. They recruited college-aged adults, middle-aged adults, and older adults, and these participants made FOKs in a semantic memory task. Specifically, they answered general knowledge questions (e.g., *What is the former name of Muhammad Ali?*), and if participants did not know the answer (*Cassius Clay*), they responded by saying "I don't know." Next, for each question that participants did not know, they made an FOK by estimating the degree to which participants knew the answer even though it could not be currently recalled. FOKs were made by selecting one of four options: definitely do not know, maybe do not know, could recognize the answer if told, could recall the answer given hints and more time. By selecting the first option participants indicated that they did not know the answer, by selecting the second or third option, they indicated that they were uncertain, and by selecting the fourth option, they indicated that they knew the answer. Finally, participants received a multiple choice test on the same items. To evaluate FOK accuracy, Lachman et al. (1979) estimated the proportion correct on the final test as a function of FOK judgment. More questions were correctly answered with a "do know" FOK relative to "uncertain" FOKs and "don't know" FOKs, and young and older adults' FOKs were similar.

Evidence of age equivalence in FOK accuracy during semantic memory tasks is also evident with other estimates of relative accuracy (e.g., Allen-Burge and Storandt 2000; Butterfield et al. 1988; Hertzog et al. 2010a; Marquie and Huet 2000). For instance, Butterfield et al. (1988, Experiment 2) measured FOKs by having participants make *relative* FOK judgments or *absolute* FOK judgments. Relative FOKs judgments were made by selecting one general knowledge question (relative to others) for which the correct answer would be correctly recognized on a

later test. Absolute FOK judgments were made by making a binary yes/no judgment, indicating whether the answer to the general knowledge questions would be correctly recognized on a later test. Butterfield et al. (1988) evaluated the relative accuracy of both types of FOKs by calculating within-participant correlations between FOKs and final test performance. Correlations were moderate (0.44–0.57), they significantly exceeded chance, and they did not differ between the age groups.

In contrast with semantic memory tasks, the accuracy of older adults' FOKs in episodic memory tasks is less clear. In some cases, older adults' FOKs are less accurate relative to young adults' FOKs (e.g., Morson et al. 2015; Perrotin et al. 2006; Souchay and Isingrini 2012; Souchay et al. 2007; Thomas et al. 2011). For instance, Morson et al. (2015) evaluated the accuracy of young and older adults' FOKs on an episodic memory task as well as a semantic memory task. For both tasks, participants attempted to recall the answer to a general knowledge question, provided a yes/no FOK judgment if an answer could not be retrieved, and received a recognition memory test. The episodic memory task included an initial study phase prior to the first recall attempts during which participants studied the general knowledge questions with the correct answers. As is evident from Fig. 4, young and older adults' correlations did not significantly differ on the semantic task. However, older adults' correlations were significantly lower on the episodic memory task than on the semantic task, and they were significantly lower than those of young adults. Thus, aging negatively influenced the accuracy of FOKs when the task involved episodic memory.

It is perhaps unsurprising that older adults demonstrate deficits in the accuracy of the FOKs during episodic memory tasks. Older adults typically have deficits in learning new information (i.e., episodic memory), but semantic memory typically maintains (or even improves) with age (for a review, see Zacks et al. 2000). Thus, older adults' poorer episodic representations would produce fewer or less diagnostic cues and hence lead

Metacognition in Older Adulthood, Fig. 4 FOK accuracy as measured via within-participant correlations between FOKs and final test performance (Data estimated from Morson et al. (2015, Table 1))

to lower FOK accuracy. Further, deficits in episodic memory can be related to deficits in frontal lobe functioning, which may explain why older adults demonstrate deficits in FOK accuracy during episodic tasks. To test this idea, Souchay et al. (2000) evaluated young and older adults with neuropsychological tests and found that frontal lobe functioning accounted for a large proportion of individual's variance in FOK accuracy.

Even so, age-related deficits in FOK accuracy are not always observed in episodic memory tasks (e.g., Eakin et al. 2014; Hertzog et al. 2010a; MacLaverly and Hertzog 2009). The explanation for the mixed results in the accuracy of older adults' FOKs in episodic memory tasks remains in question, and there are several explanations for the disparate outcomes. One is that each study employs slightly different methodology – such as the nature and organization of the information to-be-learned, how FOKs are measured, and the nature of the final test. A second possibility is that differences in the samples of young and older adults across studies could contribute to the discrepant outcomes. Participant characteristics such as level of education and executive functioning are likely to influence the accuracy of FOKs. Thus, if different samples of older adults were targeted, this may contribute to conflicting conclusions across studies. These are just two of many possible explanations, so what is clear is that additional research is needed to delineate when older adults will have impairments

in the accuracy of their FOKs and when they will not.

In sum, the literature on older adults' monitoring during retrieval is somewhat mixed. In some cases, older adults demonstrate impairments, and in others they do not. Conclusions are as follows: (1) To-date, the majority of evidence suggests that older adults' monitoring during retrieval maintains with age. (2) Nevertheless, some important deficits have been discovered, so additional research is needed to clarify when age deficits will occur in the accuracy of monitoring during retrieval.

Metacognitive Control

A primary way to assess older adults' ability to control their learning is to examine whether they make good decisions when studying and/or retrieving information from memory. Effective decisions are critical because they can influence actual learning and memory: When study decisions are effective, learning will be optimized, and when study decisions are ineffective, learning will suffer. For the purposes of this entry, the focus is on older adults' ability to regulate their learning via item selection and study time allocation (see Fig. 2). To preview, the typical finding is that older adults' ability to control their learning is intact; however, there are a few instances in which age-related differences in control have been observed.

Item Selection

One way to evaluate the quality of older adults' study decisions is to determine whether they choose to study items that they have already learned or items that they have yet to learn. Ideally, older adults should select to study more unlearned items compared with well learned items. Dunlosky and Hertzog (1997) investigated this issue by presenting young and older adults with 36 word pairs and having them make a delayed JOL for each. One group of participants (self-chosen-items group) was instructed to select 18 items for restudy. In the other group (worst-learned-items group), a computer selected 18 items for restudy by choosing the items for which participants had assigned the lowest judgments. Both young and older adults in the self-chosen-items group chose to study the items that they had learned less well (i.e., the items that they had given lower JOLs). Thus, young and older adults made beneficial study decisions by selecting items they have yet to learn.

It is also informative to examine whether older adults choose to study easy or difficult items and if their selections differ from those made by young adults. Price et al. (2010) investigated this by presenting young and older adults with a 3×3 grid of Spanish–English vocabulary translations with item difficulty (easy, medium, difficult) explicitly labeled. In each grid, the Spanish words were presented and participants selected an item to get the English equivalent. This allowed for the observation of which words were selected, how difficult the selected items were, and how long they were studied. Both young and older adults' selections began with easy items and progressed to more challenging items. Further, older adults selected to study easy items more frequently than did young adults. This is consistent with Metcalfe's (2002) region of proximal learning model, which suggests that people select items for study that are closest to their current level of mastery. Price and Murray (2012) replicated and extended these findings using Chinese–English translations without explicitly stating the normative difficulty of the items.

As previously noted, older adults typically have deficits in episodic memory, so it is imperative that they focus on remembering the most important information. Interestingly, Castel et al. (2002) demonstrated that older adults are able to do this. They presented young and older adults with multiple lists that each contained 12 words. Each word was paired with a point value from 1 to 12. Further, they instructed participants to earn as many points as possible by remembering as many words as possible and by placing emphasis on the words paired with the higher values. They found that both young and older adults selectively remembered more high value items than low value items. This finding has been consistently observed (e.g., Castel et al. 2007, 2011, 2013), suggesting that older adults do have the ability to exert control over their learning in an advantageous way (i.e., remembering more valuable information). However, Price et al. (2010) showed that when the high value items were difficult (rather than easy), older adults no longer opted to study those items. Although this could be taken as evidence of impaired metacognitive control, Price et al. (2010) found that older adults' avoidance of the difficult items was correlated with lower memory self-efficacy (MSE). Thus, it is possible that older adults avoided difficult items because they had less confidence in their memory generally, which produced lower learning goals. Even so, there are a few cases in which older adults' item selection is suboptimal.

Tullis and Benjamin (2012) presented young and older adults with a list of concrete (e.g., table-dog) and abstract (e.g., justice-gravity) word pairs and had participants assign delayed JOLs. After study, participants were instructed to select half of the items for restudy. Participants in the honor group restudied the items they selected, and participants in the dishonor group restudied the items they did not select. Finally, participants received a free recall test. As with previous work, young and older adults chose to restudy the less well-learned items (i.e., those with lower JOLs). Further, young adults' recall benefited from having their study decisions honored. However, older adults did not show this benefit, which may indicate that the

older adults had a deficit in control. Even so, older adults have a hard time remembering abstract words (e.g., Hertzog et al. 2013). Thus, they may have selected a disproportionate number of abstract items for restudy, which would be more challenging to remember and could have contributed to the apparent age-related control deficit.

In sum, research on older adults' ability to control their learning via item selection suggests that older adults exert control over their learning in a similar manner as do young adults (i.e., they select least well-learned items, items that are closest to their current level of mastery, and items of higher value). Although there is some evidence of age-related impairments in control (e.g., Tullis and Benjamin 2012), the literature largely converges on the conclusion that self-regulated learning via item selection is largely spared with age.

Study Time

Do older adults allocate study time in a similar manner as do young adults in order to retain the maximum amount of information? Hines et al. (2009) investigated this question with two study-test trials during which they presented young and older adults with word pairs and had them make immediate JOLs. On the first trial, presentation time was experimenter paced (4 s for young adults and 6 s for older adults) to equate memory performance on the first test. On the second trial, presentation time was self-paced. After each study trial, participants engaged in a recognition memory test on which they determined whether each word pair had been previously studied and provided a confidence judgment (CJ) of how certain they were in their answer. Both age groups spent more time studying the items with lower JOLs, lower CJs, and items they got wrong on the first trial. This demonstrates that older adults effectively used their monitoring (JOLs and CJs) to guide their study behaviors (study time allocation) in the same manner as did young adults.

In addition, Froger et al. (2012) found that older adults adjusted their study time based on item difficulty when provided with effective strategies to enhance their memory. Specifically, they presented young and older adults with highly

related word pairs (easy items) and weakly related word pairs (difficult items) and varied how much "environmental support" they gave each group. In the high environmental support group, participants were informed of study strategies (e.g., sentence formation, route rehearsal) to use to remember the word pairs as well as the effectiveness of each strategy. In the low environmental support group, participants were informed of study strategies with no information about their effectiveness. Finally, in the no support group, participants were not given any information about study strategies. When no environmental support was given, older adults spent a majority of their time studying easy items. However, in the high environmental support group, older adults spent more time studying the difficult items, suggesting that when given information about how to effectively learn difficult items, older adults shifted their study behaviors to enhance memory for the difficult items. Froger et al. (2012) determined that this shift in study time was a result of the increased time it takes to implement these study strategies. This suggests that older adults do not spontaneously adopt effective study strategies, but when they are instructed to use them, older adults do so.

Finally, research has demonstrated that older adults are able to efficiently allocate study time to valuable or important information. For instance, Castel et al. (2013) presented young and older adults with a grid of 30 point values (labeled 1–30) with corresponding words hidden from view unless a particular value had been selected. Participants were given 2 min to study items to elevate their score. They found that older adults chose to study high value items more frequently (Castel et al. 2002) and for longer durations than did young adults. For older adults, this is beneficial, because they will be unable to remember everything, and they can compensate by spending more time on the important information.

Even if older adults make similar choices as young adults, it is critical to determine the degree to which they use monitoring to guide their study time (Dunlosky and Connor 1997; Krueger 2012). To that end, Dunlosky and Connor (1997) presented young and older adults with word

Metacognition in Older Adulthood,

Fig. 5 Within-participant correlations between JOLs and Study time on each trial and for each age group (Data estimated from Dunlosky and Connor (1997, Fig. 2, Top panel))

pairs and allowed them to self-pace their study on three study-test trials. In addition, they collected delayed JOLs for each item to determine whether participants were using their metacognitive monitoring (JOLs) to regulate their study behavior (study time allocation). On each of the three tests, participants engaged in a cued-recall test for one-third of the items. Young and older adults chose to restudy the items that they had learned less well (via lower JOLs and recall). Further, correlations between JOLs on one trial and study time on the next trial were negative for both groups: higher JOLs were associated with less study time. However, correlations were lower for older adults than for young adults (see Fig. 5). This could be taken as evidence that the older adults had a deficit in their ability to use monitoring to allocate study time because they appeared to use their monitoring to a lesser extent than their younger counterparts (Dunlosky and Connor 1997; Souchay and Isingrini 2004). However, older adults tend to show inferior memory performance and have lower memory self-efficacy (MSE) relative to young adults. Thus, it is also possible that the older adults focused their study time on the items they had already learned to ensure that they retain those items on a later test. Further, age-related differences in the relationship between monitoring and control are not always observed (Stine-Morrow et al. 2006).

In sum, older adults make similar decisions as do young adults when allocating study time, suggesting that metacognitive control is spared

with age. However, the extent to which older adults use their monitoring to guide control via study time is unclear. Some evidence suggests that older adults use their monitoring to a lesser extent than did young adults; however, other evidence reveals no age differences.

Conclusions

The field of metacognitive aging continues to expand and increase knowledge of metacognitive function with aging in adulthood. Evidence to-date suggests that older adults have some impairments in metacognitive our understanding. Older adults' metacognitive monitoring remains largely intact with age, although there are a few instances in which older adults' monitoring is impaired. Similarly, older adults' metacognitive control remains largely intact with age, although older adults demonstrate some deficits in control. Accurate metacognitive function is critical because metacognitive processes are inter-related, and they influence actual cognition. Thus, older adults may be able to compensate for age-related impairments in cognition, so improving upon metacognitive processes is an important point of intervention. Metacognitive intervention studies have established improvements in monitoring and self-regulation following interventions that were also associated with improvements in older adults' cognition (e.g., Bailey et al. 2010; Dunlosky et al. 2003, 2007a). Most importantly,

increasing the accuracy of metacognitive processes and improving upon older adults' cognitive functioning have the potential to improve the quality of older adults' lives.

Definitions

mHealth: mobile and wearable health information including sensing technologies and mobile web

and mobile device applications (apps) with the potential to improve physical and mental well-being.

Introduction

Innovation in mobile and wearable health information and sensing technologies and applications (mHealth) has the potential to improve well-being, both physical and mental, and to reduce the cost of health care among older adults in numerous ways (Parker et al. 2013). From health monitoring and health education and behavior change to falls sensing and mobile health alerts to the simple pleasure of communication and connectedness, mobile technologies are changing the lives of older adults. The ongoing study of mHealth in fostering health behavior change among older adults will require a multidisciplinary approach to consider proximal (e.g., physical activity, chronic disease management, cancer survivorship) and distal (e.g., social engagement and participation) aspects as well as the development of perspectives of how mHealth may affect psychosocial changes in older adults (Ziegelmann and Koll 2015; Gellis 2015). This chapter will cover the challenges and opportunities for mHealth for older adults and a summary of current uses of mHealth for chronic disease self-management and care.

By the year 2030, one-fifth of the US population will be age 65 or older, growing from 40 million in 2010, to an estimated 72 million in 2030 (Parker et al. 2013). With age comes an increased likelihood of multiple chronic health problems or comorbidities leading to an increased need for health and chronic disease management (Centers for Disease Control and Prevention (CDC) 2003; Federal Interagency Forum on Aging-Related Statistics 2012). Aging demographics combined with ongoing innovations in mobile health technology and apps suggest that mHealth interventions may hold great potential as a platform to reduce healthcare costs and improve health outcomes among older adults. However, adoption among older adults differs from the general population in a number of important ways

and demands a closer look. According to the Pew Internet Research Center, older adults in the US have been slower than their younger counterparts to adopt mobile technology. However, adoption continues to deepen over time (Smith 2014).

As with any demographic group, older adults are highly heterogeneous and, not surprisingly, adoption of mobile technologies varies by segment along age groups and sociodemographic status. According to a 2014 Pew study, a majority of older adults (77%) own cell phones, but only 17% of these older adults are using smartphones. Among older adults, adoption of tablets and e-readers is higher than smartphones, with some 27% of seniors owning a tablet, an e-book reader, or both (Smith 2014). Among seniors, those who graduated from college are nearly three times more likely to own a tablet or smartphone than those who did not attend college; those with annual household incomes of \$75,000 or more are four times more likely to own mobile technology than those with household incomes of less than \$30,000 per year (Smith 2014). According to a 2012 Pew study on mHealth, the most commonly downloaded health apps are those pertaining to exercise, fitness, pedometers, or heart rate monitoring. Across all age groups, 38% of health app users download apps for those uses.

Younger adults are more likely to use health apps than their older counterparts. Among younger users ages 18–29, 24% had health apps, as compared with 19% for those ages 30–49. Among older users ages 60–64, 16% used health apps as compared to 10% among those ages 65 and older (Fox and Duggan 2012).

Challenges of mHealth Apps: Poor Form Factors and Infrequent Use of Health Behavior Change Theory

Improvements in two areas of design may make mHealth apps of greater use to older adults and help resolve barriers to adoption: (1) Inclusion of form factors that support physical needs of older adults including hearing loss, poor eyesight, and lessened dexterity; and (2) Application of

intervention design elements, content, and activities that adhere to health behavior change theories that may make the apps more relevant to older adults' daily lives.

Wildenbos et al. developed a framework for usability analyses of mHealth tools for older adults. Their framework includes factors such as cognitive barriers, physical impairments, motivational issues, and visual/perceptive barriers. The results of their analyses suggest that longer learning time and poor visual acuity were among the most common barriers (Wildenbos et al. 2015). The issues of longer learning time among older adults may affect motivation for adoption as well. Optimally, mHealth app developers could engage with older adults to review interface design (e.g., size of font, button colors, and placement) as well as reviewing navigation and task flow logic. Other factors such as privacy and security and the ability to have apps personalized, preconfigured, and loaded with data may also support increased adoption.

An important question is the extent to which mHealth apps for chronic disease management and other apps for older adults are theory based. In a study of 65 cancer survivorship mHealth apps, built on both the iOS and Android platforms, Vollmer Dahlke et al. used qualitative coding methods to assess the application of health behavior change and communication theories (Vollmer Dahlke et al. 2015). The apps were assessed using a coding derived from taxonomy of 26 health behavior change techniques developed by Michie et al. (2013). The taxonomy was adapted based on the characteristics of mHealth apps that are specific to information processing and human computer interaction such as control theory and feedback systems. The mHealth apps in the Vollmer Dahlke study varied greatly based on their rankings in use of theoretical elements of health behavior change including personalization, tailoring, and interactive feedback. The study's findings were consistent with prior research that asserts that mHealth interventions could benefit from increased use of health behavior and communications theories in their design (Vollmer Dahlke et al. 2015).

Health Apps Research and Use Among Older Adults

Despite concerns for low adoption rates, there are a number of types of mHealth apps and technologies targeted for older adults, some for use with medications and others focused more on health or disease management interventions, including lifestyle changes and health monitoring. While not a systematic review, the following sections provide a current snapshot of the field of mHealth apps designed for the purposes of improving or managing health of older adults. An underlying assumption is that better self-management leads to enhanced quality of life, as demonstrated in national studies of chronic disease self-management programs (Ory and Smith 2015).

Physical Activity Apps and Older Adults

The major chronic diseases of older adults including cardiovascular disease, cancer, stroke, obesity, and Type 2 diabetes are linked to lack of regular physical activity and increased sitting time. Accelerometers built into smartphones, smart watches, and wearable sensor devices are increasingly used in mHealth apps to provide cost-efficient and user-directed ways to enhance physical activity. The apps use data collected by the smartphone's technology including accelerometers, cameras, voice recorders, and speakers to collect and wirelessly share the data with the apps' cloud-based databases. App databases may include the users' goals and physical characteristics, and the app algorithms can be designed to record, summarize, and report user data. Many physical activity apps provide feedback through motivational messaging via social media and additional incentives through social leader boards, game-like virtual prizes, and trophies.

Current research on the use of mHealth physical activity apps among older adults is relatively sparse, and there is a need for well-designed studies. A recent review of 379 physical activity apps by Knight et al. (2014) suggests a continued failure of mHealth apps for physical activity in providing guidance on current public health

recommendations for adults to engage in 150 min weekly of moderate exercise and muscle strengthening activities for at least 2 days per week. None of the apps in the systematic review provided evidence-based information on moderate physical activity, and only seven of the apps reviewed provided evidence-based information on muscles strengthening activities (Knight et al. 2014). A limited efficacy study (30 participants drawn from a convenience sample) of iCanFIT, a mobile web application, suggested that older adult cancer survivors' quality of life and engagement in regular physical activity improved significantly after the use of iCanFit (Hong et al. 2015). The iCanFit app used evidence and theory-informed design and deep engagement with older stakeholders to ensure usability and acceptability (Hong et al. 2013).

Mental Health and Social Connectedness

Prior research in life expectancy and quality of life in mental health literature indicates that older adults with integrated social support and connectedness (e.g., family, friends, neighbors, church, and community groups) are generally less depressed and report greater well-being (Fiori et al. 2006). Beyond email, Facebook is the mobile technology most used by older adults. However, a recent Pew study suggests that among online adult users age 65 and over, 16% use Pinterest and 12% are on LinkedIn (Fox and Duggan 2012). As of September 2014, fully 72% of online American adults (approximately 62% of the entire US population) use Facebook. Among those, 48% are users ages 65 and older (Smith 2014). Video calls (e.g., Skype, AppleTalk, Google+) are also used by approximately 15% of older adults to connect socially with friends and family (Fox and Duggan 2012). A study by Hutto et al. (2015) of older Facebook users indicated that, after controlling for factors such as age, gender, ethnicity, socioeconomic status, and marital status, directed mobile communications as opposed to broadcast communications or passive consumption of content was correlated with reduced loneliness as well as increased social role satisfaction among older adults (Goins et al. 2011).

Activities of Daily Life and Aging in Place

Older adults prefer to remain in their homes for as long as possible, and the thought of being "forced" to leave home is stressful for many older adults (Fiori et al. 2006; Hutto et al. 2015; Bacsu et al. 2012). Healthy aging in place is more than just a matter of physical health. According to current literature, it also involves elements of culture, community, and spirituality and is strongly related to self-efficacy and self-perceptions of health and well-being (Goins et al. 2011; Pierce 2001; Tang and Lee 2011). Remote monitoring of health status for older adults, especially for those in rural areas or who are homebound, vary from simple alert necklaces linked to a home security system to full telehealth systems associated with medication adherence and chronic disease monitoring. In a recent study by Paniker and Kumar, the development and validation of a tablet PC used in conjunction with a noninvasive body sensor system was tested as a rural telehealth application (Panicker and Kumar 2016). The system included real-time, continuous collection of physiological parameters (i.e., blood pressure, pulse rate, and temperature) and fall detection of a patient using a wrist device sensor unit. Wireless transmission of acquired health data was transmitted to a tablet PC managed by the medical staff in a primary health center. Any abnormal conditions were automatically identified and alert messages were given to a medical professional in real time (Panicker and Kumar 2016).

Other emerging mHealth technologies including robots connected through mobile technology hold promise to support physical activity, aging in place, and psychosocial support through the provision of care and companionship. Use of robots is currently limited due to expense and lack of safety standards (Smarr et al. 2014) but adoption of robots and associated apps is expected to increase over time. Current robot technology for older adults is focused on Activities of Daily Life (ADL) by assisting in fetching objects or retrieving dropped objects. For example, the Dusty robot aids older adults by picking up objects dropped on the floor. This is especially helpful as older adults drop items an average of 5.5 times per day and reaching and bending to pick up objects may be

associated with falls (Smarr et al. 2014). Developed by the German firm, Fraunhofer IPA, Care O Bot is able to move safely among humans, to detect and grasp typical household objects, and to safely share them with their human companions (Graf et al. 2009).

Type 2 Diabetes

Self-management is now considered the appropriate strategy for Type 2 Diabetes in which lifestyle and diet are considered critical to management. Health professionals have traditionally delivered chronic disease self-management (CDSM) interventions for Type 2 diabetes to individuals in one-on-one or group situations, often with regular follow-up as reinforcement. mHealth technologies appear to offer less expensive and resource intensive interventions and may also be tailored to be culturally and linguistically appropriate. Examples of Type 2 Diabetes apps are those that provide diet tracker and food selection guidance. Some apps also provide goal setting for increased physical activity. A framework study by Hale et al. reviewed mHealth apps for Type 2 Diabetes using a health behavior theory-based approach (Hale et al. 2015). The researchers suggest that patients would benefit from guidance from health care providers in a patient-centered approach to match apps to individual health needs and goals, and that such a practice had greater potential to increase the effectiveness of therapy (Hale et al. 2015). A systematic review by Arnhold et al. included a usability examination of Type 2 Diabetes apps to determine if the available apps served the special needs of diabetes patients aged 50 or older (Arnhold et al. 2014). Their findings suggested that usability of apps for this age group was moderate to good. However, this finding applied to apps offering a small range of functions and documentation of analytical functions in these apps showed significantly lower usability scores. The researchers suggested that future development of apps for this age group should include significant participation from both providers and older adults and that transmission of data to health providers would be an important future feature (Arnhold et al. 2014).

Cancer Care and Survivorship

The probability of developing invasive cancer increases dramatically with age: for males age 60–69, the probability is 1 in 7; for females age 60–69, it is 1 in 10; for males age 70 and over the probability increases to 1 in 3; and for females age 70 and over it is 1 in 4 (Siegel et al. 2015). Cancer patients undergoing chemotherapy and radiation and survivors having completed therapy experience both medical and psychosocial side effects of their care that can negatively affect their well-being and quality of life. mHealth technologies that allow prompt intervention early in the process can help minimize side effects and also provide important education, communication, and psychosocial support for cancer survivors and caregivers.

The mHealth cancer care and survivorship apps that appear to be firmly based in health behavior change theory are similar in that they require personalization and some degree of tailoring, are highly interactive, include some type of quality of life questions or assessments, suggest goals and actions, and provide social engagement and the mobilization of social norms taking into account both the physical and psychosocial needs of survivors (Vollmer Dahlke et al. 2015). The more potentially effective apps were either developed by cancer advocacy groups, clinical associations, or academic researchers, which suggests that the information offered in these apps is more likely to be based on evidence and clinical research and developed using health behavior theories. Examples include the following: (1) *Livestrong Cancer Guide and Tracker* app, available only for iPad; (2) *Cancer.net* developed by the American Society of Clinical Oncology, available on iOS and Android platforms (and also offers a Web-based version and one that is translated into Spanish); (3) *My Cancer Manager* developed by the Cancer Support Community and available only as an iOS app; and (4) *MyHealthFinder*, a mobile web, iOS and Android app to help cancer survivors and those affected by other chronic diseases find clinical and non-clinical care resources using geolocation tools and web-based information developed by the Texas A&M Health Science Center School of Public Health.

Falls and Falls Prevention

Each year, millions of older people fall, with one of three older people falling each year: falling once doubles the chances of falling again. Annually, 2.5 million older adults in the USA are treated in emergency rooms for falls (Kramarow et al. 2015). In 2013, unintentional injuries were the eighth leading cause of death among US adults aged 65 and over, resulting in nearly 46,000 deaths (Kramarow et al. 2015). Continuing advances in inexpensive, miniature, wireless sensors and wearable smart devices can quickly and accurately quantify and monitor body motion producing objective measures of an individual's balance and gait. These devices can help therapists focus on specific physiological reasons for difficulty in walking or balance during activities of daily life. Body monitors can be used to measure and document increased changes in sway or gait measures and also provide documentation of changes as a result of therapy. The relationship between functional disability, fear of falling, falls, and quality of life may be reciprocal, with each affecting and interacting with one another, suggesting that in addition to physiological issues, psychological and psychosocial issues including fear, should be considered as part of falls prevention training and education (Patil et al. 2013).

Falls monitors can be designed to provide immediate biofeedback to users and provide supporting behavioral and training cues to allow them to focus attention and engage in exercise or activities to support improved balance. The engagement of therapists participating in remote data analysis could be used for telemedicine communication to support home and community-based falls prevention exercise programs and allow older adults more opportunity to age safely in place. While the mobile technology for falls monitoring and prevention may be developing and emergent in the marketplace, there is little data on adoption and little current research on usability and acceptability among older adults.

A systematic review of 44 studies of technology devices for falls and injury prevention by Omaki et al. included only two mobile device studies. Both of these studies indicated that mobile technologies improved behaviors

around injury prevention (Omaki et al. 2016). A randomized control study currently underway by Delbaere et al. (2015) is focused on falls prevention using a tailored, home-based balance training delivered through a tablet computer. Intervention participants are being asked to complete 2 h of exercises per week for 2 years. Both groups will receive an education program focused on health-related information relevant to older adults, delivered through a tablet computer via weekly fact sheets. The intervention group is receiving balance training delivered through a tablet computer at home and are given exercise equipment (i.e., a foam cushion, a stepping box, and exercise mat). This large, 500 person trial will measure falls and fallers over a 12 month period as measured through falls diaries. Secondary outcome measures will be assessed to understand how mechanisms underlie any fall reduction and to determine to what extent the training transfers to other falls prevention-related outcomes such as balance, gait, and mobility; concern about falling; cognitive function; and overall physical activity levels (Delbaere et al. 2015).

Alzheimer and Dementia Care

Mobile phones and smartphones are being used for different purposes in dementia and Alzheimer care including location finding through Global Positioning Systems (GPS) and use of photos in smart phones to support memory recall. GPS, available in most mobile phones, can be used as an assistive technology for caregivers – both home and institutional – to create virtual geographical “fences” and to prevent elopement in wandering behavior of older adults with dementia. The prevalence of older adults who wander is reported to be as high as 63% among those suffering from Alzheimer's (Petonito and Muschert 2015). Wandering in unsafe environments increases risks of falls, hip fractures, sleep disturbance, getting lost, elopement from care facilities, and death.

Cipriani et al. reviewed several studies related to accurate and successful location of persons who had wandered using mobile phones as reliable tracking devices (Cipriani et al. 2014). Bosco and Laconi are experimenting with the use of

smartphones that can be programmed to take photos every 5 min during the day to aid in developing interventions aimed to improve adaptive responses to environmental situations. Audio recordings can also be enabled for use with photos to promote self-awareness and to record and reproduce autobiographical multimedia that can be used during reminiscence tasks that may take place with caregivers and supportive staff (Bosco and Lancioni 2015).

Palliative and End-of-Life Care

Four illness trajectories that are most prominent for patients with progressive chronic illness are cancer, organ failure, the frail elderly, and dementia. Physical, social, psychological, and spiritual needs of patients and their caregivers for palliative and end-of-life care are likely to vary according to which trajectory patients are following (Murray et al. 2013). mHealth apps may have a role in each of these trajectories in minimizing symptom distress and supporting the well-being – both for patient and caregiver. Smart phones and tablets have the potential to support remote symptom monitoring and management and can provide linkages to both healthcare professionals and caregivers as part of palliative care supporting communication and psychosocial care in addition to symptom and medication management. McCall et al. explored the use of mobile phones for communication of symptom management between patients and health professionals in order to assess acceptability and usability. In addition to self-reporting of symptoms, the platform provided semi-tailored self-care advice (McCall et al. 2008). While their systematic review did not include smart phones or tablets, the researchers suggested the potential for mHealth technology including Skype, Twitter, and blogging as digital tools to support palliative care and end-of-life communications among patients' families and healthcare professionals (McCall et al. 2008).

The smartphone app, *My Health Care Wishes: An Advance Directive Manager* developed by The American Bar Association offers management and storage for both individual and family profiles and documents including advance directives, living wills, healthcare powers of attorney, do not

resuscitate (DNR) orders, and Physician Orders for Life-Sustaining Treatment (POLST) documents (http://www.americanbar.org/groups/law_aging/MyHealthCareWishesApp.html). The app is offered both as a free, basic version and as a more advanced paid version and is designed to ensure and support information sharing during a medical crisis so that advanced care directives are immediately at hand and can be delivered wirelessly in minutes via PDF format to the ER, the hospital, and medical professionals (http://www.americanbar.org/groups/law_aging/MyHealthCareWishesApp.html).

Conclusion

A significant consideration for adoption of mHealth applications among older adults is the role of perceived relevance to daily life – how does an app fit with the older adults' perceived needs, interest, and relevance (Sourbati 2009). Additional concerns for older adults, especially those 80 and older, are design and interface issues, the need for training and support, and cost factors in relation to a limited or fixed income. Older adults may also have greater concerns for the security and sharing of personal and health information with mobile technologies. Of significant concern for adults who fail to adopt mobile and Internet technology is missed opportunities to receive important communications at the local, state, and national levels, including emergency notifications and financial and community communications.

Advancements in mobile technologies show great potential for significant impact and reach in health education, monitoring, and support for health behavior change and improved quality of life among older adults. Increased penetration and adoption of smartphones and tablets across sociodemographic groups, race, and cultural divides suggest ongoing increase and uptake of mHealth applications and technologies. Perhaps, we should not be surprised at adoption of mHealth technologies among those who are 65 and older or those shortly approaching this age group. Older adults ages 65 and older still in the workforce, or

preparing to soon retire, may have already worked 30-plus years with technology starting with mainframes and progressing through desktops, laptops, smartphones, and tablets.

Thus, it is not surprising that older adults, including those in their 80s and 90s, have the potential to embrace mobile technology for health and well-being. Mobile technology is making it easier for older adults to stay in touch with family, friends, and medical professionals to age in place and live and travel more independently. According to the Pew studies, older mobile technology users are confident in their ability to search for health information and to find and get help when they need it (Smith 2014; Fox and Duggan 2012).

A better understanding of mHealth usability and accessibility and perceptions of benefit and relevance among older adults, perhaps segmented by age groups and socio-demographics, may help direct future interventions and research studies aimed at improving the health and well-being of this growing segment of the US and global population.

Synonyms

Aging in distance; Immigrants; Immigration

Definition

Human migration refers to the movement by people from one place to another with the intention of settling temporarily or permanently in the new location. Migration can refer to movement from one country to another or to movement within the same country, such as rural farmers moving to cities to permanently settle in urban areas. This entry, however, focuses on international migration, which almost always involves cultural transition.

International Migration and Cross-Cultural Adjustment of Older Immigrants

Globally, international migration has been steadily increasing. According to the Population Division of the Department of Economic and Social Affairs of the United Nations (www.unpopulation.org), the number of international migrants worldwide reached 232 million in 2013, an increase from 175 million in 2000 and 154 million in 1990. A growing concentration of international migrants is found in developed regions. In 2013, migrants constituted 10.8% of the total population in developed regions compared to 1.6% in developing regions. Europe and Asia combined host nearly two thirds of all international migrants worldwide, with Europe hosting the largest number (72 million), followed by Asia (71 million) and North America (53 million). Other major destination regions are Africa (19 million), Latin America and the Caribbean (9 million), and Oceania (8 million). The ever-increasing flow of people through international migration is one of the most significant contributors to the multicultural society we live in today.

Older migrants who come to settle in the receiving country are aging alongside the rest of the rapidly growing aging population. Take Australia, for example. The Australian Bureau of Statistics reports that Australia's population is currently growing at 1.8% per annum, the fastest among OECD countries. Most striking, the 65⁺ population is growing more than twice as fast (84.8%) as that of the total population (36%). Moreover, within this fast-growing aging population, the percentage of older adults from culturally and linguistically diverse backgrounds is expected to rise from 23% in 2011 to 30% by 2021 (Migliorino 2013). It has been widely recognized by scholars that a diverse aging population presents major challenges to aged care services, as well as to individuals, families, and communities. This is because differences in beliefs, values, and worldviews due to life experiences under different economic, social, and cultural conditions may lead to variations in

expectations of aging and aged care. Meeting these expectations requires social support, family support, community care, and intergenerational communication, all of which can positively contribute to the successful aging of older adults from diverse backgrounds.

Although the reasons for migration vary, all immigrants face the same task of *cross-cultural adjustment*—a process through which immigrants are integrated into the host cultural environment. Previous research consistently indicates that integration (maintaining home culture *and* participating in host culture) is the most preferred strategy by immigrants because integration offers them the opportunity to keep their heritage cultural traditions while developing a positive relationship with the mainstream (host) society. Previous research evidence indicates that integration is linked to better psychological adjustment, a sense of belonging, and a feeling of acceptance (e.g., Berry 2005). However, the path to achieving integration is not straightforward. People adapting to new cultures face changes in diet, climate, housing, roles, social networks, communication, norms, and values. Integration requires immigrants to move between their home culture and the mainstream culture of their new country. This process often involves a mental reconciliation of sometimes incompatible pressures for both assimilation into the mainstream culture and differentiation from it. Some immigrants flourish and achieve identity harmony through the process of cross-cultural adjustment, while others flounder and experience identity conflicts.

Over and above cross-cultural adjustment that immigrants of all age groups undergo, older immigrants face the challenge of aging in a foreign land. Broadly speaking, there are two groups of older adults with diverse cultural backgrounds: those long-term immigrants who grew old in the receiving country and those who migrated at an older age (65⁺), including those who have become separated from family networks in their homeland to join their children who have already settled in the receiving country. For both groups of older immigrants (i.e., those who migrated at an older age and those who grew old in the receiving country), aging in distance creates a range of

challenges not only for themselves but also for their younger family members, as detailed below.

For those older immigrants who made the migration journey during their later years, they not only face the daunting challenge of leaving their homeland at an older age, but they also have to tackle adjustment problems in a new country that is often different from their home country in terms of values and lifestyles. Even for those older immigrants who moved to join their adult children in the receiving country, they very often feel isolated from their younger family members because they are unable to adjust to life in the new country as quickly. A key barrier to their cross-cultural adjustment in the new country is their lack of host language proficiency. In a study on older Koreans in New Zealand, a participant who could not speak English well stated, "I felt becoming deaf, blind, and mute after immigration and living in an inconvenient paradise" (Park and Kim 2013, p. 159). Similarly, Lee and Yoon (2011) reported that a lack of English language competency is a significant predictor of lower well-being among this immigrant group, as evident in higher levels of anxiety and depression, lower self-control, and lower general health. Research examining how cultural transition influences older immigrants' health has found that the lack of host language competency, a large distance between heritage and host cultures, the loss of old friendship circles, and perceived prejudice by the immigrant are important factors that negatively affect older immigrants' psychological well-being (Chou 2007).

For those who migrated to the receiving country in their earlier years and thus grew old in the host country, things might not be necessarily easier. In a number of studies involving multiple older immigrant groups who migrated at a young age and grew old in the United States, researchers found that older immigrants from Korean, Chinese, Mexican, Russian, and Eastern European backgrounds are subject to higher health risks than non-immigrants, often resulting from depressive symptoms and disorders (see Chou 2007). One explanation may be that older immigrants tend to maintain close ties with their heritage culture and prefer to live in ethnic enclaves,

which in a way restrict their social network to co-ethnics. In contrast, current young immigrants who are better educated than earlier generations, in general, and second or third generations of immigrants are more likely to have wider social networks in the host country, and they tend to adapt more easily to the host cultural environment. Intergenerational differences in values and lifestyles might lead to conflicts between the older immigrants and their adult children or their grandchildren. For example, many older Asian immigrants in Western countries treasure collectivist culture, which emphasizes the importance of viewing the self as inherently connected to the social network of family members and friends. In contrast, their children, who grew up in more individualist cultures like North America, tend to value personal independence and the importance of individual goals over group goals (Wong et al. 2006). In traditional Asian cultures, decisions concerning the marriage of adult children need to be made by the extended families on both sides because marriage in collectivist cultures means alliance of two extended families. However, for the younger immigrants who grew up in the more individualist cultures, whom to marry is a decision that is supposed to be made by the couple themselves. Conflicts might occur between the older generation and the younger generation with regard to decision-making process for the choice of marriage partners. Intergenerational conflicts could negatively affect communication between the older immigrants and their adult children.

At the societal level, receiving and giving social support occur through an individual's social network. Social support provides both instrumental support (e.g., help from a friend to get medication from a chemist store) and emotional support (e.g., companionship provided by a friend from the home country). Such social relationships are beneficial to health and psychological well-being. Early generations of immigrants who grew old in the host country tend to limit their social networks to friends from the same ethnic background. This may be due to convenience, as such ethnic network is often developed from networks of their family or extended families or neighbors from the

same ethnic background, or it may stem from a desire to remain connected with their old home country. As older immigrants' mobility decreases with age and as their children move out of the family house when they reach adulthood, the opportunities for their children to drive them to different places to meet with friends are likely to decrease. Lack of opportunities to participate in social activities can further contribute to older immigrants' feeling of social isolation, which negatively affects health and well-being.

Clearly, older immigrants experience unique stressors related to social isolation, identity loss, depression, anxiety, low self-esteem, and communication barriers (Chow 2004). Those stressors might be broadly grouped into three categories: (a) physiological changes which make them more vulnerable to the effect of loss of control over their own life; (b) age-linked changes or loss of old social roles and the demand to adapt to changes in new social roles, such as retirees or immigrants; and (c) loss or diminished social support due to decreased mobility, health problems, and cultural transition. Such experiences not only limit their successful aging opportunities and psychological well-being but also negatively affect their families and their community. They often feel that they neither belong to where they come from nor to where they are residing. Although such feelings might be experienced by immigrants of all age groups, this sense of belonging to nowhere tends to be felt more strongly among older immigrants as they become more dependent on others in the later years of their life. Despite these challenges, most research on migrants has focused on younger populations, leaving us with very limited knowledge of how older immigrants simultaneously deal with cross-cultural adjustment and aging in a foreign land.

Culturally Appropriate Aged Care for People from Diverse Backgrounds

The capacity to successfully embrace and navigate a new culture has been an important factor that influences the perception of health and well-being among older immigrants. A multitude of

social, personal, cultural, and family constraints associated with being an older immigrant presents significant challenges to successful aging. They affect access to and utilization of resources and highlight the need for a coordinated approach to filial responsibilities, honoring traditions, personal values, and meeting social expectations. Due to early childhood socialization in the home country, immigrants often arrive with an established set of ideas regarding aged care, family relations, religious beliefs, and access to formal care services. Those culturally based assumptions often result in culture-specific understandings of aged care, which may not be understood or shared by the host society. Yet little is known about the experience of aging as an immigrant, particularly for those who find themselves aging in a country which is culturally and linguistically distinct from their country of origin.

Intercultural researchers have acknowledged that cultural isolation and linguistic difficulties increase immigrants' dependence on their children and a diminished probability of seeking assistance from formal care providers. Panagiotopoulos and colleagues (2013) conducted a study to delineate differences in the well-being of Greek and British Australian widowed immigrants and to compare the impact of widowhood on well-being. Their findings showed that support from family is more crucial for the well-being of Greek widows compared to their British counterparts. Similarly, many older immigrants from Asian backgrounds are often economically dependent on their children, and they are reluctant to access formal care for fear that it would be seen as familial rejection. However, while a culture of family care is held strongly among many older immigrants, social norms associated with the tradition of filial piety (i.e., the expression of responsibility, sacrifice, and respect for one's elders and ancestors, including taking care of one's parents) have changed due to the contemporary family structure and mainstream cultural systems which are oriented toward individualism.

Specifically, research on Asian immigrants in Western countries show significant departures from the norms of filial piety and an overall

Westernization of care practices, both in relation to what families actually do for their elderly parents and what older people themselves now expect (Chow 2004). While it is widely accepted that the role of the family is more vital for older immigrants who age in a foreign land than if they remained in their homeland, intergenerational relationships between older immigrants and their offspring may have changed in the new cultural context. In traditional Chinese culture, daughters-in-law, who become part of their husband's family, are responsible for caring for their husband's older parents. Older Chinese parents who sacrificed their personal interest for the betterment of their children (e.g., working to provide better education opportunities for their children) would expect a reciprocal filial obligation from their children or children's family to care for them. However, such expectation might not be shared by younger generations of immigrants who view their roles of caring for their older parents more in the provision of financial support, rather than fulfilling the role of a personal carer. Consequently, those who were once considered the primary carer for older parents are no longer obligated to provide personal care, but rather duties of filial piety is fulfilled by providing financial support to older parents. Therefore, the experiences of older immigrants can be adversely affected by a hidden source of isolation and exclusion in the new cultural context. Discrepancies in the expectations of elderly immigrants, their family, their community, and the larger society can negatively impact the capacity of aged care services to effectively meet the needs of older immigrants and their families.

The cumulative effects associated with migration to a foreign country, cultural distance between old-world traditions and the new cultural environment, and difficulties in accessing culturally and linguistically appropriate health care and resources are detrimental to older immigrants' well-being. While public health policies have focused on meeting the increasing demand for formal aged and health-care facilities and services, one often overlooked dimension of population aging is the diversity of the aging population. It is essential that care capacity building occurs in tandem with an understanding of the experiences

of older people and their families from diverse cultural backgrounds. In an attempt to illustrate this point, Lood, Gustafsson, and Ivanoff (2015) conducted a pilot study to evaluate a person-centered 4-week health program in Sweden. The program used translated information materials and bilingual health professionals and evaluators for both program development and provision. The 40 participants were at or over 70 years of age and had migrated to Sweden from Finland, Bosnia and Herzegovina, Croatia, Montenegro and Serbia. Over a 4-week period, the participants in the *senior meetings* group held weekly meetings to discuss about different tools for health promotion in everyday life; each participant in the *preventative home visit* group was visited by one of the health professionals involved in the study to provide information and advice on various forms of activities to support aging in the community. The participants in the *control group* did not receive any intervention, but they had access to conventional aged care services from the municipality (e.g., home-help services). The findings from this study showed that the linguistically and culturally adapted health programs had a high retention rate of participants (86%), largely due to its person-centered approach. The participants responded favorably to the program being tailored to their language preferences. They also welcomed an approach that focuses on how each person can convert his or her resources into the actual achievement of a desirable state of health. The study shows the importance of tailoring health programs to linguistic preferences of older immigrants in order to build authentic and productive relationships between older immigrants and caregivers. This study also highlights the importance of connecting older people from culturally and linguistically diverse backgrounds with their communities and families to help them age well by remaining socially connected and active.

Recent research on older adults from Western cultures shows that group processes and social identities are effective resources to improve psychological adjustment in response to life changes (Haslam et al. 2014). The social support gained from a large network can provide individuals with

meaning and purpose in life, promote a sense of well-being, and allow integration into the larger society, thus positively influencing health and well-being. Older adults who have supportive social networks tend to enjoy better physical and mental health compared with those who are without such social networks. However, these processes and interventions need to be understood, adapted, and implemented for linguistically and culturally diverse communities. Moreover, improving the possibilities for older adults to take control over their health is an increasingly important public health practice. For example, Consumer Directed Care (CDC) is a new approach in community aged care that is being introduced in many Western countries (Laragy and Allen 2015). It is a radical departure from the traditional agency-directed aged care in that it aims to give more choice and control to aging persons. CDC programs aim to assist older people to live as independently as possible in their own homes and to maximize their choice and decision-making abilities while ensuring their safety and promoting restorative health. Health promotion in this area has previously been visualized to succeed with this approach, but the research has primarily focused on older adults who are native born, leaving the generalizability to people who are foreign born unexplored. However, CDC opens up a new avenue for the provision of culturally appropriate care to older people from diverse backgrounds.

Culturally appropriate aged care has significant consequences for the well-being of elderly immigrants, their children, communities, and the wider society. There is a need to advance our understanding of when and how individuals, their family, and the community can work together to promote successful aging. To date, documented research supports claims that the quality of community care depends on older immigrants having access to the services along with family support, yet little is known about why social isolation persists. Notably, we have limited knowledge of how older migrants' expectations match, or do not match, those of their family and community. Culturally appropriate interventions can also be delivered through digital medium. Through

Internet-enabled devices such as tablets, iPads, mobile phones, and computers, many older immigrants can keep contact with their old social circles such as old friends in home country, access news in their ethnic language, seek advice on health issues from medical professionals, and participate in workshop discussions virtually. All these activities may help to keep older immigrants socially connected and integrated. In an aging and culturally diverse society, it is important from both ethical and public health perspectives to explore how aged care services can become more culturally appropriate for older adults from diverse backgrounds.

Conclusion

Global trends of international migration have resulted in a sizable population aging outside of their places of origin. This demographic shift means that those countries with large aging migrant populations have economic and social imperatives to support successful aging of people from diverse backgrounds. This has resulted in a growing demand for culturally appropriate care, with implications for government, communities, aged and health-care providers, and social services. In particular, most developed nations share the growing need to support those who are aging in a foreign land, although the size and projected growth of the aging migrants vary across countries. A cross-cultural perspective is crucial for service delivery and policy development to meet the specific care needs of the diverse aging population.

Many variables including age, gender, living arrangement, length of residence in the migrated country, health, social roles, education, income, and social support contribute to psychological stressors in older immigrants. Older immigrants may have different health-care needs due to differences in cultural values, beliefs, and language. Differences in expectations of family support, cultural background, length of residence in the receiving country, possibility for returning to their country of birth, morbidity patterns, and language skills are but a few of the many factors

that are likely to shape experiences of aging and need for aged care among elderly immigrants (Kristiansen et al. 2015). Formal aged care providers need to ensure that their service takes into account the important role of family in providing vital informal support while also addressing the difficulties posed by language and literacy for older immigrants when they are faced with the need to access formal care. Developing culturally appropriate models of care to enhance successful aging and improve health outcomes is a challenge that we face today because service development and delivery need to be responsive to the culturally diverse population.

Mild Cognitive Impairment

Sylvie Belleville, Simon Cloutier and
Nick Corriveau-Lecavalier
Psychology Department, Research Centre, Institut
Universitaire de Gériatrie de Montréal, Montréal,
QC, Canada

Synonyms

Cognitively impaired not demented (CIND); Mild cognitive decline; Mild neurocognitive disorder

Definition

Alzheimer’s disease (AD) is a neurodegenerative disorder and its symptoms progress on a continuum from very mild deficits to dementia. Thus, the transition from normal cognition to dementia is not sudden, but rather a gradual process during which the number and severity of symptoms increase over time. The term mild cognitive impairment (MCI) is used to identify older adults whose performance on neuropsychological tests

is deemed abnormal for their age and educational level but is insufficient to interfere notably with activities of daily life and to justify a diagnosis of dementia. Many individuals who meet the criteria for MCI will progress to more severe symptoms. Hence, the condition might indicate a prodromal phase of Alzheimer's disease. Persons with MCI might also suffer from other age-related neurodegenerative disorder. It has been proposed that an MCI phase might also precede Parkinson's disease dementia, Lewy-body dementia, vascular dementia, and frontotemporal dementia.

Current Knowledge

The Concept of Mild Cognitive Impairment in the Continuum of Alzheimer's Disease

Dementia is a syndrome characterized by pervasive cognitive impairment and loss of autonomy. The number of individuals suffering from dementia worldwide was estimated to be 44 million in 2013 and is expected to rise considerably with the increase in population and life expectancy, especially in low- and middle-income countries. Though dementia can result from a range of brain illnesses, its most common cause is AD. AD is a progressive neurodegenerative disease characterized by two core pathological hallmarks: extracellular deposits of amyloid beta protein and intracellular neurofibrillary tangles. The disease has devastating impacts on the social, economic, and psychological well-being of affected individuals, and it requires that substantial research efforts be devoted towards its understanding. Yet the cause of AD remains elusive. One major challenge is to identify patients as early as possible. Early diagnosis would facilitate identification of the causal mechanisms of the disease. It would also allow for the early implementation of prevention strategies or treatments, before the devastating effects of AD can take place.

Currently, AD is only confirmed by its histopathological hallmarks upon postmortem examination. The premortem diagnosis is provided on the basis of a set of inclusion criteria to confirm abnormal deterioration of cognitive functions and

exclusion criteria to reject other etiologies as causative of the cognitive deficit. For many decades, the clinical diagnosis of AD was provided at the dementia phase, when cognitive impairment was pervasive and severe enough to significantly impact autonomy. Yet, it is now agreed that the clinical criteria for dementia identify patients many years after the onset of pathological events that lead up to AD and that the prodromal phase can span up to 15–20 years preceding dementia. This has generated considerable belief that AD could be diagnosed much earlier. A large number of terms have been proposed to identify this prodromal phase of AD; however, MCI is the one that prevails.

Historical Background

One of the earliest syndromic classifications of age-related cognitive decline was provided by Kral (1962), who contrasted “benign senescent forgetfulness” with “malignant senescent forgetfulness.” In this syndromic classification, “benign senescent forgetfulness” referred to a gradual decline of memory or cognition, which did not impact significantly on daily functioning. This was contrasted with a “malignant” form that was associated with dementia. The use of the term “mild cognitive impairment,” to describe patients who present significant cognitive decline but do not yet meet the criteria for dementia, may be originally attributed to a research team at New York University that used it in 1991 in the context of the stages proposed by the Global Deterioration Scale (GDS) (Flicker et al. 1991; Reisberg et al. 1982). The GDS comprises six stages of cognitive decline: Stage 1 – no cognitive decline, Stage 2 – very mild cognitive decline, Stage 3 – mild cognitive decline, Stage 4 – moderate cognitive decline, Stage 5 – moderately severe cognitive decline, and Stage 6 – severe cognitive decline. Stage 4 corresponds to early dementia. Patients in Stage 3 only experience mild deficits that would not interfere notably with activities of daily life. In 1991, Flicker and colleagues (1991) found that the mildly impaired subjects (classified in Stage 3) showed significantly poorer performance than healthy controls on tests of recent

memory, remote memory, language function, concept formation, and visuospatial praxis. They used the term MCI to identify this condition. Following this first conceptualization, Zaudig proposed (1992) three types of MCI based on the *Diagnostic and Statistical Manual of Mental Disorders*, 3rd Edition-Revised (DSM-III-R), and on the World Health Organization’s *International Statistical Classification of Disorders and Health Related Problems*, 10th revision (ICD-10). Type 1 only involved memory impairment, Type 2 was characterized by impairment of memory and another cognitive domain, and Type 3 involved Type 1 or 2 with deterioration of emotional control, social behavior, or motivation. These early works laid the foundation for some of the more recent MCI classifications (Petersen et al. 2001; Winblad et al. 2004), NIA/AA (Albert et al. 2011).

Recent Conceptualizations and Criteria

Based on follow-up studies of a large clinical cohort by the Mayo Clinic in the 1990s, Petersen and his colleagues posited that many persons with MCI were in the prodromal phase of dementia. They proposed a set of criteria to identify those individuals (Petersen et al. 1999) (see Table 1 for a summary of the main criteria for MCI based on recent conceptualizations): Persons with MCI complained about their memory, showed objective memory difficulties beyond what is expected considering their sociodemographic characteristics, did not show general cognitive impairment, still performed their daily activities independently, and failed to meet clinical criteria for dementia. Follow-up studies of the group indicated that every year 10–15% of persons meeting those criteria went on to develop AD, a far higher

rate than that observed in the normal population (1–5% per year) (see Gauthier et al. 2006). Later studies indicated that the progression rate of MCI varied as a function of their recruitment source, criteria, and follow-up length but was still much larger than that of non-MCI individuals. The work led by Petersen at the Mayo Clinic has had a considerable impact on the field, by providing well-defined criteria that stimulated an explosion of studies investigating prodromal AD and facilitated cross-study comparisons. Overall, these studies showed that the clinical and pathophysiological characteristics of MCI are close to those found with dementia of the Alzheimer type, supporting the notion that MCI captures a group of individuals in a transitional state between normal aging and dementia.

In spite of their heuristic value, the initial criteria were criticized on a number of grounds and other conceptualizations were proposed (Table 1; Petersen et al. 2001; Winblad et al. 2004). One major criticism was that MCI is a heterogeneous condition and that cognitive symptoms are not restricted to the memory domain. As the initial criteria only included memory deficits, they failed to cover the entire range of symptoms that are found in prodromal AD. Thus, it was proposed that individuals with MCI and only memory deficits should be identified as having amnesic MCI, and the term “multidomain amnesic MCI” should be used to identify those with deficits in memory as well as in other cognitive domains. In turn, the authors suggest using the term nonamnesic single- or multidomain MCI for individuals presenting deficits in one or more domains other than memory (Petersen et al. 2001). There are also discussions regarding the heterogeneous etiology of MCI. It is now broadly agreed that different profiles might represent different etiologies, supporting the importance of qualifying the symptomatic profiles of MCI.

In 2011, the National Institute on Aging and the Alzheimer’s Association workgroups (NIA/AA) on diagnostic guidelines for Alzheimer’s disease proposed an updated set of criteria for MCI that distinguished clinical criteria from criteria to support research (http://www.alz.org/research/diagnostic_criteria and Table 1) (Albert

et al. 2011). They proposed that the MCI clinical criteria be based on two processes. First, the clinician should establish the presence of clinical and cognitive criteria: (1) presence of a concern about a *change* in cognition, reported by the patient, an informant, or a clinician; (2) evidence of an impairment in one or more cognitive domains; (3) preservation of independence in functional abilities; (4) not demented. Second, the clinician should examine if the etiology is consistent with AD pathophysiology by: (1) ruling out vascular, traumatic, medical causes of decline; (2) providing evidence of cognitive decline over time, where possible; (3) reporting history consistent with AD genetic factors, where relevant. For research purposes, the workgroup proposed the use of biomarkers to document the likelihood of AD as the underlying etiology. Hence, the presence of positive markers of amyloid deposition (Cerebrospinal fluid (CSF) or Positron emission tomography (PET)) and neuronal injury (Tau, Fludeoxyglucose-PET (FDG-PET), structural MRI) would indicate that there is a high likelihood that the MCI is due to AD.

The DSM-5 (American Psychiatric Association 2013), published in 2013, also incorporated the notion of prodromal AD. However, the terminology is strikingly different from that used to describe MCI. The manual proposed three types of acquired neurocognitive disorders: delirium, minor neurocognitive disorders, and major neurocognitive disorder, with etiological subtypes for the latter two. Major neurocognitive disorder refers to dementia and, where applicable, can be attributed to Alzheimer’s disease. The criteria for minor neurocognitive disorder are similar to those generally proposed for MCI (Table 1). They include: (1) a modest decline of at least one cognitive domain; (2) the decline has no significant impact on professional or social activities, though it is recognized that those activities might require more effort, adaptation, or compensation; (3) the decline does not occur during an episode of delirium; and (4) it is not explained by another mental disorder. When diagnosing a minor neurocognitive disorder, the clinician is expected to specify its etiology and whether it is accompanied by behavioral symptoms. The clinician will

diagnose possible AD when there is objective decline in memory and at least one other cognitive domain, onset is insidious, decline is gradual, and when there is no evidence of a mixed etiology. To support a diagnosis of minor neurocognitive disorder with probable AD as an etiology, the clinician must have evidence of insidious onset, gradual decline, *and* presence of a genetic mutation related to AD.

Cognitive Symptoms

Characterizing the cognitive deficits found in MCI is critical for neuropsychologists who contribute to diagnose AD and MCI and whose assessments are used to guide intervention strategies. For this reason, the study of cognitive impairment in MCI has been the subject of considerable research efforts. As a result, clinicians now have a fairly well-delineated picture of the impairments found in MCI. Episodic memory – the record of personal events encoded in their spatiotemporal context – is impaired early and quite extensively in persons with MCI. Episodic memory deficits were reported when tested with verbal or nonverbal material, with or without retrieval cues (Belleville et al. 2008). Among the different measures of episodic memory, delayed recall and associative memory, the ability to bind different items, are particularly sensitive in MCI (Belleville et al. 2008). This is unsurprising, given the hippocampal damage found early in prodromal AD. In addition, numerous studies reported evidence of impaired executive functions and attentional control in MCI. Impairments were found using tests that reflected different executive components: inhibition capacities, working memory, switching, and divided attention (Belleville et al. 2007, 2008; Dannhauser et al. 2005). Impaired executive functions might indicate a more severe stage of MCI. However, it has also been suggested to reflect comorbid conditions that are characterized by executive deficits, particularly vascular diseases and/or depression.

AD and MCI are both progressive; however, most studies have failed to reveal the patterns of changes as cognitive deficits unfold. Natural history studies can characterize these changes that

occur as MCI progresses and provide the opportunity to study the trajectory of symptoms in different cognitive domains. Findings from natural history studies show that the decline occurs faster in MCI persons, compared to cognitively healthy controls (Wilson et al. 2010). However, the trajectory of this decline varies greatly depending on the cognitive domain. Decline in a number of nonmemory cognitive domains (e.g., visuospatial abilities, inhibition) appears to be a gradual process, a continuous, linear trend (Cloutier et al. 2015). In contrast, episodic memory and working memory present a distinct pattern of decline: years of stable performance followed by a rapid decline, just prior to a dementia diagnosis. This decline pattern suggests that dementia may coincide with a failure of compensation in these memory domains (Twamley et al. 2006; Clement and Belleville 2010).

Noncognitive Symptoms

Although MCI is typically defined as a cognitive syndrome, other noncognitive symptoms often occur. Many individuals report depressive symptoms, anxiety, signs of apathy, and sleep disturbances (For a review, see Apostolova and Cummings 2008). It is not entirely clear whether those symptoms are psychological reactions to the cognitive changes of MCI or whether they are pathognomonic. Notably, many studies indicate that those symptoms can predict progression from MCI to dementia (Apostolova and Cummings 2008). This finding supports the notion that they are not due to the psychological distress caused by memory challenges, but rather result from biological changes associated with the disease. One possibility is that the symptoms reflect the presence of neuropathology in regions involved in emotional regulation.

Neuroimaging Studies and Other Biomarkers

Neuroimaging is a prominent field of MCI research, because it has tremendous potential to provide early in-vivo biomarkers of MCI pathophysiology. In addition, functional brain imaging can reveal the patterns of compensation and neuroplasticity that occur during progression of MCI.

Pittsburgh Compound-B (PiB) is a tracer used in positron emission tomography (PET) to observe amyloid deposition in the brain. Persons with MCI who have significant amyloid burden are at a higher risk of converting to AD, and a higher PiB retention is correlated with poorer performance on episodic memory tasks (Forsberg et al. 2008). CSF can also provide sensitive markers of MCI pathophysiology. Compared to controls, MCI patients who will later progress to dementia have significantly lower CSF A β 42 (marker of amyloid) levels and higher CSF Tau (marker of neuronal injury) and phosphorylated Tau (pTau; marker of tangles) levels (Andreasen et al. 2003), a pattern similar to that found in demented AD patients. These biochemical changes in CSF are the first detectable markers of the disease, and the combination of low CSF A β 42 and high CSF Tau/pTau is a strong predictor of future cognitive decline in MCI.

Fludeoxyglucose (FDG)-PET is a marker of glucose uptake, which is an indirect measure of brain activity and metabolism, and reflects neuronal integrity. Hypometabolism, particularly in the temporoparietal regions, is a predictor of future progression in persons with MCI (Chetelat et al. 2003). Evidence of hypometabolism using FDG-PET, one of the earliest markers of the disease, was demonstrated in regions associated with episodic memory (hippocampus, entorhinal cortices), prior to showing cognitive symptoms or significant atrophy in presymptomatic carriers of familial type AD mutations (see section on genetics) (Mosconi et al. 2006).

Because the technique is widely available, noninvasive, reliable, and not costly images based on magnetic resonance imaging (MRI) have been well investigated. Structural MRI studies have demonstrated that the atrophy rate of many regions of the brain follows a linear and distinct sequence as the individual progresses toward dementia (Risacher and Saykin 2013). At the very beginning of the disease, atrophy is principally observed in the medio-temporal lobe, as the hippocampal volume reduces by 3% annually. As the disease becomes more severe, atrophy tends to spread to other cortical regions like the lateral temporal, parietal, and frontal lobes

(Risacher and Saykin 2013). Moreover, Apolipoprotein e4 (ApoE4) allele, a well-investigated gene in AD, has been shown to have a modest but significant effect on the annual atrophy rate (ApoE4 Risacher and Saykin 2013). More precisely, ApoE4 carriers show a faster annual rate of atrophy of the hippocampal and entorhinal cortices.

Whereas neuronal integrity decreases gradually during the MCI phase, fMRI studies have shown a paradoxical inverted u-shape function to express task-related brain activation. Dickerson et al. (2004) were the first to report such a selective relationship between fMRI activation, degree of impairment, and subsequent clinical decline among individuals with MCI. They found that greater activation in the parahippocampal gyrus (PHG) and hippocampal formation (HF) during encoding was associated with future clinical decline over an average of a 2.5-year follow-up period. They came to the conclusion that hyperactivation in these regions probably reflected compensatory mechanisms that are specific to predementia patients. Clément and Belleville (2012) elaborated a model of compensation-related activation in the brains of individuals with MCI, according to disease severity and task nature. They proposed that during the early phase of MCI, when there is only mild neuropathology in the region involved in a task, performance would be optimized by hyperactivating that region, as well as by recruiting additional regions that were not implicated in the task. However, as the disease gets more severe and affects compensatory regions, the brain would no longer have the capacity to overrecruit and compensate. This compensation breakdown would result in less activation and fewer regions involved in a task, a pattern similar to that found in demented patients. Clément and Belleville (2012) proposed that the point at which compensation-related mechanisms would be observed during the progression of the disease is related to the nature of the task. They found that compensation occurs earlier for associative recognition, which relies on brain regions that are altered early in the disease, than for item recognition, which depends on brain regions impaired later in the disease. In this study, the

brains of participants in a very early phase of MCI showed greater activation in regions known to be involved in episodic retrieval (e.g., dorsolateral and ventrolateral prefrontal cortices). Moreover, their brains recruited also additional regions: more posterior (i.e., precuneus, right temporal lobe, inferior and superior parietal lobules) and bilateral regions (i.e., prefrontal cortex) that are not usually involved in verbal episodic tasks or retrieval. Individuals with more severe MCI showed a shift in compensation mechanisms on tasks involving cognitive processes that are impaired later in the disease (an item recognition task). During the item recognition task, their brains showed hyperactivation in regions known to be involved in episodic retrieval and recruited additional bilateral regions (e.g., the prefrontal cortex). In contrast, the associative memory task resulted in lower activation, fewer regions involved in the task, and poorer performance. This suggests that these individuals' brains were not able to compensate for that task.

To summarize, the neuroimaging techniques and biomarkers available to clinicians and researchers help facilitate early diagnosis, identify the etiology, and understand the pathophysiology of the disease, as well as the dynamic processes of compensation. Different markers have different uses and advantages. For instance, PiB-PET and FDG-PET show similar diagnostic accuracy for MCI, but PiB-PET may be better for identifying AD as an etiology of MCI. However, PiB retention is thought to rapidly reach a plateau during the prodromal phase, and hence, might not be the best indicator of disease severity.

The Genetics of MCI

One of the most well-known and researched genes in AD is the ApoE gene. The $\epsilon 4$ variant increases one's risk of developing MCI and converting to AD (Poirier et al. 1993). Genetics research has identified many other "risk genes" of AD, such as the clusterin (CLU) gene or the complement receptor 1 (CR1) gene (Bettens et al. 2013). Mutations on these genes augment one's risk of developing dementia but are not causative. A very rare type of AD, called autosomal-dominant familial AD, is caused by mutations on the amyloid

precursor protein (APP), presenilin1 (PSEN1), and presenilin2 (PSEN2) genes (Bird 2012). This familial type is characterized by early onset, generally before the age of 60, and represents fewer than 1% of all AD cases. This form of AD is preceded by a prodromal, or MCI, phase. Therefore, autosomal-dominant MCI and AD represent a unique resource to study: not only the cognitive profiles of the mutation carriers but also the imaging and biochemical markers of the disease in its early phases.

Predicting Dementia in Persons with MCI

A problematic issue regarding MCI is that its prognosis is uncertain. Whereas the majority of individuals with MCI will progress to dementia, a proportion varying between 13.5% and 44% will remain stable or revert back to normal (see Gauthier et al. 2006; Albert et al. 2011). It is thus critical to identify those individuals who will develop AD. Many studies use longitudinal and prospective protocols to differentiate persons with MCI who will progress to dementia from those who will not. Cognitive measures have demonstrated very promising results for predicting dementia. Tests of episodic memory, especially associative memory, have been shown to be the most robust predictors; measures of working memory, executive functions, perception, and language have also been shown to be reliable predictors (Belleville et al. 2014a, b). However, prediction is optimal when neuropsychological assessments examine episodic memory along with multiple cognitive functions. For example, Belleville et al. (2014a) assessed a cohort of individuals with MCI using a battery of tests measuring episodic memory (macro elements of the MEMO-TEXT and free recall of words in the Free and Cued Recall Test), working memory, executive functions and attentional control (Alpha-Span), perception (orientation match and object decision of the BORB), and language (object-naming of the DO-80). Over an average of a 4.5-year follow-up period, their test battery predicted the individuals with MCI who would later develop AD and those who would remain stable, with an overall accuracy of 87.7%.

In the field of neuroimaging, most studies have focused on medial temporal structure. Atrophy within these structures is observable many years prior to diagnosis, with the hippocampal volume being the strongest predictor (Trzepacz et al. 2014). For example, hippocampal and entorhinal cortex atrophy have been shown to predict AD in those with MCI, with an accuracy of 60% over a 2.5-year follow-up period. When combined with clinical data, the accuracy reached 78.8% (Belleville et al. 2014b). Other parts of the brain have also been shown to be reliable predictors of dementia. Peters et al. (2014) assessed individuals with MCI over a 2-year follow-up period using neuropsychological and MRI data. They demonstrated that atrophy of the right anterior cingulate and the right middle frontal gyri could predict progression toward dementia with an accuracy of 75%. Furthermore, they elaborated a model combining atrophy of the right anterior cingulate gyrus with neuropsychological tests measuring episodic memory (immediate free recall and immediate recognition of the Memoria Battery). Their model showed prediction accuracy of up to 87.5%. PiB-PET amyloid imaging has also been shown to be a reliable prediction technique, especially in combination with MRI measures. Trzepacz et al. (2014) assessed individuals with MCI using PET and MRI techniques over a 2-year follow-up period. The MRI scan of the temporal cortex showed 72% accuracy, followed by a PiB-PET scan of the lateral temporal cortex and MRI scans of the entorhinal cortex and hippocampus, both with 68% accuracy. Combined, the MRI and PiB-PET data had an accuracy of 76%.

Overall, studies have shown that both cognitive and neuroimaging measures are useful in predicting progression to dementia. Predictive accuracy increases substantially when the different types of predictors are combined. As research begins to focus on earlier phases of the disease, an approach combining multiple cognitive measures with biomarkers will be required to support predictive accuracy and to understand the interaction between these predictors. This reflects the

NIA/AA criteria for MCI of the Alzheimer type, where biomarkers take a prominent role in combination with clinical indicators to identify the underlying etiology of the disorder.

Management, Prevention, Intervention

In the absence of disease-modifying treatments, many scholars have recommended using prevention or intervention strategies to delay the onset or progression of the cognitive symptoms of AD. To have the greatest effect, these strategies would likely have to be implemented early, specifically during the MCI phase, when the individual is still motivated and has the capacity to learn and apply new strategies and behaviors. Many studies have examined whether cognitive interventions – techniques and programs designed to increase or optimize cognition – improve cognitive functioning in persons with MCI. Different types of training have been tested but most of them focused on episodic memory. Most of the programs that were used in MCI to improve their memory relied on compensatory techniques. Hence, participants were taught different mnemotechnics that make use of their intact visual imagery of semantic knowledge capacities to support memory encoding. A few programs have also relied on less demanding memory techniques, for instance, spaced retrieval techniques or vanishing cues. Most of the programs provided to MCI were multicomponential in that they not only targeted memory but also other cognitive domains, most often attention/executive functions. Results indicate that episodic memory, attention, and well-being can be improved by strategic attentional or memory training and that it can sustain over time (Simon et al. 2012). In addition, brain imaging indicates that those interventions can increase brain activation in alternative and specialized regions (Belleville et al. 2011; Hampstead et al. 2011). Those studies indicate that cognitive training programs can be a powerful tool and have beneficial effects during the MCI phase. Furthermore, cognitive training has a direct effect on the brain of those individuals, which indicates that it might increase brain reserve and brain plasticity.

Epidemiological studies have shown that lifestyle factors can increase the risk of cognitive decline, dementia, and AD and might account for up to 50% of the AD cases worldwide. Physical activity, diet, vascular risk factors, education, depression, and lifelong cognitive stimulation are among the modifiable risk factors that have the strongest relation with dementia. A successfully implemented prevention approach that targets these modifiable factors in persons at risk of AD has the potential to have a tremendous impact on the number of cases. Large-scale multimodal prevention trials are being carried out worldwide to determine whether improving some protective lifestyle factors in older age can reduce cognitive decline in persons at risk for the disease. The Finnish Geriatric Intervention Study to Prevent Cognitive Impairment and Disability (FINGER), a double-blind randomized control trial, enrolled 1260 older adults with a vascular risk of dementia. Participants received an intervention of healthy diet, physical exercise, vascular risk monitoring, and cognitive training versus general health advices. The authors recently reported that the intervention reduced the rate of cognitive decline over a two-year period when compared to the control group (Ngandu et al. 2015). The Multidomain Alzheimer Preventive Trial (MAPT) study (Vellas et al. 2014) examined whether a multidomain intervention including nutritional counseling, physical exercise, cognitive training, and social activities, in combination with omega-3 fatty acid supplementation, would reduce cognitive decline in older adults with a subjective complaint or risk of frailty.

Future Directions

The study of MCI has been influential and is growing quickly. Yet, there are still a number of unresolved issues related to the criteria, prognosis, early clinical manifestation, progression, and management of MCI. Given that new criteria have been proposed to identify those in the early stage of AD, studies will be required to test their

validity and evaluate whether all items are necessary. Another important challenge is to identify the source of interindividual variability among cognitive profiles and resistance to pathology and to identify the factors that contribute to different profiles. Studies on brain resilience and brain reserve will contribute to better understand why individuals vary in their resistance to neurodegenerative diseases.

Longitudinal studies of MCI and the use of complex methodology and statistical models will be critical to better understand how symptoms change during the early phase of the cognitive disease. For instance, it is generally assumed that decline occurs in a linear fashion; however, it is possible that more complex trajectories better explain the progression of cognitive symptoms during the MCI phase. Recent studies suggest that some domains are characterized by many years of stable performance, followed by a rapid decline just prior to AD diagnosis. Thus, future studies will have to assess complex patterns to provide an accurate picture of how the decline unfolds in the years preceding a dementia diagnosis. These should include persons with subjective cognitive decline. Some of these individuals might stand in a very early phase of the disease and their longitudinal assessment might be the key to reveal the earliest cognitive symptoms of AD.

The study of familial Alzheimer's disease (FAD) mutation carriers has been an important area of research. Carriers of mutations on the APP, PSEN1, and PSEN2 genes represent an ideal population for studying the early phases of dementia, due to the certainty that they will receive a future AD diagnosis. It is also possible to estimate their age of onset, based on the age at which their parent received his/her diagnosis. However, we need to know when and how symptoms unfold in mutation carriers and to assess whether individual or lifestyle characteristics affect the symptomatic expression of the disease in this population. We also need to improve our knowledge of how the preclinical phase of FAD compares with that of sporadic AD.

There is still work to be done in the field of cognitive test development. As research moves towards studying earlier phases of the disease, neuropsychologists will need access to more sensitive measures and algorithms to identify the earlier cognitive changes. Technological advances in the fields of virtual reality, information and communication technologies, continuous performance monitoring, wearable or environmental sensors, and online testing might provide promising innovations. In addition, multimodal biomarker models that combine cognitive and clinical measures with innovative biomarkers will be necessary to optimize predictive models of dementia. Furthermore, future studies involving neuroimaging should examine the relationship between structural damage and activation patterns. Because compensation mechanisms are likely highly active during prodromal AD, functional brain imaging can contribute knowledge of these mechanisms taking place as brain damage progresses. Such knowledge will shed light on the way by which the brain expresses resilience during the early phase of the disease.

Finally, the MCI phase has been identified as one that might be a suitable target for intervention and secondary prevention strategies. Reducing the cognitive symptoms and delaying their impact on independence are potentially powerful approach to reduce the number of dementia cases worldwide. However, designing and implementing efficient intervention and prevention strategies is challenging and will require more research to identify responders, optimal temporal therapeutic windows, and ways to overcome barriers to behavioral changes.

Supporting such an ambitious research agenda will require large longitudinal studies of well-characterized cohorts with clinical follow-up and, ideally, postmortem analysis of the brain to identify the etiology. The increasing efforts to develop national and multinational initiatives that use large cohorts and allow analyses of big data sets will enable these questions to be addressed. To be successful, those efforts will require at least some partial harmonization of clinical and data collection procedures. In addition, there will be a need to train clinicians to the

notion of MCI in the context of slowly evolving neurodegenerative diseases so that the concept translate more rapidly from research to the clinical practice.

Mindfulness

Definition

Mindfulness is “the awareness that emerges through paying attention on purpose, in the

present moment, and nonjudgmentally to the unfolding of experience moment by moment” (p. 145) (Kabat-Zinn 2003).

Introduction

Mindfulness is an ancient practice that has gained popularity in Western cultures in the past few decades. There is a large body of research demonstrating a wealth of benefits of mindfulness practices in the adult population. Recently, there is growing interest in the benefits of mindfulness and its many approaches in the elderly given this population’s unique characteristics and challenges. In an era with increased awareness, inquisition, and proactive attitudes toward healthy aging, there is keen interest in behaviors and practices that may help prevent negative effects of aging. Excitingly, many mindfulness-based approaches are extending into the doctor’s office as a way to improve or maintain wellness throughout the life span, including in the elderly.

This entry will first review the general goals of mindfulness practice and evidence for its impact on multiple aspects of functioning and will report on clinical and non-clinical populations in which it has been studied. The second part of the entry will discuss factors that are unique to the elderly population that give rise to the benefits of consistent mindful practice. Next will be a discussion of select methods that have adapted mindfulness techniques specifically for the elderly and a review of the emotional, cognitive, and biologic benefit of mindfulness practice in this population. Finally, we will provide an illustrative example of one experience at the Mayo Clinic is presented in which mindfulness practices have been incorporated and embraced to promote quality of life, as well as cognitive and emotional wellness, in an elderly population with mild cognitive decline.

Mindfulness Approaches and Methods

Foundations of Mindfulness

Broadly stated, mindfulness is “the awareness that emerges through paying attention on purpose, in the present moment, and nonjudgmentally to the

unfolding of experience moment by moment” (p. 145) (Kabat-Zinn 2003). The practice of mindfulness is an active, conscious skill incorporating several interrelated foundational attitudes that, among many benefits, help to improve quality of life, cope with medical conditions, reduce stress, and live more simply (Sood 2013a). While there are many variations and definitions of mindfulness, most hold general principles in common, including non-judging, patience, a beginner’s mind, trust, non-striving, acceptance, and letting go (Kabat-Zinn 1991), which are reviewed here briefly.

The attitude of *non-judging* during conscious awareness of one’s thoughts and experiences disengages the automatic tendency to place a label or value on something as “good” or “bad,” “right” or “wrong” and instead allows the mind to simply observe that act, thought, or event as it is. With a nonjudgmental consciousness, a more steady state of awareness may be achieved rather than experiencing highs and lows. *Patience* within mindfulness practice allows the mind to be more fully present with the current experience, and observing (nonjudgmentally) all aspects of the experience, rather than letting the mind rush toward the future or wonder back to past events or thoughts. The attitude of *beginner’s mind* encourages awareness of each experience as if it is occurring for the first time. This curiosity of a novel stimulus allows a fuller awareness of its unique aspects that may have otherwise been clouded, distorted, or glossed over due to prior experiences or thoughts. A deeper sense of *trust* in one’s feelings and intuition develops through mindfulness practice and allows the individual to become more authentically oneself and able to see the good in others as well. The *non-striving* quality of mindfulness is another way in which the mind is aware of the moment to moment present. That is, rather than working toward a specific goal such as “to have less pain” or “to be less stressed,” the non-striving attitude gives one permission to experience fully each present moment as it is, rather than as a means to an end. The attitude to *accept* things, and observe them, as they are rather than wasting cognitive and emotional energy on wishing they were something else is strongly related to the final attitude of *letting go*. This is a

way of embracing the present for all that it is and to not let the mind reject certain thoughts or experiences and hold on to others. Instead, letting go allows the mind to freely, nonjudgmentally, accept each moment as it occurs for what it is in a manner that is open to patiently experience the next.

Although discussed individually, these attitudes are interrelated and improve with practice. The reader is challenged to consider these foundational principles of mindfulness throughout the discussion of how mindfulness may be incorporated and applied in a variety of settings and populations, with particular attention and benefit to the elderly.

Mindfulness Interventions

Because of the adaptability of mindfulness principles and their benefit across populations, mindfulness-based techniques have been incorporated into treatments and interventions for a number of clinical and non-clinical populations. In particular, using the basic principles of mindfulness, Kabatt-Zinn (1991) created a mindfulness-based stress reduction (MBSR) foundational treatment approach. Traditionally, MBSR combines mindful meditation and yoga in an 8-week course requiring weekly meetings and home practice. This basic MBSR intervention has been applied to many different populations, including those with chronic pain, cancer, insomnia, substance abuse (Grossman et al. 2004 for review), and even neurodegenerative populations, including those with Parkinson’s disease (Pickut et al. 2013). Aspects of mindfulness and cognitive-behavioral therapy have been combined into other widely used interventions that have been shown to be effective, including dialectical behavior therapy, acceptance and commitment therapy, and mindfulness-based cognitive therapy for depression.

Attention and interpretation therapy (AIT) is a mindfulness approach developed by Dr. Amit Sood at the Mayo Clinic intended to decrease stress and enhance resilience (Sood 2013b). He asserts that human attention instinctively focuses on threats and imperfections, which in turn roots attention in the past and future. AIT focuses on

guiding attention away from overfocus on the self and redirecting attention to the present moment and replacing negative thoughts with those of gratitude and compassion. In AIT, learners use practice and journaling to focus on the five pillars of gratitude, compassion, acceptance, meaning, and forgiveness. The Stress Management and Resiliency Training, or the “SMART” program, is an adaptation of AIT which can be administered in just one or two brief sessions (less than 2 h total) (Sood et al. 2011). Originally designed to address stress among busy physicians, the SMART intervention has shown promise in clinical populations, including women with breast cancer (Loprinzi et al. 2011). Mindfulness-based interventions, such as SMART, AIT, and MBSR, are now offered at major medical centers across the United States and worldwide and are increasingly accepted as mainstream and covered by insurers.

Recent work has sought to apply the traditional MBSR program and in some studies customize mindfulness techniques to the unique aspects of the elderly population.

Factors Unique for Elderly

Each developmental stage in life brings with it unique challenges. As a cohort, individuals approach the later stages of life with cumulative experiences in their history and unique challenges and goals for the future. According to Sood et al. (2011), if left unfocused, the mind tends to wander and ruminate on past experiences or worry and attempt to anticipate future experiences. The content of these ruminations may differ decidedly for the elderly as they approach the latter stages of life. Alternatively, mindfulness challenges the elder to live in and fully experience the present nonjudgmentally. Thus mindfulness in the elderly may help to increase focus on an appreciation for the present, which ultimately may lead to increased quality of life.

The elderly population is more likely to experience a number of physical symptoms, from orthopedic pains to more severe chronic medical conditions. The accumulation and increased severity of these biological changes may lead to withdrawal from pleasurable physical activities

and the health benefits and social interaction they may provide. These changes may lead to an increase in negative emotions (Rejeski 2008). Cognition also changes as the biological system ages, even in healthy aging. This population may face unique financial challenges and is more likely to experience illness of friends and relatives (de Frias 2014). The elderly are at a unique stage where they are required to integrate these cumulative life experiences and stressors with a “conative balance,” or living their remaining life with values that may be different than when they were younger and in a way that will shape the way others remember them when they pass (Rejeski 2008). These challenges could be uniquely addressed by mindfulness approaches that promote awareness to the present without judgment or evaluation. Indeed, a recent study found elders who were more mindful had greater emotional health in late life and may be less reactive to external stressors (de Frias 2014), suggesting that mindfulness may help elders stay presently focused and remain resilient in the context of threats to quality of life.

Within the context of these characteristics, Zellner Kellar et al. (2014) are creating a Mindfulness-Based Cognitive Approach for Seniors (MBCAS), specifically geared toward the elderly. The goals of this 8-month program include training the conscious awareness of the elders to “observe current experience with non-judgmental awareness, identify automatic behaviors or reactions to current experiences that are potentially nonadaptive, and enhance and reinforce positive coping with typical difficulties they face in their daily lives” (Zellner Kellar et al. 2014). Preliminary data suggest that elders who completed this program reported a positive change in depression scores, well-being, and self-esteem (Zellner Kellar et al. 2014). While more data are needed, the structure and goals of this approach appear promising.

Applications and Effects of Mindfulness

Mindfulness techniques may be incorporated into daily activities and routines or can be practiced in dedicated sessions/settings. These techniques may also be practiced at either the individual or

group level. As distinguished from meditation, mindfulness does not necessarily require a quiet environment. Rather, mindfulness is about being fully in the sensory experience of each moment without judgment. As such, common applications of mindfulness techniques include mindful eating, mindful walking, mindful breathing (Sood 2013a), as well as body scan or systematic awareness of various aspects of the body, and sitting meditation (Kabat-Zinn 1991). Additionally, a growing practice of physical activity that readily incorporates aspects of mindfulness is yoga (Rejeski 2008). All of these activities are frequently applied to the elderly population, including in gentle yoga as will be described in the illustrative example at the end of this entry. There is growing literature demonstrating the benefit of mindfulness-based practice in the elderly, including emotional improvement and social well-being, cognitive health, and neurobiological benefits.

Emotional and Social Benefits

A growing number of studies suggest mindfulness benefits the emotional and social well-being as well as quality of life in the elderly population. For example, modifying the mindfulness-based cognitive therapy (MBCT) Segal et al. (2002) developed initially for depressive populations, Foulk et al. (2014) conducted a series of 8-week MBCT sessions for older adults (mean age 72.9 years) with symptoms of depression and/or anxiety. This team took care to modify experiential practice in the weekly sessions to improve physical comfort, such as sitting in a chair or using pillows for support during floor exercises, or incorporating a “body scan” physical awareness of sensation rather than walking meditation, to reduce physical burden. With these age-appropriate modifications, elders who completed the program reported significant improvement in symptoms of anxiety, less ruminative thoughts, and fewer sleep-related problems. They also found a trend toward less depressive symptoms (Foulk et al. 2014). Together, this study supports the value of combining mindfulness, cognitive, and behavioral strategies into a unified treatment as an alternative to pharmacotherapy.

Other studies that use the traditional MBSR also show emotional benefit in elders. For example, Lenze et al. (2014) found improvement in a self-report measure of worry in elders who completed either 12- or 8-week MBSR programs. Similar findings including general improvement in levels of emotional distress and mood measures after MBSR have been shown in older adults (Young and Baime 2010). Interestingly, one study involving 73 older adults found that those elders who scored higher on a mindfulness self-report measure also reported higher psychological well-being (Fiocco and Mallya 2015). Engaging in mindfulness practice has also been associated with improvements in perceptions of quality of life in nursing home residents (Ernst et al. 2008). In a comprehensive review, Prakash et al. (2014) theorize that these many emotional benefits of mindfulness in the elderly may be related to an increased ability to minimize one’s reactions to external events that are out of one’s control as well as to minimize the internal pains that one creates in response to undesirable events or thoughts. This theory is similar to the notion of disconnecting pain from suffering, which is a common goal of mindfulness-based approaches. With the emotional benefits of mindfulness practice, including enhanced emotional control and less reactivity, the individual may be more open to fully experience each moment without judgment or labeling. This more consistent steady state of emotional health lends well to enter into more meaningful relationships with others (Sood 2013a). Mindfulness has also been shown to reduce self-perception and thoughts of loneliness in elders (Creswell et al. 2012).

Cognitive Health

Data from behavioral and neuroimaging studies suggest that mindfulness practice in the elderly may improve cognitive control by developing an improved ability to maintain goal-directed attention (Prakash et al. 2014). A review of cognitive outcome studies of mindfulness practice reveals a positive impact on a variety of cognitive domains in the elderly, particularly attention, memory, executive functioning, processing speed, and overall general cognition (Gard et al. 2014),

perhaps related to improved maintenance of goal-directed attention. One study comparing the effects of 8-week and 12-week MBSR programs found improved memory on formal neuropsychological testing after MBSR, with similar benefit found with the 8- and 12-week programs (Lenze et al. 2014). Another review of mindfulness effects in the elderly found evidence for positive effects on attention, cognitive flexibility, memory, and verbal fluency and structural brain changes with the use of magnetic resonance imaging (MRI) (Marciniak et al. 2014). The authors further suggest that mindfulness may be of particular benefit as a non-pharmacological technique that may help prevent or delay cognitive decline.

Biological Effects

In addition to the apparent cognitive benefits of mindfulness in the elderly, a number of studies have found that mindfulness is correlated with structural brain and biologic changes, implicating mindfulness as a potential way to promote brain health and plasticity. For example, Pickut et al. (2013) compared a group of patients with Parkinson's disease who completed an 8-week MBSR program and compared structural brain scans before and after the mindfulness intervention to a wait-list control group. The mindfulness group showed increased gray matter density in the right amygdala, bilateral hippocampi, and bilateral caudate compared to the control group (Pickut et al. 2013). This study suggests MBSR may be associated with brain plasticity even in a neurodegenerative clinical population.

Other biological effects of mindfulness include potential downregulation in pro-inflammatory gene expression in leukocytes of elders who completed mindfulness interventions (Creswell et al. 2012). Immune system response and changes in biomarkers of longevity as well as mood improvements are apparent even when incorporating mindfulness into sitting meditation, body scan, and particularly yoga in the elderly (Gallegos et al. 2013). Additionally, in a sample of elderly African Americans living in low-income urban housing, a greater reduction in systolic and diastolic blood pressure was found in a group who received MBSR compared to a

social support control group (Palta et al. 2012), which may have important implications for primary care settings as a non-pharmacological intervention aimed at reducing blood pressure and minimizing medical visits.

In summary, the apparent health and quality of life benefits of mindfulness have propelled its use into mainstream culture and, increasingly, into the healthcare setting. Efforts to promote health through mindfulness may have profound benefit at the primary care level of intervention to reduce later cost of those who may have otherwise developed medical conditions requiring expensive treatment and/or long-term care. Indeed, while more research is needed, mindfulness techniques may prove to be of particular benefit as non-pharmacological methods to prevent or slow the progression of cognitive decline in the elderly by modifying many known dementia risk factors such as hypertension, cerebral blood flow, depression, oxidative stress, and metabolic syndrome (Marciniak et al. 2014).

Illustrative Example

Mayo Clinic offers a therapeutic intervention called HABILIT[®] – Healthy Actions to Benefit Independence and Thinking. HABILIT[®] is a 50-h program for persons living with mild cognitive impairment and their support partner to learn skills that compensate for memory loss through procedural based training, along with new lifestyle habits aimed at optimizing brain health and overall wellness. One of five components of HABILIT[®] is yoga that includes the practice of mindfulness.

Those diagnosed with mild cognitive impairment face an unpredictable future that often includes the likelihood of dementia; therefore it is natural for them to have negative feelings and to perceive their situation as unjust or even hopeless. Support partners (most often spouses) face their own health and emotional challenges that center on the ambiguity of the diagnosis, the changing relationship, and worries about the future. Stress seems inevitable for both the person with the diagnosis and the support partner.

Stress however results from the interface of the actual events in one's life and one's thoughts. Therefore, mindfulness practices offer a way for

HABIT[®] participants to focus their thoughts in a more positive way that can contribute to their overall well-being and quality of life.

Early on, some HABIT[®] participants are a bit reluctant about mindfulness practices, but this apprehension serves as more of a benefit than a barrier. After a few sessions participants realize that they “can do” yoga and practice mindfulness. They learn that what often gets in the way are their doubts brought on by thoughts telling them what they can or cannot accomplish. Because mindfulness does not rely on memory, in fact recalling the past or remembering can be an obstacle, the practice of mindfulness takes advantage of retained abilities. This provides the opportunity for couples to participate in yoga and mindfulness together and be a part of something not as a person living with memory loss or a care partner, but as a mutually shared experience.

Those who participate in HABIT[®] are most often over the age of 60, and the spousal couples have generally been together for a long time. As a result, they have established well-worn communication patterns. However, when memory loss happens for one of them, usual communication patterns break down. What follows are often episodes of blame, misunderstanding, agitation, and anger. Couples and families need new ways of communicating.

For those living with cognitive impairment, the verbal and nonverbal forms of communication they receive from a spouse or family member can set the tone for a positive or negative experience. By practicing mindfulness, care partners become aware of their body language, tone of voice, thoughts, and feelings. In doing so, they have a chance to slow down and reset the mind. As a result, they can respond with less reactivity and choose to communicate in a way that honors their partners' need to feel respected, validated, worthy, and capable. When this occurs, the relationship between the caregiver and the person living with dementia can transform into one of greater reciprocity and interconnectedness. Renewed hope can emerge.

“When it feels like we are having a failure to communicate moment, I know it’s time to slow down, hold hands, and just be.”

- HABIT participant

Conclusion

There is a growing body of evidence supporting the benefit of mindfulness-based approaches in the elderly population. Mindfulness may be a stand-alone practice or can be incorporated into other interventions. It can also be practiced individually or in a group format. The flexibility of mindfulness makes it easy to incorporate into daily life activities, such as walking, eating, and sitting, all done mindfully, being aware of each sensation or thought and experiencing it for what it is without judgment or labeling. This practice has been shown to provide cognitive, neurobiologic, biologic, emotional, and social benefits in the elderly, which together contribute to optimal and peaceful daily living and enhanced quality of life.

Definitions

Empty nest – post-parenting period occurring after all children have left the family home.

Mental health – an umbrella term encompassing emotional and cognitive health.

Follicle-stimulating hormones (FSH) – a hormone essential to pubertal development menstrual cycle and fertility.

Estradiol – the primary female sex hormone.

Final menstrual period (FMP) – the last menstrual period signifying the onset of postmenopause.

“Disability-adjusted life years” (DALYs) – represent the number of years lost due to illness, disability, or early death.

Women’s Mental Health

Women have a disproportionately high representation of cognitive and mental health disorders. Two-thirds of those with dementia are women (Alzheimer’s Association 2014), with more women than men suffering from mental health problems and with women having a 70% risk of developing depression in their lifetime (Diniz et al. 2013). Not only is the biological basis of disease different in women but increasingly the contribution of social and lifestyle factors to women’s mental health are being understood. There is important evidence that not only our social environments but also our work, occupation, attitudes to health, sociodemographics, lifestyle, and social psychology all significantly influence the presence of disease (Then et al. 2014). Women hold different roles in society and earn less than men, both of which influence health and well-being (Marmot et al. 2012). The impact of social factors on morbidity needs further investigation to improve women’s health in aging.

The menopausal transition and the onset of postmenopause are a time of considerable physiological and psychosocial change. This period leading up to the onset of postmenopause has been the main focus of research in women, although with our aging populations more than a third of a women’s life is now spent in the postmenopause. A discussion of women’s mental health necessitates a reference to the stages of reproductive aging, and hence we will begin by defining these.

The Stages of Reproductive Aging

The final menstrual period (FMP) occurs between 47 and 51 years of age (McKinlay 1996) and is a physiological marker for the shift from the menopausal transition into the early postmenopause.

The first stage of the early postmenopause (Stage 1a) is determined retrospectively and represents the first 12 months following the final menstrual period (Harlow et al. 2012). The second stage of early postmenopause (Stage 1b) is also of 12-month duration and is the period in which follicle-stimulating hormones (FSH) increase and estradiol levels decrease as they move toward stabilization (Harlow et al. 2012). These rapid hormonal fluctuations are associated with increased vasomotor symptoms, such as night sweats and hot flushes, which are most likely to occur during the first 2 years following the FMP (Harlow et al. 2012). The third stage of early postmenopause (Stage 1c) is estimated to last between 3 and 6 years, during which time FSH and estradiol have stabilized (Harlow et al. 2012). The duration of the early postmenopause is therefore between 5 and 8 years. The late postmenopause follows the early postmenopause and continues for the remainder of a woman’s life.

With the advances in medical technology, and the increasing life expectancy of woman in developed countries, the duration of the late postmenopause can encompass up to half of a woman’s life (Harlow et al. 2012). Accordingly, research identifying significant health issues relevant to women in the late postmenopause is essential to improving the mental health of older individuals.

Mood Disorders and Aging

One of the key areas of health impacted by increasing age is mental health. Mental health is a blanket term that encompasses both psychological and cognitive disorders such as dementia, depression, and anxiety. Mental disorders and associated substance abuse are the leading cause of years of life lost due to disability globally, and mental illness is more common in women (Whiteford et al. 2013). These issues are prevalent in the older population. A study of older emergent patients reported more than half had cognitive impairment, nearly a third were clinically depressed, and more than a quarter had delirium (Goldberg et al. 2012). There are dramatic increases in the incidence of mood

disorders after 65 years in women and 75 years in men (Mojtabai 2015).

The advent of cognitive decline and mood disorders is particularly relevant to aging women. By 2030, depression is predicted to be the second leading global cause of “disability-adjusted life years” (DALYs), which represent the number of years lost due to illness, disability, or early death (Lopez and Mathers 2006). Gender differences in the prevalence of depression have consistently shown women to be at greater risk, with a 2:1 to 4:1 ratio reported (Kessler et al. 1993). Data examining the relationship between aging and depressive symptoms is mixed, with some showing a decrease and others an increase as individuals get older. The mixed findings are thought to be a result of methodological inconsistencies, in particular differences due to sampling effects.

Trajectory of Mood in Reproductive Aging

The higher incidence of depression in women has been shown to begin in adolescence before reducing when women are 55 years or older, corresponding roughly with the course of reproductive aging in women, as defined by the stages of reproductive aging criteria (Harlow et al. 2012). As such, it was proposed that the changes in ovarian sex steroids are associated with the stages of reproductive aging and may contribute to a woman’s increased risk of experiencing depressive symptoms during this period (Freeman 2015). Several studies have examined the relationship between biological transitions associated with changes in sex hormones, including the postpartum and the menopause.

Studies of depressive symptoms and negative mood in the stages of reproductive aging have provided mixed results, with some showing an increased risk for depressive symptoms and others showing no relationship. A recent investigation examining the ratings of depressive symptoms in relation to the final menstrual period (FMP) showed that the risk of depressive symptoms was higher prior to the FMP and lower afterward

(Freeman et al. 2014). The postmenopausal period can encompass almost half of a woman’s life and represents a period where both midlife and late-life risk factors for depression are present. Determining the true prevalence of depression in the late postmenopause, a period that continues for the remainder of a woman’s life, is complicated by the difficulties inherent in examining late-life populations in general.

Methodological inconsistencies make it difficult to determine the true rates of depression in older adults. In a recent review of the prevalence of depression in the elderly, Djernes (2006) found that 0.9–9.4% of individuals living in private households met criteria for depressive disorders compared to 14–42% in institutional living. He also found that being female and meeting criteria for cognitive impairment were two of the main predictors of depression (Djernes 2006). Depressive symptoms are often seen in individuals with dementia and are thought to often precede cognitive decline.

Factors Influencing Gender Differences in Mood

Risk factors for experiencing depressive symptoms in midlife (ages 45–55 years) include a range of psychological, social, and physiological variables, including past history of depression, hot flashes, physical health problems, psychosocial stressors, financial difficulties, stressful life events, and negative attitudes to aging and menopause (Keyes and Goodman 2006).

Studies of older Western populations have found that risk factors for depressive symptoms in late life include pain, chronic illness, institutionalization, history of depressive disorder, bereavement, having a disability, living alone, insufficient social support, developing a new health condition, having a limited ability to perform physical activities, not having a spouse, and perceiving one’s health as poor (Djernes 2006 and Freeman et al. 2014). For women in the late postmenopause, the risk of depression appears to reduce, but remains higher for women having undergone surgical postmenopause (Campbell et al. 2015).

The influence of social activity on depressive symptoms in women is significant and different to that in men. Women are more vulnerable to social factors associated with depression (Carayanni et al. 2012), and social activity reduces depressive symptoms in women but not men (Flaherty and Richman 1989). There is good evidence that social support and engagement decreases stress and depression, while increasing life satisfaction and well-being (Glass et al. 2006). Targeting such factors is particularly important in women.

Cognition and Aging

The second component of mental health encompasses cognitive function and disease. Cognitive function is critical to health, quality of life, and function in aging and impacts not just the individual but their entire community (Eddy and Rickards 2013). Cognitive impairment can be seen as a loss of self and may lead to other issues such as malnutrition, lack of physical activity, and comorbidity increasing the likelihood of dependence and institutionalization (Stange et al. 2013).

Cognitive function is particularly important in aging as cognitive decline is a risk factor and indicator of dementia (Mebane-Sims 2009). Dementia risk increases substantially with age, doubling every 5 years after the age of 65 (World Health Organization 2011). As the age of the population increases, the prevalence of dementia is predicted to almost double every two decades (Alzheimer's Disease International 2015). Alarmingly, there are an estimated 9.9 million new cases of dementia worldwide every year, approximately equating to a new case every 3.2 s. The global cost of dementia in 2015 was approximately US\$818 billion, a figure that is projected to increase to US\$2 trillion by 2030 (Alzheimer's Disease International 2015).

Given the substantial impact of dementia worldwide, factors that influence cognitive function in aging are critical to global health. Gender has been identified consistently as a key predictor of cognitive health in older age across the world (Alzheimer's Disease International 2015).

Trajectory of Cognition in Aging

Some decline is experienced in cognitive functions as part of the normal aging process. Over the course of the lifespan, cognition changes in a curvilinear fashion, developing from infancy through to adulthood and then gradually deteriorating over the adult lifespan. Increasing age leads to significant reductions in several cognitive domains such as speed of processing and visuospatial ability (Hoogendam et al. 2014). This is due to changes in brain architecture which occurs with age. There are two key changes in brain structure: shrinkage of the frontal lobe and a decrease in white matter. Frontal lobe volume decreases at an approximately linear rate throughout adulthood, dropping by approximately 10% by the age of 80, caused by a reduction in both the overall number of neurons and synapses in this area (Lemaitre et al. 2012). White matter volume, on the other hand, peaks at around 45–55 years of age (coinciding with the age of menopause) and declines markedly after age 60 (Giorgio et al. 2010). Demyelination can result in a gradual slowing of neuron firing rates which negatively affects cognition (Lu et al. 2013). Both of these age-related processes can be expected to have profound effects on cognitive function.

Sexual Dimorphism in Cognitive Health

There are marked differences between genders in aging cognitive health. Women are disproportionately represented in both the prevalence and severity of dementia. Prevalence figures illustrate that women are approximately two-thirds more likely to suffer from dementia than men (Alzheimer's Association 2015). Some have argued that this gender bias may be attributable to longevity; that as women tend to live longer, they have greater opportunity to develop age-related disease (Alzheimer's Association 2015). However, emerging research has found that women with the same level of Alzheimer's disease pathology are three times more likely to develop the disease than men (Erol et al. 2015). This finding suggests that women may be inherently more susceptible to cognitive disease

compared to men. Women have more severe disease and rapid decline (Holland et al. 2013) than age-matched men, and between the ages of 70 and 79, women are twice as likely as men the same age to develop Alzheimer's or other forms of dementia (Alzheimer's Association 2014). Women and men differ cognitively, and in cerebral pathology, and risk profiles are significantly different between the sexes. It is therefore unlikely that sexual dimorphisms in cognition are simply due to lifespan differences; rather, the evidence suggests that there are underlying sociobiological factors.

Psychosocial and Biological Factors Influencing Gender Differences in Cognition

The biological differences between men and women may partially contribute to the variations in cognitive function. However, while there is significant pathophysiological evidence that hormonal exposure influences cognition, the relationship was questioned when the Women's Health Initiative was unable to demonstrate a cognitive benefit for hormone therapy (Klein and Rapp 2004). This has led to suggestions there may be a therapeutic window for benefit, with recent trials like ELITE designed to explore this potential with initial promising results (Hodis and Mack 2014).

It is important to note that sexual dimorphism in cognitive function is influenced by psychosocial factors as well as biological factors. Psychosocial risk factors have generated substantial interest in cognitive research in recent years, including education level, social activity, and employment. However these factors are all heavily influenced by gender and the social context. Women growing up in the early to mid-1900s were likely to have less educational opportunities than men (Alzheimer's Association 2015), and low educational attainment is a known risk factor for cognitive decline and dementia (Alzheimer's Association 2014). Similarly, women of that age bracket are less likely to be employed than men (Rice et al. 2011), a trend that may also predispose them to cognitive decline.

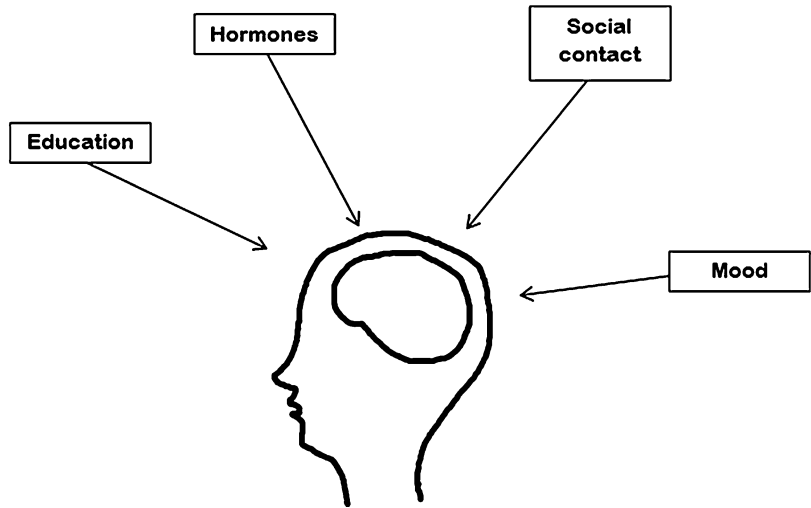

Changes to social contact occurring with age are of particular importance to the discussion of gender and cognition. The transition into aging marks a key shift in social identity, with a number of major life events including death of a spouse and the departure of children from the family home. These events are particularly relevant for older women's health, as women are more likely to experience widowhood and are prime candidates for empty nest syndrome (van den Hoonaard et al. 2013). Social activity is also especially important for older women's cognitive health. Women tend to have larger and more varied social networks than men (Simon et al. 2014). This is critical to cognitive health, as poor social engagement is known to increase the risk of cognitive impairment and dementia (Alzheimer's Association 2014). The detrimental impact of poor social engagement on cognition is often circular, with cognitively impaired women often lacking in social contact (Godfrey and El-Badri 2009). This effect is twofold, as poor social contact also increases the likelihood of depression, which may in turn increase the risk of cognitive disease (Fig. 1).

Mood and Cognition in Reproductive Aging

The interrelationship between mood and cognition is integral to cognitive health. More than 10% of Alzheimer's disease cases worldwide are attributable to depression (Barnes and Yaffe 2011). Even milder depressive symptomology has been found to increase the risk of dementia by 60–70% (Cherbuin et al. 2015). Cognition also has equal impact on emotional health, with pathological cognitive decline often occurring concurrently with neuropsychiatric symptoms such as anxiety, depression and depressive symptoms, aggression, irritability, and apathy compared to cognitively normal individuals (Shahnawaz et al. 2013). As women are more likely to suffer from poor emotional and cognitive health than men, there may be a compound effect on mental health that far exceeds the burden of either in isolation.

Mood and Cognition in Aging Women,

Fig. 1 Cognitive function is influenced by a variety of factors, all of which can be affected by gender

Conclusion

The menopause is thought to be a time of increased risk for the development of mood disorders, yet there continues to be no definitive answer as to the true influence of this biological transition (Freeman 2015). Depressive symptoms decline as women progress through the late postmenopausal stage and into late life (Campbell et al. 2015). The postmenopause also marks a key period for cognitive function, with the risk of dementia doubling every 5 years from age 65 (World Health Organization 2011). White matter volume also decreases rapidly after 65, leading to dramatic changes in cognitive abilities (Giorgio et al. 2010). As cognition and mood are intrinsically related, these constructs must be considered together in order to understand developmental changes. The gender differences in both mood and cognition in aging are not solely attributable to biological changes, but are influenced by a number of psychosocial factors and by the interrelationship between these constructs.

Chapter Summary

- 90% of the gains in life expectancy for postmenopausal women are spent with a disability.

(continued)

- 14–42% of older adults living in institutions meet criteria for depression.
- Depressive symptoms reduce as postmenopausal women age.
- Cognitive health is a key issue in the postmenopause.
- Postmenopausal women have greater prevalence and severity of cognitive disease compared to age-matched men.
- Psychosocial factors including educational opportunities, social contact, and hormones influence women's mental health.

Motivation to Continue Work After Retirement

Reidar J. Mykletun
 Molde University College, Molde, Norway

Synonyms

Bridge careers; Continuity; Life transitions; Motivation; Older workers; Re-employment; Retirement; Workforce retention

Definition

The concept of *Retirement* implies leaving one's organizational position or career path of considerable duration, after middle age, with the intention of subsequent reduction of psychological commitment to work. *Motivation to work* implies the psychological process that influences how personal effort and resources are allocated to actions pertaining to work, including the direction, intensity, and persistence of these actions. Motivation to work after retirement might appear as a paradox. Nevertheless, retirement is changing from an abrupt event to a process often stretching over several years where the employee remains attached to work and contributes to the value creation, either in his/her career organization or a new one, on part- or fulltime contract. Central drivers of this behavior may be the meaning inherent to work, identity as an employee, social relations, and monetary gains.

Introduction

The contemporary call for more years at work for older workers grows out of the demographic changes especially demarcated by the "baby boomers" who now retire from work, the decline in birth rates from the 1960s and onwards, and the increasing longevity that is taking place in the western world. Most western societies foresee future breaches of workforce and competences

and high pressures on pensions and social security systems, which will be difficult to handle due to the consequent changes in dependency ratios between those at work and those provided for. As a remedy to this, national authorities have urged for extensions of work careers for the older workers, motivated by financial concerns and fear of future poverty, especially among the aging population (<http://www.oecd.org/employment/livelonger-worklonger.htm>).

Several ongoing changes, at least in the OECD countries, may increase the likelihood of extended work careers and post-retirement re-employment to take place: The life expectancy is increasing as are the years with good health, leading towards a larger and more active aging population. Pension rules and regulations are being transformed in several countries to stimulate more years at work, which may be efficient as higher income is generally appreciated in consumer-oriented cultures. The life course has become more de-standardized and individualized, and the gender revolution, which led to a dramatic increase in women's participation in working life, has taken place. The level of education is higher. Organizational changes have been more frequent, in part driven by global economic turbulence (Sargent et al. 2012). In the contexts of a raising knowledge economy, much of the work requires less physical capacities but more cognitive activities and social interaction, which may make extended careers more interesting and challenging to older workers. These changes may affect retirement schemes and practices in several ways, and it may become easier and more attractive for some older people to continue working.

To some extent, the decision to retire "early," "on time," or "late" including to prolong one's work career beyond the "on time" age of retirement depends on the individual's own motivation. This entry discusses motivational factors that may add to our understanding of work career extensions for older workers. It is assumed that personal and proximal and distal context factors play a role in motivations for and decisions about retirement or post-retirement re-employment (Wang et al. 2014). The entry is organized as follows: As the concepts of retirement are undergoing a

change in meaning and becoming more dynamic in nature (Sargent et al. 2011), the entry first defines and discusses the retirement concept and its related concept of *bridge employment and bridge careers*. Second, recent development in the concept of *work motivation* is discussed before reviewing some recent and central research on *motivation for post-retirement re-employment and working beyond the retirement age*. The entry concludes with summarizing the current state of knowledge in this field and indicates areas for further research.

Retirement

Retirement has been defined by Feldman as “. . .the exit from an organizational position or career path of considerable duration, taken by individuals after middle age, and taken with the intention of reduced psychological commitment to work thereafter” (Feldman 1994, p. 285). In most western countries, retirement was invented in the late nineteenth century mainly to cover several needs related to the growing middle class, among these to be a tool to attract loyal workers but also to administer the termination of their employment in what was thought of as being a most rational way, that is, at a given age. The development of the pension systems continued up to the World War II postwar period in order to solve some of the poverty problems for the older citizens from the working class (Sargent et al. 2012). Retirement has been rather abrupt as it has been mandatory at a certain age, varying today from 60 years of age (e.g., in Turkey) to 72 (e.g., in Norway, from July 1, 2015). The average mandatory retirement ages in the OECD countries are about 65 years for men and 63 years for women, as in some countries (e.g., Australia, Austria, Poland, and Turkey) different retirement ages for men and women have existed up to recently. The effective retirement ages are lower than the mandatory, and for OECD countries on average, only about 60% of the workforce aged 50–64 work in part- or full-time paid jobs (<http://dx.doi.org/10.1787/9789264201484-en>), leaving considerable room for escalation.

Lower mandatory retirement ages are often set for special occupations, such as air pilots, police, armed forces, sailors, and firefighters, and one might expect that previous employees in such occupations would be inclined to reengage in working life after their formal retirement.

Some countries have introduced an early retirement age, constituting a “window of retirement opportunities” between the set early retirement age and the mandatory retirement age. For instance, in Norway this window ranges from 62 to 72 years of age and in Finland from 63 to 69. Inside this window, the individual might start drawing on his pension. The longer the individual stays at work and the longer he/she waits before drawing on the pension, the higher is the annual pension allotted to him/her. Moreover, a few leading nations such as the USA, Australia, and the UK have abandoned the mandatory retirement ages but kept an age limit after which the individual is entitled to draw on pension schemes. In such instances, a relative definition of retirement age is needed, as, for instance, “Retirement age is when an employee chooses to retire” (<https://www.gov.uk/retirement-age>).

Retirement is a major role transition and probable end point of one’s work career. Major role transitions involve contrasts between the current and the new role, unclear structures and guidelines for decision making, potential elevated stress due to uncertainties, and the need for the individual to employ motivated behavior to form and execute plans for the adjustment to the new circumstances (Wanberg and Kammeyer-Mueller 2008). Role theory argues that retirement may demolish one’s work-role identity (see Bush and Simmons 1990, as cited in Wang et al. 2014). Such loss of role identity can lead to reduced well-being, depression, anxiety, and stress (Thoits 1992, as cited in Wang et al. 2014), especially for retirees that strongly identify with their work role (Quick and Moen 1998; Reitzes and Mutran 2004, as cited in Wang et al. 2014). The individual might be motivated to avoid the discomfort of losing his/her role identity, which in turn may become a motivator for work career extension in line with the continuity theory (Atchley 1989, see below). Holding negative expectations towards retirement

predicts willingness to extend one's work career (e.g., Davis and Cartwright 2011). On the positive side, the older workers who feel committed to his/her work prefer to retire late (Davis and Cartwright 2011). Regardless the outcome, motivational processes will be central in the decision processes and the adjustments to the new or more or less changed roles, including a probable resocialization in one's own family.

Bridge Employment and Post-retirement Re-employment

In their classic contribution, Hornstein and Wapner (1985) identified four attitudinal dimensions towards retirement: "transitions to the rest of life," "a new beginning," "continuity," and "imposed disruption." As attitudes, they have motivational functions by allocation of individual resources towards the attitude-related behavior. While *imposed disruption* still applies to many workers with referral to mandatory retirement ages or being laid off due to health issues or otherwise made redundant, *continuity* and *a new beginning* have increasingly entered the agenda of the workforce's retirement decisions. The "nature" of retirement has been changing from being mainly an abrupt role transition from work to nonwork to gradually becoming deinstitutionalized, diversified, and individually tailored solutions including gradual reduction of workload, part-time employment, or post-retirement re-employment in the same or a different organization. These new ways of retirement may be conceived of as developmental processes where the individual gradually transfers the allocations of own efforts and resources from work to nonwork activities. Such gradual transitions may be supported by public and organizational pension schemes and flexible human resource management practices, which are becoming increasingly popular in the USA, Canada, the UK, Australia, Japan, and northern Europe (Alcover et al. 2014).

Working after retirement is often referred to as *bridge employment*, defined here as "...jobs that follow career or full-time employment and precede complete labour-force withdrawal" (Alcover

et al. 2014, p. 7, see also Henkens and van Solinge 2014 and Wang et al. 2014). Bridge employment may be regarded as forms of retirement that contribute to prolonging the individual's work career (Alcover et al. 2014; Wang et al. 2014). Such employment may be *career consistent*, that is, within the same type of work in the career organization or in another workplace, which would be attainable for workers with a lower level of education. For some, "phased retirement" applies, which means a gradual reduction in working hours in one's career job (Wang et al. 2014). *Noncareer* bridge employment is a job in another type of work in one's career organization or in another organization (Alcover et al. 2014). This adaptation might be easier for workforce with a higher level of education, which may be flexible in relation to new work demands (Wang et al. 2014). "Encore retirement" means to reduce or terminate one's career job to engage in voluntary work for the better of one's society (Wang et al. 2014); however, this type of engagement will not be included in the present discussion. Bridge employment may also occur as *self-employment* leaning on entrepreneurial skills in addition to the individual's career-related competences, while the expression *full retirement* may be used to denote the final withdrawal from the workforce (Alcover et al. 2014). The smallest role adjustments are required if the individual becomes re-employed in the same work and workplace as he is retired from, but motivation to continue in that partly new role is still required. Being re-employed in the same type of work in a different workplace requires more adjustments and in many instances a strong motivation to continue working. Full termination of paid work participation will require the largest adjustments and a different motivation.

However, in this field, some conceptual confusion exists with possible consequences for the interpretations of the research findings. When defined as above, bridge employment does not require that an actual retirement has taken place. Hence, bridge employment might refer to employment before the full retirement takes place, which is not always synonymous with the notion of working *after retirement*. Some researchers of

bridge retirement are not explicitly stating whether their sample consists of post-retirement employees. Gradually reducing one's workload (phased retirement) or reentering working life after retirement might matter concerning work motivation (Parry and Taylor 2007; Henkens and van Solinge 2014; Isaksson et al. 2014); however, there are few research studies explicitly addressing this topic. Furthermore, in some countries (e.g., Norway), it is possible to draw on a limited early pension while still being active in the same job as before and without any act of retirement. In such instances, receiving pension may not be used as an indicator of retirement; the partial pension is rather an economic encouragement to prolong the working career of the individual.

Motivation to Work

Motivation to work may be broadly defined as "psychological process that influences how personal effort and resources are allocated to actions pertaining to work, including the direction, intensity and persistence of these actions" (Kanfer et al. 2008, p. 5). Defined this way, work motivation varies across individuals and across situations for the same individual. It is determined in the interfaces between individual (e.g., cognitive, emotional, physiological) and contextual (e.g., social, technical) factors and is subject to hurried as well as unhurried changes as functions of forces internal and external to the individual. The motivational processes connect intentions and resource allocations in relation to specific actions and include the concepts of self-regulatory and operational processes. The person's allocation of personal effort and resources to actions represents his/her means of personal control over his/her own behavior. Motivation must alter as an antecedent to a change of someone's voluntary behavior, and this is at the core of the issue of choosing to work after retirement. In that situation the choice of where to allocate personal efforts and resources is among a wider range of alternatives than usually found within the workplace, as work tasks are now competing with and compared to

leisure activities. It is here assumed that the salience of different goals will alter, depending on the attractiveness of various external structures and individual factors.

During the twentieth century, a multitude of constructs and theories has been proposed to capture aspects of work motivation, but no single theory accounts well for all individual characteristics, contexts, and situations. Concepts related to goal choice, goal striving, goal continuity, and self-determination theories hold strong positions in current research (Kanfer et al. 2008) and may be central to motivation for working after retirement. Of particular interest in the discussion of post-retirement re-employment is the self-determination theory proposed by Deci and Ryan (2000). This theory proposes that an understanding of the human motivation must acknowledge the innate psychological needs for competence, autonomy, and relatedness. These needs may be satisfied in several ways, but for an individual approaching retirement, re-employment should be tempting at a workplace that he/she had been strongly involved with, where challenges had been successfully managed and the social relationships had been rewarding (Isaksson et al. 2014). If the individual also holds a strong belief in his/her own abilities to master challenges in working life (work-related self-efficacy), a re-employment with a new employer or being self-employed should also be a way to satisfy these innate psychological needs.

Kanfer et al. (2008) argued that the three broad themes of *content*, *context*, and *change* capture most of the established knowledge about work motivation, and they are all relevant to the issues of re-employment after retirement. *Content* refers to the theories that focus on the individual's internal mental structure and the operations by which the self and the external events make meanings and drive motivated action. It is considered as "intrinsic," it may be learned or genetically disposed of, and it addresses biological, cognitive, personality, or affective structures that are observed to produce rather stable patterns of behavior. Goal striving and self-determination theories belong to these themes. For instance, a feeling of occupational goal attainment may pull

the individual out of work, while perceiving unfinished work-related goals may delay retirement (Bal et al. 2010). Some individual factors may change as a correlate of aging, for instance, a reduction in working ability, which is likely to be experienced by approximately 30% of the aging workers (Ilmarinen 1999; McGonagle et al. 2015) and which affects the reallocation of personal efforts and resources away from further participation in working life (McGonagle et al. 2015; Syse et al. 2014). On the contrary, good health, which constitutes one of the foundations of high work ability, relates positively to being engaged in bridge or post-retirement work (Wang et al. 2014). Age itself relates negatively to bridge employment and post-retirement employment: The higher the age, the less likely it is that the person will be involved in working additional years (Davis and Cartwright 2011; Kim and Feldman 2000). Likewise, life expectancy relates to motivation for prolonging one's work career. Those who for some reasons expect to have a shorter time left are unlikely to be involved in bridge employment or post-retirement employment, while those who believe they will have many years left to live more often plan for a longer work career (Wang et al. 2014). Subjective health may be an underlying factor influencing both subjective life expectancy and career planning. The higher the level of education, the more likely it is for workers to prolong their careers (Syse et al. 2014; Dorfman 2009; Kim and Feldman 2000).

Context refers to the external environments in private spheres and at the workplace. In the private sphere, various tasks and phases of life present a long list of challenges to the individual and to the balance between the private life roles and the work roles. A good financial status and leisure interests may pull the individual towards retirement. Family factors, such as having a retired spouse, act as a pull factor towards retirement for workforce with lower levels of education, while this "partner effect" is decreasing the higher level of education the focal person has got (Syse et al. 2014). At the workplace, factors such as work organization, structures, methods, and the tasks themselves may give access to resources that

are not available outside the workplace. This also applies to leadership, social relationships, and workplace climate. Thus, the quality of the workplace as compared to the attractiveness of the alternatives will affect the motivation to stay or go. Workers who report high work-stress levels may be less inclined to seek bridge or post-retirement employment as in such instances retirement may be an escape from stress (Wang et al. 2014). Moreover, it is obvious that basic issues such as the availability of bridge or part-time jobs and leaders who do not hold negative stereotypes about older workers and do not promote younger colleagues at the costs of the older ones will influence the decision latitude for older workers to take on post-retirement re-employment (Isaksson et al. 2014; Wang et al. 2014).

It should be kept in mind that the dominating career models still being held by managers and HR departments are based on theories about career models from the 1970s. In those models, retirement was one of the most predictable career stages happening at a time and "...being characterised by individual decline and disengagement" (Sargent et al. 2011, p. 315). Consequently, the organizational responses to the individual's request for reengagement after retirement may be negative and ruin the motivation for a prolonged work career, and some managers would not consider it as an option to offer a re-employment. Furthermore, as time passes, national and organizational pension systems and their development will guide the inhabitants to see what is expected to be the adequate retirement ages and, most likely, inspire the development of social norms and macro level abstractions such as national, regional, or even local retirement cultures. National differences in workforce participation by the older workers across nations (<http://dx.doi.org/10.1787/9789264201484-en>) indicate that such cultures exist, with cultures supporting the highest participation rates to be found in Northern Europe, Switzerland, Japan, New Zealand, and the USA, while cultures supporting the lowest participation rates found in Southern Europe. The individual who wants to extend his/her work career by engaging in post-retirement re-employment must transgress such

social norms and established cultures regarding retirement. Depending upon his/her personality and resources, this may either trigger or extinguish his/her motivation for even making an attempt.

Change refers to the dynamics of motivation over time and contexts. Singular events, such as retirement, may be a radical individual and contextual change that profoundly affects one's allocations of personal effort and resources from the work to the nonwork arena. The effect may vary across individuals and contexts depending on whether the person is anticipating or facing the consequences of one's own retirement decision, or being forced to retire by work-related push factors, such as loss of work ability, age discrimination, or set retirement ages (Wang et al. 2014). A perceived loss of control over these reallocation processes may follow from forced retirement or being pushed out from the workplace by negative attitudes towards aging workers. Such loss of perceived control over where to allocate one's personal effort and resources affects work motivation, work satisfaction, engagement, and commitment (Kanfer et al. 2008). Options for re-employment after retirement may then function as regaining perceived control. However, older workers who hold negative thoughts about retirement may be positive to engage in bridge or post-retirement employment (Davis and Cartwright 2011; Wang et al. 2014). Along similar lines, Achtle (1989) advocated the *continuity theory*, which claims that individuals will strive to maintain consistency in lifestyle and patterns over time. Thus, when about to leave work through retirement, individuals may strive for continuity in social relationships and if possible in activity patterns. When entering in bridge or post-retirement employment, the individual might reduce or eliminate the disruptive effects that may follow retirement and retain preretirement social, physical, and mental activities (Wang et al. 2014). The increasing popularity observed in the Netherlands (Henkens and van Solinge 2014) and especially in the USA (Wang et al. 2014) of post-retirement re-employment or bridge employment may be examples representing the continuity motivation, which

falls under the change theme, although it represents reluctance to undergo changes.

Empirical Studies on Motivation for Bridge Employment and Post-retirement Employment

Motivation to work beyond retirement is still an under-researched topic. A few studies employing qualitative approaches exist along with some few leaning on quantitative, cross-sectional designs. Few longitudinal studies have yet appeared. Examples of qualitative studies will first be reviewed, followed by some quantitative studies and a study aimed at exploring special areas with the motivation theories. A major distinction in motivation lies in the difference between a consumption-based orientation and a producer-based orientation (Sargent et al. 2011, 2012). The consumption-based orientation embraces "...lifestyles including leisure, pleasure, experiences and the use of goods, knowledge and service, as well as education. Being producer-based refers to being engaged in market-based activities – working for pay as well as socially productive activities that contribute to the well-being of society such as the provision of volunteer services" (Sargent et al. 2012, pp. 12–13). Clearly, this indicates two distinct motivational patterns, the first marked by seeking hedonic pleasure tone and the second by enjoying eudemonic pleasures. However, indeed shades of gray apply here.

Parry and Taylor (2007) interviewed 12 men and 12 women living in three contrasting areas of England: a London inner city area with the most diverse labor market, a South West England semi-rural area with rather affluent and older population, and a former industrial urban area in the north with typically low income from the state pensions. Of those retired, 17 were re-employed in a broad range of branches, and some continued to be engaged in self-employed activities. Weekly working hours ranged from 10 to 35. Two distinct groups were identified, the "workers" and the "professionals/creatives." A third group, the "self-employed," overlapped both of these. The "workers'" orientation towards work was

instrumental and influenced by a strong work ethos: as being used to hard work and familiar with instable jobs, bad working conditions, and unemployment. Work was a needed source of income and was sharply separated from their private lives. They regarded their pension as merited rewards and held a consumer-based orientation to their retirement. Participation in unpaid voluntary work was uncommon. The *self-employed* expressed a desire for independence. Some had inherited their business or the family had traditionally run their own business. It was often a family affair, and running the business was in the blood. They enjoyed working after their retirement, demonstrated a more producer-based orientation towards retirement, and in particular, this was the case if they were not dependent on their income from their work.

Contrasting to this group, the professional and creative workers represented a middle-class group that had extended training and was familiar with careers that offered high levels of choice, autonomy, and flexibility. Their orientation towards work was different: Work was central to their identity and was to continue for their lifetime, and they did not see any boundary between their work and their lives. The nature of the work was more important than their salaries, and some engaged in voluntary, unpaid work. For the self-employed professionals in this group, practicing skills and developing their knowledge were key motivators, and work was a personal endeavor. The creatives, on the other hand, pursued their artistic desires by freelancing combined with some part-time work that secured their income. Some had a family background with this way of living. As retirees, they continued the lifestyle they had before retirement, and they appreciated the extra income from work on top of their pensions. The majority of the self-employed workers and professionals had a smooth transition into retirement. They continued their previous work but reduced the intensity, and their contributions were limited by age discrimination, progressive intensification of work, and labor-force restructuring. Their work often transgressed into the voluntary sector as unpaid work, and they were mainly able to choose the

most suitable combinations of financial and creative rewards.

Isaksson et al. (2014) reported results from a small qualitative study where nine Swedish workers aged 61–68 years participated. Six out of these nine were interested in post-retirement employment as a way to decrease work intensity and make the transitions between full-time work and full-time retirement stepwise and smooth. Most would prefer to continue in their present jobs. Extrinsic or contextual factors such as finance and the quality of the work and workplace played a role for all, but the importance of these factors varied between the workers, from very limited to very high. Intrinsic or content factors were more important, however. To feel needed in the workplace, help colleagues, and contribute to unit efficiency were central to all. Second, flexibility and variety were appreciated as an alternative to boredom, and ideally, individual non-standardized deals should be made with each older worker to create a win-win situation for him/her and the workplace. Third, possibilities for learning and self-development were sought for, and forth, the social relationships at work were highly valued.

A recent study by Sargent et al. (2011) additionally augmented the understanding of individual's motivation for post-retirement re-employment. They interviewed a nonrandom sample of 35 retired Canadian managers and executives with an average age of 59 years, who on average had been retired for 3 years. The analyses were based on metaphors and combinations of metaphors into meaningful units. The study identified four different retirement patterns, named after their content as: (a) exploring new horizons, (b) searching for meaning, (c) contributing on own terms, and (d) putting your feet up. None of these patterns were characterized by disengagement and decline. The group contributing on own terms was the most likely to engage in post-retirement re-employments, that is, "...staying the course, downshifting and detox. [...] These metaphors combine to tell a story of retirement as an opportunity to engage in professional activities on one's own terms and shifting to a more manageable life-style after being freed from a

demanding career” (Sargent et al. 2011, p. 321). The style chosen by this group keep them agile and prevent declines, and the search is more in direction of eudemonic pleasure. Contrary to this pattern of adjustment, the putting-your-feet-up pattern contained regaining of control, autonomy, and freedom from an oppressive work schedule where retirement was seen as a liberation from a psychic prison and a reward for a demanding work life. This style is more into seeking hedonic pleasure. The pattern of exploring new horizons was filled with excitement, exploration, and engagement. For this group, retirement meant moving forward and involved development of oneself and own identity, and the group was mainly consumer oriented. Finally, the pattern searching for meaning contained both a loss of structure and aimlessness, a detox, and a liberation. This group considered a turn towards a producer-based orientation, where re-employment might be an option. In interpreting these findings, one should bear in mind the rather low age of the interviewees and that they probably had access to wider decision latitudes and were better off financially than most people were. However, the findings do challenge the traditional decline and disengagement mental model of retirement; instead, they present retirement as “realignment” for a life of ease and pleasure where leisure is a resource needed to restore the organism after the long exposures to work demands.

Traditionally, academic workforce in positions as professors has been offered a working relationship as professors emeriti, which means retired professors, at their career institutions. The amount of remunerations for such post-retirement “re-employment” might vary from zero to a modest salary or just the access to research resources. Being highly educated and used to complex, autonomous, and varied work, this group constitutes one example of workforce and work environments that are becoming increasingly customary in the area of the knowledge-based economies. Dorfman (2009) conducted several studies of professors emeriti, including a follow-up study of why they continued to work after an age of 70 years. The sample of this study included

13 “survivors” of the initial sample of 18 professors, which in this study were reinterviewed at ages between 80 and 84 years. Their work consisted of research and teaching. The main reason for extending their work careers was professional in the sense of enjoyment of the work itself and the feeling of doing something important. Research was considered as a creative process that kept one going, always bringing up something new. The teaching was especially rewarding when students raised questions that forced the professor to rethink an issue. Teaching and research were considered interrelated activities, and there were weak boundaries between work and nonwork activities. Those who had withdrawn from work explained their decisions mainly by changes in personal resources and students’ attitudes.

Furthermore, a well-known study by Kim and Feldman (2000) from 1999 employed a sample of 879 professors who had accepted an early retirement offer in 1994 from the California University, and 42% of these responded to the survey. Predictors of bridge employment were the personal factors of low age, good health, long tenure, and low salary. Contextual factors such as a spouse still working and still supporting own children also predicted participation in bridge employment. Finally, it should be noticed that engagement in bridge employment predicted retirement satisfaction.

Such studies employing quantitative approaches add significantly to our understanding of motivation to prolong working careers beyond the point of retirement. Henkens and van Solinge (2014) analyzed data on post-retirement re-employment from the NIDI Work and Retirement Panel, an ongoing longitudinal survey of older workers in the Netherlands. The proportion of the workforce that had been re-employed increased from 19% in the 1936–1941 cohort to 39% in the 1950–1951 cohort. The results demonstrate the growing interest among older workers in bridge jobs, thus becoming more producer based in their retirement orientation, as well as showing how the labor market needs the competences of these experienced workers. The younger the individual was at the point of retirement, the

more likely he or she would be re-employed. Most of these jobs were part-time employment with an average of 17 h per week. Twenty-six percent were self-employed, another 8% switched between self-employment and salaried work, 12% worked with their previous employer, while 50% worked with a new employer. Near half of the reentrants were very satisfied with their bridge job, while only 30% had been very satisfied with their career job before their retirement. The higher level of education the reentrant had, the higher was the likelihood to have a bridge job, and the more challenging was the bridge job and the less job stress he/she experienced. Higher flexibility was an important advantage of the bridge job compared to the career job, especially with regard to being able to take extra days off from work.

The respondents in this study gave two main reasons or motivations for post-retirement re-employment. The primary motivation given was that they liked their work, and this motive was given by two-thirds of the self-employed. The second motivation was financial reasons. This motivation was reported by 20% of the re-employed but was the prime reason for 43% of those in poor health conditions, while reported by only 12% of those in good health conditions. Needs for social contacts and feeling bored paid only a modest role as motivation for re-employment.

Some theory-driven studies have addressed issues within motivation theories as they apply to older workers. For instance, Wöhrmann et al. (2014) tested a theoretical model for post-retirement career planning based on social cognitive career theory (SCCT) on a nonrandom sample of 124 German workers with a mean age of 56 years, ranging from 49 to 65 years of age. They found that occupational self-efficacy predicted interest in occupation-related activities and in post-retirement career outcome expectations, both of which predicted post-retirement career intentions, which finally predicted post-retirement career planning activity. However, the model accounted for only 9% of the variance in this end variable. This implies that other variables are important in explaining such career planning

activities, but still one may argue that self-efficacy, interest, and outcome expectations stand out as person-related factors of post-retirement re-employment motivation.

Bal et al. (2010) studied the role of future time perspectives in relation to psychological contract fulfillment among 176 retired and re-employed Dutch workers aged 65–69 years. Three types of psychological contract fulfillment were analyzed: economic, socio-emotional, and developmental. Such contracts were defined as “individual beliefs, shaped by the organization, regarding terms of an exchange agreement between individuals and their organization [. . .] Both employee and organization are assumed to have obligations towards each other, and these obligations are interdependent” (Bal et al. 2010, p. 475). Furthermore, the concept of future time perspective refers to “how much time individuals believe they have left in the future. It is a flexible, cognitive-motivational, and age-related construct that changes over time” (Bal et al. 2010, p. 475). Individuals holding an open and long-term perspective on the future were assumed to see opportunities and look for work and organizations that may fulfill their needs for long-term perspectives on development. These individuals focus on information and how to expand their knowledge also at the workplace. Individuals with shorter time perspectives will have lower demands for developmental opportunities and are less inclined to react to organizational inducements. The results showed that future time perspective is an important factor in the work motivation, especially for older workers. Individuals with an open future perspective received more developmental fulfillment and reacted more to psychological contract fulfillment related to employee obligations. Hence, the social, economic, and developmental exchange relationships are especially important for the older workers with an open future time perspective. As a consequence, the socio-emotional relationships between the older workers and their organization (leader) should be nurtured by increasing flexibility, healthy work-life balance, and respectful treatment. Older workers who feel their future time is

running out feel less obliged towards the organization when the organization offers financial inducements to increase their motivation and are more receptive towards inducements in the shape of benevolence.

Conclusions

The review and discussion outlined above inform about ongoing transformations regarding the form, timing, and meaning of retirement. These transformations are partly driven by, and partly responded to, national governments calling for extensions of older workers' careers. Concerns about national economies are the prime driving factor, whereas fewer of the work organizations and the workers' unions have heralded the same questions yet. Such reluctance will most likely retard the wanted future changes in retirement policies and practices.

Individual orientations towards retirement seem to express two basic orientations: Either they are consumer based, searching for a more hedonic lifestyle, or they are producer based, searching for a eudemonic type of pleasure through the joy of work. However, other orientations are identified, like searching for new horizons and searching for meanings. To some extent, such patterns will reflect the available options of the actual retirement context, but in many instances, retirement does not reflect the career models from the 1970s where retirement was conceived of as decline and disengagement. At the content (or personal) level, motivation for taking on a producer-based orientation in retirement is supported by good health, low age, and high level of education. Contextual factors contributing to this orientation include financial needs, care for children, a spouse still employed, and the quality of the work and work environment. Especially, enjoyment of the work is a central theme, indicating that some workplaces offer access to socio-psychological, economic, and technical resources that the older workers find more attractive to be engaged in than those made available in the leisure contexts. The type of work that is attracting

most post-retirement re-employment is characterized by high levels of skills and qualifications, autonomy, and reasonable decision latitudes, thus largely in concert with the self-determination theory of human behavior. This concept of access to workplace resources is a finding largely overlooked by previous research, thus constituting a contribution to knowledge. It is partly supporting role theory of retirement as abrupt and unpleasant change of roles that are central to one's identity and consequently to be avoided, but different from this in the sense that not all types of work are equally attractive. The same arguments apply to continuity theory, while the focus on resources inherent to the work itself may be consistent with goal-oriented theories.

Motivational Theory of Lifespan Development

Joseph S. Kay and Jutta Heckhausen
 Department of Psychology and Social Behavior,
 School of Social Ecology, University of
 California, Irvine, CA, USA

Definition

The Motivational Theory of Lifespan Development (MTD) explains the processes by which humans optimally pursue their developmental goals. Development is most successful when humans pursue appropriate goals, engage in goal-directed efforts to pursue their goals, and disengage when goals have been achieved or are no longer attainable. MTD has implications for goal attainment, health, and well-being across the lifespan.

Synonyms

Lifespan theory of control; Optimization in primary and secondary control

Motivational Theory of Lifespan Development

Humans operate in a complex environment in which prospects for achieving meaningful life goals wax and wane according to biological and social opportunities and constraints. The Motivational Theory of Lifespan Development (MTD) (Heckhausen and Schulz 1993; Heckhausen et al. 2010) expands on the lifespan theory of control (Heckhausen and Schulz 1995; Schulz and Heckhausen 1996) and describes the processes by which humans operate within their environment in order to optimally pursue developmental goals. According to MTD (Heckhausen and Schulz 1993; Heckhausen et al. 2010), development occurs throughout the lifespan and is successful when individuals are able to match their goal-directed efforts with the opportunities available to them and select behavior that is beneficial across multiple life domains and in the long run while maintaining a diversity of goals. MTD views humans as active agents in shaping their own development throughout their lives. This entry presents a brief history of the origins of MTD and expands on key concepts, applications, and empirical findings supporting the importance of viewing development throughout the lifespan from the MTD perspective.

MTD and Lifespan Developmental Psychology

MTD is a theory of lifespan developmental psychology. Baltes (1987) identified several key propositions that characterized research and theories on lifespan development generally and which are applied in MTD. Lifespan developmental psychology stresses that development is a lifelong process. Development can be continuous across life stages and includes gains and losses that can

occur simultaneously or sequentially, either across life domains or within a single domain. Finally, the developmental course is determined by a person by context interaction such that outcomes are the result of social and biological constraints as well as individual experiences and efforts.

The Motivational Theory of Lifespan Development defines successful development as the development and maintenance of task mastery across a range of domains throughout the lifespan (Heckhausen et al. 2010). The optimal developmental strategy requires active regulation to allow individuals to select their goals in such a way that they are tailored to the opportunities available to them, respond to failure by increasing efforts, engagement, and use of other motivational strategies if the goal is attainable or disengage and redirect efforts if the goal is unattainable (Heckhausen and Schulz 1993; Heckhausen 1997). Matching goals and motivational control strategies to opportunities have beneficial implications for mental health and objective success in achieving developmental goals when healthy (Heckhausen et al. 2010) as well as when facing life stressors or illness (Hall et al. 2010; Wrosch et al. 2000). Furthermore, believing that one has control over one's environment and goal achievement is related to more effective use of goal engagement strategies and ultimately greater success in attaining one's goals (Shane et al. 2012; Heckhausen et al. 2012).

Heckhausen et al. (1998) identified and measured three categories of goal striving and control strategies: *optimization*, *primary*, and *secondary control* (OPS). Optimization measures an individual's tendency to select goals that are appropriate given the opportunities available, produce positive and not negative outcomes across multiple life domains at the same time, and are beneficial for long-term development. Optimized goals accurately reflect opportunities for control (Chang et al. 2006; Haynes et al. 2009), consider how that goal will affect goals related to other domains of life (Riediger et al. 2005), and maintain or build competence across multiple domains of life (Heckhausen and Schulz 1993). Selecting an appropriately attainable goal is important, as it

leads to increased goal engagement (Wrosch and Schulz 2008).

Once a goal has been selected, individuals use primary control strategies (i.e., those aimed at effecting change in the world in order to achieve a goal) and secondary control strategies (i.e., those used to influence one's own motivation) to pursue that goal (Rothbaum et al. 1982). Over the course of the lifespan, primary control capacity follows an upside down U shape, with a peak in adulthood and declines in old age, while secondary control capacity continues to rise throughout the lifespan (Wrosch et al. 2000; Heckhausen 1999). People seek to maximize primary control over their environment throughout their lives (Heckhausen and Schulz 1995, 1999a), although they recognize that primary control declines in old age (Lachman and Firth 2004) and therefore must adjust goals accordingly.

Primary control can be differentiated as selective primary control (SPC) or compensatory primary control (CPC) (Heckhausen and Schulz 1993, 1999b; Baltes and Baltes 1990). SPC refers to an individual's ability and tendency to invest time and effort into a goal, develop skills to help pursue that goal, and persevere despite difficulties. CPC, on the other hand, refers to an individual's use of external supports to help achieve a goal, whether that be through enlisting other's help or guidance or seeking new or different ways to achieve that goal. For example, when seeking a promotion with higher pay, a worker's SPC strategies would involve the investment of time and effort into his or her job and development of leadership skills that would help attain that promotion. If that promotion were more difficult to attain, the worker could enlist CPC strategies by contacting his or her network of colleagues for advice about how to approach the manager to request a promotion (i.e., enlisting others' help) or search for a different job that meets his or her desired salary goals (i.e., seeking alternate ways to achieve a goal). Primary control striving is associated with improved likelihood of achieving a goal (Shane et al. 2012; Fiksenbaum et al. 2006) as well as with better psychological health throughout the lifespan (Wrosch et al. 2002, 2005).

If primary control strategies are insufficient to achieve a desired goal, individuals must also use secondary control strategies. First, individuals can use selective secondary control (SSC) strategies, which consist of motivational strategies to aid in goal pursuit, such as enhancing the value, expected benefit, or perceptions of control related to that goal or devaluing other goals. These strategies boost the effectiveness of primary control strategies and ultimately help goal attainment across a range of life domains (Hamm et al. 2013; McQuillen et al. 2003). The worker, for example, can increase motivation by focusing on the importance of getting a better job in order to support a family or focus on the benefits the additional money will bring.

If that goal remains unattainable, compensatory secondary control strategies (CSC), which consist of disengagement from the goal and of self-protective strategies to change goal-related cognitions in order to minimize the negative impact of failure (Mendola et al. 1990; Gollwitzer 1990), become necessary. Disengagement in this situation can be adaptive when the individual withdraws both effort and commitment to a goal in order to pursue a more attainable goal (Wrosch et al. 2003a). Furthermore, specific self-protective cognitions can help to reduce the negative psychological consequences that come from failing to attain a goal (Wrosch et al. 2005, 2003b). If, for example, the worker realizes a promotion or better job is unattainable, the worker can disengage from his/her career goal, remember that money is not the only thing in life that matters (i.e., devalue the prior goal), and increase focus on family (i.e., reengage in a different goal). For self-protection, he can remind himself that it was not his/her fault that he did not get the promotion and that some colleagues are worse off.

MTD in Relation to Other Developmental Theories

In addition to MTD, two other major developmental theories of regulation were developed. The dual-process model of assimilative and accommodative coping (Brandstädter 1989; Brandstädter and Rothermund 2002) highlights the importance of perceptions of control over a given goal in

determining whether an individual actively strives to achieve the goal (when it is perceived to be controllable) or reevaluates the goal (when it is not). When goals are perceived to be controllable, individuals enter into an *assimilative* mode, in which intentional effort is put forth in an attempt to regulate the environment to achieve goals. On the other hand, when goals are perceived to be unattainable, individuals enter into an *accommodative* mode which helps to adjust goals according to the constraints present and redirects efforts to more attainable goals. Second, the theory of selective optimization with compensation (SOC) (Baltes and Baltes 1990; Baltes 1997) describes three components to adaptive development. Individuals must make a *selection* between different possible goals in order to pursue one to master. Selecting an appropriate goal to pursue allows one to *optimize* adaptive capacity and increase overall functioning, while *compensation* is necessary when suffering functional losses or when goals become unattainable.

Although the details may differ, these theories, as well as MTD, share a common theme that successful lifespan development requires that individuals be actively engaged in goals they have selected when these goals are attainable. When goals are no longer attainable, all three theories explain that individuals must take steps to change their efforts and cognitions to avoid pursuing impossible goals. However, in addition to goal engagement and disengagement, MTD highlights the importance of meta-regulation (Haase et al. 2013). Individuals must actively regulate their goals to ensure that their engagement and disengagement efforts are aligned with the opportunities available to them and to position themselves so that they are able to succeed across multiple domains throughout their lives. MTD also specifies that goal pursuit occurs in distinct and sequential action phases, which involve biased cognitive processing in order to optimize goal engagement.

Action Phases and the Decisional Rubicon

The Motivational Theory of Lifespan Development adopts a phase-sequential model from motivational action theory (Gollwitzer 1990;

Achtziger and Gollwitzer 2010; Heckhausen 2007). MTD describes three discrete stages of goal pursuit, the transitions between which should be discrete and non-gradual. Each stage of the goal pursuit process is characterized by a unique set of strategies that can be used for optimizing development and distinct types of cognitive processing.

Pre-decisional phase. The first stage takes place before the individual has selected a goal to pursue. At this time, the ideal strategy is to be deliberative in order to select the most appropriate goal based on biological and cultural opportunities and constraints and developmental norms (Gollwitzer 1990; Gollwitzer et al. 1990). This is the phase for optimization; ideally during this phase, the individual attempts an unbiased and realistic analysis of the situation, including of one's abilities and constraints, and the likelihood of attaining different goals as well as the benefits that would result from those goals (Beckman and Gollwitzer 1987).

Goal engagement phase. The selection of a goal to pursue is considered a decisional Rubicon, referring to Julius Caesar's irreversible decision to move his legions across the Rubicon, which set him on a path that could not be altered. Crossing the decisional Rubicon marks a distinct shift from deliberation to active goal pursuit. After the decisional Rubicon has been crossed, the individual must focus on strategies to achieve the selected goal. Depending on the ease of attaining the goal and the urgency with which it must be attained, differing levels of the control strategies may be used as described above, with SPC and SSC increasing with the urgency of the goal and CPC being used when the goal is urgent (Heckhausen 1999). During this goal pursuit stage, rather than considering alternative goals, the individual focuses almost exclusively on attaining the selected goal. At this time, perceptions of control increase, and more generally, processing shifts toward implemental mindsets (Achtziger and Gollwitzer 2010).

Goal disengagement phase. A second shift in goal engagement occurs when control opportunities have diminished or when other goals take priority, that is, after the deadline for that goal

has passed. A goal deadline has passed when the goal has been completed or when the opportunity for its completion has passed unsuccessfully. Engagement in a goal whose deadline has passed becomes maladaptive and so should drop precipitously (Heckhausen 2000). When a goal has been completed successfully, the cycle begins anew, with the individual building on his or her successes and reentering the pre-decisional phase characterized by optimization. If, on the other hand, a deadline has passed without the successful completion of that goal, CSC strategies must be used in a self-protective manner, since remaining fully engaged with an unattainable goal would be harmful (Heckhausen 1999; Heckhausen et al. 2001). Disengagement from one goal allows for reengagement in a more attainable goal.

Importantly, shifting between goal engagement and disengagement requires an active monitoring process in order to identify when it is no longer adaptive to pursue a chosen goal either because it has already been attained or because it is no longer attainable and to ensure that primary and secondary control strategies match each other (Hamm et al. 2014). Active regulation occurs during each stage: first to identify a goal to pursue, second to tailor goal engagement strategies to the opportunities, and finally to monitor goal progress within the changing landscape of opportunities and constraints in order to identify when it is no longer adaptive to continue pursuing the chosen goal.

Application of MTD to Successful Aging

Evaluating successful aging, from the perspective of lifespan developmental psychology, must account for individual difference in abilities and constraints and must consider indicators that are relative to those individual abilities and constraints (Baltes and Baltes 1990). This differs from a medical perspective of aging, according to which success is viewed more objectively, as high-functioning and free from disease. Within the lifespan developmental approach, the Motivational Theory of Lifespan Development defines successful aging as maximizing control across

multiple domains of life and for a longer period of time in spite of biological constraints (Schulz and Heckhausen 1996). Throughout life, individuals must use both primary and secondary control in order to achieve their goals. Toward old age, primary control declines as biological and social constraints limit the opportunities to successfully attain goals in different life domains. At the same time, secondary control use continues to increase throughout old age (Heckhausen 1997; Lachman and Firth 2004) allowing individuals to compensate for declining skills and increasingly disengage from goals that become unattainable.

Appropriate optimization of goals, engagement, and disengagement has significant implications for health, well-being, and mortality among both healthy and ill older adults. Accurate perceptions of control are critical for well-being and long-term mortality. Among older adults, shifting goals toward preventing loss becomes adaptive as opposed to being detrimental among younger adults (Ebner et al. 2006). Typically, aging adults experience a significant decline in well-being just prior to death, which can be buffered by perceptions of control (Gerstorf et al. 2014). Gerstorf and colleagues (2014) found that over a 25-year period, perceptions of control over one's environment were associated with higher well-being late in life, and both reduced and later declines in well-being prior to death. Higher levels of perceived control may indicate that those older adults are better prepared to face declines in functioning, since those who feel that they have more control over their environment and health goals remain more engaged in health and lifestyle demands related to aging (Tomasik and Silbereisen 2013). Those who are more engaged in health behavior and those who focus their efforts on primary control strategies more effectively cope with their challenges and report better psychological and physical well-being (Haynes et al. 2009; Wrosch and Schulz 2008).

Among older adults with illnesses, the match between engagement or disengagement and the opportunities for illness management is critical, since it allows individuals to focus their efforts on goals that are attainable and avoid engaging with unattainable goals. Older adults facing

progressive and irreversible illnesses such as progressive vision impairments (Boerner et al. 2010; Wahl et al. 2007), multiple sclerosis (Pakenham 1999), or Parkinson's disease (McQuillen et al. 2003) report using a variety of control strategies to help cope functionally and psychologically. Indeed, both engagement and disengagement can be adaptive, depending on the opportunities and constraints present. Among older adults with acute health problems, for whom goal engagement can lead to effective management and reduction of symptoms or severity, goal engagement predicts greater health and longevity, and disengagement predicts worse health and shorter longevity; in contrast, among those with chronic health problems, for which improvement is not a realistic goal, disengagement was predictive of better health and engagement with worse health (Hall et al. 2010). Thus, neither engagement nor disengagement can be considered inherently adaptive or maladaptive; they must be considered in the context of the opportunities present.

Aging and Lines of Defense

In aging adults facing increasing disability and progressive declines in functioning, the primary goal should be to maintain functioning and control while avoiding futile battles. Goal selection and the use of primary and secondary control strategies to engage in attainable goals and disengage from unattainable goals are critical (Heckhausen et al. 2013). When facing progressive declines, individuals should organize their goals into "lines of defense" according to their attainability so that motivational resources are not wasted in battles that will inevitably be lost. Aging individuals should use primary and secondary control strategies to fully engage in goals that are attainable and meaningful, while disengaging and withdrawing efforts from those goals that are unattainable (Heckhausen et al. 2013; Heckhausen 2005). Given that diseases may progress, the adaptiveness of the lines of defense must be monitored; if a functional goal becomes unattainable, efforts should be withdrawn and a new line of defense organized.

Heckhausen et al. (2013) suggest aging or ill adults organize goals into one of four main lines of defense, depending on their functioning. Among healthy aging adults with few limitations, goals should focus on preserving functioning and disease-free status. Engaging in preventative-health and health-promoting behaviors is most adaptive. Among individuals with subclinical disease, a second line of defense should be drawn such that the functional goal is to prevent any disease progression. These individuals must acknowledge that they are not entirely disease free and should strive to maintain full functioning and prevent any declines.

Should an illness progress to chronic disease status, health goals should focus on preventing disease progression or reverting to subclinical disease status. At this stage, individuals must disengage from the goal of remaining disease free and reengage in goals related to preventing decline. In doing so, they may be more readily able to use health control strategies which lead to better psychological health and improved well-being and reduce the negative impact of health problems (Wrosch et al. 2002). Health goals may begin to include those related to daily functioning to maintain independence, first by altering the environment or using technical aids (Becker et al. 2005), then by recruiting help (Berg and Upchurch 2007), and finally by focusing on only most important elements of independence and maintaining flexibility in order to better cope with reduced functioning (Zimmer et al. 1997). Use of control strategies should be cyclical, characterized by engagement in an appropriate line of defense, disengagement when that is no longer feasibly maintained, and then reengagement in a next line of defense. Finally, when facing a terminal illness, functional goals should be to reduce to psychological and physical suffering and to promote acceptance by disengaging from health goals in order to focus on coming to terms with their death (Gerstorff et al. 2010); failing to do so may lead to increased psychological distress prior to death.

These lines of defense can also be organized in reverse when individuals are aiming to expand their functioning and rehabilitate capabilities

when recovering from an illness or injury. For example, when recovering from radical prostatectomy, patients organized their functioning goals based on their health (i.e., degree of incontinence) such that those who were least incontinent were engaged in goals related to self-reliance, and those most incontinent focused on disengagement and using aids to support their functioning (Knoll et al. 2014). As predicted by the lines of defense model (Heckhausen et al. 2013; Heckhausen 2005), as patients' health improved, they reengaged in higher functional goals (Knoll et al. 2014) indicating that goals are not static but can (and should) be organized and adjusted according to one's capacity.

Summary

The Motivational Theory of Lifespan Development (Heckhausen and Schulz 1993; Schulz and Heckhausen 1996; Heckhausen 1997; Heckhausen et al. 1998) proposes that people select goals based on the opportunities and constraints present in such a way as to promote development across multiple domains and preserve a diversity of goals. Once goals have been selected, primary and secondary control strategies are activated to maintain engagement. When opportunities decline to a critical extent, individuals need to disengage from that goal in order to free up motivational resources to reengage in a newly selected goal. Research has consistently demonstrated that the ability to select the optimal goal and to tailor the engagement and disengagement strategies used has significant implications for goal attainment, health, and well-being among a range of populations across the lifespan. Still, there is work yet to be done. For example, it is not always clear why some individuals are better able to optimize their goals and engagement strategies than others or whether interventions to help individuals better optimize their goals, engagement, and disengagement would be effective. Additionally, most research related to MTD across the lifespan uses self-report measurements. Given that self-reports may reflect biases in recall or information processing, other measurement

types should be considered, including those of nonconscious processes and behavioral sampling via ambulant devices, assessments which do not share the biases inherent in self-reports. Although more work is needed, it is clear that across many contexts and throughout the lifespan, research on MTD has demonstrated the adaptive capacity of individuals and contributes to our understanding of the optimal motivational strategies to develop and maintain that capacity.

Motive Congruency and Person–Environment Fit of Aging Workers

Guido Hertel
Department of Psychology, University of
Münster, Münster, Germany

Synonyms

Equilibrium; Motivational balance; Need–supply fit; Self-knowledge

Definitions

According to the theory of dual motive systems (e.g., McClelland et al. 1989), two independent motive systems exist within humans: *Implicit motives* which are usually unconscious and directed toward intrinsic incentives of activities (e.g., task enjoyment, being together with others) and self-attributed *explicit motives* directed toward extrinsic incentives of activities (e.g., monetary benefits, acknowledgment from others). *Motive congruency* is considered in this entry as positive correlation between implicit and explicit motives within a person. Whereas high motive congruency is assumed to be connected with positive experiences, low motive congruency should be connected with negative experiences due to motive conflicts (e.g., Kehr 2004).

Person–environment fit at work is defined as compatibility between characteristics of an individual worker and the work environment (Kristof-Brown et al. 2005). This entry focuses on the compatibility between individuals' needs at work and the perceived opportunities to fulfill these values in the current work environment, which is a specific subtype of person–environment fit and described as *need–supply fit* (e.g., Kristof-Brown et al. 2005; Krumm et al. 2013).

Achieving Balance Across the Lifetime

Achieving and maintaining a good balance between different needs and desires, as well as

between individual needs and the surrounding environment, is a general theme in many philosophical and religious traditions. For instance, “know thyself” has been an aphorism for self-reflection, learning, and acceptance of limited capabilities (among other meanings) in Ancient Greek and Latin philosophies. Moreover, achieving balance both within the personal mind as well as in the interaction with others and with the environment is a basic maxim of many religious frameworks. In essence, these traditions might suggest that a good balance of needs and desires is a major goal and an indicator of a successful human life to be achieved across the lifespan (see also Baltes and Baltes 1990; Higgins et al. [in press](#)).

In psychology, the idea of balance and equilibrium of needs and desires can be found in various concepts of congruency between different motive systems and of “fit” between personal motives and supplies of the environment. Consistent with the more general approaches described above, the experience of such congruency and fit is thought to be associated with higher satisfaction and well-being and with more energy and motivation, for instance, during flow experiences at work (e.g., Csikszentmihalyi 1990) or self-regulatory fit (e.g., Higgins 2009). However, although initial concepts exist on how motive congruency and person–environment fit might develop over time, few empirical studies have yet addressed the relationship between individuals' age and such concepts of balance.

The general research questions reviewed in this entry are twofold. First, it is examined whether motive congruency and person–environment fit are more likely with higher chronological age of a person, as might be suggested by ideas from philosophy and religious traditions that achieving balance is a major goal in human life. Second, it is explored whether *low levels* of motive congruency and person–environment fit are connected with more negative experiences for older as compared to younger persons, which should be the case if a good motivational balance is perceived as a general goal in life. In doing so, the entry focuses on occupational work settings as a major domain in human life with important implications

on persons' self-perception and well-being. However, it might well be that the principles discussed in this entry can also be found in other life domains.

Overview of this Entry

In the following sections, the two research questions are first examined in the context of motive congruency within a person. Then, the two research questions are explored in the context of need–supply fit as a subtype of person–environment fit focusing on motivational processes. In both cases, specific assumptions on age contingencies are derived and discussed in light of available empirical studies. Finally, a preliminary summary on this emerging research is provided, followed by a discussion of open questions and directions for future research.

Congruency Between Implicit and Explicit Motives

Human *motives* can be understood as networks connected with specific cognitions about goal states or incentives that have implications for the selection of behavior and the devotion of time and energy (e.g., Schultheiss 2008). For instance, a person with a strong affiliation motive actively seeks opportunities to build social relationships and spend time with others. Such motives can be both consciously available as self-directed attributions, or rather unconsciously as impulses, needs, or desires. A prominent approach that considers these different forms as independent motive systems is the theory of dual motive systems (McClelland et al. 1989). According to this theory, explicit motives are understood as self-attributed needs and wishes that are openly acknowledged by a person and initiate controlled behavior toward extrinsic incentives (e.g., monetary benefits, acknowledgment from others). Such explicit motives can be measured with self-report questionnaires (e.g., Jackson 1984). Implicit motives, on the other hand, are usually not conscious and initiate spontaneous behavior toward

intrinsic incentives of the behavior itself (e.g., task enjoyment, connecting with others; McClelland et al. 1989; Schultheiss 2008). Implicit motives can be measured with projective tests (e.g., Pang and Schultheiss 2005) or semi-projective measures (e.g., Sokolowski et al. 2000).

Although implicit and explicit motives refer to similar goal domains (e.g., affiliation, achievement, or power), the independence of the two motive systems can lead to different congruency patterns within an individual (Köllner and Schultheiss 2014; McClelland et al. 1989). For example, a person can have either (a) both a high explicit and a high implicit motive for affiliation or (b) both a low explicit and a low implicit motive for affiliation or (c) a high explicit and a low implicit motive for affiliation or (d) a low explicit and a high implicit motive for affiliation. Whereas the first two cases reflect high motive congruency (i.e., high correlation between implicit and explicit motives), the latter two are examples for low motive congruency or motive conflicts (i.e., low or negative correlation between implicit and explicit motives). Notably, the relative degree of motive congruency can vary for different motives (e.g., affiliation, achievement, or power) within a person.

The consequences of high and low motive congruency are manifold and can predict motivation, well-being, and behavior beyond the predictability of either explicit or implicit motives alone (e.g., Brunstein 2010; Lang et al. 2012). For instance, Lang and colleagues (2012) have demonstrated significant effects of motive congruency on job performance up and beyond the effects of the single motives alone. An interesting question, however, is whether motive congruency and its consequences are qualified by a person's chronological age.

Age and Congruency Between Implicit and Explicit Motives

Following the basic idea that balance of individual motives might be a major goal in human life, it might be assumed that motive congruency increases during persons' lifetime. Such increase

might be explained by intraindividual as well as external processes. Among the intraindividual processes are learning, self-reflection, and accumulated experiences, which might lead to a constantly improved self-knowledge of individuals. Over time, persons might realize what their “true” needs and desires are based on experiences that have led to enduring and deep satisfaction and enjoyment. Such increasing self-knowledge might not occur automatically; however, “through self-observation and analysis, greater congruence between the two types of motives can be achieved” (McClelland et al. 1989, p. 700). Indeed, whereas implicit motives are considered as stable dispositions, explicit motives are considered to be adjustable by individuals due to self-observations and inferences about motivational processes (e.g., Thrash et al. 2010).

This is particularly relevant in the work domain where discrepancies between explicit motives (e.g., a person considering her-/himself as being a tough manager) and implicit motives (e.g., having a high affiliation desire) might lead to strain and unsuccessful work behavior (e.g., avoiding necessary decisions because these might be not popular and risk the sympathy from others; see also McClelland et al. 1989). Learning repeatedly that necessary job behavior is difficult or even aversive for an individual might eventually lead to changes in her/his self-perception (Thielgen et al. 2015b). Over time, such iterative learning and adjustments of explicit motives should lead to higher motive congruency for older as compared to younger workers. This assumption is congruent with findings indicating an increasing self-reflection and integration of affect and cognition during adulthood (e.g., Labouvie-Vief 2003). Notably, older workers might also have more opportunities for adjustments of explicit motives because they often have higher autonomy and control at work (e.g., Ng and Feldman 2010).

In addition to learning and accumulation of experiences, older as compared to younger persons might also be more *motivated* to achieve motive congruency. Socioemotional selectivity theory (e.g., Carstensen 2006) suggests that preferences of goals are affected by perceived temporal boundaries. In particular, the perception of

time being limited should prioritize goals related to regulation of emotional states and well-being. This general principle not only holds for preferences across the whole life-span but also for goals related to more specific time frames, such as the occupational career of a person from entering the job life until retirement age (e.g., Zacher and Frese 2009). Based on socioemotional selectivity theory, older as compared to younger workers might be more motivated to successfully regulate their emotional states and well-being, including their motive congruency. Indeed, low motive congruency can be frustrating and function as a “hidden stressor” when explicit motives are in conflict with the fulfillment of implicit needs and desires (Baumann et al. 2005) or when striving for explicit motives is not fueled by enjoyment and pleasure (Kazén and Kuhl 2011).

Empirical research on the interplay between motive congruency and age is scarce, particularly in connection with work-related experiences. However, initial data have confirmed the assumed higher motive congruency of older workers for affiliation motives. In two studies using different measures of implicit motives (i.e., the Picture Story Exercise, Pang and Schultheiss 2005, and the Multi-Motive-Grid, Sokolowski et al. 2000), Thielgen et al. (2015b) found a higher congruency between implicit and explicit affiliation motives for older as compared to younger workers. In this motive domain, workers seem to adjust their explicit motives over the life-span considering experiences such as success or failure at work or more explicit feedback from supervisors, colleagues, or HR representatives (e.g., coaching or counseling).

However, it should be noted that age differences in motive congruency were not observed for power or achievement motives in these initial studies. In addition, a recent meta-analysis based on 47 empirical papers (mostly with university students, though) found also no significant age moderation of motive congruency. Thus, high motive congruency seems to be determined by many other influences, among them both person factors (e.g., self-monitoring) as well as environmental influences (e.g., feedback culture, autonomy; see Thrash et al. 2010, for a review). As a

consequence, low motive congruency and related motive conflicts might be found not only among younger workers but also among older workers. An interesting question, then, is whether the consequences of (low) motive congruency at work are different depending of workers' age.

Age-Contingent Consequences of Motive Congruency at Work

Although older workers might be more likely and motivated to achieve motive congruency, not all older workers might do so. Interestingly, the basic rationale for the assumed positive relationship between persons' age and motive congruency has also implications for the experienced contingencies of motive congruency for different age groups. Indeed, the popular assumption that older persons are more balanced and well adjusted than younger persons might create corresponding expectations and norms that, in turn, might influence both social and self-perceptions of individuals. Moreover, low motive congruency is likely to be connected with difficulties in emotion regulation and frustration of implicit motives (e.g., Kehr 2004), which should be experienced as particularly fatal if persons have only a limited future time perspective (see Carstensen 2006), for instance, because they are close to retirement. Thus, experienced consequences of low motive congruency might be more negative for older as compared to younger persons (Thielgen et al. 2015b). In the work domain, a central indicator for such experienced consequences is job satisfaction.

In general, empirical studies have demonstrated motive congruency to be related to well-being and motivation (e.g., Brunstein 2010). For the work domain, an initial study (Thielgen et al. 2015b) has shown that congruency of affiliation motives is positively related with workers' job satisfaction, particularly when both implicit and explicit affiliation motives are strong. Moreover, these contingencies of motive congruency were moderated by workers' age such that low congruency of affiliation motives was connected with lower job satisfaction for older as compared to younger workers.

However, age did not moderate congruency effects of achievement or power motives on job satisfaction in this study (Thielgen et al. 2015b).

These selective effects might be partly explained with differences in the motives' sensitivity for different outcome measures. Indeed, a main strategy to maintain positive well-being is to connect with others and seek social support. Thus, congruency and the fulfillment of affiliation motive might be highly relevant for job satisfaction (Thielgen et al. 2015b), whereas congruency of achievement or power motives might be more relevant for work motivation, strain, or self-esteem (e.g., Kazén and Kuhl 2011; Thielgen et al. 2015a). Indeed, Thielgen et al. (2015a) using a longitudinal design documented that both congruency of affiliation motives and congruency of achievement motives were positively related to work motivation, consistent with the assumption that motive congruency increases the likelihood that workers pursue goals at work that are congruent with their implicit motive structure (Kehr 2004). In fact, low congruency of achievement motives can be seen as persistent handicap for individuals' work motivation that might often be overlooked by both workers themselves as well as by supervisors or career counselors due to the unconscious nature of implicit motives (Baumann et al. 2005).

Moreover, the consequences of low congruency of achievement motives were again moderated by workers' age. Interestingly, however, low congruency of achievement motives was more strongly related to demotivation for younger as compared to older workers. Older workers, in contrast, were found to have higher self-regulation strengths than their younger colleagues and seemed to be better able to compensate low congruency of achievement motives (Thielgen et al. 2015a). This finding is in line with life-span theories of human motivation suggesting that persons develop self-control strategies over time to master challenges and obstacles (Charles 2010; Heckhausen et al. 2010). While the fulfillment of affiliation motives can be experienced immediately, fulfillment of achievement motives is rather a prospect for the future. Thus, the different directions of the observed age moderation

of congruency consequences seem plausible given the different time horizons of motive fulfillment (Thielgen et al. 2015a).

In general, motive congruency seems to correspond to different experiences within each of the motive domains, an idea that is well in line with the theory of dual motive systems (McClelland et al. 1989). Whereas motive congruency in the affiliation domain was associated with job satisfaction (Thielgen et al. 2015b), motive congruency in the achievement domain seems to be more strongly associated with motivation and engagement at work (Thielgen et al. 2015a). Finally, motive congruency in the power domain has been found to be associated with stress and well-being for managers (Kazén and Kuhl 2011). The observed age moderation effects show that chronological age cannot only correlate with motive congruency per se but also qualify the experienced contingencies of motive congruency, for instance, at work. These results confirm the second research question of this entry.

Person–Environment Fit

In addition to intraindividual balance of motives, compatibility between individuals' motives and the surrounding environment is another aspect of achieving a good balance in life. Such person–environment fit is particularly important for the work domain. In particular, subjective need–supply fit as a motivation-specific form of person–environment fit (Kristof-Brown et al. 2005) covers the compatibility between workers' motives and perceived opportunities to fulfill these motives at work (e.g., Krumm et al. 2013). While workers' needs can include both implicit and explicit motives, empirical research on need–supply fit has usually considered explicit motives so far (i.e., work values; see Thielgen et al. 2015a, for discussing also implicit motives as component of need–supply fit).

In general, need–supply fit has been assumed and shown to have positive consequences on major outcomes in the work domain, such as work motivation, performance, and job satisfaction (e.g., Cable and DeRue 2002; Kristof-Brown

and Guay 2011). In particular, if workers perceive their current job to be highly compatible with their work values, job satisfaction is assumed to be high (Krumm et al. 2013). On the other hand, if workers perceive only few opportunities to fulfill their work values, job satisfaction should be rather low. Again, an interesting question is whether these effects are different as a function of workers' age.

Age and Person–Environment Fit at Work

Following the general rationale introduced in the beginning of this entry, age might not only be positively related with indicators of motive congruency but also with making adjustments to the external environment as a major developmental goal. This is particularly relevant for the work domain, where career advancement often enables to increase the match between individual motives and work conditions. Indeed, personal development and promotion are often based on seniority principles, providing more leeway, flexibility, and financial security for older workers. In addition, given an increasing priority on emotion regulation with higher age (Carstensen 2006), older workers might also be more motivated to achieve high job satisfaction and therefore might even adjust their expectations to the job supplies available (Zacher et al. 2014). This reasoning would predict an increasing perceived person–environment fit and, more specifically, an increasing perceived need–supply fit with higher age at work.

However, admittedly, there are also considerable difficulties to achieve and maintain a high need–supply fit over time. First, the job environment today is often changing due to career progression or market changes, requiring frequent adaptations to challenges and opportunities at work. This might also include changes in management policies or in the recognition from supervisors or colleagues (e.g., increasing age discrimination; Feldman and Vogel 2009; see also Zacher et al. 2014). Second, persons' work values itself often shift as a function of individual age (e.g., Hertel et al. 2013; Kooij et al. 2011;

Ng and Feldman 2010; Stamo \ddot{u} v-Ro β snagel and Hertel 2010), and these shifts might not always concur with ongoing changes in the job environment. Thus, maintaining a high compatibility between individual needs and job supplies seems to be a constant challenge requiring adjustments not only in the beginning of a career but also later on.

As an initial empirical exploration, Krumm et al. (2013) examined the possible contingencies between workers' age and perceived need–supply fit in a cross-sectional study with 471 workers from various working fields. In line with the latter reasoning, the authors observed no significant correlation between age and perceived need–supply fit, neither for specific work value clusters nor for an overall measure of need–supply fit. Thus, (current) work environments as well as age differences in work values seem to pose constant challenges on the maintenance of high need–supply fit even though, and this has been also found in the study of Krumm et al. (2013), a significant correlation between need–supply fit and job satisfaction suggests that high need–supply fit is a desirable state both from a worker's and an employer's perspective. However, what about potential age effects on these consequences of need–supply fit?

Age-Contingent Consequences of Person–Environment Fit at Work

Parallel to the reasoning related to motive congruency, it can be assumed that the relation between need–supply fit and job satisfaction is qualified by workers' age. More specifically, experiencing high need–supply fit might be particularly important for older workers (Krumm et al. 2013). This prediction rests again on the more general assumption from socioemotional selectivity theory (Carstensen 2006) that emotional self-regulation becomes more important when future time perspective decreases. At work, workers should place higher value on need–supply fit the less time they perceive to be remaining for achieving such fit. In addition, social norms might pose higher expectations on older workers to experience high need–supply fit. Therefore, older

workers might be more sensitive to discrepancies or incompatibilities between their work values and current opportunities at work and react more negatively (e.g., in their job satisfaction) when their perceived need–supply fit is low.

Indeed, Krumm et al. (2013) found that the relationship between perceived need–supply and job satisfaction was moderated by workers age, showing a stronger relationship for older as compared to younger workers. This pattern was consistently observed for four out of five clusters of need–supply fit, i.e., extrinsic growth values (e.g., advancement, status), generativity values (e.g., meaningful work, helping others), affective values (e.g., enjoyment, social contacts), and context-related values (e.g., job security, health). Consistent with the socioemotional selectivity theory (Carstensen 2006), workers seemed to be more sensitive to incompatibilities between their needs and the respective job supplies when their future time perspective at work is more limited. Apart from direct implications for age-differentiated human resource management (e.g., Hertel et al. 2013; Hertel and Zacher *in press*), these findings might contribute to a more differentiated understanding of the overall relation between workers' chronological age and job satisfaction (e.g., Ng and Feldman 2010). Workers' age seems to moderate not only the relative importance of different work values (e.g., Kooij et al. 2011) but also the impact of different facets of perceived need–supply fit as contribution to overall job satisfaction. Future research is desirable to examine such age-specific antecedents of job satisfaction in more detail.

Summary and Future Research Direction

Based on ancient wisdom, classic philosophy, and religious traditions, achieving balance within oneself and in interaction with the environment might be seen as a major goal in human life. This is reflected in social expectations about older persons and might put pressure on individuals to concur with such normative beliefs. However, in addition of such external norms, the experience of subjective states of balance is motivating in itself,

including feelings of happiness and high motivation as described in research of flow experiences (Csikszentmihalyi 1990) or self-regulatory fit (e.g., Higgins 2009; Higgins et al. in press). Older persons might not only have more opportunities to achieve such balance through learning, accumulated experiences, and self-reflection, but older persons might also be more motivated to achieve such balance because limited time perspectives increase the priorities of emotional self-regulation (Carstensen 2006). This entry sets out to review the existing empirical evidence for a connection between persons' chronological age and motive congruency as well as perceived person–environment fit. In doing so, the entry focuses on the work context as a major life domain of adults with important implications for self-definition, growth, and well-being. Two main assumptions were central in this review: First, is there evidence for a positive relation between workers' age and their within-person motive congruency or their perceived person–environment fit? Second, are the consequences of not experiencing a good motivational balance, i.e., motive congruency and/or perceived person–environment fit, moderated by workers' age?

With respect to the first question, this review has revealed only scarce evidence for a positive connection between workers' age and states of balance. Workers' age was not related to perceived need–supply fit at work. Moreover, workers' age was also not related with the congruency between implicit and explicit motives for achievement and power motives. The only evidence for a positive link between workers' age and motive congruency was found for affiliation motives (Thielgen et al. 2015b). However, given that aging per se is connected with increasing priorities on emotional self-regulation and nurturing social connections (e.g., Carstensen 2006; Kooij et al. 2011), the higher motive congruency in the affiliation domain might be due to a general age shift in the strength of explicit affiliation motives rather than to an increased self-reflection of older workers. Thus, consistent with a more skeptical stance of other researchers (e.g., Köllner and Schultheiss (2014), higher age seems to be not automatically connected with higher motive

congruency, even though older persons should have more learning opportunities and a higher motivation to achieve high motive congruency.

With respect to the second question, the review has revealed considerable evidence that contingencies of motivational balance at work are indeed moderated by workers' age. Older as compared to younger workers showed more negative job satisfaction when perceived need–supply was low (Krumm et al. 2013). Moreover, older as compared to younger workers showed more negative job satisfaction when motive congruency was low (Thielgen et al. 2015b). Interestingly, however, when considering work motivation as outcome variable, older as compared to younger workers reacted less negatively to low motive congruency. In fact, younger workers reported more demotivation than their older colleagues (Thielgen et al. 2015a). In contrast, older as compared to younger workers were found to possess more volitional strength that seemed to enable them to better compensate low motive congruency with self-management strategies (cf. Kehr 2004). Thus, the implications of higher age for the experience and motivational or behavioral consequences of balance states seem to be more complex and additionally qualified by the type of outcome measure as well as alternative coping resources (see also Hertel et al. 2015).

Of course, these are only initial empirical results of an emerging research theme that have to be replicated and extended, including critically scrutinizing alternative explanations. For instance, more general age differences such as shifts in goal priorities (e.g., Kooij et al. 2011) or decision-making strategies (e.g., Schwarz and Knäuper 2000) should be considered when examining the relation between age and measures of motivational balance at work. Moreover, moderating conditions should be considered that might integrate partly opposing predictions on the relation between age and motive congruency or need–supply fit. For instance, Zacher and colleagues (2014) have argued that person–environment fit might sometimes be *lower* for older workers because they are more likely to remain in jobs with poor fit due to fewer perspectives to find a new job. Thus, the direction of the age-fit link

might well be moderated by industry sector, required competencies, or other job-related aspects. Moreover, person characteristics such as dispositional affectivity, self-efficacy, or proactivity are important. These different factors are best integrated into an interactionist framework.

As a final group of moderators, differences in the conceptualizations and methodologies of balance-related measures are to be considered. Whereas the current entry has focused on subjective measures of need–supply fit, more objective measures of person–environment fit might yield different results (see Zacher et al. 2014, for a discussion of different foci of person–environment fit construals) and help to disentangle adjustments in the perception of individual motives from existing individual needs. Moreover, research on the two concepts of motivational balance considered in this entry, i.e., motive congruency and person–environment fit, has rarely been connected in the literature so far, even though the constructs are closely related. Indeed, considering only explicit motives when measuring need–supply fit is neglecting a major part of an individuals' motivation (see Thielgen et al. 2015a, for initial data integrating motive congruency and task characteristics). Thus, a more integrative consideration of person–environment fit for both explicit and implicit motives might yield a more complete picture of motivational processes and changes across age.

Given that chronological age is often a standard variable reported in empirical research, meta-analyses on the connection between age and different measures of motive congruency, person–environment fit (considering both subjective and objective fit), and related measures (e.g., flow, self-regulatory fit) might be feasible (e.g., Köllner and Schultheiss (2014). Of course, such analyses require a sufficient age range to examine age contingencies reliably.

To provide insights on causal processes, longitudinal designs are inevitable, both for age effects on motive congruency and on person–environment fit. For instance, given the available cross-sectional research, it is still unclear whether high perceived need–supply fit affects job satisfaction, or vice versa. In particular, this issue needs further exploration in light of findings that older adults seem to

be more likely to use heuristics (e.g., mood as information) when answering self-report questionnaires (e.g., Schwarz and Knäuper 2000).

Last but not least, although being in its infancy, this research offers various practical implications. Given the positive implications of balance both within person (e.g., motive congruency) and in interaction with the environment (e.g., need–supply fit), it might be worthy to consider strategies that increase such congruency and fit, for instance, age-differentiated human resource management and work design that include autonomy and resources for job crafting. Moreover, coaching interventions might not only counsel workers with regard to problems with the external environment (e.g., supervisors, colleagues, customers) but also with regard to more hidden stressors due to motivational conflicts between the way they perceive themselves (explicit motives) and the way they experience enjoyment and pleasure with what they are doing (implicit motives). While such interventions are certainly beneficial in occupational contexts both from a workers' and an employers' perspective, similar interventions are also conceivable in nonwork contexts in order to support individuals on their quest toward achieving a good balance of their needs, motives, and environmental supplies across their life.

Music Therapy, Applications in Geropsychology

Jessica V. Strong
Geriatric Mental Health, VA Boston Healthcare System, Boston, MA, USA

“I regard music therapy as a tool of great power in many neurological disorders – Parkinson’s and Alzheimer’s – because of its unique capacity to organize or reorganize cerebral function when it has been damaged.” – Oliver Sacks

Synonyms

Music healing; Music-facilitated psychoeducational strategy

Definition

“Music therapy is the clinical and evidence-based use of music interventions to accomplish individualized goals within a therapeutic relationship” – American Music Therapy Association.

The population of adults in the USA is aging quickly, led by the baby boomer generation who began turning 65 in 2011. Average life span strongly influences the number of older adults in

the country, and it has risen by almost 30 years in the last century (Center for Disease Control and Prevention 2013). The CDC and US Department of Health estimated that the number of older adults in the USA will be 89 million by 2050, which is double the number of older adults in 2010 (Center for Disease Control and Prevention 2013). Although Americans are living longer, they are also coping with more chronic health conditions, including heart disease, cancer, stroke, neurocognitive disorder (i.e., dementia), and Parkinson’s disease. It is imperative that interventions are developed and practiced to address not only the underlying biology and physiology of these chronic medical conditions but also their comorbid quality of life and psychiatric features.

Music therapy is one such intervention that has become more widespread in recent years for treating a variety of populations and conditions, including children with autism, adults with serious mental illness, and older adults with neurocognitive disorders or other health conditions. Music therapy is a versatile intervention that can be implemented in a variety of settings, including hospice and palliative care, long-term care and rehabilitation facilities, and the home. The benefits of music therapy in treating different conditions and improving overall quality of life can be pronounced. The goals of this chapter are to help the reader better understand what music therapy is and how music therapy developed as a field. In addition, it will discuss current evidence for the effectiveness of music therapy and, finally, provide practical applications for the use of music therapy with older adults across a range of functional levels.

Music Therapy Defined

Music therapy can take many different forms, depending on the patient’s abilities and goals. For the purpose of this chapter, clinical music therapy (as described below), as well as music used therapeutically outside of the licensed clinical profession, will be discussed. The American Music Therapy Association defines music therapy as “the clinical and evidence-based use of music

interventions to accomplish individualized goals within a therapeutic relationship by a credentialed professional who has completed an approved music therapy program” (American Music Therapy Association 2015).

Music therapy can be implemented with an individual or in a group setting and can be receptive or active. Receptive music therapy involves the implementation of music listening (i.e., live or recorded) for the patient by the therapist, whereas active music therapy involves therapist and patient equally in the session. A session can include singing or playing along to popular or preferred songs, listening to songs for later discussion, improvisation, song writing, or the use of drumming and rhythms. In some settings, caregivers or family members can be included in session to explore meaningful communication. Group music therapy can encourage social interactions among group members and increase positive interaction with the environment. In either group or individual sessions, music therapists often employ techniques such as music listening, music reminiscence, or music play along.

The form of a music therapy session often depends on the setting and the population; there is no “typical” music therapy session. Music therapy with individuals who have more severe disabilities may be dictated primarily by the individual and his or her needs on the day of session, rather than by an external structure imposed by the therapist. Music therapy sessions with higher functioning individuals may be more organized and include more complex activities or even manualized treatments (i.e., working through planned, specific activities over the course of the session). The frequency and length of sessions depend on the individual’s need. Sessions can range anywhere from 15 minutes up to an hour or longer. Some individuals meet with a music therapist daily, others weekly or biweekly.

History of Music in Medicine

Music is a universal activity that has spanned much of human history and has been used as a form of intervention for centuries (Bradt 2006). Prehistoric tribes are thought to have used rhythms, drumming, and chanting as a way of

warding off illnesses and evils. Priests in ancient Egypt were required to be proficient at music and healing, evidence that music played a role in medicine even as far back as 5000 BC. Hippocrates believed that music had the power to bring equilibrium to those who had an imbalance in their physical or psychological being. Aristotle and Plato wrote about the effect music had on behavior and health (Bradt 2006).

The first known English publication discussing music as medicine was published in 1729 by Richard Browne (*Medicina Musica*) (Bradt 2006). In the early 1800s, two medical students of Dr. Benjamin Rush, one of the fathers of modern-day psychiatry, published their dissertations on how music influenced the course of treatment for a disease. Later that same century, a study was published on the effect of music on sleep, emotional state, and health.

Music therapy as licensed clinicians practice today began to develop after World War I (American Music Therapy Association 2015). Physicians and nurses treating veterans all over the country documented significant improvements in the veterans’ physical and emotional healing following interactions with musicians visiting and playing in the hospitals. The first music therapy textbook was published in 1936 (*Music in Institutions*), and the first formal degree in music therapy was founded at Michigan State University in 1944. Early societies, like the National Society of Music Therapeutics (founded in 1903), did not last. However, the National Association for Music Therapy (founded in 1950) and the American Association for Music Therapy (founded in 1971) combined in 1998 to form the American Music Therapy Association. International associations have also been formed, including the Canadian Association for Music Therapy, the Japanese Music Therapy Association, and the World Federation of Music Therapy.

Music Therapy: Efficacy and Application

Study Designs

Many music therapy studies employ a randomized controlled design. Typically, participants in these studies are randomly assigned to one of two

interventions: music therapy or standard care (e.g., medication management or physical therapy). Randomized controlled trials (RCTs) are the gold standard for intervention research. However, the quality of extant music therapy studies is variable. Some common issues have been described in the literature (Nilsson 2008). Generally the symptom raters are not blinded to the conditions of the intervention, leaving open the possibility for experimenter bias. In addition, studies often use convenience samples of older adults (e.g., from a single nursing home), leading to only semi-secure randomization. Other issues include lack of explicit description regarding validity of measures used to assess symptoms, using non-validated questionnaires to assess impact of music therapy intervention, or not calculating estimated power and sample sizes.

Normal Aging

Certain forms of music therapy can be implemented with normal aging older adults to address psychosocial aspects of the aging process. Contrary to Freud's belief that individuals do not learn or change after mid-life, it is well supported that changes occur in aging, including changes to a person's social network and social role. Retirement, decreased mobility, increased isolation, and other disabilities can contribute to changes in mood and social support in late life. A review of 16 individual studies found that music participation in normal aging older adults who sang in choirs added value to the aging experience, for example, increase social networks or subjective quality-of-life ratings (Skingley and Vella-Burrows 2010). In one study (Skingley and Vella-Burrows 2010), older adults were assigned to a chorale (i.e., weekly singing for 30 weeks with several performances) or usual activity (e.g., no changes to their daily routines and activities). After 1 year, the older adults who were in the choir had lower depression and loneliness ratings and fewer reported health problems compared to the older adults who did not sing in the chorus. The singing group also became more socially active in other areas of their lives across the year. For older adults, involvement in a choir can provide a sense of purpose and encourage

interactions with peers to increase social support. Choirs that can accommodate older adults including those who do not know how to read music (e.g., by providing recordings of new songs or singing repertoire that is largely known by the group), or those with transportation difficulties (e.g., by providing transportation to and from rehearsals or performances), may be even more successful.

Sleep

The architecture of sleep has been found to alter with age, due to changes to the circadian rhythm that may contribute to insomnia, daytime sleepiness, and the onset of disorders, such as obstructive sleep apnea. Many well-controlled studies have addressed the use of receptive music therapy to treat sleep disorders with mixed results. Most studies randomly assign older adults to listen to slow and soft music before bed. Multiple studies have failed to support changes on objective polysomnography tests (Chang et al. 2012; Lazic and Ogilvie 2007) that record brain waves and oxygen levels during sleep. Often participants are tested in the sleep lab of a hospital. In one study of older adults with chronic insomnia, listening to music had a significant effect on some stages of sleep, including stage 2 (shorter) and REM (prolonged). However, the music had no effect on overall sleep quality as measured by the polysomnography test and self-report questionnaires (Chang et al. 2012). When music conditions are compared to silence or to simple tones, music does not seem to improve the quality of sleep as measured by formal, objective sleep measures. However, participants without insomnia who are assigned to listen to music often report higher levels of relaxation before falling asleep compared to participants listening to nothing or to tones (Lazic and Ogilvie 2007). They may also perceive that they fall asleep more quickly when listening to music, but polysomnography results show that this is not the case.

A systematic review of non-pharmacological interventions found "adequate evidence of a moderate effect" of music-assisted relaxation on sleep. The evidence was stronger for music-assisted relaxation than other widely used sleep

interventions, including cognitive behavioral therapy for insomnia (CBT-I), progressive muscle relaxation (PMR), and stimulus control (e.g., sleep hygiene, including no naps during the day, limiting alcohol and caffeine intake within hours of bedtime, and implementing a bedtime routine to cue the body that it is time for sleep), though the effects were slightly smaller (De Niet et al. 2009). Music-assisted relaxation combines relaxation techniques (deep breathing and PMR) with music that is chosen for its slower rhythm and relaxing quality.

Psychiatric Conditions in Late Life

Studies have examined the effects of receptive music therapy on common psychiatric conditions in late life, including depression, anxiety, and pain. Results have generally been promising and consistently show a positive effect on these conditions, sometimes above and beyond other well-established interventions. Many of the studies also have low dropout rates, suggesting that individuals who participate in music therapy are engaged and invested in treatment.

Depression and Anxiety. Depression in late life has been linked to increases in other health problems, including cardiovascular risk and cognitive decline, making it a significant public health issue. Most published music therapy interventions to treat depression employ receptive music listening, rather than active music therapy participation. The dose of intervention is often 30–60 min of listening to preferred music daily to weekly over the course of a few days to a few months. In general, receptive music listening over time has been found to decrease scores on common depression measures for older adults (Chan et al. 2011). One study found large effect sizes for both depression (0.65) and anxiety (0.49); however, no significant differences at 6-month follow-up were seen although graph analyses suggested that the effect persisted (Erkkila et al. 2011).

Listening to relaxing music can reduce both physiological and subjective ratings of anxiety. One study found that individuals listening to music had decreases in heart rate, systolic blood pressure, and subjective ratings of anxiety across a variety of hospital and community settings

(Wang et al. 2014). In one study of older adults (65+yo) undergoing cardiovascular surgery, the experimental music group listened to preferred music during and after surgery, whereas the control group received care as usual. The results found that the older adults who listened to music experienced significantly lower subjective symptoms of anxiety (Twiss et al. 2006). However, to contrast these single studies, one review paper of subjective anxiety ratings reported that only half of the studies reviewed (12 of 24) found significant decreases in anxiety ratings (Nilsson 2008). It is possible that even when physiological measures (e.g., blood pressure, heart rate) show effects of music, the subjective experience takes longer to respond and is not captured on these questionnaires.

Chronic and Operative Pain. Pain can be a difficult syndrome to treat. Concerns about proper pain management coupled with concerns about prescribing pain medications that may have an effect on cognition in older adults necessitate alternative interventions for pain. Receptive music therapy has shown promising results in the treatment of chronic pain in adults. In one RCT of adults (reviewed in Chan et al. (2011) participants 21–65 yo) with chronic pain were randomly assigned to standard music (choice of recordings), patterning music (chose music to match or reverse their mood or muscle tension), or control groups who did not listen to music. Music groups reported less pain than control groups after 1 week (20% reduction in pain in both music groups, 2% decrease in control). Music groups showed a decrease in depression scores as well (23% and 15%).

Review papers have documented an effect of music on recovery time and pain ratings before and after surgery. One study found that individuals randomly assigned to the receptive music group had significantly less pain, as measured by the number of pain medications requested and received by the patient the day after surgery. Qualitatively, of the participants who had at least one episode of confusion as documented by nursing notes, 95% of these were in the control group (5% in the experimental music group). This study also measured distance of ambulation (in feet) that

each participant completed in rehabilitation. The experimental group ambulated a significantly longer distance compared to the control group on all 3 days postoperative (McCaffrey and Locsin 2006). A particularly comprehensive review included the results on 42 studies on the effect of receptive music on pain across operative settings (preoperative, postoperative, and intraoperative, not necessarily mutually exclusive). Just over half of these studies found that music had a significant effect on reducing pain ratings.

Neurocognitive Disorders

A majority of music therapy studies have focused on the treatment of neurocognitive disorders (NCDs) to increase mood, social interactions, and quality of life for individuals with this disease. Receptive and active music therapies are used with equal frequency in this population. Music may allow those with an NCD to continue to express and experience their personhood, which can allow for meaningful exchange between individuals with an NCD and family or friends. Because music can be nonverbal, it provides the perfect medium for individuals whose verbal abilities are compromised to continue to express emotions. Studies have found that music and music therapy may improve food intake and reduce behavioral and psychological symptoms of NCDs (agitation, aggression, wandering, restlessness, irritability, social and emotional difficulties); however, studies in this area generally have a weak study design and small sample sizes.

The most frequently published subset of literature examining music therapy as an intervention for NCDs is for aggressive behavior and agitation. Two review papers reported that all (Skingley and Vella-Burrows 2010) or the vast majority (Wall and Duffy 2013) of studies reviewed showed a significant effect of music therapy on agitated behavior in NCDs. Results have consistently supported short-term decreases in agitation and aggression and increases in social engagement and reciprocity after a music therapy intervention. Although patients are often less agitated during and immediately following music therapy sessions, most studies showed no long-term effects on agitation levels across time. One study

within this review found that even though there were no long-term behavioral differences (1 month after music therapy), saliva samples revealed that patients who received music therapy continued to have reduced levels of a psychological stress indicator.

Multiple studies of caregiver interaction with music therapy suggested an even stronger effect in decreasing agitation and increasing socialization when the caregiver sings or leads the musical experience (Skingley and Vella-Burrows 2010). When caregivers sang to their family member as they were performing care, agitation and aggression were lower, and individuals with NCD showed more environmental awareness (e.g., frequency of social interactions, eye contact, smiling). This effect was stronger than listening to background music during care rituals. Multiple studies cited in this review also found that caregivers provided enhanced care if they were singing through improving nonverbal communication. It is unclear if the effect of music on the caregivers is independent from the care recipient or if decreases in the care recipient's agitation, aggression, or irritability are the driving force of this effect. One study reviewed in this paper found that listening to a loved one recalling a story decreased verbal agitation whereas listening to music decreased physical agitation.

Some studies have also addressed music therapy as an intervention for individuals who have an NCD and comorbid depression. One review found a short-term improvement in mood but again no evidence for long-term changes (McDermott et al. 2013). Most studies were not determined to be "high quality" for reasons discussed previously. One RCT of older adults with NCD living in a long-term care nursing facility compared music therapy (live musician led singing and active listening) to reading therapy (social and reading activities, including local news stories, short stories, and telling jokes), which was conducted three times weekly for 2 months. Participants had a 5-week "washout" period and then attended the other group (e.g., residents in the music group for the first 8 weeks attended the reading group). They found a main effect for group belonging – participants who were in the

reading group reported higher levels of belonging. Participants who attended at least half of the music therapy sessions showed significant improvement on quality-of-life self-esteem scores over time. Participants who screened positive for depression showed decreases in these symptoms over time that were stronger in the music group than in the reading group (Cooke et al. 2010).

Parkinson's Disease

Many studies have examined the effects of active music involvement in patients with Parkinson's disease. RCTs have found that patients who are assigned to receive music therapy sessions in groups show improvements in vocal strength, verbal and nonverbal expression (Elefant et al. 2012), and gait (e.g., using music as an external auditory cue; de Bruin et al. 2010). Singing within active music therapy sessions has shown to improve vocal strength and volume as well as strengthen facial muscles, which may lead to more expressive facial expressions. In addition, studies examining the effect of music therapy with individuals with Parkinson's disease have large effect sizes (0.8 and higher).

Stroke

Similar to gait training in Parkinson's disease, stroke patients whose gait has been affected can also benefit from gait training in music therapy (Bernatsky et al. 2004). Two single studies (reviewed in Chan et al. 2011; Nayak et al. 2000) randomly assigned participants poststroke to standard rehabilitation or standard treatment plus music therapy. The studies found that the individuals who received music therapy in addition to their standard rehabilitation therapies were rated by family and staff to have improved mood, have more social interactions, and be more cooperative in other therapies (physical and occupational) and show greater gains in cognitive domains of verbal memory and attention when compared to individuals who were not receiving music therapy. These studies provide some preliminary support for music therapy in the early recovery stages from stroke for improvement in mood and possibly cognition.

Future Directions

Future research in this field should focus on improving the quality of the available intervention studies. Factors like calculating effect sizes, using well-established and validated measures to assess for change, and designs that include random assignment and blinded raters are important to help establish music therapy as an efficacious and standard intervention. Additionally, research on the mechanisms of change related to music therapy as an intervention would be helpful to understand what it is about music that leads to changes and improvements in the short term. A better understanding of these mechanisms will increase the field's ability to apply these interventions to older adults across the spectrum – from flourishing older adults adjusting to normal changes in late life to those in long-term care who struggle with psychiatric and/or medical conditions.

Synonyms

Account; Chronicle; Description; History; Portrait; Portrayal; Recital; Record; Rehearsal; Report; Rendering; Sketch; Statement; Story; Tale

Definition

Narrative = a spoken or written account of connected events; a story.

People are storytellers. From fireplaces to crowded cinemas, humans are immersed in the telling, sharing, and receiving of stories. Stories are exchanged to entertain, to express values, to form social connections, to make sense of experiences, and to teach. People understand their current experiences, anticipate the future, and reflect on the past, through stories (McAdams and McLean 2013). As social beings, individuals construct their sense of who they are – their identity – through the telling of stories. The telling of stories, or the narrative, offers a reconstruction of memories of past events and expectations of the

future, in such a way that the story no longer simply is a disjointed and factual account of one's experiences, but rather a simplified and organized rendition of one's view (Neimeyer et al. 2008). As people tell stories about their experiences, these narratives begin to define their sense of identity (Singer 2004). As cogently expressed, "selves create stories, which in turn over time create selves" (McAdams and McLean 2013, p. 235). Through such stories, people convey "who they are now, how they came to be and where they think their lives may be going in the future" (McAdams and McLean 2013, p. 233). From this perspective, identity can be viewed as "a narrative achievement. . .achieved through the stories that we tell about ourselves, the stories that relevant others tell about us, and the stories we enact in their presence" (Neimeyer et al. 2008, p. 270).

In analyses of narratives about suffering, studies have shown that adults who grow from, or feel happy following, negative life experiences make narrative sense of such experiences in a positive manner that emphasizes their agency (autonomy), communion (social connections), and redemption (reaching a valued outcome) (Adler et al. 2015). Narrators who derive such meanings from negative experiences and who emphasize the learning, agency, growth, and personal positive transformations related to those events tend to demonstrate psychological well-being, generativity, and other indices of successful adaptation to life. For example, in speaking about the death of a relative, the

narrator may emphasize a redemptive story of how the death reinvigorated a reconceptualization of one's priorities. Such observations have suggested that the way in which an individual constructs personal narratives may impact the trajectory of their mental health over time (Adler et al. 2015; McAdams and McLean 2013).

Such observations have also spurred a burgeoning interest in narrative approaches with older adults. During late life, adults may experience a number of changes and transitions that require reorganization of relationships and roles, a reconstruction of assumptions and expectations, as well as validation of existing self-views. The death of a spouse or life partner, functional and health-related difficulties, and reduced autonomy can destabilize the meanings that individuals have constructed about themselves and their world. The narrative of such events from the perspective of the older person can have significant effects on the trajectory of their growth, emotional reactions, and well-being.

What Are Narrative Approaches?

Narrative approaches in psychotherapy are those that assist individuals tell their story to validate or “re-story” their lives (McAdams and McLean 2013) – that is, to explore stories that are self-empowering. To a large extent, all psychotherapies reconstruct or validate meanings individuals hold about themselves, others, and their lives, even if such focus is not explicitly declared. For example, person-centered therapies allow the client to express their views and reflections and discover personal resources and strengths (Rogers 1951). Cognitive and behavioral therapies focus on assisting clients challenge their dysfunctional cognitions (Beck et al. 1979). Solution-focused therapies allow for the expression of personal goals and wishes (De Jong and Berg 2012). Psychodynamic therapies allow for an exploration of understandings about early and midlife experiences (Garner and Evans 2010); and interpersonal therapies draw out the attachment-based perceptions of self in context to others (Hinrichsen 2006). Despite the differences in language or

terms, the client's narrative is addressed within such therapies.

However, some therapeutic approaches are arguably more explicit in their focus on the client narratives and consider these narratives as central mechanisms of therapeutic change. These include narrative therapy, reminiscence therapy, dignity therapy, expressive writing, and constructivist approaches. Common to these approaches is the view that stories are transformative – that is, by developing alternative or empowering stories of self, the individuals can feel, act, and think in more helpful ways, resulting in improved emotional, social, and physical well-being. This entry outlines four of these approaches and the research on their efficacy when used with older adults. Reminiscence therapy is addressed in another entry.

Narrative Therapy

Narrative therapy is a postmodern approach to the practice and theory of psychotherapy, which is based on the belief that identity is formed in social, cultural, and political contexts and illuminated through stories and narratives (White and Epston 1990). The underlying principle of narrative therapy is that the world is socially constructed, that is, it is created and grounded in multiple narratives or stories told by the self or others (Gergen 1994). The therapy involves uncovering the client's dominant or problem stories, understanding them, and retelling or “re-authoring” them in alternative and more empowering ways. The therapy is focused on guiding the clients toward crafting life stories that can be used throughout therapy to support therapeutic change.

Narrative therapy involves two major stages. First, the focus in therapy is on understanding and deconstructing the dominant unhelpful story of the individual. In this phase, the individual is encouraged to externalize, objectify, or personify the problem and talk about it as a “thing.” The problem is externalized which makes the situation more manageable, and thus the problem, not the person, becomes the target for change. In the

second stage, the individuals are encouraged to reconstruct an alternative story, where alternative meaning systems are embellished through the incorporation of unique outcomes and divergent perspectives. In this phase, props (e.g., letters, certificates, self-declarations), or other people, are drawn upon to reinforce these alternative stories (Morgan et al. 2011). For example, an older individual may communicate to the therapist the dominant view of their life as involving sickness, degeneration, and frailty. Through working in therapy, this story is embellished to include the notion of the client as being a survivor to have endured beyond these physical and health challenges. The individual may then be presented with a “certificate of endurance” by the therapist, to acknowledge this new account of the client’s identity.

Narrative therapy originated in work with children and family therapy; hence, little is known about the use or efficacy of narrative therapy with older adults. Some authors, however, argue that the therapy is applicable to older adults (Morgan et al. 2011). Using a case study approach with an older woman experiencing depression, Kropf and Tandy (1998) described how narrative therapy provided the client with an opportunity to examine her life from a “survivor” perspective. The therapy was described as empowering as it allowed the older woman to cast herself in an alternative and more positive role. Gardner and Poole (2009) used an ethnographic study design involving participant observation and semi-structured interviews to investigate the experience of older adults (aged 55–70 years of age) with addiction attending an eight-session narrative therapy group. The findings from the study suggest that narrative therapy was helpful for older adults with addictions. All participants described group experiences as positive and reported the helpfulness of various aspects of the group – such as the externalization of the problem (“I’m not a bad person; I’m just a person with a problem”; p. 611) and the creation of an alternative story (“we are challenged by narrative therapy to...become aware of the story we’re telling ourselves and make choices of what short story we want to tell ourselves...”; pp. 611–612).

The researchers suggest that the approach suits older adults, because older adults have many stories to recall and to employ as alternatives to the dominant negative discourse. The researchers state that the therapy “provides the space and time for narratives that surprise, delight, or that that have been long buried and tucked away as “irrelevant” to the problem” (p. 615).

Dignity Therapy

People receiving palliative care can experience substantial physical, emotional, and existential distress, which leads to a reduced quality of life. For over a decade, dignity-conserving care has been recognized as one of the most important therapeutic considerations in palliative care (Chochinov 2002). Dignity therapy is an intervention designed to reduce existential suffering for patients approaching the terminal phase of illness. The therapy was developed from the premise that the dignity and generativity of the dying patient; that their sense of being worthy of honor, respect, or esteem; and that their sense of having an influence across time in the service of others could be validated. Patients participating in dignity therapy are invited to discuss issues that matter most and are asked to reflect on how they wish to be remembered (Chochinov 2012). The patient is asked questions such as “Tell me a little about your life history; particularly the parts that you either remember most or think are most important; When did you feel most alive?; What are the most important roles you have played in your life? And what have you learned about your life that you would like to pass along to others” (Chochinov 2012, p. 71). These questions serve to address issues that are closely related to the patient’s sense of personhood and hence to allow patients to feel that their valued narrative of self is acknowledged and validated.

The therapist assumes a facilitative role to guide the flow of the interview based on the patient’s interests and responses. The therapist pays close attention to what is said and how it is said and to modify, embellish, or add questions based on patient cues. The therapist serves as a

caring active listener who operates from a dignity-conserving stance, conveying respects for the patient, their thoughts, and their feelings. The aim of the interview is not to record the patient's complete biography, or simply "happy stories," but rather the patient's story, as defined by the patient.

Usually, the therapist meets with the patient for 1–2 sessions for a total of 1–2 h, in order to record the interview. These recordings are then transcribed and edited. The editing of the transcription involves rephrasing parts of the transcription so that it reads more like prose than a recorded conversation, is coherent, is correct in terms of time sequence, and has a dignified ending. The edited transcript is then returned to the patient for a final review. The patient has the opportunity to amend the transcript, add to it, or delete parts of the transcript. In a final meeting with the patient, the patient is presented with the final edited and reviewed generativity document (Chochinov 2012). The narrative of the individual's story is hence translated into a concrete document, which serves not only as a reminder to the individual of their core self but also as a means for leaving behind a legacy or message for others.

Evidence for the benefits of the therapy has been demonstrated through research with hundreds of patients (Chochinov et al. 2005). In 2011, a randomized controlled trial involving 441 patients found that, compared to usual care or client-centered care, dignity therapy was rated by patients as significantly more likely to have been helpful, in terms of improving quality of life and increasing a sense of dignity (Chochinov et al. 2011). Dignity therapy was also reported to be significantly better than standard palliative care in reducing sadness or depression.

In a novel application of dignity therapy to older adults living in residential care, Hall and colleagues (Hall et al. 2012) randomized 60 residents to an intervention (dignity therapy) or control (standard care) condition in 15 residential facilities in South East London. The aims of the study were to assess the feasibility, acceptability, and potential effectiveness of dignity therapy to reduce psychological and spiritual distress in such

populations. There was an overall significant reduction in dignity-related distress, although no significant differences in reduction were found between the conditions. The study authors suggested that such results may have been due to low levels of distress at baseline and hence the little room for improvement. However, compared with the control group, residents who received dignity therapy reported feeling more positive about their participation in the study and more strongly agreed that their participation heightened their sense of meaning, purpose, and hope. Although dignity therapy did not influence distress per se, it seemed to enrich the end-of-life experience for residents who received the intervention. Although more research is warranted, this study suggests that the application of dignity therapy may be beneficial to older adults, beyond the confines of palliative or hospice settings.

Expressive Writing

In all therapies, disclosure may be a powerful therapeutic agent. The act of disclosure alone – apart from any feedback received by the therapist – may be the basis of much of the healing process that takes place in therapy. Over the last few decades, this speculation has been examined through simple verbal self-disclosure through expressive writing (Jones and Pennebaker 2008). In the expressive writing paradigm, a person typically writes about emotional, traumatic, or distressing experiences (Pennebaker 1997). The person does not talk with another person, disclose information to another person, or receive feedback. The basic expressive writing paradigm involves writing about assigned topics for 10–30 min per day for one to five consecutive days. Usually, even with assigned topics, individuals write about a broad range of experiences and either choose their own topic or individualize an assigned topic.

Research has found that such writing has been associated with physical and psychological benefits. Across studies, when people are randomly assigned to write about emotional upheavals,

they show improved health outcomes relative to controls who write about superficial topics (Esterling et al. 1999; Jones and Pennebaker 2008; Pennebaker and Seagal 1999). For example, students who write about emotional topics show improvement in grades in months following the writing; senior professionals laid off from their jobs get new jobs more quickly after writing and report using less alcohol. In a meta-analysis of 13 randomized controlled trials examining the mental and physical health benefits of expressive writing, Smyth (1998) found an overall Cohen's d of 0.47 across outcomes, representing a 23% improvement among intervention participants, compared to control participants.

In what way might such writing constitute a narrative approach? Writing about trauma in multiple writings has been considered as a means for individuals to reframe or make sense of trauma, so that memory of the trauma no longer causes physiological arousal. For example, writing may help individuals link their trauma to later benefits, or to the development of wisdom, and hence develop greater meaningfulness in life. As people inhibit thoughts or feelings, they may be deprived of opportunities to assimilate, accept, or feel a sense of control over such experiences and may paradoxically spend excessive amounts of time ruminating about them. Therefore, expressive writing may assist individuals to think through these emotions and thoughts and thus bypass inhibition. In support of this speculation, some research suggests that individuals who have difficulties with, ambivalence about, or few opportunities for disclosing feelings may benefit more than those who tend to discuss their emotions more deeply (Esterling et al. 1999).

Despite the proclivity for older adults to reminisce and tell stories of their past, there is a surprising lack of studies that have examined the outcomes of expressive writing in such populations. Expressive writing has been evaluated primarily in young people (e.g., college students). Existing studies of the effects of expressive writing on mental health and physical outcomes for older adults have produced equivocal findings. In one study on the effects of expressive

writing on physical and emotional well-being in older adults (Klapow et al. 2001), 45 patients aged 66 years or older who attended a university-based geriatric primary care clinic in Alabama were randomized to an intervention or control condition. Patients assigned to the treatment condition were asked to write about thoughts and feelings associated with the most distressing event of their lives. Those allocated to the control condition were asked to write about what they did to stay healthy. Participants in both conditions were asked to write for 20 min, three times over a 2-week period. The decrease in somatic and distress symptoms and reduction in the of outpatient services were observed to be greater in the treatment group than in the control group, although these effects were not statistically significant.

Smyth et al. (1999) randomized 112 patients aged between 41 and 51 to an intervention or control condition. Participants in the intervention condition were asked to write about the most stressful experience they had ever undergone, while those in the control condition were asked to write a description of their plans for the day. Participants suffered from mild to moderately severe asthma or rheumatoid arthritis. Those who wrote about stressful life experiences had clinically relevant changes in physician-rated and objective indicators of health status and disease activity at 4 months, compared to those in the control group. The researchers explain that such improvements may have been triggered by altered representation of past traumas facilitating improvements in coping with stressful events. However, in a partial replication and extension of this study to 270 community-based patients with rheumatoid arthritis (average age = 55–60), no effects were found for the expressive writing intervention (Broderick et al. 2004).

Finally, Mackenzie et al. (2007) compared the effects of expressive writing to time management and history writing on caregiver stress levels in a sample of 40 older caregivers (mean age = 61.53 years). Participants were asked to write for 20 min on four occasions over a 2-week period. Those in the expressive writing condition were asked

to write about current stressors; those in the time management condition wrote about how they spent their time; and those in the history writing condition wrote about twentieth-century Canadian or world events that were not personally impactful. Expressive writing and history writing were not associated with significant improvements in caregiver stress. Conversely, caregivers in the time management condition experienced significant mental and physical improvements after writing. As discussed by the researchers, these results suggest that expressive writing focused on negative experiences may be less effective for older than younger adults. They also suggest that expressive writing that is focused on positive aspects of caregiving may be more effective, than writing about stressful experiences. In support of this suggestion, a reanalysis of the data by the researchers (Mackenzie et al. 2008) found that those who wrote about their current stressors in a positive, optimistic, and future-oriented tone had improved outcomes on anxiety and insomnia.

Constructivist Approach to Grief Therapy

The loss of a loved one can represent a profound life transition that disrupts the survivor's self-narrative, mood, social and occupational functioning, and fundamental assumptions of predictability, fairness, and control (Janoff 1992). For some survivors, the loss leads to a significant sense of purposelessness and futility about the future, while for others, a major reorganization of family roles, traditions, and interdependencies (Neimeyer et al. 2008). The loss of siblings, spouse, health, and home can result in the loss of validation of identity and security for older adults.

Post-loss resilience has been understood as a process of meaningful reconstruction marked by successful assimilation of losses into a positive pre-loss narrative structure and/or the accommodation of these losses into an expansive post-loss narrative (Neimeyer et al. 2008). For example, an

individual may view the death of an older sibling in late life as a sad but anticipated expression of natural order. Alternatively, individuals may reorganize, deepen, or expand their self-narratives to accommodate the changed life of the survivor. For example, an individual may consider the loss as a trigger for self-reliance and an opportunity to affirm existing resources and supports.

From a constructivist standpoint, grief can be viewed as "a struggle to reaffirm or reconstruct a world of meaning that has been challenged by loss" (Neimeyer et al. 2008, p. 270). Converging evidence from several investigators links an inability to do so with intense and protracted grieving, and that making sense of adversity significantly mediates the relationship between the impact of unexpected deaths from suicide, homicide, and accidents and grief symptomatology of the survivor (Currier et al. 2006). Other studies, however, have been somewhat less clear about the role of sensemaking in reducing grief-related symptoms (Coleman and Neimeyer 2010).

How can the therapist operate from a constructivist perspective to assist the survivor reestablish continuity and meaning in a life story that has been challenged by loss? A variety of biographical methods, metaphoric and poetic techniques, and narrative procedures have been described in the literature (Neimeyer 1999). For example, Neimeyer (1999) describes the techniques such as (a) writing an epitaph that affirms the meaning of the deceased to the survivor, (b) maintaining written or audio-recorded journal of one's experience and reaction to the loss, (c) acknowledging the imprint or legacy of the deceased on the life of the survivor, (d) deliberately choosing to maintain a connection with the deceased through integrating objects or life projects associated with the deceased into the life of the survivor, and (e) using metaphors and poetry to express one's unique experience of loss.

In a study on the effects of a 5-week Internet-based intervention to complicated grief, (Wagner et al. 2006) offered clients (average age = 37 years old) carefully tailored writing assignments, with therapist feedback to assist them to embellish

a self-narrative that assimilated and accommodated loss. The assignments consisted of recalling and recording the story of the loss as vividly as possible; drafting a letter to an imaginal friend with a similar loss to foster perspective, compassion, and meaningful attribution; integrating positive memories of the loved one into ongoing life; defining identity; sharing the story of loss with a sympathetic other; and projecting new goals. At posttreatment, clients receiving this intervention demonstrated significantly greater reduction in grief symptoms than wait list control group.

Summary

Therapists adopting a narrative approach to working with older adults share in common a careful attention to stories of their clients, as well as to the way in which the stories are narrated. Such approaches allow for the telling of stories of one's life and self, and if indicated, to assist in the embellishment and expression of more positive stories. As seen, some approaches such as dignity therapy do not require the positive embellishment of stories, while others, such as narrative and constructivist approaches, are attentive to the development of alternative and more empowering meanings that can be drawn from adversity and losses.

The field of narrative approaches can be described as theory rich, but lacking in rigorous empirical research on its efficacy particularly with older adults. Many of the approaches have been developed with younger adults or family units, rather than for older adults. For example, expressive writing paradigms have mostly been researched using student-based samples. An exception to the youth-focused research may be found in dignity therapy, where the focus of the treatment is on the revisiting of one's life and the expression of wisdom, which is arguably most suited to individuals in later life stages. However, even in this therapy, most research is focused on adults in palliative care, rather than on older adults per se.

The dominant assumption of narrative approaches is that those stories represent a powerful frame in which to reinterpret or re-author our lives. Despite the absence of research, such an assumption provides a useful heuristic for therapists working with older adults. The essence of such treatments is to discover the story of the individual and to assist the individual to recast themselves or their situations in a way that offers purpose and validation and prompts the acknowledgement of strengths and resources. Given the abundance of experiences in late life, narrative approaches may offer older adults a means to integrate such experiences and to draw from these positive and purposeful themes.

Cognitive markers; Neurobiological markers; Neurofunctional markers

Definition

Neurocognitive markers correspond to the components of cognition, along with their neurobiological and neurofunctional bases, that exhibit changes along the trajectory of normal aging.

Introduction

The aging of societies and globalization of activities both characterize the twenty-first century. Sustaining active aging, and particularly cognitive health, is one of the leading global public health priorities (WHO 2015). Aging is a dynamic process that spans across the entire life course. In order to distinguish between the normal evolution of cognition across the lifespan and cognitive impairments due to neurodegenerative diseases, it is critical to recognize the different neurocognitive markers in aging. This entry provides a description of those markers at both the functional and structural level, while also addressing the neurofunctional reorganization that occurs and is responsible for the relative preservation of cognitive abilities in normal aging.

Hedden and Gabrieli (2004) describe the age-related cognitive changes in three broad categories – *lifelong decline*, *late-life decline*, and *lifelong stability* – thus indicating that not every cognitive function follows a similar trajectory during the aging process. According to their

view, a number of cognitive components are characterized by a process of *lifelong decline*, including general speed of processing, working memory (the transient holding of new and already stored information), divided attention (the ability to execute more than one action at a time), executive function (the management of cognitive processes), and encoding of information in episodic memory (memory of events). These components of cognition show a gradual change from early adulthood and continue throughout one's life. On the other hand, components of cognition that are well practiced on a day-to-day basis appear to be affected only in the later decades of life and are thus included in the *late-life decline* category. Examples of such components are short-term memory (the capacity to hold information for a short amount of time) and semantic memory (general world knowledge accumulated over one's lifetime). Finally, some components of cognition are comparatively less affected, or show no changes in aging, suggesting that these cognitive skills exhibit *lifelong stability*. Examples of the latter category include autobiographical memory, emotional processing, word knowledge, and automatic memory processes (Hedden and Gabrieli 2004). These three different trajectories of cognitive changes may themselves differ in their lifelong deployment, from a steady decline over the years to a sudden, steeper deterioration at one point during the life course.

Regardless of the lifelong pattern, these age-related changes in cognition result from the complex influence of genetic determinants, which are further shaped by lifelong cognitive experiences such as those involving novel items and skills. At the same time, structural changes in the brain may begin to occur as early as the second decade of life. These changes are a product of some level of genetic, lifelong wear and tear mechanism that is part of the adaptive process. Aging is no exception to the general rule, where systems try to maintain a balance within its sub-components to give rise to optimal performance. These structural changes are not uniform across aging individuals, or within cognitive functions. In order to recognize the neurocognitive markers in aging, it is pivotal to understand both the

neurobiological changes that arise and the neurofunctional adjustments that occur in response to these changes and lifelong experiences. On one hand, the neurobiological changes that affect cognition include the loss of synaptic connections, significant neural loss in different parts of the brain, and synaptic alterations in distinctive cerebral circuits. On the other hand, lifelong changes in the neurofunctional organization of the brain are a product of adaptation to the neurobiological process and fine-tuning through life experiences. These life experiences are a crucial determinant in building what is referred to as *cognitive reserve*, or the ability to perform tasks as efficiently as possible with the use of available resources (Stern 2002). Experiences such as engaging in leisure activities, educational or occupational attainment, learning multiple languages, or skill building all contribute to the cognitive reserve mechanism (Scarmeas and Stern 2003).

Given the importance of ensuring quality of life in old age, there is a need to better understand both the natural course and the determinants of healthy cognitive aging. Understanding the typical neurocognitive changes in aging is essential in order to be able to distinguish between the effects of aging and those of neurological diseases that may occur in aging. Factors affecting these neurocognitive processes can help spread awareness and provide support for active lifestyle changes. The knowledge presently available regarding these questions comes from converging methodologies including psychophysics, behavioral studies, neuroimaging, and electrophysiological studies in the aging population. But prior to studying this question, it is important to discuss what is currently known about cognition and aging.

Cognition and Aging

Age-related changes in the different cognitive domains are relatively heterogeneous throughout the lifespan. Such heterogeneity can be found among different cognitive domains, as well as between individuals (Salthouse 2004). Memory, attention, executive function, visual perception, and language abilities are discussed in this order

of priority in the literature related to aging. Different components of cognition show age-related changes that can differ in quality and quantity. Factors such as motivation, adaptation, or persistence can influence the detrimental consequences of cognitive decline due to aging. Furthermore, the magnitude of decline seen in older adults due to anatomical brain changes can be compensated through environmental factors and lifestyle choices. The following sections will discuss the age-related changes in memory, attention, executive functions, visual perception, and language abilities.

Memory

Age-related decline in memory processes can take many trajectories, from linear to curvilinear. Among the different memory processes, episodic memory and working memory are the most affected by aging (Brickman and Stern 2009).

Working memory enables the processing of information from the current environment and of already stored information within a transient period of time. It is sensitive to age-related changes in executive control processes, speed of processing, and memory load. Distinct areas in the prefrontal cortex are activated in young and older adults, suggesting differences in the execution of working memory tasks (Park and Reuter-Lorenz 2009).

Episodic memory enables the registration of an event in space and time and its key feature lies in its ability to bind different fragments of the event together into a cohesive unit. This process can range from perceptual feature binding to the binding of higher-order memory process, namely, executive functions (Shing et al. 2010). There is an age-related linear and continuous decline in episodic memory from 20 to 60 years of age, followed by a steep deterioration (Brickman and Stern 2009). This decline is not influenced by the stimuli type or modality in which episodic memory is assessed (e.g., face vs. word recall; verbal vs. nonverbal task).

Implicit memory is generally preserved in older adults. Thus, the deficits in implicit memory performance, when present, mostly reflect a decline in processing speed and processing of stimuli. In the aging literature, it is usually assessed with priming

tasks (mediated through frontal and occipital regions in aging) and sequence and categorical learning tasks (mediated through frontostriatal regions in aging). However, when implicit memory deficits are present, they appear to be linked with changes in the frontostriatal circuitry (Dennis and Cabeza 2008).

Semantic memory and procedural memory are comparatively spared during the aging process and can even show some improvement with aging (Brickman and Stern 2009). This suggests that decline in semantic memory is relatively slow. Also, its decline is seen only after the seventh decade of life (Brickman and Stern 2009). The tip-of-the-tongue phenomenon is associated with the subjective accounts of memory decline by older adults (Brickman and Stern 2009). In terms of how the brain supports these types of memories, procedural memory depends on the basal ganglia and the cerebellar structures, while semantic memory is related to the posterior neocortex.

Multiple neuroimaging studies report changes in brain activation as a function of aging in areas related to memory (Grady 2008). The literature reports both positive and negative changes in neural activities depending on the task, the type of memory process, and the type of training induced. Grady (2008) highlights the existence of a distributed pattern of brain activation in older adults compared to young adults. Greater activation was reported in the ventral and dorsal prefrontal cortex in older adults during the memory task, and frontal and parietal activation was detected during the attention task. Furthermore, the medial temporal area, and more specifically the hippocampus, showed a reduced activation in memory encoding and retrieval (Grady 2008).

Episodic memory and working memory are the subcomponents of memory that are the most affected in aging. The age-related changes seen in other memory processes are mainly due to general decline in processing speed (Brickman and Stern 2009). In addition to memory, other cognitive domains are affected by aging. Attention and executive functions, which are discussed in the next section, are closely related to memory processes.

Attention and Executive Functions in Aging

Attention is usually conceived under three broad headings: selective attention, divided attention, and sustained attention. In the older population, attentional deficits are more evident in highly demanding situations. Minimal deficits are seen in selecting relevant information (selective attention) and maintaining attention for an extended period of time (sustained attention). In general, divided attention, inhibitory control, and executive attention are three processes that are influenced by aging. Inhibitory processes, which correspond to the ability to ignore irrelevant information in the environment, experience a decline with aging. These attentional processes are influenced by memory load and executive attention (Ansado et al. 2013). Executive attention is usually discussed with both attentional and memory processes and plays a crucial function in higher-order planning and programming in day-to-day activities. Verhaeghen and Cerella (2002) report higher costs in response time for older adults but only in divided attention tasks (dual-task performance and global task switching cost) with minimal signs of deficits in selective attention. The performance deficits seen in divided attention tasks are not only caused by the effect of general slowing down but are also associated with memory load. Another approach in studying executive attention is by looking at the role of error monitoring in older adults. The anterior cingulate cortex is usually associated with error monitoring in both young and older adults, with increased activation in older adults (Dennis and Cabeza 2008). Paxton et al. (2008) report a shift in performance in older adults from a proactive (more automatic) to a more reactive (stimuli-driven) strategy of cognitive control for effective performance in any task. This is described by multiple neuroimaging studies suggesting compensatory strategies at the neural level. Grady (2008) stresses the importance of frontoparietal regions for attentional processes.

Regarding executive functions, most studies suggest an enhanced activation in different brain areas as a function of age. Enhanced activation is frequently seen in the frontal and parietal areas when performing nonverbal executive function

tasks (Madden 2007). Providing a different perspective, Jonides et al. (2000) reported less activation in the prefrontal cortex in older adults. Reduced executive function is mostly influenced by changes in frontostriatal circuits in older adults (Park and Reuter-Lorenz 2009). In addition to greater neural activation in the prefrontal cortex, a decrease in occipital neural activation in older adults during tasks requiring the participant to ignore irrelevant information is also reported (Madden 2007). In contrast to this frontal increase in brain activation, Madden (2007) reports no changes in the activation of frontal regions in older adults in an oddball paradigm; in this particular study, more activation was reported in the striatum, the thalamus, and the insula in a task involving processing of irrelevant stimuli. Similar reduced activation was reported in the left dorsal prefrontal cortex in auditory attention induced by a dichotic listening task (Thomsen et al. 2004). Selective attention, which was measured by a visual search task as well as a Stroop task, was found to be less affected in aging, suggesting an overall decline in the processing of information rather than in selective attention per se. Moreover, Persson et al. (2007) reported an increased degree of deactivation with the increase in selection demand in the default mode network, which was suspended when engaged in a verb generation task.

In summary, the execution of any goal-directed behavior changes with aging. The prefrontal cortex and the anterior cingulate cortex, which show alterations in activation, are considered to be the key areas associated with these changes. One of the major steps in allocating attention stems from the perceptual analysis of internal and external stimuli, which will be the focus of the next section.

Visual Perception and Visual Cognition in Aging

Visual perception comprises visual cognition, perception, and visually guided behavior. The perceptual deficits seen in aging are associated with attentional demands (e.g., load and complexity), semantic memory, and sensory acuity. The trajectory of visual working memory performance peaks in the early twenties and exhibits thereafter a linear decline with age. Studies on the

age-related changes in regional cerebral blood flow report an increase in the prefrontal cortex activation coupled with a decrease in occipital activation. This is predominantly seen in ventral visual pathways that are involved in word and face processing (Grady 2008; Madden 2007). Age-related variations are also seen in motion perception in older adults when compared to young adults. This change is more prominent in second-order motion perception (e.g., changes in contrast, flicker, and spatial frequency). The perception of luminance changes, corresponding to first-order motion perception, shows limited age-related differences. Thus, the increase in the level of complexity in motion perception is a key factor for age-related changes in older adults. In a virtual reality environment, dynamic variations in tracking speed were seen in older adults, a phenomenon that was attributed to capacity limitation. Some neurofunctional studies report changes in the visual cortex as a function of aging during various cognitive tasks. For visually oriented cognitive tasks, enhanced activation was seen in the frontal and occipital regions, whereas the medial temporal lobes (parahippocampal gyrus) showed reduced activation (Greenlee and Sekuler 2014).

In summary, the limitation in attentional resources and the decline in processing speed can partially account for the visual perceptual deficits reported in the literature. However, positive perceptual changes do occur in aging, particularly for more complex visual stimuli.

Language and Aging

Language abilities are considered to be generally stable in aging compared to other cognitive domains. Although, there are considerable reports of decline in language in older adults, comprehension largely shows an unimpaired performance compared to language production. In general, comprehension deficits in older adults are reported in studies carried out in noisy environments, which rather suggests challenges in auditory perception. It is usually supposed that language deficits are due to impairment in central cognitive processes (Shafto and Tyler 2014). Semantic processing is usually preserved at both the sentential and word level. In fact, word

knowledge continues to improve with age. Among the brain areas involved in syntactic processing tasks in older adults, the left frontotemporal network shows changes with age in the form of an increase in frontal activities in the right hemisphere, which is even detected in low-load tasks (Shafto and Tyler 2014). On the other hand, there seems to be less of a compensatory increase in prefrontal activities during semantic and phonological tasks, a phenomenon also reported in the attention and memory domains of cognitive processes. Some of the changes seen in language abilities can be considered as resulting from the impact of deficits in working memory, executive attention, and visual/auditory sensory perceptual skills (evident as a modality-specific effect: spoken/written and reading/writing). Thus, language is the cognitive domain that is the least affected in aging. As mentioned previously, some of its components (e.g., word knowledge, discourse skills) may even show improvement with age.

In sum, the different components of cognition are differentially affected by aging within and across cognitive domains. Working memory, episodic memory, divided attention, and executive functions are more susceptible to changes related to aging. These cognitive changes are usually linked to alterations in the frontal regions of the brain. The underlying cognitive and neural architecture of the system and the interrelationship between different cognitive domains are key to understand cognitive aging. The following section addresses the neuroanatomical and neurofunctional bases of aging as a function of these cognitive domains.

Neural Bases of Cognitive Aging

The age-related changes in the neural bases of cognition occur at both the neurobiological and neurofunctional level.

Neurobiological Modifications in Aging

The main neurobiological changes in aging consist of structural and functional changes that largely occur in the medial temporal lobe, the

prefrontal cortex, and the white matter tracts. The rate of atrophy varies within and between the lobes of the brain. The frontal, parietal, and temporal lobes show more atrophy compared to the occipital lobe. Within the frontal and parietal cortices, there is a steeper decline in gray matter in the inferior subregions of the lobes (Dennis and Cabeza 2008). Compared to other lobes, the frontal region of the brain shows a faster rate of decline, with an average decline rate of 0.9–1.5% per annum (Raz et al. 2005). On the other hand, the occipital lobe shows minimal or no significant age-related atrophy (Dennis and Cabeza 2008). There is a 0.12% rate of decline per year in the cerebral cortex in young adults, whereas older adults show a 0.35% decline per year as of 52 years of age (Dennis and Cabeza 2008; Raz et al. 2005). Due to the importance of these structures in memory, specific regions of the temporal lobes are extensively studied such as the entorhinal cortex, the hippocampus, and the parahippocampal gyrus. Raz et al. (2005) carried out a longitudinal study and found considerable atrophy in the hippocampus compared to the entorhinal cortex in healthy adults, a change that is common in Alzheimer's disease. In normal aging, hippocampal atrophy ranges from 1.18% to 1.85% per annum after the age of 50 (Raz et al. 2005). In addition to cortical atrophy, there are reports of shrinkage of subcortical (Dennis and Cabeza 2008; Raz et al. 2005) and cerebellar structures (Raz et al. 2005), and of the corpus callosum (Sullivan and Pfefferbaum 2006). In terms of neuronal loss, subcortical structures show maximum change in the caudate nucleus, followed by the putamen and the globus pallidus. Similarly, the cerebellar cortex showed more shrinkage compared to the pons and the vermis. The anterior part of the corpus callosum is more susceptible to change compared to its posterior part (Sullivan and Pfefferbaum 2006). As a result of white and gray matter loss, the rate of expansion of the ventricles increases from 0.43% in young adults up to 4.25% in older adults after the age of 70 (Dennis and Cabeza 2008; Raz et al. 2005).

The rate of decline in white matter volume is also said to accelerate after the age of 50 and is characterized by a loss of synaptic connections.

Many studies have reported a greater loss of white matter compared to gray matter with increasing age, particularly after the age of 50 (Dennis and Cabeza 2008). Furthermore, atrophy is more important in the anterior regions than in the posterior regions (Sullivan and Pfefferbaum 2006). A loss of white matter and associative track integrity is believed to be associated with the age-related decrease in processing speed (Penke et al. 2010). In fact, the diminished processing speed may be responsible for the age-related deficits in executive attention, episodic memory (Penke et al. 2010), and in the general slowing of performance.

Regarding the regional cerebral metabolic rate of glucose and oxygen, the results reported in the literature are more diverse. Through the use of different methodologies, it has been established that cerebral blood flow is altered as a function of age. Similar results were found for regional cerebral metabolic rate of oxygen (Dennis and Cabeza 2008). More recently, positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) studies using blood-oxygen-level dependent (BOLD) and hemodynamic response amplitude (HDR) measures have shown that there is more decline in the activation of the visual cortex and less so in the motor cortex. Some studies report stability in hemodynamic responses in face processing up to the ninth decade of life. Changes in the dopaminergic system have also been extensively studied as examples of the age-related modifications in neurotransmitters. The changes in the dopaminergic system seem to be mostly associated with the decline in episodic memory, executive function, and motor performance, and the related deficits appear to be at the level of the striatum. Extrastriatal decline is also evident in the frontal, temporal, and occipital lobes, as well as in the hippocampus and the thalamus (Dennis and Cabeza 2008).

In summary, the anatomical alterations in the form of gray and white matter decline and of changes in cerebral blood flow, neurotransmitters, and hemodynamic responses represent most of the age-related decrement at the structural level.

However, cognitive abilities along the age continuum do not appear to change proportionately to the extent of these structural and physiological changes. It is thus important to understand the neurofunctional reorganization that occurs in aging and that is thought to be responsible for this phenomenon.

Neurofunctional Modifications in Aging: Brain-Behavior Interface

Numerous studies using neuroimaging techniques (e.g., PET and fMRI) offer critical information on the neurobiological reorganization in aging reported in visual perception, memory, attention, and executive function. As summarized in the previous section, the evolution of cognitive performance with age includes a number of cognitive markers such as speed of performance, available resources, recollection of information, processing of sensory information, and inhibition. However, these cognitive changes are in many cases less important than what could be expected given the age-related structural and physiological decline. Such a difference stems from the existence of a neurofunctional reorganization that occurs with age as an expression of constant adaptations. The fact that the brain is capable of a neurofunctional reorganization that limits the decrease in cognitive abilities has introduced the concept of cognitive reserve. The neurofunctional reorganization in brain activation with age has been captured within two observed phenomena and two frameworks. The phenomena described correspond to: (a) the existence of a hemispheric asymmetry reduction in older adults (HAROLD) and (b) the presence of a posterior to anterior shift in activation (PASA). On the other hand, the two frameworks related to the age-related neurofunctional reorganization are the *compensation-related utilization of neural circuit hypothesis* (CRUNCH) and the *scaffolding theory of aging and cognition* (STAC) (Park and Reuter-Lorenz 2009; Dennis and Cabeza 2008).

The HAROLD and PASA phenomena have been introduced to describe the adaptive nature

of the aging brain by providing some explanation concerning the localized account of neurofunctional changes.

The PASA phenomenon has been identified in studies showing an anterior shift in brain activation in older adults who maintained an adequate performance in tasks involving attention, working memory, and executive functioning.

The HAROLD phenomenon refers to a decrease in the interhemispheric differences of brain activation in older adults in memory and attentional tasks.

The CRUNCH and STAC frameworks seek to provide some insight on the causes of the neurofunctional reorganization.

The CRUNCH framework suggests that the age-related neurofunctional reorganization in aging occurs as a response to demanding situations when there are cognitive limitations such as deficient memory load or capacity limitation. The CRUNCH principle has been reported in several studies using different cognitive functions and describes a saturation of the system at higher load levels. In the CRUNCH framework, it is suggested that older adults require more resources to process the same amount of information as young adults. CRUNCH complements the STAC framework well, suggesting that a sort of scaffolding process could account for the compensation in cognitive aging. The STAC is thus presented as a recruitment principle of additional areas or networks when the primary areas are less efficient or need assistance. It provides a holistic account of neuronal plasticity in older adults as a response to the neurobiological changes. According to this framework, an alternative network is recruited, which is less focal than in young adults. Thus, the CRUNCH and STAC explain the nature of interaction between “demand” and “supply” in a particular system, aging being only one of the examples.

In sum, the aging brain undergoes significant neurobiological changes. At the same time, there is evidence suggesting that a number of neurofunctional reorganization processes occur during the same period. The question, however, remains in our ability to reconcile the presence

of such neurobiological changes with the relatively preserved cognitive abilities in aging and to link them with the ongoing neurofunctional reorganization. This reconciliation requires the introduction of a new concept: cognitive reserve.

Reconciling Structure and Function: Cognitive Reserve

The notion of cognitive reserve has been introduced to explain the existence of functionally appropriate cognitive performance in older individuals, in spite of the known anatomical and physiological changes. The reason for such a mismatch is thought to relate to the existence of adaptive changes in the brain, also referred to as cognitive reserve, that protect the individual from the adverse effects of aging. According to Stern (2002), the notion of *reserve* can be conceived from either a structural or functional standpoint. As previously discussed, there are many structural differences in the aging brain, such as brain volume, brain size, and decline in synaptic count. However, there is clear evidence of a functional reorganization that allows for the aging brain to perform in an optimal manner. These functional changes, which are considered to *sustain the existence of a cognitive reserve*, include the recourse to neural networks that are less susceptible to disruption and the involvement of previously unused networks or components of networks (Stern 2002). Cognitive reserve is now a widely used concept in the aging literature and has a vital role in contributing to the understanding of some of the determinants of the trajectory of cognitive changes as a function of age. Cognitive reserve can be useful in discussing the reduced effect of age on cognition as a function of life exposure. Life exposure includes education, occupational attainment, and engagement in leisure as well as social activities. At the same time, there are factors that can adversely affect cognitive aging. The resilience to the neurobiological changes and neuropathological damage stems from different adaptive

processes essentially corresponding to either a change (1) in cognitive strategies (which include speed of processing, resource allocation, etc.) or (2) in the recruitment of brain networks.

Factors Affecting Cognitive Reserve

Various factors are now known as having a differential impact on the nature and extent of cognitive aging.

Education and occupation – Individuals with higher levels of educational and occupational attainment show less age-related cognitive decline. It is the lifelong process of skill building that results in the development of cognitive reserve (Stern 2002), possibly leading to the selection of more efficient strategies for optimal functioning in old age.

Multilingualism – Multilingual environments also play a crucial role in building a strong cognitive reserve. Cognitive advantages in bilingual and multilingual individuals have been well documented in various studies conducted over the last 10 years (Bialystok et al. 2007). In its simplest term, it is the lifelong ability to cognitively juggle two or more languages that appears to lead to better cognitive flexibility/cognitive control. However, this advantage is not only linked to the knowledge of languages but also to the proficiency level of a particular language, thus adding to the level of cognitive flexibility.

Cognitive training – Another determinant of cognitive reserve consists of the lifelong exposure to cognitive training. Erickson et al. (2007) reported training-induced changes in the dorsal and ventral prefrontal cortex on a dual-task training program in older adults. This could be considered as a way to reduce the age-related cognitive and neural decline. In fact, improvement in older adults has been found with perceptual-cognitive training in motion discrimination and tracking speed thresholds (Legault et al. 2013).

Heterogeneity in Cognitive Aging

Our understanding of the patterns of cognitive aging has evolved over the last decades. Initially,

cognitive domains were thought of as modular systems, and thus the influence of one domain on another was rarely addressed. However, it is now known that different cognitive domains can share some basic processes, which explains why changes in some cognitive processes may affect multiple domains (Hedden and Gabrieli 2004; Brickman and Stern 2009; Grady 2008). At the same time, other cognitive processes contribute in a more restricted manner to a specific cognitive domain. With this in mind, it is crucial to describe not only within but also across domain variability. Heterogeneity in the changes occurring between cognitive domains and between individuals can provide information on individual differences in the normal aging process or on differences in various cognitive domains. Heterogeneity is also present in the way a given individual's cognitive pattern evolves over time (Salthouse 2004). As discussed in earlier sections of this entry, there are cognitive domains that are more affected than others (executive function, episodic memory, working memory > visual perception, language, semantic memory) (Grady 2008). However, beyond the existence of actual differences in the age-related changes between cognitive domains, and within these domains along the age continuum, there are also many possible sources of variability among studies reporting changes in the different components of cognition in aging that have to be taken into consideration. These sources include: (1) different types of variables measured, (2) different sample sizes, (3) longitudinal vs. cross-sectional studies, (4) differences in the amount of cognitive demand required per task, and (5) lack of control over extraneous variables (e.g., education, occupation, skill-set learning, cardiovascular disorders, diabetes, etc.) (Valdois et al. 1990).

Conclusion and Future Directions

Aging is undeniably associated with changes in cognition. However, not all cognitive abilities are changing in the same way during the aging process. In some cases such as language, some

skills are nearly unaffected by aging, while other aspects of cognition show significant decline. However, in general, the magnitude of the changes in cognitive abilities in aging is not as important as it could be predicted by the extent of the changes in the brain. The disparity between the neurobiological and cognitive dimensions of aging is reassuring as it expresses the existence of neurofunctional processes that allow the aging brain to benefit from its lifelong learning and experiences and to engage in such a way that it can achieve similar or even superior cognitive performance compared to young adults, with an apparently diminished neurobiological basis. Some of the obvious determinants of this remarkable evolution are beginning to emerge such as education, bilingualism/multilingualism, and cognitive training, which are collectively referred to as contributing to cognitive reserve. It will become important to better understand these determinants of cognitive reserve and the exact link between such lifelong activities and their impact on cognitive abilities. It will also be important to enhance the efficiency of such measures in order to counteract the impact of the aging brain for as long as possible. The neurocognitive markers of aging are starting to be better known – research should now turn its focus toward understanding the underlying determinants of age-related changes in cognition and empowering individuals to curb the impact of aging and brain diseases in aging as much as possible.

Neuropsychological Consequences of Chronic Disease in Older Persons

Synonyms

Aging; Cognition; Cognitive decline; Non-communicable diseases

What Is Chronic Disease?

The World Health Organization defines chronic disease as noncommunicable diseases (diseases not passed from person to person) that generally progress slowly and are of long duration (WHO 2014a). They are commonly divided into four types: cardiovascular diseases (such as hypertension, heart attack, or stroke), cancers, chronic respiratory diseases (such as asthma, obstructive sleep apnea, or chronic obstructive pulmonary disease), and diabetes (see Fig. 1), all of which are more common as we age.

Chronic diseases have multiple and complex causes and often occur together. That is, a single individual may be diagnosed with more than one chronic disease, since they act as risk factors for each other. When an individual is diagnosed with more than one chronic disease, it is called multimorbidity.

Chronic diseases are common (77% of people in high-income nations have had at least one during their lifetime) and can affect people at any stage of life. However, an individual is more likely to be affected by a chronic disease in older age. Nearly 40% of individuals aged 45 years and older have two, or more, comorbid chronic diseases. Whereas, by aged 65 years, around 50% of individuals will have 5 or more chronic diseases, reaching 70% by the time we are 85 years or older (AIHW 2015).

Chronic disease is the leading contributor to the fatal burden of disease (the total loss of life due to early death) in high-income nations. However, not all individuals are affected equally. Those in geographically isolated regions, people from indigenous populations, people in low socioeconomic areas, and people of older age have a higher incidence of, and higher death rate from, chronic diseases. The economic burden of chronic disease is estimated at \$30 trillion between 2011 and 2031. This cost represents an approximate 48% of global domestic product in the United States (Bloom et al. 2011).

While many chronic diseases carry a genetic loading, lifestyle factors contribute to their development and progression, including poor diet, inactivity, and smoking. Unfortunately, these

Neuropsychological Consequences of Chronic Disease in Older Persons,

Fig. 1 Chronic diseases are common; four of the most common are cardiovascular diseases, cancers, chronic respiratory diseases, and diabetes

Neuropsychological Consequences of Chronic Disease in Older Persons, Fig. 2 Percentage of adults engaging in risk factors associated with the development and progression of chronic diseases (AIHW 2015)

N

factors are common in low-, middle-, and high-income nations (see Fig. 2).

Three Common Chronic Diseases: Introduction and Prevalence

Three common, and highly comorbid, chronic diseases are cardiovascular disease, diabetes, and obstructive sleep apnea.

Cardiovascular Disease (CVD)

CVD describes a group of disorders affecting the heart and blood vessels, including coronary heart disease (in which the blood vessels supplying the heart muscle are affected), cerebrovascular disease (in which the blood vessels supplying the brain are affected, such as in stroke), and

peripheral arterial disease (which affects the blood vessels supplying the arms and legs).

CVD is the leading cause of death, globally. In 2012, 31% of all deaths, worldwide, were due to CVD, of which 75% were in low- or middle-income countries (WHO 2014a). Furthermore, CVD is the most expensive disease group, costing \$863 billion in the United States, annually. It is estimated that this health and financial cost could be reduced by 75% for a cost of \$0.43–\$2.93 per head, per annum (Lim et al. 2007).

Diabetes

Insulin is a hormone that helps us to regulate blood sugar. Diabetes is a metabolic disorder that occurs either when the pancreas does not produce sufficient insulin or when the body is unable to use the insulin it produces, resulting in

elevated levels of glucose in the blood (hyperglycemia) (Palta et al. 2014). Hyperglycemia is a common consequence of poorly controlled diabetes and, over time, it can cause marked damage to the nerves and blood vessels.

According to the World Health Organization, in 2014, approximately 9% of adults aged 18+ years had diabetes (WHO 2014a), which causes around 1.5 million deaths per year (WHO 2014a), more of which occur in low- and middle-income countries (WHO 2014b). Critically, diabetes is a growing chronic disease. According to WHO, diabetes will be the 7th leading cause of death by 2030 (WHO 1999).

Diabetes has two forms: type 1 and type 2. Type 2 diabetes (which used to be called noninsulin-dependent diabetes) is due to the body's ineffective use of insulin. Worldwide, more than 90% of people with diabetes have type 2 (Strauss et al. 2006): largely a consequence of obesity and physical inactivity. Type 2 diabetes, once a disorder of adulthood, is now increasingly being diagnosed in children.

Diabetes is not only common but costly to individual health, well-being, and quality of life. Costs to the individual include a higher rate of divorce and poorer psychological and social health when blood glucose levels are poorly controlled. When treated, diabetes costs an individual an average of \$1,700–\$2,100 in combined drug treatments, hospital care, and other medical services. Finally, diabetes is known to cause further disease and disability including eye and kidney disease and limb amputations (AIHW 2015).

Obstructive Sleep Apnoea (OSA)

OSA is a nighttime, respiratory disorder in which the throat collapses, partially (hypopneic event) or fully (apneic event), stopping the individual from breathing. Hypopneic and apneic events cause repeated, loud snoring, intermittent hypoxia (episodes of low blood oxygen each time breathing stops or is partially blocked), intermittent hypercarbia (episodes of high blood carbon dioxide because blockages in the throat prevent carbon dioxide being breathed out), and poor sleep architecture. In order to restart breathing, the individual either wakes from sleep or rises up from deeper

into shallower stages of sleep, known as physiological arousal. These arousals disrupt the normal pattern of sleep in which we cycle through lighter into deeper sleep stages around once per 90 min.

OSA is common and costly to the individual and to society, occurring in 9% of middle-aged women and 24% of middle-aged men. Furthermore, prevalence rates increase with increasing age. Costs include a two to threefold risk of motor vehicle accidents, disruptions to mood, increases in irritability, sexual dysfunction, occupational injuries and increased work absenteeism, relationship discord, and reduced quality of life. Finally, as OSA is a nocturnal disorder, it often remains undiagnosed and untreated.

CVD, Diabetes, and OSA Increase Risk of Each Other

To compound the problems experienced by individuals with these chronic diseases, they each increase risk of developing the others. A common form of CVD is hypertension (high blood pressure) and this is a known risk factor for type 2 diabetes. Diabetes is a risk factor both for OSA and for stroke and heart disease (also types of CVD). OSA appears to be a cause of CVD, including hypertension, heart disease, and stroke, and is also a risk factor for hyperglycemia and diabetes.

In addition, diabetes, CVD, and OSA are also causes of impairments in neuropsychological function, likely induced by similar mechanisms of harm. Before describing the nature of the neuropsychological impairments of each disorder, this entry first explains what neuropsychological function is, then lists the types of functions known to be impaired in CVD, diabetes, and OSA, and then considers the ways in which it is thought that each disorder causes those neuropsychological deficits.

Definition of Neuropsychological Function

The term “neuropsychological function” captures all cognitive functions that enable awareness, perception, comprehension, thinking, and reasoning and are associated with an underlying brain region

or neural network. Neuropsychological tasks are used to measure cognitive functions and make assessments about the function of the underlying brain region or network. Such tasks, when used by a trained clinician, allow for assessment of cognitive deficits, diagnosis of disease, and tracking cognitive decline.

Broadly, neuropsychological function can be divided into the overarching domains of attention, memory, executive function, visuospatial/constructional abilities, psychomotor ability, and language function. What follows is a brief explanation of these domains, associated brain regions or networks, and a typical task used to assess this domain. A full explanation of domains, facets of each domain, and assessments is beyond the scope of this entry. For readers interested in neuropsychological function, anatomical correlates, and assessment, we recommend Strauss, Sherman, and Spreen (2006); Lezak, Howieson, and Loring (2004); and Schoenberg and Scott (2011).

Attention

Attention refers to several capacities that enable and direct perception, orientation, and concentration of selected stimuli and inhibition of processing unwanted stimuli. Broadly speaking, attention involves many regions of the brain. Some key networks include sensory input and motor output systems, the dorsolateral and midlateral prefrontal cortex, the temporoparietal junction, and the intraparietal sulcus (Gobel et al. 2011). Complete assessment will examine simple attention, selective attention (focused attention), sustained attention (vigilance), divided attention, and rapid alternating attention (see Table 1 for definitions and typical tasks assessing each function).

Memory

Memory broadly refers to one's capacity to encode new information, consolidate this information, and retrieve it when needed. Key brain regions involved in memory include the hippocampus, amygdala, diencephalic structures, medial temporal lobes, entorhinal cortex, and basal forebrain (Gobel et al. 2011).

Memory can be described in many different ways, but is generally divided into explicit

(declarative memory or information you can intentionally and consciously recollect) and implicit memory (nondeclarative or procedural memory or information you know without conscious awareness of the formative experiences). Declarative memory can be further divided into episodic (personal experiences and information) and semantic memory (factual knowledge). Memory is typically thought to be processed as verbal (memory involving language) and visual/spatial (memory involving pictorial or spatial representations) content and is held in short- and long-term memory stores.

Short-term memory refers to the ability to recall a small amount of information (typically 7 +/- 2 pieces of information) within about 30 s. Sometimes, short-term memory is referred to in conjunction with working memory (see section "Executive Function," below). Working memory requires holding information in short-term memory stores while dynamically manipulating this information. Long-term memory refers to the acquisition and consolidation of new information into long term, relatively permanent stores, or learning. In neuropsychological assessment, this typically means information that is retained after at least a 20–30 min delay.

Complete assessment of memory will sample short- and long-term memory abilities, learning (acquiring knowledge with repeated presentations of stimuli), encoding (conversion of information to a form usable by the brain), consolidation (stabilization of a memory trace), retrieval (the process of pulling information from memory store), primacy and recency effects (the effect on memory of the position of items in a list), free (remembering items without cues) and cued (memory with cues) recall, recognition (identifying a known item from a list or story), and proactive (older information interferes with the recall of newly learned information) and retroactive (newly learned information hinders the recall of older information) interference.

Memory problems are the most frequent presenting neuropsychological complaint: however, what people view as a memory complaint and/or the underlying reason can be quite varied.

Neuropsychological Consequences of Chronic Disease in Older Persons, Table 1 Key neuropsychological domains and tasks that assess these domains

Domain	Facet	Description	Example task
Attention	Simple attention	Ability to perceive and concentrate on key stimuli	Cogstate detection test
	Selective attention	Attend to key stimuli while ignoring competing stimuli	WAIS Cancellation Task
	Sustained attention	Maintain attention over a set time period	Conner's continuous performance task
	Divided attention	Processing multiple stimuli at the same time	Test of everyday attention (telephone directory test)
	Rapid alternating attention	Shift attention rapidly between stimuli	Test of everyday attention (elevator counting)
Memory	Short-term memory	Holding information in mind for ~30 s	Verbal example: Digit span forward Visual example: Spatial span forward
	Long-term memory	Encoding and consolidating memory into relatively permanent stores	Verbal example: California Verbal Learning Test Visual example: Location Learning Test
Executive function	Updating	Updating and monitoring of working memory representations	Letter number sequencing
	Inhibition	Inhibition of dominant or prepotent responses	NIH Examiner – inhibition test
	Set shifting	Shifting between tasks and mental sets	NIH Examiner – set shifting test
	Generativity (fluency)	Efficiency of access to long-term memory	Controlled Oral Word Association task
	Fluid reasoning	Reasoning and problem solving, involving complex, higher-order abstraction, problem solving, and concept formation	6 Elements task
Psychomotor function		Physical movements/actions associated with conscious cognitive control	Grooved pegboard
Visuospatial/ constructional ability		Processes involved in processing visual and spatial information	Clock drawing task
Language function		The ability to produce language (expression, either oral or written) and to understand language (reception, either oral or written)	Boston diagnostic aphasia examination

Note: The example tasks in this table are designed for testing adults, although there may be child versions of some of these tasks

Full neuropsychological testing is commonly required to uncover the underlying issue.

Executive Function

Executive functions describe a set of cognitive processes responsible for volition, planning,

purposeful action, and monitoring of performance. These processes collectively manage other cognitive processes, including memory and attention. Broadly speaking the frontal cortices are chiefly involved in executive functions (Schoenberg and Scott 2011). Like other

cognitive domains, executive function is multidimensional and has been divided into shifting between tasks and mental sets (shifting), updating and monitoring of working memory representations (updating), inhibition of dominant or prepotent responses (inhibition), and efficiency of access to long-term memory (generativity). In addition, an overarching system of fluid reasoning, involving complex, higher-order abstraction, problem solving, and concept formation, is also considered an aspect of executive function.

Executive function difficulties may not be apparent in a highly structured environment. As such, complete assessment of executive function will evaluate the facets mentioned above and may include subjective or informant report of an individual's executive functioning within their environment. Subjective details about an individual's environment and their functioning within it assist clinicians with understanding the level of dysfunction and with providing appropriate recommendations.

Psychomotor Function

Psychomotor functions relate to the ability to coordinate thinking and physical movement. Psychomotor skills are demonstrated in fine and gross motor coordination, including hand-eye coordination, balance, and reaction times. Crucial neural correlates include sensory, premotor and motor cortical regions, and extrastriatal regions of the occipital and parietal cortices (Starkstein and Kremer 2001). Generally, psychomotor function is measured using physical tasks, such as tapping a finger as fast as possible, in terms of speed (reaction time) and accuracy.

Visuospatial/Constructional Abilities

Visuospatial and visuoconstructional abilities are largely automated functions, but can be consciously directed and controlled. Visuospatial abilities enable the perception and processing of complex visual stimuli, involving information about color, line, and orientation. The sensory and motor systems in the occipital and parietal lobes are crucially involved in visuospatial functions (Gobel et al. 2011).

Language Function

Language function is the capacity to learn, understand, and produce complex symbolic systems for communication, for example, spoken and written language or sign language. Brain regions intimately involved in language processing involve sensory and motor systems, the left posterior frontal cortex, and the left posterior temporal-parietal areas.

Neuropsychological Function and Aging

Neuropsychological function declines in healthy aging. Cognitive domains that show change in typical aging include expressive language, visuospatial/constructional abilities, most executive functions, and long-term and working memory (Starkstein and Kremer 2001). However, that neuropsychological decline is an inevitable consequence of normal aging is debatable. Instead, there seems to be an intricate interplay of risk and protective factors, including diet, lifestyle, cognitive and brain reserve, and disease.

Cognitive and brain reserve are thought to explain why some individuals show decline with age or disease, whereas others do not (Stern 2012). Brain reserve describes differences in the structure of individuals' brains (the number of neurons and the strength of connections between them). Cognitive reserve, by contrast, refers to individual differences in how we use our brains to perform neuropsychological tasks, which help to make us more or less susceptible to the impact of aging or disease (such as skill, expertise, or practice). Despite differences in the degree to which each individual is affected, however, it is clear that chronic disease negatively impacts on neuropsychological functioning, and this can be compounded by usual aging.

The Nature of the Neuropsychological Deficit in CVD, Diabetes, and OSA

Neuropsychological function is adversely affected by chronic disease. The three classes of chronic disease that are the focus of this entry produce a profile of neuropsychological harm with striking similarities and some differences.

Neuropsychological Consequences of Chronic Disease in Older Persons, Table 2 The neuropsychological consequences of diabetes, CVD, and OSA

Domain	Diabetes ^{2,3}	OSA	CVD ^{4,5}
Attention	D ^{2,3} Sustained: D ³ Divided: N ³ Selective: N ³	D ¹	D ⁴ , N ⁵
Memory	Verbal: D ^{2,3} Visual: D ^{2,3} Short-term: D ³ Long-term: D ³	Short-term: E ¹ Long-term (episodic) verbal (short, long, learning, and recognition): D ^{1,7} Long-term (episodic) visual (short and long): D ^{1,7}	D ^{4,5}
Executive function	D ²	D ¹ Shifting: D ⁶ Inhibition: D ⁶ Updating: D ⁶ Generativity: D ⁶ Fluid Reasoning: D ⁶	D ⁴ , N ⁵
Visuospatial/constructional abilities	D ³	D ¹	N ^{4,5}
Psychomotor function	D ²	N ¹	
Language	N ³	N ¹	N ⁵

Note: *N* evidence suggests no effect of this chronic disease, *E* equivocal findings (some evidence for deficits; some for preservation); *D* poorer performance reported in those with this chronic disease, relative to those without; *blank* no systematic review evidence available; 1, Bucks et al. (2013); 2, Brands et al. (2005); 3, Palta et al. (2014); 4, DeRight et al. (2015); 5, Gifford et al. (2013); 6, Olathe and Bucks (2013); 7, Wallace and Bucks (2013)

Table 2 summarizes systematic review evidence describing the nature of the neuropsychological deficit in each chronic disease. Where available, cognitive domains have been broken into facets of a domain.

Across OSA, diabetes, and CVD, there appears to be no marked harm to language functions and differential profiles of harm across visuospatial/constructional abilities and psychomotor function. All three of these chronic diseases show neuropsychological dysfunction, greater than would be expected for patients' age, within the broad domains of attention, memory, and executive function. However, when the overarching domains are broken into facets, such as has been conducted for memory function in CVD and OSA, harm is not ubiquitously displayed across the entire domain. For example, short-term memory has been shown to be impacted by diabetes, but does not appear to be compromised in OSA, while long-term memory, particularly for new, episodic memory, is markedly impaired both in CVD and in OSA for both visual and verbal material. Within executive function, all five

domains are affected by OSA, while for CVD there is evidence that executive function (as a whole) is impacted, and the evidence for diabetes is contradictory. It may be that facets of executive function are impaired, while others are preserved in CVD and in diabetes, explaining the contradictory review findings for the latter. Systematic reviews aimed at delineating harm within facets of a domain, for these disorders, would enable a more intricate understanding of the neuropsychological profile of harm, outline the possible functional declines, and aid with understanding the mechanisms of harm.

CVD

CVD is associated with deficits in attention, memory, and executive functions, whereas visuospatial/constructional abilities and language remain intact. In the second review (Gifford et al. 2013) for CVD, which summarized neuropsychological function in hypertension, attention and executive function remained intact, while memory function was compromised. As yet, there are no reviews into the effect of CVD on psychomotor function.

Imaging studies suggest that this pattern of deficits relates to the profuse changes to white and grey matter found in CVD.

Diabetes

Within the domain of attention, people with diabetes demonstrate impaired performance on sustained attention tasks, but not on divided or selective attention. People with diabetes show impairment across many facets of memory (verbal and visual, short and long term), and executive functions, visuospatial constructional abilities, and psychomotor function are also compromised. Language remains intact in diabetes. Imaging studies have localized damage to fronto-temporal regions (regions heavily involved in executive functions) and the periventricular nucleus (associated with memory).

OSA

Individuals with OSA experience impaired function in attention, memory (long-term verbal and visual), executive skills, and visuospatial/constructional abilities. There appears to be no harm to psychomotor functions or language abilities. Evidence in relation to short-term memory deficits is unclear, with studies reporting both preservation and impairment. Associated with these neuropsychological difficulties is neuroanatomical degeneration in brain regions implicated in these functions, including the thalamus, involved in relaying sensory and motor signals and regulating sleep and alertness; the hippocampus, involved in memory; and the amygdala, which assists with regulating emotion.

Mechanisms by Which These Three Chronic Diseases Impact on Neuropsychological Function

The striking similarities in the nature of the neuropsychological impairments seen in these three chronic diseases suggest that there may be overlap in the mechanisms of harm by which each disease impacts on neuropsychological function. However, although there is ample evidence that each of these chronic diseases is an independent risk factor for cognitive decline and dementia in older

people, the mechanisms by which diabetes, CVD, and OSA impact on neuropsychological performance are not well understood (McCrimmon et al. 2012). Candidate mechanisms include the impact of each chronic disease on blood supply to the brain, reductions in blood gas/nutrients to the brain, reductions in removing waste from the brain, deposition of harmful chemicals, and reduced brain white matter.

Impact on Blood Supply

Diabetes, CVD, and OSA compromise the blood supply to the brain. The cardiovascular system (the heart and blood vessels) is essential for supplying the brain and other cells of the body with oxygen, glucose (blood sugar), and other nutrients. Interruptions to this supply deprive the brain of vital nutrients and decrease the removal of toxic metabolites.

Additionally, diseases like diabetes, OSA, and CVD affect the small cerebral (brain) blood vessels (microvasculature) of the brain, the tiny blood vessels that are critical for carrying blood, and therefore oxygen and nutrients to the whole brain. These diseases are associated with proliferation of lesions in small cerebral blood vessels which reduce the flow of blood to the brain.

Blood Gas/Nutrient Abnormalities

The brain is particularly vulnerable to reductions in the supply of such nutrients, because it has very limited capacity to store them. Even very brief or subtle interruptions of supply can be damaging. Due to reduced blood supply, changes in small cerebral blood vessels, and changes in levels of blood gasses and nutrients, the brain receives less of the necessary “food” required by biological processes, which is likely to impact on neuropsychological functions.

Reduced Capacity to Remove Waste, Protect the Brain from Toxic Substances, and Buildup of Toxic Substances

OSA, CVD, and diabetes lead to an increase in brain metabolites (including free radicals and beta-amyloid) and impair protective brain structures (including the blood-brain barrier), and recent animal studies suggest they may also reduce the

brain's ability to remove toxic waste products. Reduced capacity to remove waste emerges due to interruptions in filtration due to changes in small cerebral blood vessels and/or to broken sleep.

Changes in small cerebral blood vessels and the proliferation of lesions alter the blood-brain barrier (BBB). The BBB separates the blood circulating around the brain in the cerebral blood vessels from the fluid circulating around our brain cells (brain extracellular fluid). Glucose and nutrients are allowed across the BBB, while bacteria are kept out. CVD, OSA, and diabetes are associated with an increase in the permeability of the blood-brain barrier (BBB). A more permeable BBB may allow bacteria, and other toxins, to pass into the brain tissue, causing harm. Similarly, increased permeability has been demonstrated in Alzheimer's disease and in vascular dementia.

While OSA is clearly a sleep disorder, CVD and diabetes also appear to be causes of poor sleep. CVD, OSA, and diabetes may result in neuropsychological impairments due to a reduced capacity to filter and remove waste from the brain due to the changes to small cerebral blood vessels noted above, in combination with poor sleep. The lymphatic system is a system of tubes and tissues throughout the body that is integral to the immune system, bathes bodily tissues in fluid, and acts to filter toxic substances from tissues by passing them into the blood stream, from where they can be excreted. The brain has no lymphatic vessels, but new research suggests a brain-specific filtration system termed the "glymphatic system" performs the same function. Animal studies have shown that this system becomes most active and efficient during sleep, with capillaries within this network opening up by more than 60% (Xie et al. 2013). Changes to small cerebral blood vessels and broken sleep deplete the efficiency with which this system can remove waste from the brain. This, potentially, leads to the buildup of toxic substances such as beta-amyloid.

Beta-amyloid is fragments of protein broken off from an amyloid precursor protein (a larger protein found in the membrane which surrounds all nerve cells), which, under normal circumstances, would be broken down by the body and eliminated from the brain. The latest thinking is that sleep disruption

impairs the brain's ability to rid itself of these fragments of protein. Because they are "sticky," they clump together, building up into plaques. These clumps of beta-amyloid are toxic to nerve cells: indeed, even very small clumps may reduce communication between nerve cells and produce inflammation. Beta-amyloid plaques are one of the hallmarks of Alzheimer's disease.

Reduced White Matter Integrity

White matter is the term used to describe the bundles of nerve fibers that connect the grey matter (the lobes of the brain) together. These nerve fibers are "insulated" with myelin, which sheathes the nerve fibers, speeding the transmission of signals. CVD, OSA, and diabetes all damage white matter, producing lesions (also called white matter hyperintensities for the way they show up in brain imaging). White matter lesions are small areas of dead cells that are thought to be due to loss of blood supply to the nerve fibers leading to damage to the myelin sheath (ischemic demyelination) or due to occlusion of small arteries resulting in nerve fiber death. White matter lesions slow and/or stop neural signals from passing back and forth in a fast and efficient manner. While some white matter changes are a normal part of the aging process, white matter lesions are associated with increased risk of stroke, cognitive decline and dementia, greater deposition of beta-amyloid, and faster decline in global cognitive performance, executive functions, and processing speed (Debette and Markus 2010).

Future Directions

A search of the literature reveals a wealth of information describing single, chronic diseases, their prevention, and care. It also reveals an understanding of the broad neuropsychological domains affected in each chronic condition alone. What is missing is a more intimate investigation of facets within domains, within each chronic disease. In addition, the nature and extent of multi-morbidity is not well understood, nor do we have a good understanding of the impact of multi-morbidity of chronic diseases on neuropsychological function. Finally, longitudinal studies

that track changes in neuropsychological function have also focused on single, chronic diseases. Few prospective or longitudinal studies are available tracking combinations of chronic diseases in order to understand how trajectories of change in neuropsychological function may be similar or different in different combinations. This is critical. We do not know if the neuropsychological impacts are simply additive or multiply in some way. We do not know if particular combinations of chronic diseases produce greater risk for neuropsychological dysfunction or faster rates of decline.

Thus, further research is required to delineate the cognitive profiles and mechanisms of harm in chronic diseases and in their combinations. Such detail would support clinicians better to recommend ways to compensate for or rehabilitate neuropsychological impairment. Such compensation may include the use of diaries for individuals with memory impairment or problem solving techniques for those with executive functioning difficulties. Critically, a better understanding of the mechanisms of harm of each disorder, and their comorbidities, will allow for the development of treatments targeting the mechanisms that cause damage and tailored to the combination of chronic diseases experienced by each individual.

Clinical Implications

Whether or not we experience chronic disease in older age is, in large part, a consequence of the cumulative effects of lifestyle; behavior and behavior change; social mobility; physical growth in the womb, in infancy, and through childhood into adulthood; and history of infection and of reproduction. Increasingly inactive childhoods (due to extended screen time) and adulthoods (due to sedentary occupations), consumption of high-fat/high-sugar foods leading to obesity, coupled with marked healthcare successes, mean that we now live longer, with the greater associated risk of living longer with one or more chronic diseases (WHO 2014a).

Clinicians from many healthcare fields can have a significant impact on people's quality of life and life expectancy by screening for these

contributors early and educating their patients as to the positive benefits of a healthy diet and lifestyle. Other sectors of society can ensure procedures and policies for effective food labeling and education about tobacco smoking and access to environments that ensure active lifestyles and to fresh foods.

Summary

Chronic diseases are noncommunicable diseases with a slow progression and long duration. Cardiovascular diseases, cancers, chronic respiratory diseases, and diabetes are common; increase in prevalence as we age; occur more commonly in geographically isolated regions, in indigenous populations, and in individuals from low socioeconomic areas; and are the leading contributors to the fatal burden of disease. Lifestyle factors such as tobacco smoking, diet, and exercise contribute to the development and progression of chronic disease.

Of these, cardiovascular disease (CVD), diabetes, and obstructive sleep apnea (OSA) are often comorbid. Diabetes, CVD, and OSA are each associated with impairments in neuropsychological function. While language functions appear to be spared, visuospatial/constructional abilities are affected in both CVD and OSA, and psychomotor functions are impaired in CVD. Consistent across all three of these chronic diseases is decreased attention, memory, and executive abilities. The striking similarities in the nature of the neuropsychological impairments seen in these three chronic diseases suggest overlapping mechanisms of harm, including reductions in blood supply to the brain, which lead to blood gas/nutrient abnormalities, to increased deposition of harmful substances compounded by a reduced capacity to remove waste products, and to reduced white matter integrity.

Further research is required to delineate differences in the neuropsychological profiles of chronic diseases and their combinations and the mechanisms of harm. Clinicians from a variety of health fields can impact the development and progression of chronic disease with early screening and education.

Neurotrophic Factors in Aging

Natália Pessoa Rocha and Antônio Lúcio Teixeira
Laboratório Interdisciplinar de Investigação Médica, Faculdade de Medicina, Universidade Federal de Minas Gerais, Belo Horizonte, MG, Brazil

Definition

Neurotrophic factors (NFs) are polypeptides involved in the maintenance and adequate

function of neurons and neuron-supporting cells. Mechanisms underlying NFs signaling may fail during neuronal repair and aging, resulting in neurodegenerative diseases, such as Alzheimer's disease (AD) and Parkinson's disease (PD) (Lanni et al. 2010).

Introduction

Neurotrophic factors (NFs) are a group of soluble polypeptides with a range of functions in nervous system development and maintenance, and survival of neurons and neuron-supporting cells.

NFs are divided into different families according to structure and function: (i) neurotrophins (NTs): nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), NT-3, and NT-4; (ii) transforming growth factor (TGF)- β superfamily which includes the glial-cell-line-derived neurotrophic factor (GDNF); (iii) neurokinin superfamily comprising ciliary neurotrophic factor (CNTF), interleukin (IL)-6, and IL-11, among others; and (iv) nonneuronal factors, for instance, insulin-like growth factor (IGF)-1 and epidermal growth factor (EGF) (Lanni et al. 2010).

Each of these NFs exerts its biological activities through receptors with intrinsic tyrosine kinase activity. Consequently, there is activation of transcription factors, and the expression of determined genes is induced. These genes encode proteins involved in regulating neuronal survival, differentiation, and plasticity (Lanni et al. 2010).

NFs are not always essential for neuronal survival, but they are at least involved in maintenance and adequate function of neurons. For instance, in the absence of NGF and BDNF, there is no loss of cholinergic neurons in young rats but reduction of cholinergic markers in aged ones. *In vitro* experiments have showed that when neurons initially grown with NGF stimulus are deprived of this NT, there is no death of old cholinergic neurons. However, NGF withdrawal resulted in downregulation of neurotransmitter-associated enzymes, cholinergic cell shrinkage, and reduction of fiber density (Svendsen et al. 1991).

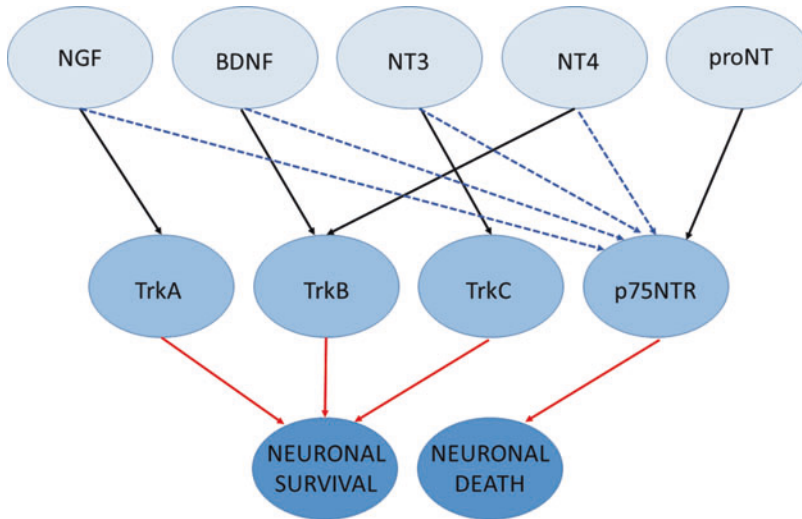

Mechanisms underlying NFs signaling may fail during neuronal repair and aging, resulting in neurodegenerative diseases, such as Alzheimer's disease (AD) and Parkinson's disease (PD). This entry will focus on the neurotrophins, NGF and BDNF, and the NFs, GDNF and CNTF, given their clinical significance in aging and neurodegenerative age-related disorders.

Neurotrophins (NTs): An Overview

NTs were first identified as promoters of neuronal survival. Currently they are also known to regulate many aspects of neural development, function, and plasticity (Reichardt 2006; Huang and Reichardt 2001). NTs act mainly through tropomyosin-related kinase (Trk) receptors. NTs directly bind and dimerize these receptors, which results in activation of the Trk present in their cytoplasmic domains.

NGF binds selectively to the TrkA receptor, while BDNF and NT-4 are selective for TrkB. NT-3 activates TrkC, although it is also able to activate less efficiently other Trk receptors. There is another NT receptor, the p75NTR, to which all NTs can bind at low affinity (Lanni et al. 2010; Reichardt 2006; Huang and Reichardt 2001). p75NTR is a member of the tumor necrosis factor receptor family. The role of p75NTR in NTs signaling was unclear, being debatable whether this receptor transmitted any signal or was merely a binding protein. Studies have shown that p75NTR indeed transmits signals important for determining which neurons survive during development (Huang and Reichardt 2001). Figure 1 shows NTs actions on their respective receptors.

NTs are synthesized as precursors, i.e., larger proteins cleaved to produce mature NTs. The mature cleaved forms of NTs, then, selectively bind NT receptors. Activation of Trk receptors pathways results in neuron survival signaling. When NTs bind p75NTR, signaling events promote cell death due to apoptosis (Lanni et al. 2010; Huang and Reichardt 2001). Uncleaved proNGF is also able to bind the

Neurotrophic Factors in Aging, Fig. 1 Schematic illustration of neurotrophins, their respective receptors, and final effects. Neurotrophins (*NTs*) act through *Trk* receptors. *NGF* binds selectively *TrkA* receptor, while *BDNF* and *NT-4* are selective for *TrkB*. *NT-3* activates *TrkC*, although it is also able to activate less efficiently other *Trk* receptors. All *NTs* can bind *p75NTR* at low affinity.

ProNTs also bind *p75NTR*. *BDNF* brain-derived neurotrophic factor, *GDNF* glial-cell-line-derived neurotrophic factor, *NGF* nerve growth factor, *NT* neurotrophin, *p75NTR* p75 neurotrophin receptor, *proNT* proneurotrophins, *Trk* tropomyosin-related kinase. $\text{---}\rightarrow$ low-affinity binding, $\text{---}\rightarrow$ high-affinity binding

p75NTR with high affinity, leading to cell death. Therefore, the precursors of *NTs* are not inactive molecules. *ProNTs*, mainly *proNGF* and *proBDNF*, trigger apoptosis via *p75NTR*, while mature *NTs* induce cell survival through *Trk* receptors (Lanni et al. 2010). Nevertheless, this canonical view has been challenged. Some evidence has indicated that *p75NTR* signaling may be involved in neuron survival. For instance, embryos of knockout mice for *p75NTR* exhibited reduced, instead of increased, cell death in retina and spinal cord (Frade and Barde 1999).

Neurotrophic Factors and Aging

Aging is accompanied by a range of alterations in all organs and systems. The central nervous system (CNS) is one of the most influenced by aging, since its cells have a limited capacity of regeneration. Age-related changes in the brain result in slowing cognitive and motor functions, typical features among elderly people. In some

people, these changes are greater than in others, and these dissimilarities can be explained by different genetic background and/or lifestyle. The loss of neuronal plasticity seems to play a major role in the aging process of the brain, but other mechanisms are also important (Yankner et al. 2008).

Neurotransmitters, mainly dopaminergic and serotonergic systems, and intracellular signaling pathways, such as kinases and phosphatases activities and calcium homeostasis, significantly change during aging process. In addition, mechanisms involved in the regulation of protein folding and degradation modify over time. Protein misfolding is involved in the physiopathology of neurodegenerative diseases, mainly AD and PD. However, protein aggregation deposits observed in AD and PD can also be seen in normal aging brains. It remains to be elucidated the precise mechanisms that determine whether brain aging is associated or not with a neurodegenerative disease. Neurotransmitters, cytokines and other inflammatory molecules, oxidative stress,

and NFs may be important in controlling neuronal death or survival and ultimately the clinical outcome of brain aging (healthy vs. pathological aging) (Yankner et al. 2008).

Nerve Growth Factor (NGF)

NGF, the first discovered NT, is essential for neuronal survival during CNS development and influences neuronal functioning throughout life. NGF is a highly conserved molecule, sharing considerable homology among species (Aloe et al. 2012).

When NGF binds the receptor TrkA, the main activated pathways are Ras-mitogen-activated protein kinase (MAPK), extracellular signal-regulated kinase (ERK), phosphatidylinositol 3-kinase (PI3K)-Akt, and phospholipase C (PLC). When NGF binds the p75NTR, c-Jun-N-terminal kinase-p53-Bax (JNK) and nuclear factor kappa B (NF- κ B) signaling pathways are activated, which may determine cell death via apoptosis in the absence of coexpressed TrkA (Aloe et al. 2012; Fig. 1).

In the brain, the highest NGF levels are found in the hippocampus and cortical regions. Experiments using animal models showed that NGF is mainly produced by neurons in the hippocampus and cortex and retrogradely transported to cell bodies of basal forebrain cholinergic neurons (BFCN). BFCN express both TrkA and p75NTR receptors, and NGF acts regulating survival and maintenance of these cells. BFCN and their projections to hippocampus and cortex are involved in learning and memory functions. Alterations in NGF levels have been associated with cognitive changes during normal (or physiological) aging and cognitive impairment in neurodegenerative diseases such as AD.

Using a vector-based RNAi approach, the blockade of TrkA receptor expression resulted in worsening attentional performance in aged but not young adult rats. In animals with preserved TrkA levels, attentional performance correlated positively with TrkA levels. Among aged rats, poorer attentional performance was associated with lower TrkA levels expressed in cholinergic neurons in the nucleus basalis of Meynert and substantia innominate. Aging and TrkA

suppression increased cortical proNGF levels. Aging also increased cortical p75NTR densities in the cortex (Parikh et al. 2013). These results highlight the role of NGF/TrkA/p75NTR signaling in cognition, one of the most affected functions in aging. In fact, a range of evidence has indicated a link between NGF and cognitive function. For instance, levels of the membrane-associated p75NTR are higher in the hippocampal formation of human AD brains than in age-matched controls (Chakravarthy et al. 2012). Amyloid-beta also binds p75NTR in neurons *in vitro*, leading to apoptosis (Yaar et al. 1997).

Changes in NGF levels in age-related disorders have also been demonstrated. Late-life depression (LLD) is one of the most common neuropsychiatric disorders in the elderly population and is a risk factor for neurodegenerative diseases, mainly AD. Serum NGF levels were reduced in elderly patients with LLD in comparison with nondepressed elderly controls. Elderly subjects with previous depressive episodes also showed a significant reduction in serum NGF levels compared to controls. These results support the hypothesis of a reduced neurotrophic support in LLD (Diniz et al. 2013).

Brain-Derived Neurotrophic Factor (BDNF)

BDNF is the most widely distributed NT in the CNS, occurring mainly in the hippocampal formation, cerebral cortex, and amygdaloid complex. BDNF expression rises during brain development, reaching the highest level after birth. BDNF levels do not decay with aging, which is suggestive of its important role in the adult brain. Like NGF/TrkA signaling, MAPK, PI3K/Akt, and PLC signaling cascades are activated when BDNF binds the TrkB receptor. Also similar to NGF, when BDNF binds p75NTR, NF- κ B and JNK signaling are activated. BDNF binds the TrkB receptor with high affinity, playing a role in neuronal survival and maintenance. BDNF is also important for neurogenesis, since it promotes neural progenitor cells differentiation into neurons and the subsequent survival of these new neurons. Interestingly, processes that stimulate neurogenesis such as exercise, dietary energy

restriction, and cognitive stimulation are associated with an increase in hippocampal BDNF levels (Lanni et al. 2010).

Despite the well-established role of BDNF in neuron development and survival and neurogenesis, its profile in the aging brain is still a matter of debate. While some studies have found a decrease in BDNF levels in aged brains, others have failed to show any alteration in BDNF concentration during aging process (Lanni et al. 2010).

Increased BDNF/TrkB signaling might prevent cognitive impairment in the early stages of AD, accompanying brain reserve. However, high levels of TrkB might not be sufficient to prevent cognitive decline with further amyloid beta deposition and AD progression. There is increased neuronal TrkB expression in CA1 region brain samples from cognitively intact individuals with AD pathology (Braak & Braak stages I–II) when compared to cognitively intact individuals with no AD pathology (Kao et al. 2012). A more feasible way for assessing CNS levels of NTs in humans is using cerebrospinal fluid (CSF) samples. Since LLD is an important condition among elderly subjects and is associated with cognitive impairment, the neurobiological links between LLD and MCI/AD have been studied. Age-matched healthy controls presented higher CSF BDNF levels when compared to individuals with LLD (with mild cognitive impairment (MCI) or with no cognitive impairment). In LLD group, patients with mild cognitive impairment (MCI) had lower CSF BDNF levels in comparison with patients without cognitive dysfunction. The reduction of the availability of BDNF in the CNS may indicate increased vulnerability to the development of age-related disorders such as LLD and MCI (Diniz et al. 2014).

In addition to brain and CSF samples, peripheral blood levels of BDNF have been investigated. Plasma BDNF levels were found altered (i.e., increased and decreased) in AD patients in comparison with age-matched controls (Faria et al. 2014; Forlenza et al. 2015). The increase in circulating levels of BDNF in AD might reflect an adaptive or compensatory mechanism for neuronal damage. This result does not corroborate the

hypothesis of a decreased NFs availability in AD. A possible explanation is that peripheral levels of BDNF would increase in the early stages of dementia and decrease according to the progression of neurodegenerative changes. Patients' disease status varies among different studies, explaining discrepant (increased vs. decreased levels) results.

Not only BDNF but also serum levels of NGF and GDNF were found reduced in cognitively impaired subjects, including MCI and AD patients, in comparison with controls. After controlling for age, gender, and cognitive performance, only BDNF and NGF levels remained statistically diminished in cognitively impaired group. Interestingly, the group of MCI patients who progressed to dementia upon follow-up presented lower BDNF and NGF levels (Forlenza et al. 2015). These findings reflect the importance of NTs, notably BDNF and NGF, in cognition and aging-associated cognitive diseases.

Studies have shown that physical exercises, notably muscle strength exercises, are able to increase BDNF levels. Particularly, one study found that after muscle strength exercises, elderly women presented improvement in depressive symptoms accompanied by increase in BDNF plasma levels. The increase in NFs levels, especially BDNF, has been indicated as one of the potential mechanisms of action of physical exercise in depression, mainly because of its effects on neuroplasticity (Pereira et al. 2013).

Glial-cell-line-Derived Neurotrophic Factor (GDNF)

GDNF is the main NF of the GDNF family ligands, which are polypeptides belonging to the TGF β superfamily. GDNF is relevant for embryonic dopamine neurons development and for survival of mesencephalic dopaminergic neurons. Both in vitro and in vivo studies have shown that BDNF is involved in neuritic outgrowth and survival of dopaminergic neurons in several areas, such as the substantia nigra, BFCN and brainstem, and noradrenergic neurons and Purkinje cells (Lanni et al. 2010). GDNF is also present in axons from peripheral nerves and

Schwann cells. GDNF and its receptors were found to be broadly expressed in the hippocampus. GDNF supports synaptic transmission and participates in learning and memory processes.

Even though its name indicates a glial source, GDNF is also produced by neurons, being present in abundance at striatal medium spiny neurons that receive dopaminergic projections from substantia nigra. Similar to NTs, GDNF is also retrogradely transported to cell bodies.

GDNF binds the receptor GFR α 1 resulting in tyrosine kinase Ret receptor activation, which starts several signaling transduction pathways, such as the MAPK, Erk-1 and Erk2, and the serine-threonine kinase Akt. Therefore, GDNF regulates neuronal differentiation and survival by controlling the expression of antiapoptotic genes, such as Bcl-2 (Lanni et al. 2010).

GDNF is mainly associated with motor function. Apart from cognitive deficits, aging is also characterized by impairment in motor functioning with slowness and coordination difficulties. Decreased dopaminergic transmission in the basal ganglia is one of the main mechanisms behind aging-related motor changes. GDNF has neurotrophic effects on dopaminergic neurons, and several aging and PD animal models have shown the beneficial effects of GDNF in dopaminergic system associated with motor improvement. For this reason, GDNF has been studied for PD treatment. Clinical trials testing GDNF-based therapies for PD treatment are shown in Table 1.

Although GDNF was originally identified as a specific trophic factor for dopaminergic neurons, it also supports survival of motoneurons. In vitro experiments have demonstrated that GDNF was much more potent than neurotrophins such as BDNF and neurokinins such as CNTF in supporting survival of purified embryonic rat motoneurons. In vivo, exogenously supplied GDNF was able to support the survival of all neonatal rat facial motoneurons that were deprived of target-derived factors by axotomy (Henderson et al. 1994). These findings highlight GDNF as a promising candidate to slow the loss of function, degeneration, and death of

motoneurons in diseases such as amyotrophic lateral sclerosis (ALS) and the spinal muscular atrophies (SMA).

Ciliary Neurotrophic Factor (CNTF)

CNTF is the main member of the neurokinin family. It is synthesized by astrocytes, acting through autocrine and paracrine signals of astrocytic activation and hypertrophy in response to injury to the CNS. CNTF is also produced in the periphery, in muscle, released by motoneurons terminals and then retrogradely transported to cell bodies. CNTF also seems to be involved in peripheral nerve injury.

CNTF acts through the activation of the Janus kinase/signal transducer and activator of transcription (JAK/STAT) signaling pathway. When CNTF binds the alpha subunit of the CNTF receptor (CNTFR α), it induces the recruitment of two transmembrane receptor proteins gp130 and LIFR β , resulting in tyrosine phosphorylation and the downstream activation of the JAK/STAT pathway. Once the pathway is activated, STAT proteins translocate to the nucleus, bind gene promoters on the DNA, causing DNA transcription and activity in the cell.

CNTF is mainly expressed in glial cells, playing a role in glial differentiation and development. The collaborative effects of CNTF with NTs have been reported, with synergic effects on development and maintenance of distinct neuron types. For instance, when CNTF is administered together with BDNF in BFCN, a synergic effect on cell survival was observed (Lanni et al. 2010).

A range of evidence from experiments in vitro and in vivo animal models have shown a link between CNTF and neurogenesis dependent on dopamine D2-receptor in the subventricular zone and the dentate gyrus of the hippocampus (Mori et al. 2008). Since dopaminergic dysfunction is a hallmark of neurological disorders, such as ALS and PD, CNTF has been proposed as a putative strategy for treating these diseases. Nevertheless, some attempts to use CNTF as a therapeutic agent had unsatisfactory results, such as failure in achieving sufficient concentrations in the brain, poor efficacy, and adverse effects.

Neurotrophic Factors in Aging, Table 1 Clinical trials performed for testing neurotrophic factors therapy in Alzheimer’s disease and Parkinson’s disease

Study	Drug	Trial design	Endpoint classification	Estimated enrollment	Follow-up period	Outcomes	Status
<i>Clinical trials involving neurotrophic factors in Alzheimer’s disease treatment</i>							
NCT00087789	CERE-110 (AAV2-NGF), intracerebral injection	Nonrandomized, follow-up, open-label phase 1 trial	Safety	10	24 months	Given the overall tolerability of the neurosurgical procedure under general anesthesia, they decided to start a phase 2 trial	Completed
NCT00876863	CERE-110 (AAV2-NGF), intracerebral injection	Multicenter, randomized, double-blind, follow-up phase 2 trial	Efficacy	50	24 months	No published results	Active, not recruiting patients. The study started in September 2009 and the estimated final data collection was completed by December 2014
NCT01163825	ECB-NGF, intracerebral implants	Nonrandomized, controlled, follow-up, open-label phase 1 trial	Safety and tolerability/efficacy study	6	12 months	Follow-up MRI at 3 and 12 months postimplantation showed no evidence of inflammation or device displacement. At 12 months, implants were successfully retrieved, and low but persistent NGF secretion was detected in half of the patients	Active, not recruiting patients. The study started in January 2008 and the estimated final data collection was completed by December 2011
NCT00017940	Ex vivo gene therapy (intracerebral injections of autologous fibroblasts genetically modified to express human NGF)	Uncontrolled, follow-up, open-label phase 1 trial	Safety	8	18 months	Stereotaxic injections were completed safely in six of eight subjects. After mean follow-up of 22 months in six subjects, they observed an improvement in the rate of cognitive decline and no long-term adverse effects of NGF occurred	Completed

NCT000001180	AIT-082 (potential action mechanism: stimulus of neurotrophic factors production), orally administered	Multicenter, randomized, double-blind phase 2 trial	Efficacy	36	5 weeks	There were no significant differences by treatment arm on the clinical or neuropsychological evaluations. AIT-082 was rapidly absorbed by the oral route with a half-life suitable for dosing once or twice daily. No problems with tolerability or safety were found	Completed
<i>Clinical trials involving neurotrophic factors in Parkinson's disease treatment</i>							
NCT00875316	Cogane™ (PYM50028, promote the release of both GDNF and BDNF), orally administered	Randomized, controlled, double-blind phase 1 trial	Safety	36	28 days	No published results	Completed
NCT01060878	Cogane™ (PYM50028, promote the release of both GDNF and BDNF), orally administered	Randomized, controlled, double-blind phase 2 trial	Efficacy	425	28 weeks	Failed to show any clinical benefits	Completed
NCT00985517	CERE-120 (AAV-nerturin), intracerebral injection	Randomized, double-blind phase 1/2 trial	Safety/ efficacy	60	36 months	Considered safe and well tolerated according to preliminary safety and tolerability results from six subjects with PD who received bilateral stereotactic injections of CERE-120 into the substantia nigra and putamen	Active, not recruiting patients. The study started in September 2009 and the estimated final data collection was completed by November 2014

(continued)

Neurotrophic Factors in Aging, Table 1 (continued)

Study	Drug	Trial design	Endpoint classification	Estimated enrollment	Follow-up period	Outcomes	Status
NCT00006488	Recombinant human GDNF, continuous, unilaterally infused administered through an implanted intraputaminaal catheter and programmable pump	Phase 1 trial	Safety/ efficacy	10	24 weeks of infusion	Improvement in the motor scores at 24 weeks compared with baseline scores. Improvements occurred bilaterally, as measured by balance and gait and increased speed of hand movements. All significant improvements of motor function continued through the washout period (5 weeks). The only observed side effects were transient Lhermitte symptoms in two patients	Completed
NCT01621581	AAV2-GDNF (convection enhanced delivery to bilateral putamen)	Nonrandomized, open-label phase 1 trial	Safety/ efficacy	100	5 years	Not available yet	Recruiting

AAV adeno-associated virus, *AD* Alzheimer's disease, *BDNF* brain-derived neurotrophic factor, *ECB* encapsulated cell biodelivery, *GDNF* glial-cell-line-derived neurotrophic factor, *MRI* magnetic resonance imaging, *NGF* nerve growth factor, *PD* Parkinson's disease

Neurotrophic Factors as Therapeutic Agents for Neurodegenerative Disorders

Aging is followed by several physiological changes, being the CNS one of the most affected. Abnormal NFs support during aging seems to play a major role in the pathophysiology of age-related neurodegenerative disorders, such as AD and PD. The major challenge in the treatment of neurodegenerative diseases is to identify a disease-modifying strategy able to slow or even to halt disease progression. Unfortunately, until now there is no such available therapy.

Since NFs are regarded as neuroprotective molecules, some attempts to use them in patients with neurodegenerative disorders have been made. There are some completed and ongoing clinical trials with this purpose, which are summarized in Table 1.

For AD treatment, the main tested NF was NGF. Based on the evidence of NGF positive effects on cholinergic neurons and cognition, NGF-based therapies have been proposed for AD treatment. One study showed that two from six patients enrolled in a clinical trial had positive results regarding cognition, electroencephalography, and nicotinic receptor binding after 12 months of encapsulated cell implants releasing NGF (EC-NGF) therapy. Of note, surgical implantation and removal of EC-NGF in the basal forebrain were safe and well tolerated (Eriksdotter-Jönhagen et al. 2012). After 12 months, there was an increase in both choline acetyltransferase (ChAT) and acetylcholinesterase activities. The activity of soluble ChAT correlated with cognition, CSF tau and amyloid-beta levels, in vivo cerebral glucose utilization and nicotinic binding sites, and morphometric and volumetric magnetic resonance imaging measures. In this study, three out of six enrolled patients had improvement in clinical outcomes (Karami et al. 2015). Table 1 shows clinical trials testing NGF-based therapies for AD treatment. Although trials have demonstrated safety and tolerability in NGF administration, studies failed to demonstrate the efficacy of NF-based strategies.

Regarding PD treatment, the most promising NFs are from the GDNF family, neurturin and

GDNF. Two open-label phase 1 studies involving PD patients investigated the delivery of neurturin using stereotactic injection of a viral vector (adeno-associated virus serotype 2, AAV2) in the putamen or both the putamen and the substantia nigra pars compacta. The procedure was safe and tolerable, with some clinical improvement. Unfortunately, when multicenter, double-blind, phase 2 randomized control trials were performed, no significant difference regarding motor symptoms between those who received AAV2-neurturin and the sham surgery group was observed up to 24 months of follow-up (Kalia et al. 2015). Old studies with GDNF in human PD also showed safety and tolerability. Currently, an open-label study is using a gene therapy approach with AAV2-GDNF and a convection enhanced delivery system for intraputamin GDNF in advanced PD (Table 1).

It is worth mentioning that some drugs clinically used to treat AD (memantine) and PD (levodopa, rasagiline, pramipexole, ropinirole, apomorphine) share the property of modulating NFs levels in the brain regions involved in the pathophysiology of the respective disease (Lanni et al. 2010).

Conclusions

NFs are very important for neuronal development, survival, and maintenance. Aging is accompanied by several physiological changes, being the CNS one of the most affected. NFs imbalance is an important feature in age-related neurodegenerative disorders, being putative candidates to disease-modifying therapies.

Definition

The New England Centenarian Study (NECS) currently investigates centenarians and their family members in order to identify determinants of healthy aging and exceptional longevity. Their findings contribute to medical and genetic topics related to extreme longevity.

Background to the NECS

The New England Centenarian Study (NECS) (<http://www.bumc.bu.edu/centenarian/>) was founded in 1994 as a population-based study of all centenarians living within eight towns near Boston (Massachusetts, USA). The focus of the study was on the prevalence of Alzheimer's disease and other dementias in centenarians.

Gradually, the focus of the NECS transitioned from a population-based study focusing on medical issues into a study also inviting volunteers to investigate the characteristics of centenarians and their family members and identifying determinants of healthy aging and exceptional longevity (New England Centenarian Study Website: <http://www.bumc.bu.edu/centenarian/>; Sebastiani and Perls 2012). The NECS has recruited centenarians from throughout the United States as well as internationally (New England Centenarian Study Website: <http://www.bumc.bu.edu/centenarian/>).

The NECS has extended its recruitment to include siblings of centenarians and their

offspring in order to examine potential genes they may have in common and lifestyle factors that contribute to the ability to achieve extreme old age and live a healthy long life. Additionally, the NECS recruited younger referent subjects from families lacking longevity along with spouses of centenarians' offspring (Sebastiani and Perls 2012).

There has also been a specific endeavor to locate and recruit supercentenarians (persons aged a 110 or more) with the focus of discovering the genetic and environmental factors that facilitate living to extreme old age (New England Centenarian Study Website: <http://www.bumc.bu.edu/centenarian/>; Sebastiani and Perls 2012).

Participants and Procedures

From 1994 to 2012, the NECS has recruited approximately 1,800 centenarians and 123 supercentenarians, approximately 600 centenarian offspring (in their 70s and 80s), and 437 controls (Sebastiani and Perls 2012).

The majority of centenarians in the study were born between 1880 and 1910, with a median age of 103 years. Of these centenarians, 85% are women and 15% are men. Among supercentenarians, the female prevalence is approximately 90% (New England Centenarian Study Website: <http://www.bumc.bu.edu/centenarian/>; Sebastiani and Perls 2012).

Potential subjects were detected via the town census, local obituary listings, councils on aging, local newspapers, and nursing homes (social workers, physicians, and visiting nurses). Also, voting records and media alerts were used (Sebastiani et al. 2012a; Perls et al. 2003). Today, eligible subjects can directly contact research staff to take part in the study. Details for participation are provided on the NECS website (<http://www.bumc.bu.edu/centenarian/>).

Subjects and their families were contacted by mail with a letter providing a description of the study and a postage-paid response card (Perls et al. 2003). The response card requested the subjects (or their proxy) to indicate that they are indeed a centenarian, whether or not they have a

living sibling, and whether they provide informed consent for recruitment for the study. If no response was received, a follow-up letter was sent. If attempts by mail were unsuccessful, attempts were made to contact the subject by phone. In some cases, neighbors were contacted to verify that the subjects are alive and visits were made to the subjects' home or residence.

Upon first contact, subjects were asked if they possess a birth certificate to validate their date of birth (Perls et al. 2003). If they do not, relevant information was obtained to locate the birth certificate. After all attempts were exhausted and the birth certificate was not obtained, then multiple corroborative pieces of evidence indicating the subject's age were requested. These may include: census data, military certificates, old passports, school report card, family bible, and baptismal or other church certificate. If the subject had children or siblings, their birth dates and birth order were noted to cross-refer their age in relation to the subject's age.

The only exclusion criteria for the NECS have been the inability to validate age (Andersen et al. 2012).

Once the subject's age was validated, they were asked to complete a series of questionnaires and provided a blood kit to obtain a small blood sample for the genetic aspects of the study (Perls et al. 2003).

Measures

Questionnaires were used to assess a range of characteristics including: demographics, lifestyle choices, medical history, current medication, family pedigree, and physical (i.e., Barthel Index) (Andersen et al. 2012) and cognitive function (i.e., Blessed Information-Memory-Concentration [BIMC] Test) (Andersen et al. 2012).

Small blood samples were collected for the genetic aspect of the study (Sebastiani and Perls 2012). A dementia scale test was administered over the phone (Sebastiani and Perls 2012). Approximately 30% of the subjects provided consent to donate their brains for further study after they have passed away (New England

Centenarian Study Website: <http://www.bumc.bu.edu/centenarian/>).

Funding

The National Institute on Aging (NIA), National Institute of Health (NIH), William Wood Foundation, and Martin Samowitz Foundation currently fund the study (New England Centenarian Study Website: <http://www.bumc.bu.edu/centenarian/>). Previously the study received funding from Alzheimer's Association, Ellison Medical Foundation, Alzheimer's Drug Discovery Foundation, American Federation Aging Research, and Glenn Foundation for Medical Research (New England Centenarian Study Website: <http://www.bumc.bu.edu/centenarian/>). All studies were approved and supervised by the Boston University Medical Campus Institutional Review Board (New England Centenarian Study Website: <http://www.bumc.bu.edu/centenarian/>).

Findings from the NECS

The NECS has published in excess of 110 peer-reviewed papers (New England Centenarian Study Website: <http://www.bumc.bu.edu/centenarian/>). As it is beyond the scope of this entry to provide a broad review of the NECS findings, the following section focuses on four major areas of discovery and their associated publications.

Genetic Signatures of Exceptional Longevity in Humans

Exceptional longevity is a complex phenomenon influenced by a combination of environmental and genetic factors (New England Centenarian Study Website: <http://www.bumc.bu.edu/centenarian/>). This study investigated the genetic contribution of exceptional longevity by conducting a genome-wide association study. It was hypothesized that the genetic contribution to exceptional longevity gets larger and larger with increasing age. The participants in this study included 801 centenarians (mean age at death 104 years) and 914 genetically matched healthy controls (i.e., spouses of

centenarian offspring, children of parents who died at age approximately 73, and from individuals from the Illumina control database).

Three steps were taken to build a genetic model of exceptional longevity: (1) Genetic marker analysis: to identify genetic markers that are significantly associated with exceptional longevity, (2) genetic risk modeling: to produce genetics risk profiles (based on nested Bayesian classifiers), and (3) cluster analysis of the profiles: to discover genetic signatures and correlate these to different survival patterns of exceptional longevity.

As hypothesized, results of the study found 281 genetic markers with 61% accuracy in predicting who is 100 years old, 71% accuracy in predicting who is 102 years old or older, and 85% accuracy in predicting who is 105 years old or older. That is, the prediction gets stronger with increasing ages greater than 100. These 281 genetic markers are associated with approximately 130 genes that may play a role in age-related diseases such as Alzheimer's disease, cancers, diabetes, heart disease, high blood pressure, and basic biological mechanisms of aging. Additionally, centenarians and younger people in the general population had the same amount of variants that were linked with increased risk for age-related diseases. Their exceptional survival advantage may therefore be due to the existence of longevity-associated genetic variants that are protective and counter the negative effects of such disease gene variants.

The 281 genetic markers can be used to create genetic profiles. A subgroup of subjects were found to have genetic profiles in common (genetic signatures). Ninety percent of the 801 centenarians were grouped into clusters characterized by one of 27 different genetic signatures of differing predictive values of exceptional longevity. These genetic signatures were also associated with varying predispositions to subgroups of centenarians such as those who completely escape Alzheimer's disease or those that delay heart disease until the final 5% of their lifetime.

The results of this study were replicated in other studies showing that many of the variants are associated with survival to extreme ages

(Sebastiani et al. 2013). A limitation of this study however was the use of Bayesian classifiers, which guarantees robustness although there are many alternative approaches to genetic risk modeling.

Health Span Approximates Life Span Among Supercentenarians: Compression of Morbidity at the Approximate Limit of Life Span

Supercentenarians, individuals who are 110 years old and older are extremely rare, existing in industrialized nations at a rate of about one per five million people in the population (Andersen et al. 2012). James Fries (1980) proposed the compression of morbidity hypothesis, which states that as a person ages and reaches the limit of human life span, this would compress the time of developing diseases towards the very end of their life. This study investigated whether or not people who reach the limit of human life span actually compress their morbidity towards the end of their lives.

Participants of the study included: 104 Supercentenarians (aged 110–119 years, 13% men, 87% women), 430 Semi-Supercentenarians (aged 105–109 years, 20% men, 80% women), 884 Centenarians (aged 100–104 years, 25% men, 75% women), 343 Nonagenarians (aged 87–99 years, 38% men, 62% women), and 436 controls (different age groups corresponding to the ages of onset for diseases). These participants were followed for an average of 3 years (range 0–13 years). The age of onset of cognitive and physical disability, individual disease, and morbidity were examined using survival analysis.

Results of the study indicate that the older the age group, the later the onset of cognitive and functional impairment and age-related diseases such as cancer, cardiovascular disease, dementia, and stroke. Specifically, the hazard ratios for these diseases appeared progressively shorter with older and older age, and the amount of time spent with disease was shorter with older age group. In figures, there was a downward trend in the average percentage of years with disease, being 17.9% in control group, 9.4% in nonagenarians, 8.9% in centenarians, and 5.2% in supercentenarians.

Supercentenarians were very similar in terms of the exceptionally delayed age of onset of age-related diseases compared to centenarians. This shows that there may be some factors (presumably genetic) in common that enable them to be so similar. The overall morbidity was also progressively delayed with increasing age. Therefore, as hypothesized, as the limits of the human life span were effectively reached with supercentenarians, compression of morbidity was generally detected.

The study further discovered that for all the centenarian age groups, men were better off than women in terms of physical and cognitive status. Paradoxically, male centenarians are fitter than females but females have a much greater probability of surviving to extreme old age. This could be explained by women being better able to survive with age-related diseases and functional impairment compared to men, whereas mortality associated with these diseases are greater for men. Therefore there is a “select survivor effect” in which men who survive to extreme ages, compared to women, do not have the diseases and associated impairments that cause mortality at younger ages.

The advantage of this study was the large number of supercentenarian participants. There are a substantial number of prevalence studies of age-related diseases in the literature; however, participants of these other studies are mostly less than 105 years old.

The major limitation of this study was the healthy volunteer bias – that is, participants who are healthier were more likely to take part in the study. Additionally, the sample was enhanced with centenarians who have familial history of exceptional longevity. These participants were therefore more likely to achieve exceptional longevity than centenarians without such a familial history.

Whole Genome Sequence of Male and Female Supercentenarians, Both Ages >114 Years

Human aging is affected by a combination of genetic, lifestyle, and environmental factors (Sebastiani et al. 2012b). The genetic element could explain approximately 20–25% of the

variability of human survival to the mid-eighties but may have a larger impact on survival to the nineties and beyond. Supercentenarians typically delay or escape disability and age-related diseases, and this exceptional survival is possibly determined by a genetic tendency that has both common and rare genetic variants. This study therefore investigated and described the complete genomic (DNA) sequence of two supercentenarians.

The study consisted of two subjects, one male and one female both born before 1897, and were more than 114 years old at the time of testing. Their actual age were confirmed by birth/baptism certificates and US census records. Both subjects were Caucasian and were selected for this study due to their exceptional life spans and health span. That is, the average Blessed Information-Memory-Concentration Test scores of both subjects were greater than average of the NECS supercentenarian sample until they died. Furthermore, both subjects exhibited delays in the ages of onset of disability. Peripheral blood was collected for each subject and used for DNA extraction. Illumina’s Clinical Laboratory Service subsequently sequenced the DNA samples using the Illumina Genome Analyzer II.

The results of the study showed that, first, the sequence variant spectrum of both subjects’ DNA sequence was predominately comparable to current non-supercentenarian genomes. In addition, both subjects did not carry most of the well-established human longevity enabling variants previously published in the literature. Both subjects had a comparable number of known disease-associated variants respective to most human genomes sequence at present. Approximately 1% of the variants these subjects held is novel and may direct to new genes that influence exceptional longevity. Finally, both subjects were enriched for coding variants close to longevity-associated variants that had been found through a large genome-wide association study.

These analyses indicated that there were both common and rare longevity-associated variants

that may counter the effects of predisposing disease variants and lengthen life span. Also, the continued analysis of the genomes of both subjects provided insight into the genetic processes that add to the maintenance of health during extreme aging.

Although the two genomic sequences do not give sufficient data for general inference on the genetics of exceptional longevity, they provide the foundation in generating a reference panel of exceptionally long-lived individuals and contribute insights regarding the genetic backgrounds that may be instrumental to exceptional longevity.

The NECS has made the whole genome sequence of both subjects available on a data base at the National Institute of Health. This enables researchers to retrieve all of the data and use them for their own exploration.

Middle-Aged Mothers Live Longer

Previous studies have observed an association between older maternal age at birth of last child and exceptional longevity (Sun et al. 2015). These studies showed that women's ability to obtain exceptional longevity and their ability to bear children at an older age have common determinants and that prolonged fertility could be a marker of slower aging. The current study further investigated this phenomenon (Alpert et al. 1997).

Participants of this study consisted of 132 women born in 1896 and living in the suburban Boston area. They included 78 female centenarians and 54 women who died at 73 years of age in 1969. Next of kin of the subjects were located using data obtained by the Massachusetts Registry of Vital Records to get consent to participate in the study. Comparisons were then made between these two groups. Comparing women with the same year of birth minimized concerns about temporally related influences upon fertility such as health- and contraception-related trends, fluctuations in the economy, and war. The exclusion criterion for this study was if the women have not had the opportunity to have children, such as hysterectomy or never married before 35 years of age. No significant differences were found between the two cohorts in relation to loss of

spouse before age 45, rate of hysterectomy, marriage without children, and religion or years of education.

Results of this study revealed that women who lived to a minimum age of 100 were four times more probable to have had children while in their forties compared with women from the same birth cohort who had their last child at a younger age and lived only to age 73. This indicates that the ability to bear children after age 40 may be a marker for slow ageing and subsequently the ability to achieve exceptional longevity.

The study of such women predisposed to extreme longevity may also have implications regarding the theoretical basis of menopause and human life span. During the first quarter of this century, fertility-enhancing interventions for older women were not available. Under these circumstances, late menopause as well as pregnancy after 40 may be associated with extreme longevity. In addition, these women may also possess a decrease in susceptibility to age-related diseases that contribute to living longer.

Research has discovered that women who took estrogen were less likely to develop Alzheimer's disease or if the disease had already developed, they were likely to show delays in the disease onset. This may be true for women who experience late menopause, as they have prolonged exposure to endogenously produced estrogen (or other concomitantly produced substances). Avoiding or delaying age-related diseases that can cause premature mortality such as Alzheimer's disease, heart disease, or stroke could therefore be related to achieving longevity.

The evolutionary mechanisms that select for genetic variants that facilitate survival long after the age at which reproduction ends could be explained by allowing women to bear more children (Perls and Fretts 1998, 2001). This is consistent with the disposable soma theory, which states that there is a tradeoff in energy allocation between reproductive health and repair/maintenance roles. Women who age more slowly and delay/escape age-related diseases that negatively affect fertility may have biological mechanisms that strengthen the efficiency of energy production, therefore assisting the delay in the tradeoff.

The findings of this study provide support to previous research that demonstrated a positive association between older maternal age and higher odds for surviving to extreme old age.

Conclusion

The New England Centenarian Study (NECS) is one of the largest studies of centenarians in the world. It began as a population-based study of centenarians in Boston and expanded to investigating medical and genetic research questions related to longevity by investigating characteristics of centenarians, their family members, and spouses. Today, the NECS continues to collect data, and those interested can contact research staff to participate.

Findings from the NECS are immense, spanning more than 110 peer-reviewed papers. This entry focused on four discoveries and publications. Firstly, the genetic contribution to exceptional longevity gets larger with older age. Centenarians and those in the general population share the same number of genetic variants that increase risk for age-related diseases; however, a number of genetic signatures were predictive of exceptional longevity. Secondly, health span approximates life span among supercentenarians: as the limits of human life span were effectively reached in supercentenarians, compression of morbidity – that is, the time of developing diseases towards the very end of their life – was observed. Thirdly, the whole genome sequences of male and female supercentenarians have been analyzed, identifying both common and rare longevity-associated genetic variants that may counter the effects of disease-risk variants and extend the life span. Lastly, middle-aged mothers live longer than younger mothers, indicating a positive association between older maternal age at birth of last child and exceptional longevity. That is, women were four times more likely to be a centenarian if they had their last child while in their forties. These studies provide invaluable insights into the mechanisms of exceptional longevity and can be used to inform models for aging well.

Normative Cognitive Aging

Jonna Nilsson and Martin Lövdén
Aging Research Center, Karolinska Institutet and
Stockholm University, Stockholm, Sweden

Introduction

The term cognitive aging refers to the change in cognitive abilities (e.g., memory, reasoning, processing speed, and language) that is associated with chronological age. Research on this topic strives to describe, explain, and predict within-person change in cognition across adulthood. The research field is integrative in nature with roots in both cognitive psychology and lifespan development research and often interprets cognitive changes within the broader context of health conditions and biological factors. The longitudinal and multifactorial nature of cognitive aging and its inherent focus on a variable that cannot be experimentally manipulated (i.e., chronological age) demand specialized methodological approaches. While cognitive performance is typically measured in a controlled laboratory setting on a computer or with pen-and-paper tests, the test results are reliably associated with functioning outside the laboratory, including work performance and various health factors (Salthouse 2012). In the aging population, individual differences in cognitive performance are also associated with the level of independence in performing daily activities, such as cooking, budgeting, taking medications, and travelling. Cognitive aging research is therefore important for understanding how age-related changes in cognition can be expected to affect the daily life of individuals as well as the society at large.

Methodological Principles

Age as a Variable of Interest

Since age cannot be experimentally manipulated, it does not qualify as an independent variable in the classical sense. As such, even though

cognitive change can be demonstrated to occur in parallel with increases in chronological age, age cannot be said to *cause* cognitive change. In fact, since age defines the passing of time since birth, it merely represents a descriptive axis against which developmental phenomena can be arrayed (Wohlwill 1970). Increasing age can instead be understood as an indirect and general measure of the intricate network of developmental sources that by complex interaction shape cognition across the lifespan.

Given the limitations of age as a variable of interest, alternative operational definitions of developmental time have been proposed. Biological age, or BioAge, aims to capture the underlying vitality of essential biological systems (DeCarlo et al. 2014). The markers that constitute a BioAge measure have varied between studies and range between being relatively distal to cognition (e.g., sensory function, blood pressure) to having more direct relevance to cognition (e.g., oxidative stress, neuroinflammation). In support of its application, BioAge has been found to explain more age-related variance than chronological age in cognitive level and change at an individual level. The biological status of an individual, as indexed by BioAge, therefore could provide a superior developmental axis against which cognitive change can be understood. Given the diversity of biological markers with links to cognition, as well as potentially relevant nonbiological markers, the creation of theoretically motivated multivariate models of cognitive development represents an important target for future effort in the field.

Normative Cognitive Aging

It is not straightforward to separate normative cognitive aging from pathological cognitive aging, particularly in very old age. One difficulty comes from the fact that age-related cognitive change generally forms a continuum instead of falling into discrete groups of normal and abnormal patterns of change (Deary et al. 2009). For example, it is known that individuals who will later develop Alzheimer's disease display lower cognitive performance several years before clinical diagnosis.

Consequently, a more or less arbitrary level of cognition is often applied to isolate individuals who demonstrate a presumably normative pattern of change. Such levels can vary widely, from only excluding volunteers with a dementia diagnosis to excluding all volunteers who demonstrate mildly lower cognitive performance according to some predefined criteria. To add to the complexity of defining a normative sample, various age-related health factors other than dementia affect cognition (e.g., cardiovascular disease and diabetes). A critical consideration and ongoing debate in the field is therefore what pattern of age-related change can and should be considered normal or healthy.

Experimental Methods

The typical approach to studying within-person change in cognition as a function of age is to repeatedly administer the same cognitive test to a large sample of individuals at multiple time points from birth to death. An alternative to this longitudinal approach is the cross-sectional approach, which involves administering the cognitive test only once but to two or more samples of different ages. The longitudinal and cross-sectional approaches come with advantages and disadvantages (Schaie 1965). While both methods can be described as unifactorial designs with age as the only factor, they differ in that the cross-sectional method utilizes independent samples, while the longitudinal method utilizes dependent samples. The most damaging limitation of the cross-sectional design is that it does not allow the direct study of cognitive change at an individual level and thus also the study of between-person differences in individual change. Another important drawback is the so-called cohort effects that arise from that the age samples differ not only in regard to age but also in regard to birth cohorts, which means that results cannot be interpreted as pure age effects. The longitudinal design suffers from different limitations. Repeated testing in the cognitive domain means that the dependent variable cannot be assumed to be unaffected by the repeated observations. In fact, practice effects are common and should not be underestimated. Longitudinal designs are also

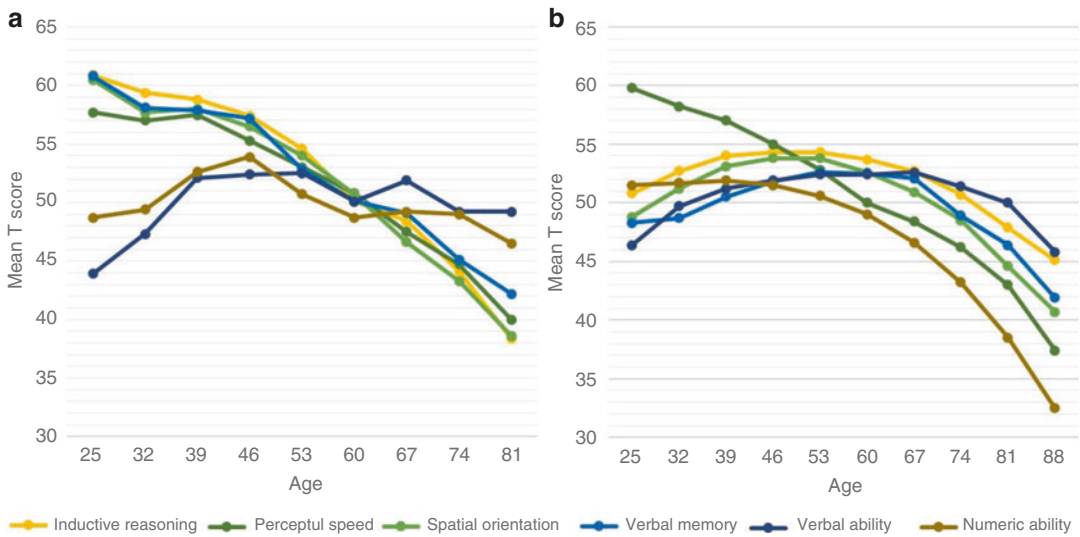

limited by the fact that results are specific to the birth cohort under study.

A more advanced approach involves combining the longitudinal and cross-sectional designs in a bifactorial model with age and cohort as components (Schaie 1965). In such a cohort-sequential design, the same cognitive test is administered to several birth cohorts (e.g., those born in 1950, 1960, and 1970) at the same ages (e.g., at age 60, 70, and 80). Under some assumptions, this design can allow for teasing apart the variance associated with chronological age from variance related to cohort and practice effects.

Differential Decline Across Cognitive Abilities

Different cognitive abilities show distinct relationships to chronological age. Cross-sectional studies reveal that well-practiced skills and acquired knowledge show improvement or stability until late in life, while abilities that are thought to capture the efficiency of cognition, such as processing speed and reasoning, follow a linear decline with an earlier onset (Schaie 1994). Differential decline has been reported also among the declining cognitive abilities, ranging from age correlations of $r = -0.52$ for processing speed and $r = -0.40$ for reasoning to $r = -0.27$ for short-term memory (Verhaeghen and Salthouse 1997). Above and beyond average decline, moment-by-moment intraindividual variability in cognitive performance, most markedly processing speed, also increases reliably in old age (Hultsch and MacDonald 2004). In support of its application, intraindividual variability in processing speed has been found to be superior to the average in predicting subsequent cognitive change.

Cross-sectional and longitudinal investigations have generally produced consistent results in terms of which cognitive domains that are most vulnerable to decline as a function of age. However, discrepant results have emerged when it comes to both the rate and the onset of the decline (Fig. 1, adapted from Schaie (1994)). While cross-sectional studies tend to demonstrate a linear

Normative Cognitive Aging, Fig. 1 Cross-sectional estimates (a) and longitudinal estimates (b) of age-related change in cognition (Adapted with permission from Schaie (1994))

decline that starts in early adulthood, longitudinal studies show decelerating improvements across young adulthood, peaks in middle age, and accelerating declines thereafter, with the exception of processing speed, which starts to decline already in early adulthood (Schaie 1994).

The differential relationship between age and different cognitive abilities has influenced theories of cognitive and intellectual development, with two-component models of age-related cognitive decline now being widely accepted in the field. In such models, one component captures the process-based cognition that is strongly associated with age, while the other captures knowledge-based cognition that remains relatively stable (Horn 1989). The models can also be understood in terms of an interaction between a biological (process-based) component determined by neurophysiological status and a cultural (knowledge-based) component determined by biographically acquired knowledge. While the biological component declines as a result of deterioration of the supporting neural infrastructure with increasing age, the cultural component continues to increase as long as the biological component allows the acquisition, maintenance, and production of knowledge (Baltes et al. 2007).

Other models of cognitive aging provide a more explanatory structure of age-related cognitive changes. Variants of cognitive resource theory postulate that a large proportion of age-related cognitive change can be reduced to a small number of sources, namely, an age-related restriction on cognitive resources (Hertzog 2008). The processing speed theory postulates that most if not all of age-related cognitive decline can be accounted for by changes in processing speed. Other variants have emphasized the importance of working memory capacity, self-initiated processing deficits, and inhibitory loss. Empirical evidence supports the need for such common cause models; over 60% of the interindividual variance in cognitive change in old age is shared across different cognitive abilities. However, since not all variance can be accounted for by common factors, ability-specific accounts also have a natural place in the field. Such accounts are not concerned with explaining overall age-related cognitive change but focus on age-relationships within specific cognitive domains. In the associative deficit hypothesis, for example, age-related decline in episodic memory is proposed to be underpinned by a deficit in creating and retrieving links between single units of information.

Differential Decline Between Individuals

Individual differences in cognitive status in old age depend on two factors: prior cognitive ability and the change trajectory that follows. Prior cognitive ability is perhaps the strongest predictor of cognitive status in old age. Even at the age of 80, childhood intelligence contributes 50% or more to the level of cognitive ability (Deary et al. 2009). While such between-person differences in level of cognitive performance remain relatively stable across adulthood, between-person differences in cognitive change trajectories tend to be more sizable in old age, reflecting that changes in performance are steeper for some than for others (de Frias et al. 2007). Although some of the heterogeneity in cognitive trajectories in old age is accounted for by pathological conditions, such as dementia, the same pattern appears to hold even for the positively selected segment of individuals who are deemed to age “normally.” Cognition therefore does not adhere to a pattern of universal nomothetic change with age. The heterogeneity clearly questions the usefulness of an average aging pattern and begs the question of what factors that predict within-person change in cognition.

A large number of factors, genetic and environmental, are thought to shape individual change trajectories. Heritability estimates are often based on comparisons of relatives who differ in terms of genetic relatedness (e.g., identical vs. fraternal twins) or environmental similarity (e.g., reared apart vs. reared together), which means that estimates can differ between populations of different ages as well as between different times of measurement. In normal populations, heritability estimates for cognitive level range between 40% and 70% and tend to increase in midlife and decrease again in late adulthood with corresponding changes in non-shared environmental variance (Reynolds 2008). The direct genetic influence on cognitive *change* trajectories is thought to be much weaker. An alternative approach to understanding the genetics of cognitive aging is to identify candidate genes. Despite a large number of studies being published, there is only one candidate gene that has been consistently associated

with cognitive change in old age. This gene, which codes for apolipoprotein E (APOE), has been associated with an increased risk of late-onset Alzheimer’s disease but also with cognitive change in healthy aging.

In addition to genetic determinants, lifestyle and health factors are thought to be important in cognitive aging. Work complexity and educational exposure have been related to the level of cognition in old age (Hertzog et al. 2008). However, such factors tend to be unrelated to cognitive change, which suggests that they represent individual differences in prior cognitive ability or effects that operate on cognition earlier in life. In contrast, other lifestyle factors, such as engagement in cognitively stimulating leisure activities, social activities, and physical exercise, reliably predict cognitive level, and changes in these factors are associated with changes in cognitive performance in old age (Hertzog et al. 2008; Prakash et al. 2015). Several health factors, including cardiovascular disease, metabolic disorders, and smoking, are also thought to play a role in old-age cognition. Relative to genetic influences, which are necessarily non-modifiable, lifestyle factors and health factors are to some extent open for modification.

Recent Trends

Intervention Studies

The influence of modifiable factors on cognitive decline in old age suggests that a certain degree of prevention may be possible. At an applied level, prevention and intervention studies therefore hold great promise for improving cognitive ability with major implications for the individual as well as for the society at large. By allowing for causal inferences, intervention studies also make critical contributions to the understanding of the mechanisms that underlie cognitive change in old age.

The literature has recently seen an explosion of interest in different factors with potential of improving cognition in old age. Cognition itself represents an obvious target and consequently numerous studies have implemented training of cognitive strategies and processes. A critical

aspect of cognitive interventions is that the training gains must be shown to generalize to non-trained tasks. This ultimately aims to demonstrate an extension to everyday cognition through effects on processing efficiency rather than on knowledge and expertise. In this regard, training of cognitive processes, such as working memory and executive function, as opposed to cognitive strategies has been put forward as being more promising. However, meta-analytical results in old adults have indicated that working memory training may not result in reliable transfer of training gains to fluid intelligence measures (Melby-Lervag and Hulme 2015). In more detail, while studies with passive control groups tend to show small but significant transfer ($g = 0.15$), studies that include an active control group that receives a task of similar content and duration do not ($g = 0.02$). The existing evidence for transfer effects following working memory training therefore remains confounded by nonspecific effects, such as expectancy, motivation, computer use, and social interaction. Another popular target for intervention studies is physical fitness. In such investigations, previously inactive individuals engage in a physical exercise regime during a fixed period of time. In older adults, moderate-intensity aerobic exercise has been found to have a modest but significant effect on cognitive performance in several domains (Prakash et al. 2015). Longer training regimens, longer training sessions, and regimens combining strength and aerobic exercise have been associated with greater cognitive gains.

Considering the modest effect sizes associated with single-domain interventions, an alternative approach has been to target several domains simultaneously. Since the independent contributions of the manipulated domains cannot be distinguished, multi-domain intervention studies tend to adopt a more applied approach. Recent evidence suggests that a combination of interventions targeting diet, exercise, cognitive training, and vascular risk monitoring is associated with maintained or improved cognition over a 2-year period in older individuals (Ngandu et al. 2015). Similar to single-domain intervention, however, effect sizes are limited. Considering the

multifactorial origins of cognitive aging, it is possible that even a relatively long-term multi-domain intervention in old age only reflects a small modification in the context of a lifelong accumulation of environmental and genetic effects. On the other hand, even small effects provide important clues about the underlying mechanisms of cognitive aging and can have a monumental impact in a public health context.

Theoretical Perspectives

Detailing the pattern of cognitive change across the lifespan can be likened to trying to hit a moving target. The well-established cohort effect (or Flynn effect) supports the appropriateness of this metaphor; mean intelligence scores show a steady increase between subsequent generations when measured at the same ages. In aging populations, such cohort differences have been demonstrated both in regard to level of cognitive performance and to trajectories of cognitive change (Skirbekk et al. 2013). Different change patterns are believed to be due to a continuous interaction between genetic predispositions, contextual influences, and individual decisions, which likely differ between cohorts. Since a change trajectory derived from one birth cohort cannot be safely assumed to apply to other birth cohorts, research efforts are increasingly going beyond description to also investigating underlying mechanisms. The reasoning is that the proximal causes and mechanisms of cognitive change are likely to be similar across cohorts, even though the timing and impact as a function of chronological age may be different.

Within-person change in cognition occurs at more than one time scale. Cognitive aging refers to the enduring change in cognitive performance that occurs over the course of a decade or more. However, in addition to such developmental change, within-person change also occurs at a much shorter time scale and in a less enduring manner, for example, through processes of practice and learning. Critically, longitudinal investigations are typically based on assessments that are completed several years apart, which limits the temporal resolution of the measurement and confounds estimates of long-term cognitive aging

with shorter-term practice effects (Rast et al. 2012). Measurement burst designs offer an approach to estimating such short-term changes by comprising a number of closely spaced assessments, separated by days, hours, and even minutes. The improved accessibility to devices that allow remote cognitive testing, including home computers, smartphones, and tablets, represents an important aspect for the feasibility of such a design. Integrated into a longitudinal design, measurement bursts can improve the precision of the occasion-specific score as well as allowing long-term age-related change to be separated from short-term variability. Furthermore, it allows for an examination of the relationships between within-person changes in cognitive as well as biological variables at different time scales and how such relationships may change as a function of age. Indeed, the relationship between moment-to-moment variability in cognitive performance and subsequent cognitive change in old age exemplifies such a relationship (Hultsch and MacDonald 2004). Taking one step further, a longitudinal burst measurement design would also allow the investigation of the prospect that the mechanisms underlying within-person change at different time scales, such as learning and cognitive aging, might share important principles.

With an increased focus on the mechanisms underlying cognitive aging, the field is gradually merging with the field of neuroscience. As a result, general frameworks of how to frame and understand the role of the brain in age-related cognitive decline are becoming increasingly important. The characteristics of such metatheories can be categorized into three themes: brain reserve, cognitive reserve, and brain maintenance (Nyberg et al. 2012). According to the brain reserve view, various protective factors during the life course, such as education and occupation, will lead to higher cognitive performance that is maintained into old age. The cognitive reserve account instead states that such protective factors may aid compensatory reactions to age-related brain changes. Thus, while a greater brain reserve would provide more time until the critical threshold for functional impairment is reached, a greater cognitive reserve would

provide more efficient compensation mechanisms to counteract negative effects when they occur. According to the brain maintenance account, protective factors are instead proposed to prevent age-related brain changes from occurring in the first place, allowing the brain to remain young with optimal function for longer. While useful as general frameworks, further progress in the field, including operational definitions, will be required to disentangle the relative importance of the reserve and maintenance views. Particularly, it will be important to identify the various processes that give rise to the different but likely complementary mechanisms of cognitive aging.

Definition

The role of food constituents in modulating age-related metabolic changes to impact positively on healthy life expectancy.

Introduction

Nutrition is a fundamental pillar in physiological survival. In addition, it is the lifestyle habit with perhaps the greatest impact on healthy life expectancy (HLE) or the quality of life span, because it is practiced several times a day most days of life.

Nutrition and aging are closely intertwined in negative and positive feedback loops. Firstly, aging can impact on nutrition processes through reduced organ function, impaired digestion and absorption of nutrients, or loss of appetite. This in turn impacts on the nutrition status – or how well nourished one is – and therefore on overall mental and physiological functions. In addition to the burden of malnutrition outcomes, the aging process may accelerate due to scarcity of protective and regenerative substrates. Secondly, the chronic signaling of good or poor nutrition is slow acting and cumulative, just like aging mechanisms. The biochemical effects of daily food choices cumulate into health outcomes that surface as decades add up. The outcomes could be a fit and healthy physiology during the retirement phase of life, with minimal decline from aging. Or conversely, the outcomes could be the gradual onset of chronic disease, disabling the last 30 years of life and speeding up the onset of mortality.

In the search for solutions for HLE in an aging population, the role of nutrition as a corner stone in the prevention of aging and chronic disease deserves careful attention, as indeed it can be a friend or a foe.

This paper will explore three main topics: (1) a definition of nutrition and its processes, (2) a description of how aging influences the nutrition processes and related outcomes, and (3) an evaluation of how nutrition can modulate the aging process through the example of systemic inflammation, with highlights on current foci of nutrition research.

The Nutrition Process

Nutrition is foremost the intake and transformation of foods to provide the necessary

nourishment for optimal physiological function. Many will argue that nutrition is also – or perhaps primarily – about the pleasure of eating, tastes and smells of food, or sharing meals with friends and family (Wardlaw et al. 2016). While these factors are of definite relevance when describing nutrition, only “nutrition for nourishment” will be considered in this discussion.

Nutrition: Intake, Digestion, Absorption, Metabolism, and Transport of Food Constituents

Food constituents consumed are not useable by cells until they have been digested into small monomers, absorbed by the absorptive cells along the gastrointestinal tract (GIT), metabolized, and finally transported to cells for uptake. Nutrition is a five-step process. Briefly, a set of mechanical steps involves the structures and organs of the GIT in breaking down food matter, starting from the teeth in the mouth. Digestive juices, hormones, and enzymes secretions from organs and cells along the GIT orchestrate the chemical digestion of food particles, in order to free micronutrients and break down macromolecules into monomers. Absorptive cells along the GIT perform biochemical transformations and release nutrients into the portal vein or the lymphatic circulation. Further metabolism occurs in the liver, to convert vitamins and minerals into their biologically active form. Bacteria inhabiting the GIT digest the remaining undigested food particles, fiber, and polyphenols and in the process produce metabolites. Hormone signaling and transport molecules are required to deliver most nutrients to the cells. For example, the insulin signaling induces the recruitment of transporters to the muscle cells’ membrane for glucose uptake and conversion to fuel that is useable for physiological function: adenosine triphosphate (ATP) (Wardlaw et al. 2016).

This brief summary highlights the complexity of the nutrition process. Optimal nutrition relies not only on ingesting optimal foods but also on a well-functioning GIT and its related organs. Decline in aging can reduce the efficiency and impair the mechanical and chemical steps of nutrition, as outlined further.

What’s in Food?

Foods contain a variety of constituents within a matrix. Food constituents are generally categorized according to the biochemical role they have (Wardlaw et al. 2016).

- *Macronutrients* yield energy, which metabolic pathways convert to ATP. Macronutrients also provide the building blocks for body structures and for the formation of DNA products. Macronutrients include protein, fats (saturated, trans mono- and polyunsaturated), and carbohydrate. Alcohol is not a macronutrient per se, but it yields energy. Table 1 outlines the energy-containing food constituents, with their energy yield in calories and kilojoules per gram (Wardlaw et al. 2016).
- *Micronutrients* do not yield energy but are required in the metabolic pathways of energy production that convert macronutrients into ATP. They are also required as cofactors in a plethora of functions such as detoxification mechanisms, bone formation, DNA and neurotransmitters synthesis, nerve impulse transmission, or gene expression signaling. Commonly, 14 or so vitamins and 14 or so minerals are considered essential to the diet, based on the clinical evidence available on deficiency signs and symptoms in the absence of these nutrients. Other trace minerals are present in food; however, clinical evidence of essentiality is lacking at this point in time (Wardlaw et al. 2016; Higdon 2003).
- *Phytonutrients* (also referred to as *phytochemicals*) form the large family of plant constituents, which don’t qualify as micronutrients. They contribute to colors of plant material and include the various types of fiber found in

Nutrition in Aging, An Exploration of a Close Relationship, Table 1 Energy-yielding food constituents

Constituents	Calories yield per gram	Kilojoules yield per gram
Protein	4	17
Fat	9	37
Carbohydrate	4	16
Alcohol	7	29

fruit, vegetables, whole grain, herbs, and spices. Small amounts of each phytonutrient are consumed through the diet; however, the large variety of constituents in this family suggests that in a diet rich in fresh fruit, vegetables, and whole-grain plant foods, the total intake of phytonutrients is substantial. While essentiality in the diet has not been determined in terms of deficiency signs and symptoms, phytonutrients have demonstrated *in vitro* biological activity, including gene expression signaling in a variety of pathways such as the regulation of inflammation, the antioxidant defense, and chemoprevention, qualifying them as bioactive food constituents (Wardlaw et al. 2016; Williams et al. 2004).

Furthermore, in populations following dietary patterns, which include a large variety of phytonutrients – such as the traditional Mediterranean diet (TMD) (Hoffman and Gerber 2013) – the antioxidant defense and anti-inflammatory pathways are shown to be significantly upregulated, compared to control populations with less dietary exposure to phytonutrients. The predicted long-term outcome, based on surrogate markers of chronic disease such as circulating inflammatory cytokines, insulin sensitivity, and endothelial function, is an overall protective effect (Wardlaw et al. 2016).

Table 2 outlines the micronutrients considered essential and some examples of phytonutrients with established biological activity.

Water is also present in food, as are various additives, in greater or lesser amounts. As a rule of thumb, the more processed a food is (longer shelf life or multi-ingredient designer packaged foods), the more likely it will contain additives for preservation, plastic packaging-related toxins such as endocrine disrupting chemicals, or food processing-related toxins such as advanced glycation end products. Additives and food preparation toxins may add significant burden to the liver detoxifications system, the inflammatory pathways, and the aging process (Wardlaw et al. 2016). The association between health outcomes, food additives, and food packaging is the topic of active public health research. In the

Nutrition in Aging, An Exploration of a Close Relationship, Table 2 Food constituents: essential micronutrients^a and phytonutrients

Vitamins	Minerals	Examples of phytonutrients
Vitamin A	Calcium	Anthocyanidin
Thiamin (B1)	Chromium	Beta-glucans
Riboflavin (B2)	Copper	Catechins
Niacin (B3)	Fluoride	Curcuminoids
Pantothenic acid (B5)	Iodine	Daidzein
Pyridoxine (B6)	Iron	Geneistin
Biotin (B8)	Magnesium	Gingerol
Folate (B9)	Manganese	Hydroxytyrosol
Cobalamin (B12)	Molybdenum	Lycopene
Choline	Phosphorus	Lutein
Vitamin C	Potassium	Procyanidins
Vitamin D	Selenium	Quercetin
Vitamin E	Sodium	Resveratrol
Vitamin K	Zinc	Sulforaphane

absence of robust human evidence on the acceptable ranges of exposure to these compounds or causal relationship with chronic disease, this topic is not included in the present discussion. Readers are referred to references provided (Gore et al. 2015; Ramasamy et al. 2005).

How Much of Each Nutrient is Required for Optimal Health?

Public health organizations determine nutrient targets per life stage for macro- and micronutrients (but not phytonutrients to this day) based on the currently available human scientific evidence on requirements. The targets provide guidance to avoid micronutrient deficiencies in the average healthy population and suggest dietary targets to reduce chronic disease, where the evidence for a link between the food constituent and the disease is robust. An example is the recommended target for daily fiber intake, based on the link between high-fiber diets and reduced risk of colorectal cancer (Wardlaw et al. 2016; Higdon 2003).

From the nutrient targets, eating guidelines are devised for the general, not older, healthy

population, in order to cover the recommended nutrient intake through foods, considering equity and sustainability (Wardlaw et al. 2016).

Reference ranges for nutrient targets do not take into account individual characteristics, such as genetic polymorphisms in key metabolism enzymes, overall health status, previous and current comorbidities, medication use, physical activity, environmental factors, and stage of life, which all may alter requirements. Nutrition professionals tailor the nutrient targets based on individual requirements and may advise on supplementations where needed (Wardlaw et al. 2016).

If Some is Good, More Must Be Better? Nutrients Versus the Whole Food Matrix

A greater understanding of the role played by individual nutrients in biochemical pathways should not distract from the sources in which these nutrients are found, namely, in foods, and how they should be consumed, namely, in dietary dosage. A dietary dose of any nutrient is the amount at which it is found in the whole food. This is usually a small amount. Food constituents contained in the whole food matrix are combined with other micro- and macronutrients, including fiber, phytonutrients, and usually water, to provide a variety of nutrients with synergistic effects on absorption and bioavailability. For instance, vitamin C plays a role in free radical neutralization, as an electron donor. When it is consumed in an orange, it comes with flavonoids, themselves bioactive in cell signaling and gene expression for improved antioxidant function. The vitamin C and flavonoids are combined to fructose and glucose for energy production and with fiber to feed the gut bacteria that also play a significant role in the modulation of immune function (Wardlaw et al. 2016).

Nutritionism and Nutraceuticals

The reductionist approach, perhaps imposed by research paradigms required to demonstrate causality, may have led to a distorted perception of nutrition, where the single nutrient becomes the focus, rather than the whole food, in achieving a particular health outcome. “Nutritionism” is

viewed as the reduction of nutrition to the isolated constituents associated with health benefit in *in vitro* experimental findings (Wardlaw et al. 2016). As a result the concept of nutraceuticals emerged, offering bolus pharmacological doses of isolated nutrients, sometimes combined with a few others in propriety formulae not found in whole foods. For instance, the bioactive constituent resveratrol found in the skin of red grapes, and therefore in red wine, is consumed in small amount when eating grapes (0.5 mg per cup) or drinking a standard glass of red wine (1.5 mg per 150 mL). It is consumed within the matrix of the original grape juice, which also includes a large variety of other phytonutrients. Resveratrol capsules in nutraceutical products provide up to 1500 mg each of pure resveratrol extract, with no other phytonutrient (Poulsen et al. 2015).

The reductionist view of nutrition has proposed the hypothesis that “if some is good, more is better,” but with little to no evidence to support this hypothesis in humans. To the contrary, evidence has mounted over the last two decades to demonstrate that pharmacological (as opposed to dietary) dosages of micro- and phytonutrients taken daily as capsules are not associated with the prevention of chronic disease, but instead were shown to increase the incidence of all-cause mortality in large retrospective and prospective cohorts (Goodman et al. 2011; Bjelakovic et al. 2012).

Antioxidant Nutraceuticals to Fight Aging?

The antioxidant therapy approach to preventing aging decline purported that free radicals should be aggressively fought with antioxidants in high-dose capsules to prevent oxidative stress and damage that lead to aging. The lack of successful outcomes with this approach, also called the “antioxidant paradox,” has since been explained by new understanding on free radical behavior and biology. This includes the following: (1) *in vitro* free radical neutralization by antioxidant nutrients may not be duplicable in physiological conditions due to the complexity of homeostatic mechanisms involved, and (2) free radicals such as reactive oxygen species (ROS) are also critical signaling molecules in the

activation of the endogenous antioxidant defense and detoxification systems (Halliwell 2013; Finkel and Holbrook 2000). A rise in free radicals triggers the activation of the nuclear factor erythroid 2-related factor 2 (Nrf2), which induces the expression of gene coding for antioxidant and detoxification enzymes. These enzymes constitute the endogenous antioxidant system that is operating 24 h a day, 7 days a week. Suppressing free radicals aggressively by ingesting large doses of antioxidant nutrients may switch off this mechanism or reduce its efficacy with an overall imbalance in endogenous signaling pathways (Cardozo et al. 2013). Furthermore, large bolus doses of antioxidant nutrients taken once a day may result in cellular imbalance of cofactors and increase in reactive species. Indeed, when vitamin E donates an electron to stabilize a free radical, it becomes itself an unstable molecule and requires stabilization by vitamin C, for example. Large bolus doses may thus result in a sudden increase of reactive molecules that may have deleterious effects (Hoffman and Gerber 2013; Halliwell 2013). On the other hand, a sudden increase in concentration of ROS leads to the increase in inflammatory cytokines production, by activation of the nuclear factor kappa-light-chain-enhancer of activated B cells (NF- κ B). Increased systemic inflammation is a driver of chronic disease, as will be discussed further.

While modulating the concentration of circulating free radicals remains a focus in prevention and management of aging-related and chronic disease, it is the maintenance of the redox homeostasis status that appears of greater importance, where the balance between reducing and oxidizing molecules is actively maintained (Finkel and Holbrook 2000).

Safety of Pharmacological Dosages of Nutrients

Consuming high bolus doses of one or more nutrients is therefore “not better,” unless evidently, deficiencies have been identified biochemically (Higdon 2003). The micronutrient target ranges mentioned earlier indicate the upper levels of intake for vitamins and minerals for which toxic levels of intake are known (Higdon 2003). Water-soluble vitamins in excess will mainly be

excreted via the urine, but fat-soluble vitamins and minerals may remain stored in body tissues with significant toxicity implications (Wardlaw et al. 2016). Targets for phytonutrients have not been established, other than recommendations to consume a diet rich in fresh plant products to increase exposure (at dietary dosage) to these bioactive constituents. However there is no evidence on the long-term safety or toxicity of pharmacological doses of phytonutrients consumed as nutraceuticals. The common assumption is that since they are coming from foods – rather than being synthetic pharmaceutical molecules – they must be safe. Consuming 6 kg of tomatoes, 4 kg of carrots, and 4 kg of kale would barely be possible in 1 day and certainly not on a daily basis. Nutraceutical products offer the phytonutrients contained in this amount of food in one capsule, but it is unknown if the constituents are fully absorbed, if cells can deal with such high dosage, and if this is safe (Poulsen et al. 2015; Valtueña et al. 2008).

Nutrient Density in Dietary Patterns

Consuming daily a large variety of micro- and phytonutrients within the whole food matrix is characteristic of a *nutrient-dense* dietary pattern, and this “is better” indeed. Nutrient density generally describes the variety and ratio of micronutrients and phytonutrients to calories contained in the food. Nutrient-poor foods – or empty calories – are devoid of micro- or phytonutrients but provide calories through carbohydrate and fat primarily, such as crisps, chocolates bars, and pastries. Nutrient-dense foods can also be energy dense, such as dried fruit or mixed nuts (Wardlaw et al. 2016).

Nutrient density at dietary dosage confers a variety of beneficial molecular stimuli and at multiple occasions throughout the day (as opposed to one capsule daily). The human evidence for the short- and long-term benefits on HLE and life span of nutrient-dense dietary patterns are best demonstrated by the traditional Mediterranean diet (TMD) (Hoffman and Gerber 2013). This dietary pattern is rich daily in fresh plant-based raw and cooked foods and condiments, as well as including dairy products, fresh seafood, lean

meats, moderate (red) wine drinking, and abundant use of extra virgin olive oil providing the combination of monounsaturated fatty acids and a variety of phytonutrients of the polyphenol family. In addition, the TMD pattern promotes meals made of several dishes (increased variety of foods), and meals prepared freshly that reduce the exposure to processed and refined nutrient-poor foods (Hoffman and Gerber 2013).

The nutrient-density and macronutrient composition, combined with the minimal exposure to processed foods, is thought to explain the numerous health benefits attributed to the TMD. The evidence in humans for health benefits ranges from the primary prevention of coronary heart disease in a high-risk population, to the reduced or delayed onset of chronic disease, and aging-related decline in immune function, antioxidant defense, DNA repair, and cognition (Estruch et al. 2013).

The Influence of Aging on Nutrition and the Related Health Outcomes

Optimal nutrition relies not only on nutrient-dense food choices but also on a well-functioning gastrointestinal tract and related organs and structures, as described earlier. With the aging process, degenerative mechanisms can gradually impair nutrition (Wardlaw et al. 2016). Food intake may be reduced due to a loss of appetite or a loss of pleasure when eating. A loss of acuity in olfactory and gustatory function alters the sensory perception of food, influencing food choices and intake (Wardlaw et al. 2016). Mechanical and chemical digestive functions may become less efficacious, reducing the amount of nutrients being absorbed. The metabolism of converting vitamins to their biological active form may become impaired. The availability of nutrients to cells may thus become severely reduced. If undernutrition and malabsorption are sustained over time, the deficiencies in energy, protein, and essential micronutrients result in weight loss, loss of lean body mass, and malnutrition (Wardlaw et al. 2016; Hickson 2006). A decline in overall metabolism, immune function,

cognition, and well-being ensues, promoting the exacerbation or development of underlying chronic diseases. Nutrition therapy prioritizes the increase of energy and nutrient density in each mouthful, to stop weight loss and restore nutrient sufficiency (Hickson 2006).

Of note, malnutrition is defined as an imbalance (deficiency or excess) between nutrients and energy requirements and dietary intake, causing measurable outcomes on weight, body composition, metabolic function, and clinical markers. As such, malnutrition applies to overweight individuals as well, where the imbalance between energy intake and requirements results in accumulation of excess fat mass. Excess weight can also be associated with micronutrient deficiency due to a nutrient-poor diet, as excess energy intake does not guaranty nutrient density, as previously discussed. Furthermore, obesity can mask sarcopenia (Prado et al. 2016) (the loss of muscle mass) resulting from the aging process or underlying chronic disease. Protein and micronutrient malnutrition promotes sarcopenia at any weight (Prado et al. 2016).

It is worth noting that overweight to moderate obesity (with good micronutrient status) is suggested to be protective in aging and should not be undermined. The healthy weight range for adults is a weight resulting in a body mass index (BMI) between 20 and 24.9 kg/m². A recent meta-analysis of 32 studies including subjects over the age of 65, living independently in the community, confirmed previous findings in cohort follow-up studies that the adult BMI recommendations may not be suitable for the older age group. The meta-analysis found that individuals over 65 years old, with a BMI between 23 and 31 kg/m², had a significant lower risk of all-cause mortality compared to individuals with a BMI under 23 kg/m² or over 33 kg/m². There are currently no adjusted recommendations from the World Health Organization on the healthy BMI range in the older population; however, local public health organizations have reviewed guidelines based on study results and derived recommendations (Winter et al. 2014).

Table 3 outlines the possible effects of aging-related function decline on nutrition processes.

Nutrition in Aging, An Exploration of a Close Relationship, Table 3 Changes that may occur with aging, impacting on the nutrition processes

Structures, digestive processes, or other factors influenced by aging and outcomes		Nutrition-related consequences ^a
Reduced hunger and appetite	Early satiety due to reduced stomach stretch capacity, reduced ghrelin secretion, increased circulating inflammatory cytokines acting on the central nervous system in reducing hunger	The reduced dietary intake for extended time leads to energy, protein, and essential nutrients malnutrition. Weight loss and loss of lean body mass, loss of strength and balance. Deficiency symptoms associated with nutrient deficiencies
Reduced or loss of acuity in smell and taste	Food tastes and smells bland. The cues from the smell of food that normally signal appetite and the start digestive secretions are absent	
Loss of teeth or ill-fitting dentures	Difficulty and pain when chewing food. Larger chunks are being swallowed, or avoidance of specific foods such as fresh fruit requiring chewing, leafy and raw vegetables, nuts, meat, multigrain breads, etc.	May lead to indigestion if food is not chewed adequately, or protein food is not broken down by hydrochloric acid and pepsin. Nutrients are not available for absorption if food was not chewed or avoided. Examples of nutrients at risk include individual amino acids, iron, zinc, vitamin B6, B12, and folate. May lead to nutrient deficiencies
Reduced hydrochloric acid production, reduced secretion, and conversion of pepsinogen to the active form pepsin	Bacteria contained in foods are not neutralized efficiently. Protein is not denatured and broken down into smaller particles for enzymatic cleaving; nutrients are not freed for absorption	
Reduced intrinsic factor production by gastric cells	Intrinsic factor is required for the absorption of vitamin B12 in the distal ileum. Reduced gastric function results in less intrinsic factor being produced	Impairment of vitamin B12 absorption and deficiency signs and symptoms over time
Reduced pancreatic and liver function: reduced digestive enzymes and bile production	Macronutrients are not broken down adequately to monosaccharides, amino acids, and small fat droplets for absorption. Micronutrients are not available for absorption. Undigested food particles remain in the intestine unabsorbed	Reduced nutrient absorption, resulting in nutrient deficiencies over time; indigestion, diarrhea, and steatorrhea
Reduced or impaired liver function	Impairment of cholecalciferol to calcitriol conversion. Impairment of vitamins to coenzyme active form conversion. Reduced transport protein production. Reduced alcohol, xenobiotics, and medication metabolism	Deficiency in biologically active vitamins and related impaired pathways. Impairment of vitamins, fatty acids, and mineral transport to cells. Slow break down of alcohol
Reduced or impaired kidney function	Impairment of cholecalciferol to calcitriol conversion. Impaired clearance and reabsorption of electrolytes in the kidney. Impaired excretion of waste products	Dehydration or water retention. Nausea and loss of appetite. Blood pressure fluctuations
Reduced intestinal smooth muscle function	Reduced peristalsis; low-fiber diets reduce stretch signaling of the small further	Constipation; increased risk of diverticulae and diverticulitis. Reduced appetite and food intake
Reduced thyroid and growth hormones	Decreased lean body mass, increased fat mass, reduced metabolic rate	If the dietary intake is not adjusted accordingly, weight gain may result

(continued)

Nutrition in Aging, An Exploration of a Close Relationship, Table 3 (continued)

Structures, digestive processes, or other factors influenced by aging and outcomes		Nutrition-related consequences ^a
Increased circulating pro-inflammatory cytokines	Reduced cellular sensitivity to insulin, increased risk of arteriosclerosis, and other chronic disease	Reduced insulin-mediated glucose uptake, hyperglycemia, increased burden on the pancreas to secrete insulin, formation of advanced glycation end products. Inflammatory cytokines may suppress hunger
Change in gut microbiota profile	Change in the amount and diversity of gut microbiota. Change in the ratio of <i>Firmicutes</i> (reduced) and <i>Bacteroidetes</i> (increased). Significant decrease in <i>Bifidobacteria</i> and increase in <i>Proteobacteria</i>	Increased diarrhea and resulting poor nutrient absorption. Increased gut permeability and resulting increased inflammatory cytokine production as enteral toxins translocate. May affect hunger signaling
Polymorbidity and polypharmacy, herbal supplements use	The nutrient-drug interactions and the herb-drug interactions interfere with nutrient or medication absorption and metabolism and may increase clearance or half life	Loss of, or increased appetite, nutrient deficiency signs and symptoms
Loss of joint mobility, joint degeneration, change in body composition with loss of lean body mass and increase fat mass; increased visceral adiposity	Decline in endocrine function and anabolic metabolism; change in protein metabolism Loss of muscle strength and function Going out to purchase fresh food regularly, cooking meals, using cutlery, and opening food packaging may become difficult and painful Increase in systemic inflammation with increased visceral adiposity	Energy requirement decrease, but protein requirement increase. There may be fat mass gain if energy intake is not adjusted to decreased requirement The diet may become less varied by convenience and may contain less nutrient-dense foods because cooking is a tiresome burden. This may lead to nutrient deficiencies and weakness
Sedentary indoor lifestyle	Lack of exposure to the outdoor and UVB ray exposure A sedentary lifestyle may reduce hunger – because of being less active or conversely promote boredom snacking	Reduced vitamin D production opportunity by the skin. Snacking often on packaged foods increases intake of salt, saturated fat, refined sugar, overall nutrient-poor foods
Living alone, feeling lonely, depressive symptoms	Cooking for oneself may become a burden and appears “unnecessary.” Loss of interest for taking care of self	Reduced food intake or less-varied dietary intake requiring less cooking and preparation. Loss of appetite and interest in foods, with resulting malnutrition outcomes

^aFor full details on consequences of specific nutrient deficiencies, consult reference (Higdon 2003) and additional links provided.

This is by no means an exhaustive list, and all factors may not apply systematically or in all living conditions (independent or in age-care facility). These factors however need consideration when assessing the nutrition status of elderlies and when troubleshooting for the management of poor nutrition status.

The effects of aging on nutrition are multiple and can have the consequences of aggravating the aging process in positive feedback loops, as the paucity of nutrients availability for biochemical pathways further promotes the aging decline (Wardlaw et al. 2016). The awareness of mechanisms that can affect nutrition allows for the

prevention and adaptation to avoid deleterious long-term effects. Nutrition professionals play a key role in addressing aging-related nutrition issues. In addition, the use of functional foods, as discussed further, may be particularly relevant in this context.

Nutrition in the Modulation of the Ageing Process

To achieve a slowing down of functional decline and compression of morbidity, avoiding diet-related chronic disease appears a sensible approach. Nutrition is the most significant lifestyle habit, besides sleeping, based on time involved and frequency. It can thus be viewed as both the preventative measure and the slow acting foe *par excellence*, due to the chronically repeated stimuli. Indeed, food constituents and dietary patterns act beyond the mere provision of energy and cofactors in physiological pathway. They also can counteract or contribute to the common denominator of aging and chronic disease: systemic inflammation (Calder et al. 2011; Minihane et al. 2014).

Inflammation, Aging, and Chronic Disease

Physiological aging is characterized by some degree of chronic low-grade systemic inflammation, with persistently raised inflammatory biomarkers such as C-reactive protein (CRP), interleukin-6 (IL-6), and TNF-alpha. This inflammatory status coined “inflammaging” (Franceschi and Campisi 2014) is partly explained by: an overactive innate immune system in aging (while the adaptive immunity tends to decline) (Fagiolo et al. 1993); a change in body composition that favors accumulation of visceral adipose tissue that is proficient at secreting pro-inflammatory factors (Prado et al. 2016); a reduction in gut microbiota mass and shift in variety resulting in loss of gut integrity and a pro-inflammatory enteral milieu; and a decline in cellular antioxidant and detoxification functions (O’Connor et al. 2014).

It is well established that the pathophysiology of most chronic and aging-related disease is linked to chronic inflammation (O’Connor

et al. 2014). Dysregulations in cardiometabolic conditions (insulin resistance, type 2 diabetes, atherosclerosis, and nonalcoholic steatohepatitis), in cancer, arthritis, and neurodegenerative disease arise from chronic low-grade systemic inflammation. For example, the rise in circulating inflammatory cytokines IL-6 and TNF-alpha interferes with insulin signaling, leading to insulin resistance in metabolic tissues normally insulin sensitive. Hyperglycemia and hyperinsulinemia ensue and promote the development of nonalcoholic fatty liver disease and type 2 diabetes. This hyperglycemic and inflammatory milieu causes vascular endothelium damage, which develops into atherosclerosis and related cardiovascular disease (O’Connor et al. 2014).

The chronic inflammatory state generated by the aging process may be preceded by the earlier onset of obesity. Excess weight can be stored in hyperplastic and hypertrophic adipocytes. The latter secrete more pro-inflammatory (IL-6, TNF-alpha) and less anti-inflammatory factors (adiponectin, interleukin 10 (IL-10)), resulting in chronic low-grade inflammation. The rise in circulating inflammatory factors generates an increase concentration in reactive molecules and species. If antioxidant molecules concentration is low (antioxidant nutrients lacking in the diet and poor endogenous antioxidant enzymes production), free radicals concentration progresses to oxidative stress, to activate NF-κB, the transcription factor for inflammatory cytokine genes expression (Wardlaw et al. 2016; Calder et al. 2011).

Food Constituents in the Modulation of Inflammation

Dietary choices throughout life expose the internal milieu chronically to factors that either activate or downregulate inflammatory pathways in a variety of mechanisms. A selection of these factors is discussed here:

1. Over-intake of dietary energy results in an overall positive energy balance and may develop into obesity. Hypertrophic adipocytes and visceral adipose tissue are associated with a low-grade inflammatory status as explained earlier (Wardlaw et al. 2016).

2. Polyunsaturated fatty acids (PUFA) are precursors of eicosanoids involved in the inflammatory response. Arachidonic acid, an omega 6 PUFA found in meats and eggs, is the precursor of pro-inflammatory prostaglandins, while the omega 3 PUFA eicosapentaenoic and docosahexaenoic acids are precursors to anti-inflammatory prostaglandins. While both omega 3 and omega 6 fatty acids are important in physiological function, the ratio of omega 6 to 3 fatty acids in the diet promotes a dominantly pro- or anti-inflammatory milieu. The typical Western dietary pattern, characterized by abundant meat and other animal products consumption, but low in plant and animal sources of omega 3 PUFA, is associated with a pro-inflammatory status, because the ratio of omega 6 to 3 is high (Calder et al. 2011).
3. Numerous food constituents, such as vitamins A, C, E, polyphenols, and carotenoids, act as electron donors to neutralize free radicals. Furthermore, a variety of minerals in the diet are required as cofactors for the function of endogenous antioxidant enzymes. For example, superoxide dismutase requires zinc and copper, and glutathione peroxidase requires selenium for their free radical neutralizing function. These food constituents contribute to redox homeostasis and the reduction of NF- κ B activation by an elevated concentration of reactive species (Wardlaw et al. 2016; Halliwell 2013).
4. With the development of nutritional genomic investigations, the understanding of the nutrient-gene relationship has provided new mechanisms of action by which food constituents are involved in the modulation of chronic inflammation. While these mechanisms are primarily demonstrated in *in vitro* experimental models, they shed some light on how nutrient-dense energy patterns promote health, prevent chronic disease onset, and reduce aging decline (Müller and Kersten 2003).

Specific food constituents have been identified as activators or inhibitors of transcription factors that induce the expression of genes coding for pro-inflammatory cytokines,

detoxification, and antioxidant enzymes. The inhibition of NF- κ B binding to the DNA by curcuminoids from turmeric results in the downregulation of inflammatory cytokines and other inflammatory mediator expression. Activation of Nrf2 by hydroxytyrosol in extra virgin olive oil, or sulforaphane in broccoli sprouts, upregulates the expression of a variety of cyto-protective enzymes. As a result, the neutralization of free radicals suppresses NF- κ B activation by these reactive species (Cardozo et al. 2013; Müller and Kersten 2003).

Another example is omega 3 PUFA that are ligands for the nuclear peroxisome proliferator-activated receptors (PPARs). PPARs induce the transcription of an abundance of genes involved in tissue-specific metabolism. Via gene expression, PPAR-alpha regulates inflammation in the vascular endothelium, while PPAR-beta and PPAR-delta regulate inflammation in the adipose tissue. Thus, the regular presence – or absence – of omega 3 PUFA in the diet can impact on the inflammatory status (Grygiel-Gómiak 2014).

5. The investigation of the effects of food constituents and dietary patterns on the epigenome is also revealing promising mechanisms for the prevention of aging and chronic disease. Methyl group binding is one of many epigenetic mechanisms. It generally suppresses gene expression. Methyl group donors are abundant in nutrient-dense dietary patterns (examples include folate, choline). During development, the *in utero* environment, the health, and nutrition status of the mother during pregnancy all program the fetus' epigenome to influence chronic disease susceptibility, aging, and longevity.

The epigenome is plastic. It continues to respond to environmental factors throughout life and changes with the aging process. Dietary patterns and food constituents may have thus a significant influence on epigenetic modifications. The chronic state of hyperglycemia, for instance, was shown to upregulate epigenetically the expression of NF- κ B in macrophages and vascular cells. Similarly,

pro-inflammation epigenetic modifications were observed when cells were exposed to hypercholesterolemic conditions (Wardlaw et al. 2016; Park et al. 2012).

It is still too early to determine clearly how dietary patterns can be modified to epigenetically influence the aging process favorably and prevent chronic disease. The currently available evidence nevertheless points to yet other mechanisms by which daily nutrition choices may influence aging outcomes.

6. Probiotics (microorganisms that colonize the gastrointestinal tract) and prebiotics (fermentable food constituents such as fiber, a variety of polyphenols) assist in maintaining the diversity and mass of gut bacterial colonies.

It is now well recognized that the gut microbiota is linked to immune, cardiometabolic, and neurological function. Newly emerging knowledge is providing understanding in the mechanisms of actions. The gut bacterial diversity is significantly modified with aging, resulting in less variety and change in dominant phyla (more *Proteobacteria* and *Bacteroidetes*, less *Firmicutes*). Bacterial populations play a significant role in gut integrity. Poor gut integrity promotes permeability and translocation of endotoxins to the circulation, with resulting promotion of low-grade inflammation. Increased inflammation in turn affects bacterial diversity. Gut permeability increases with aging, as bacterial diversity and mass decrease.

Bacterial profiles respond rapidly to diet composition by adjusting in diversity. However it is unclear how long dietary changes need to be maintained to sustain the change in diversity. More intriguing, it appears that diet composition primarily influences the types of metabolites produced by the bacteria from dietary substrate fermentation, more so than the variety of bacterial species. It appears that food constituents have a nutrient-gene relationship with bacterial DNA that results in the production of metabolites with beneficial or deleterious effects on host health.

The content of fermentable substrates in dietary patterns is therefore of great

significance in modulating inflammation. The short chain fatty acids (butyrate, propionate, and acetate) produced from bacterial fermentation confer health benefits as varied as protection from colon cancer, regulation of energy metabolism, modulation of the inflammation response of hypertrophic adipocytes and macrophages, and cognition. A Western dietary pattern, characterized by high sugar, low-fiber refined starch products, high fat, and high meat intake, generates bacterial fermentation products that promote the inflammatory milieu. Conversely, traditional vegetarian dietary patterns are associated with bacterial diversity and metabolite profiles that downregulate inflammation by modulation of the immune system (Wardlaw et al. 2016; Franceschi and Campisi 2014; Keenan et al. 2015).

7. Processed carbohydrate foods (refined starches, sugars found in sweetened processed foods) are all digested into simple sugars, such as glucose and fructose. Hyperglycemia from high glucose absorption causes postprandial inflammation. When these foods are consumed all day long, the inflammation pathways are chronically triggered. Advanced glycation end products (AGEs) are produced during food processing methods (high-heat baking, roasting, and frying) and endogenously in chronic high hyperglycemia. AGEs activate NF- κ B, with the resulting pro-inflammatory gene expression cascade. Dietary patterns that contain a dominance of packaged baked goods and sweetened foods promote AGEs production and a pro-inflammatory state. Increased concentration of circulating AGEs consumed in the diet is associated with type 2 diabetes, chronic kidney disease, and heart disease (Ramasamy et al. 2005).
8. Moderate alcohol consumption in humans is observed to reduce circulating pro-inflammatory cytokine interleukin (IL)-1- α and increase the anti-inflammatory cytokine IL-10 in healthy and in high risk for heart disease individuals. This is in addition to promoting favorable cardiovascular protection (inhibition of fibrinolysis, increasing high-density lipoprotein (HDL) cholesterol,

improved endothelium function, increased insulin sensitivity). When alcohol is consumed as red wine as opposed to spirit, additional benefits are observed on inflammatory markers: IL-6 and CRP are decreased, suggesting that the abundance of polyphenol phytonutrients contained in red wine contributes to reducing inflammatory pathway activity (Hoffman and Gerber 2013).

9. Fat intake recommendations in the prevention of chronic disease such as cardiovascular disease have for long focused on reducing the overall amount of fat intake, saturated fat, dietary cholesterol, and more recently trans fats (Wardlaw et al. 2016). The current evidence tends to challenge the “low-fat” message, in light of positive results in a primary prevention intervention with individuals at high risk of coronary heart disease, involving the traditional Mediterranean diet pattern with the inclusion of daily substantial amounts of olive oil. The fat intake equated to 47% of total energy intake (when healthy-eating recommendations are no more than 35%). The fat intake was however issued mainly from mono-unsaturated fatty acids, contained in olive oil, very low exposure to trans fats, and moderate amounts of saturated fat (Estruch et al. 2013). In numerous human trials, higher trans fat (partially hydrogenated vegetable oils in baked and deep-fried products, and margarines) consumption is associated with increased circulating pro-inflammatory cytokines and factors that impair endothelium function, compared to low trans fat intake. In vitro experiments show activation by trans fats (among a variety of deleterious effects) of NF- κ B with increased monocytes and endothelial cell expression of TNF- α and IL-6 (Mozaffarian et al. 2006). Furthermore, the association between saturated fat intake and dyslipidemia is considerably weakening in the literature, with the evidence that numerous lifestyle and other dietary factors (such as high sugar intake) are associated with raised total cholesterol and triglycerides, lowered high-density lipoprotein, and raised low-density lipoprotein cholesterol

(Ruiz-Núñez et al. 2016). It appears that the type of fat, more so than the quantity per se in the diet, is of importance, with a dominance of unsaturated fatty acids (mono and poly) and reduced exposure to trans fats for optimal health outcomes.

In the context of diet-induced inflammation, it is both *what one consumes* and *what one does not consume* that influence the low-grade inflammatory status throughout life (Barbaresko et al. 2013). Dietary patterns describe the combination of foods and beverages, as well as how food is sourced and prepared and how frequently foods are consumed (Wardlaw et al. 2016).

In the long-term prevention of aging disease, the role of nutrition factors in modulating low-grade inflammation acutely and chronically certainly deserves serious consideration. However, it is always important to focus on the relevant dietary priorities at any given time point. On the background of advanced aging, with loss of weight and malnutrition, for example, the priority is not to limit processed food intake to avoid AGEs exposure, but rather to increase energy, protein, and micronutrient intake first, even if this means consuming processed sweetened foods that encourage appetite (Wardlaw et al. 2016; Hickson 2006).

Food as Medicine: Functional Foods and Super Foods in the Prevention and Management of Aging Decline?

Functional foods are generally defined as foods that have been manufactured specifically to provide health benefits of disease prevention in addition to providing the usual selection of macro- and micronutrients. The health benefit may come from an added ingredient or nutrient to the traditional recipe (calcium added to orange juice, milk with added omega 3 fatty acids) or an increased concentration of a specific nutrient as a result of breeding and agriculture technology (eggs with omega 3 fatty acids, tomatoes with more lycopene concentration) or a particular combination of nutrients to confer additional benefits (yogurt with additional probiotics and added soluble fiber) (Webb 2011). Super foods are the foods

that contain in their natural state a high concentration of nutrients with known health benefits (oats are rich in the soluble fiber beta-glucans; salmon is rich in omega 3 fatty acids; extra virgin olive oil is rich in monounsaturated fatty acids and antioxidant polyphenols) (Wardlaw et al. 2016).

Functional and super foods are of particular interest in the context of aging disease prevention or the management of chronic disease in aging. Functional and super foods increase the nutritional value of each mouthful. The high concentration of food constituents conferring benefits is embedded within the food matrix. This provides nutrient density and food constituents of interest, with the usual energy provided from macronutrients contained in this food. Compared to nutraceutical capsules, the dosage of nutrient is within dietary dosages and therefore physiologically relevant. With cautious examination of food labels and ingredients contained, these foods may be a suitable addition for gut health, balanced blood lipids, modulation of blood glucose, modulation of inflammation, increased micronutrient absorption, etc. (Fagiolo et al. 1993).

Conclusion

Nutrition has a significant long-term role to play in the goal of extending healthy life expectancy. Food is made of (1) macronutrients providing energy and the building blocks of body tissues, (2) micronutrients involved in biochemical reactions, and (3) phytonutrients assisting in pathways of disease prevention. The effects of nutrition go however beyond the mere provision of energy and cofactors in physiological pathways; it is also a significant source of signals for gene expression resulting in specific phenotypic outcomes.

This is a double edge sword: certain food constituents trigger gene expression patterns promoting the foundations of chronic disease, while others trigger gene expression patterns that promote metabolic health, resilience, and the prevention of chronic disease over time. It is therefore both what is consumed daily and what is not

consumed that must be considered, because food constituents can either exacerbate or dial down chronic systemic inflammation and redox homeostasis. Favoring nutrient density in the whole food matrix over nutrient-poor processed foods with bolus doses of nutrients in nutraceuticals is key in the modulation of aging chronic disease, by reducing the effects of chronic inflammation and oxidative stress.

Dietary priorities are primordial when approaching nutrition in advanced aging. Prevention of weight loss and quality of life becomes the priority over aiming to reduce diet-induced inflammation. Micronutrient supplementation may be required, when aging decline affects the efficiency of the digestive tract. Every mouthful counts: calorie (if there is unintentional weight loss), protein, and nutrient density may be improved by using functional foods. Furthermore, the healthy weight is age specific. Keeping a healthy weight and body composition is key to reducing chronic disease risk.

The gut microbiota has emerged as a significant partner in health. It responds to dietary factors and aging mechanisms (as well as numerous other factors) by changing in variety and mass and producing metabolites that impact profoundly on host health.

As aging is not avoidable, nutrition presents itself as a primary prevention measure to ensure good health is part of aging. Ideally, the prevention approach would start early in life. The relationship between nutrition and healthy aging is nevertheless one of continuous adjustments for optimal outcomes.

³University of Miami Miller School of Medicine, Miami, FL, USA

Definition

Overweight and obesity are defined as abnormal or excessive fat accumulation that may impair health. Specifically, the World Health Organization (WHO) defines overweight as a body mass index (BMI) equal to or greater than 25 kg/m² and less than 30 kg/m² and obesity as a BMI equal to or greater than 30 kg/m² (WHO 2013).

Synonyms

There may not be a proper synonym for obesity. Albeit commonly done in conversations, obesity and overweight are not truly interchangeable terms. The definitions for obesity and overweight (based on BMI) are standard. However, when discussing with patients, special care must be

taken to address the problem and convey the message appropriately. Introducing the issue as weight gain can facilitate engagement in the discussion, but proper definition of terms would need to include the description of obesity as a disease and incorporate concepts covering obesity-related conditions, complications, and comorbidities.

Overview

Obesity has been linked to impaired medical, functional, and social health and recognized as a disease by the American Association of Clinical Endocrinologists and the American Medical Association (AACE Position Statement et al. 2012; AMA 2013). Globally, obesity affects 13% of the world adult population, doubled since 1980 (WHO 2015). However, there are major differences between high-income and low-income countries. For example, the burden of obesity is greater in the United States, where more than one third of adults have obesity (CDC 2014).

Obesity affects segments of the population differently. While public health has recently focused on rising rates in children and adolescents, attention must be paid to the older population. According to the 2011–2012 National Health and Nutrition Examination Survey (NHANES), 35.4% of US individuals aged 60 and above were categorized with obesity (BMI \geq 30 kg/m²) and 36.2% with overweight

(BMI 25 to 29.9 kg/m²). These numbers represent a statistically significant increase in prevalence from 2003 data, in contrast to obesity prevalence rates in younger adults, which did not change (Ogden et al. 2014).

Furthermore, with the dual burden of an obesity epidemic in the aging population and in children and adolescents, we may see rising prevalence of obesity and its impact in health and function throughout their lifespan, with greater prevalence of chronic obesity-related conditions and healthcare costs.

Etiology and Pathophysiology

While the biochemical, hormonal, and pathophysiological processes leading to obesity are quite complex, the basic etiology is an imbalance between caloric intake and caloric expenditure (AHA 2013). In older adults, inactivity due to functional impairment contributes to the caloric imbalance. However, weight gain in the older person is confounded by physiologic age-related changes in body composition (Zamboni et al. 2005), and even in the absence of obesity, fat mass increases and muscle mass decreases.

This decrease in muscle mass, called sarcopenia, and the loss of muscle strength, called dynapenia, can co-occur with obesity in the older person, a synergy (sarcopenic obesity) that is associated with worse functional decline than muscle changes or obesity alone (Stenholm et al. 2009; Kalyani et al. 2014). However, consensus on a definition of sarcopenic obesity and widespread clinical application are lacking. A systematic literature review used eight different definitions of sarcopenic obesity to project prevalence in older US adults and found a range of 4.4–84% in men and 3.6–94% in women (Batsis et al. 2013). Moreover, sarcopenic obesity impacts cardiometabolic health, disease development, and mortality. A study on 2,943 older adults, classified as sarcopenic obese, sarcopenic nonobese, non-sarcopenic obese, and non-sarcopenic nonobese, found that individuals with sarcopenic obesity had higher likelihood of

having insulin resistance, metabolic syndrome, and CVD risk factors (Chung et al. 2013).

In addition, older individuals face symptoms of impaired psychological and sexual function, leading to poor quality of life (Han et al. 2011). Older adults have a greater prevalence of depression and other mental health problems, as well as stressful life events like the death of a spouse and retirement, which can lead to eating disorders (Gadalla and Piran 2007; Ng et al. 2013), followed by increased caloric intake and weight gain. The bidirectional relationship between obesity and depression (Byrne and Pachana 2010) and anxiety disorders can be associated with functional limitations (Gonçalves et al. 2011) which then can lead to sedentarism, physical inactivity, increased weight, and more depression. This trajectory can be complicated with any of the abovementioned issues related to changes in body composition and physical function, thus leading to a negative vicious cycle and perpetuation of the problem (Valencia et al. 2014).

Social factors like social isolation and lack of meaningful social interaction have been related to obesity, as they are also associated with other risk factors for poor metabolic health, such as older age, male sex, minority classification, and lower socioeconomic status (Stringhini et al. 2012; Yang et al. 2013). In addition, researchers have found an association between the neighborhood environment (hazards and socioeconomic deprivation) and obesity in community-based older adults (Glass et al. 2006, Keita et al. 2014).

Effects of Obesity in Older Persons

Medical Domain

Obesity has been clearly identified as a risk factor for several medical conditions, including type 2 diabetes (T2D), cardiovascular disease (CVD), hypertension, stroke, gall bladder disease, osteoarthritis, and even certain cancers, including breast and colon cancer. According to recent surveillance data, prevalence of diabetes among US adults over 65 years old ranges from 22% to 33%, based on diagnostic criteria used (Kirkman et al. 2012). Projections predict this prevalence

to increase 4.5-fold by 2050, compared to a three-fold increase in the total population (Narayan et al. 2006). Older adults are at increased risk for T2D due to a combined effect of increasing insulin resistance and pancreatic cell dysfunction. In addition, diabetic individuals over 65 years old have the highest rates of lower-extremity amputation, myocardial infarction, visual impairment, and end-stage renal disease, compared to other age groups.

The link between obesity and cardiovascular disease is influenced by augmented adipocyte secretion of leptin, increased levels of c-reactive protein, higher stroke volume, and a pro-inflammatory state, all of which lead to changes in cardiac and endothelial morphology and function. These changes in older persons with obesity lead to a range of cardiovascular disease, including hypertension, coronary artery disease, congestive heart failure, and atrial fibrillation (Lavie 2004). The obesity-related chronic diseases described above affect older adults as new-onset cases or as long-standing cases, which are ongoing since earlier in life. Age alone is a risk factor for many of them.

Functional Domain

Functional disability constitutes impairments in mobility, instrumental activities of daily living (IADLs), and activities of daily living (ADLs). The latter include activities such as bathing, dressing, toileting, transferring, feeding, and continence, while IADLs include the ability to use a telephone, to shop, or to handle finances. Impairment in these activities is a common cause of morbidity and mortality in older individuals. A large body of literature suggests a relationship between obesity or BMI and risk of functional disability (Launer et al. 1994; Bannerman et al. 2002; Jensen and Friedmann 2002; Larrieu et al. 2004).

Evaluation of the US National Health and Nutrition Examination Survey (NHANES) data from 1999 to 2004 found that BMI and waist circumference were associated with higher prevalence of all measures of disabilities. The associations were stronger in women than in men (Launer et al. 1994). In a sample of 8966 older French

community dwellers, there was a significant association between BMI and mobility, continence, ADL, and IADL in women and a significant association with mobility only in men (Larrieu et al. 2004). At BMI greater than 40 kg/m², higher functional decline can be expected, more so in women (Jensen and Friedmann 2002).

The increased risk of functional disability holds with increased waist circumference, an important distinction because abdominal fat increases with age, even in individuals without obesity (Chen et al. 2002; Guallar-Castillon et al. 2007; Chen and Guo 2008).

Mental/Psychological Domain

Obesity has also been linked to increased risk of adverse mental health outcomes, including mood and anxiety disorders. In a survey of 9125 US adults, obesity was associated with an approximate 25% increase in odds of major depressive disorder, bipolar disorder, and panic disorder. Odds of substance abuse disorder decreased by approximately 25% in individuals with obesity. These associations held across all age groups (Simon 2006).

A large body of literature examines the reciprocal relationship between obesity and depression, an especially relevant association as 8–16% of community dwelling older adults experience clinically relevant depressive symptoms, and 1–4% have major depression (Blazer 2003). Cross-sectional studies have repeatedly revealed an association between obesity and diabetes (de Wit et al. 2010), both associated with increased risk for depression. A systematic review and meta-analysis of 15 longitudinal studies examining this bidirectional relationship found an odds ratio of 1.55 for baseline obesity increasing risk of depression at follow-up and an odds ratio of 1.58 for baseline depression increasing risk of obesity at follow-up (Luppino et al. 2010). A 5-year prospective study in US adults 70–79 years old found that baseline depression was associated with a significant increase in sagittal diameter and visceral fat (Vogelzangs et al. 2008).

Several biological mechanisms in obesity have been hypothesized to contribute to depression,

including a pro-inflammatory state, dysregulation of the hypothalamic-pituitary-adrenal (HPA) axis, and brain changes induced by insulin resistance. Social stigma around obesity may also be a contributing factor. The reciprocal pathway of depression to obesity may also be mediated by a hyperactive HPA axis, unhealthy lifestyle, or side effects of antidepressant medications.

Understanding the Obesity Paradox in Older People

An obesity paradox has been described as better health outcomes in older people with greater than normal weight. Through a number of studies, researchers reported decreased mortality and complications as well as better outcomes in older adults with overweight or obesity, when compared to leaner counterparts. Earlier studies compared subjects with BMI greater than 25 kg/m² with those below 25 kg/m². The latter group includes subjects with underweight, which is associated with frailty syndrome, terminal – potentially undiagnosed – conditions, and other medical issues, all of which likely contributed to poorer outcomes in the “lean” subjects. More recent studies addressed this issue and, excluding patients with underweight, still reported a paradox for patients with type 2 diabetes and heart failure (Carnethon et al. 2012; Hainer and Aldhoon-Hainerová 2013). Importantly, other researchers have reported opposed results, finding no evidence for an obesity paradox (Flegal et al. 2013; Tobias et al. 2014). However, reports on a paradox, indicating that a greater weight is potentially associated with better outcomes, can be confusing and potentially negate meaningful clinical interventions, lead to clinical inertia, or, even worse, foster misunderstanding toward weight gain. The obesity paradox concept must be properly understood in the right context. Even though the original studies reported to control for several covariables, they mostly did not incorporate a geriatrics approach, which would have considered the role of physical function.

Several studies have addressed the potential flaws in the approach made by the obesity

paradox. The most important clinical application from these concepts is that for any older adult, with normal or increased weight, modest intentional weight loss through proper lifestyle improvements and slowly but progressively increasing physical activity can reduce morbidity and mortality risks. In other words, BMI alone is a great tool for screening purposes, but physical function, functional reserve, and cardiorespiratory fitness are truly the variables that differentiate health status within and across BMI groups. Older individuals with overweight or obesity can certainly benefit from lifestyle interventions and purposeful modest weight loss and progressively increasing exercise and increasing levels of physical activity (Lavie et al. 2014; McAuley and Beavers 2014; Barry et al. 2014; Banack and Kaufman 2014).

Improvements in cardiorespiratory fitness and physical function in older patients with obesity, rather than clinical inertia and sedentarism, are more likely to contribute to their health, regardless of the baseline weight. Understanding the obesity paradox means there should not be clinical inertia toward obesity and weight gain management in older people. Older adults with obesity can benefit from modest intentional weight loss, through lifestyle and exercise, to improve their cardiorespiratory fitness and physical function and enjoy the myriad of benefits related to exercise, including improvements in health and well-being, even if they remain within the same BMI category (Valencia et al. 2014).

Current Management Recommendations

Intensive Lifestyle Intervention and Intentional Weight Loss

The guidelines from the American Heart Association, the American College of Cardiology, and the Obesity Society support intensive lifestyle interventions (ILI) as the first-line therapy for obesity in any age group, including the aging population (Jensen et al. 2014). ILI includes decreasing calorie consumption, increasing physical activity, and modifying unhealthy behaviors.

The guidelines emphasize addressing psychosocial or behavioral characteristics and outcomes and involving psychologists as part of the interdisciplinary teams taking care of patients with obesity.

When ILI leads to a 7% weight loss, the relative risk of T2D decreases by 40–70%, as seen in the Finnish and the Diabetes Prevention Program (DPP) (Tuomilehto et al. 2001; Knowler et al. 2002). These are landmark studies for early interventions in older persons with obesity, given their increased risk to develop diabetes. Furthermore, the DPP results showed ILI leading to disproportionately higher weight loss in older participants, and that being older was the strongest predictor of achieving weight loss goals (Wing et al. 2004). Although a reduction in CVD from IWL has not been documented, the Look AHEAD study showed that ILI improved CVD risk factors; decreased levels of sleep apnea, depression, and loss of mobility; and increased quality of life (Korytkowski 2013).

In order to achieve the documented benefits, lifestyle intervention programs must be tailored to the myriad age-related barriers seen in older adults, including frailty, limited mobility, loss of muscle mass, and multimorbidity. Likely due to these barriers, the DPP did not enroll significant numbers of individuals over 70 years old or with functional or cognitive impairment.

Pharmacologic Intervention

There is limited evidence for the use of weight loss medications in older adults. The safety profile is likely different across these agents, and the studies made for the approval of these agents included few to no older people. Future studies on this age group would be desirable, especially for healthy older individuals who properly understand the risks and benefits, under proper specialized supervision (see below section “[Future Directions](#)”).

Surgical Intervention

Bariatric surgery is an accepted, effective treatment for obesity and its metabolic complications, but its role in older adults remains unclear. Concerns raised about effectiveness include whether

impaired functional status and mobility in the older patient may preclude adequate response to bariatric surgery. In addition, the higher rate of medical comorbidities in this age group has led to safety concerns and the classification of patients over 60 years as high risk.

An analysis of 48,378 bariatric procedures in the American College of Surgeons National Surgical Quality Improvement Program found that patients over 65 years old experienced prolonged hospital stay, but did not have higher risk of major complications (Dorman 2012). In contrast, an earlier study from 99 academic centers found that older patients had significantly higher overall, pulmonary, hemorrhagic, and wound complications. In-hospital mortality rate was also higher, but did not exceed expected, risk-adjusted mortality (Varela 2006). Thus, the authors conclude bariatric surgery to be safe in older patients. A recent systematic literature review involving 8,149 patients and 26 studies showed that complication rates and outcomes of hypertension, diabetes, and lipid disorder resolution were comparable to patients less than 60 years old (Giordano and Victorzon 2015).

Future Directions

Focus should be paid to better understanding lifestyle modification interventions for management of obesity in the aging population. First, further investigation, constituting studies with long-term follow-up, is needed to understand the impact of modest intentional weight loss on cognition and cognitive outcomes in older persons. In addition, clear evidence on factors related to adherence to weight loss interventions in older persons is still lacking. Furthermore, research into the behavioral aspects of weight loss management in older persons requires special attention to new technologies and approaches to physical activity monitoring and tracking, especially since our aging populations is more computer savvy and technologically savvy.

From a clinical perspective, healthcare professionals and healthcare systems ought to increasingly recognize the epidemic of obesity and

weight gain in older adults and implement active screening and timely interventions, individualized to each patient. To date, there is very limited data on weight loss medications in older adults. With a growing number of pharmacologic agents, further experience and research in this age group will provide more information on appropriate clinical use. Similarly, as bariatric surgery expands in younger populations, experience and research will add to the dearth of data in older persons. Obesity is a chronic, complex, perpetuating disease, in a world where the population is aging, with longer life expectancy and, in some areas, better health outcomes. Thus, standard of care interventions for younger adults, such as pharmacologic and surgical treatments, might take a place in the management of obesity in healthy or relatively healthy older persons, particularly those with preserved physical and mental function and enough life expectancy to suffer negative consequences from untreated obesity. Further research is required to carefully understand outcomes and identify who benefits the most from pharmacologic and surgical interventions.

Summary

Obesity and weight gain are prevalent in older adults and can negatively impact their health, physical and mental function, quality of life, and survival. Proper screening and evaluation include the assessment of psychosocial or behavioral characteristics and outcomes, followed with comprehensive interventions, including the involvement of psychologists as part of the interdisciplinary teams taking care of these patients. Standard of care aims to the successful implementation of individualized lifestyle interventions aiming toward modest intentional weight loss, through improvements in diet and behaviors, physical activity, and exercise tailored to this age group. Modest weight loss may not alter the weight category of the patient, as based solely on BMI, but the resulting improvements in cardiorespiratory function, physical and cognitive function, medical and psychological diseases,

well-being, and quality of life are desired outcomes in the older adult with obesity.

Synonyms

Age-related changes in health and well-being; Gains and losses related to well-being and health; Physical and mental health; Psychological well-being; Subjective well-being

Definition

Health is not merely the absence of disease but a multidimensional construct, reflecting dimensions of physical, mental, and social well-being (Pinquart 2001). Frequently used objective indicators of physical health are, for instance, blood pressure, cholesterol, body mass index, psychosomatic complaints, fatigue, and insomnia. Frequently used indicators of mental health or psychological well-being are feelings of anxiety, depression, and irritation. Social well-being is characterized by social support, social connectedness, and low social exclusion. These dimensions of health are usually assessed in terms of an individual's subjective self-rated perceptions of well-being (Ng and Feldman 2013). The literature on well-being, more specifically, differentiates between hedonic well-being (i.e., high levels of life-domain satisfaction, general life satisfaction, positive affect, and a low level of negative affect) and eudaimonic well-being (i.e., successful personal development in terms of purpose in life, environmental mastery, autonomy, and competence) (Delle Fave et al. 2011). For occupational health, the dimensions of physical, mental, and social well-being are described in the context of

Magdalena Bathen: deceased.

work. Over time, constraints in occupational health may result in a decline in an individual's performance and to chronic health and well-being problems such as symptoms of burnout, depression, and cardiovascular diseases.

With regard to the concept of age, one needs to differentiate between an older adult as compared to an older worker. The age range in the active workforce is narrower than the age range in the general population. People typically retire at the age of 65. Thus, the usual cutoff point for older workers in research is 40 years of age. In contrast, an older adult in the general population is older than 65 or 70 years of age (Ng and Feldman 2013).

Introduction

In industrial countries, the population grows older and the retirement age continues to rise so that there is an increase in the number of older workers who are past 60 years of age. At the same time, there is a tendency in both general society and empirical research to focus on and document deficiencies and problems associated with older age. A common negative age stereotype is that older workers suffer from more health problems compared to young workers (Ng and Feldman 2013). A perspective on gains and resources that are also evident in older people has largely been missing. Organizations can no longer neglect occupational health-related issues in the subgroup of older employees. There is an increasing need for organizations to provide conditions necessary to ensure maintenance of occupational health, well-being and safety, and to change attitudes toward aging and age stereotypes. Managing health and preventing early retirement may be one of the key challenges in the context of an aging workforce (Zacher et al. 2014a; Ng and Feldman 2013).

The aim of the present chapter is to provide a better understanding of the relationship between the age of workers and their health and well-being at work. In the following section, age-related changes that are documented in the literature are summarized. Second, this chapter focuses on personal resources, characteristics, conditions, and

strategies that might help older workers to manage potential deficiencies and problems related to health and well-being, and that account for successful aging at work. Third, implications and directions for future research as well as for practical interventions are briefly discussed.

Age-Related Changes in Occupational Health and Well-Being

Theory and research suggest that there are a number of physical and psychological changes that occur in individuals over their lifespans and these may affect their occupational health and well-being (Zacher et al. 2014a; Scheibe and Zacher 2013; Ng and Feldman 2013). These changes in indicators of health and well-being refer to both losses and gains.

For instance, people experience age-related changes in their cognitive capacities. The capability to solve problems, think logically, and temporarily process and retrieve memory information tends to decline with age. Older people also tend to experience lower health and well-being. Yet, the decline in people's self-reported health status is more strongly evident and most likely in the subgroup of old-old individuals (>75 years). This group of people is likely to report, for instance, worse overall fitness, hearing problems, insomnia, or cardiovascular diseases (Pinquart 2001). Thus, health-related problems that are evident in the general population are likely to occur when people have already left the active workforce (Ng and Feldman 2013).

If older *workers* face any health-related problems at all, these problems are more likely related to decline in clinical or objective indices of physical health (e.g., blood pressure, cholesterol level, body mass index), but generally tend to be unrelated to their mental health status, psychosomatic complaints, or their self-reported physical or cognitive health (Ng and Feldman 2013). Hence, aging in the workplace is more strongly linked to objective physical health, while mental health problems are not more common in older than in young workers (Pinquart 2001; Ng and Feldman 2013). For mental health outcomes,

some previous research has even provided evidence for a U-shaped relationship: Middle-aged workers in the range between their late 20s to early 40s tend to report lower levels of occupational mental well-being compared to young or older workers (Zacher et al. 2014b). A potential explanation is that workers in this stage of life need to fulfill various expectations related to different social roles, such that role overload, role conflicts, and ambiguities may deplete their mental and cognitive resources.

Apart from age-related losses, people also experience developmental gains over their lifespans that may positively influence their health and well-being. For instance, older workers are more likely to report higher levels of job involvement and job satisfaction and lower levels of burnout symptoms as compared to young workers (Ng and Feldman 2010). While there is an age-related decrease in extraversion and openness to experience, people experience an increase in agreeableness and conscientiousness over time. Also, people's general experience-based knowledge, vocabulary, and judgment are relatively stable or may even improve with age (cf. Zacher 2015). In addition, goal orientations change over one's lifetime, such that older workers tend to focus on preventing resource losses and maintaining existing resources instead of maximizing gains (Zacher et al. 2014a; Lang and Carstensen 2002). Their limited temporal perspective and expectations concerning their personal future at work are related to an improvement in emotional response and the control and regulation of negative and positive emotions. Emotional stability increases and mood fluctuations decrease over the lifespan with the peak in emotional balance being reached in the mid-60s. This positive emotional capacity of older workers may benefit their occupational health and well-being (Scheibe and Zacher 2013).

One reason that speaks against a strong decline in older workers' perceived health is selective survivorship in the workforce or the "healthy worker survival effect" (Pinquart 2001; Richardson et al. 2004). According to this effect, people who remain employed at older ages tend to be healthier than those who leave their jobs, because

people who are employed generally need to be healthy in order to work. The general population, however, also includes those people who are unable to work due to health-related problems. The healthy worker survival effect provides a potential form of selection bias that is difficult to control in empirical research.

Another explanation for the fact that the young-old workers (i.e., 40–65 years) are generally likely to maintain their health at work and may suffer, if at all, from clinical indices of physical health problems than from self-reported mental or cognitive health problems is the availability of resources to effectively cope with these potential deficiencies in mental or cognitive health. Whereas physical health and well-being are more strongly determined by genetic dispositions and biological aging processes, mental well-being can be better self-controlled by employees (e.g., by using cognitive-behavioral self-management strategies) (Ng and Feldman 2013).

Based on theory and evidence from lifespan approaches, the following section in this chapter focuses on the importance of resource availability, personal characteristics, and cognitive-behavioral strategies that may be used by older workers to deal with changing circumstances and to manage and compensate for health-related problems and deficiencies.

Successful Aging and Managing Age-Related Changes

Human aging is characterized by increased interindividual heterogeneity. Some workers are better able to manage their aging process than others. This effect is referred to as successful aging at work. In general, the definition for successful aging varies across studies and comprises a number of criteria and supportive factors (Zacher 2015). Besides the maintenance of cognitive and physical functioning, a strong focus in research is placed on personal characteristics such as wisdom and resilience (Ardelt 2000; Baltes and Baltes 1990).

One perspective on successful aging at work is based on person-environment fit theory (Zacher

et al. 2014a; Edwards and Cooper 1990). It describes personal factors and characteristics that are relevant to cope with environmental demands. If employees' characteristics do not mesh well with work demands, low levels of P-E fit are associated with greater occupational strain and poorer well-being (Edwards and Cooper 1990).

The P-E fit perspective is particularly useful to explore the relationships among age and occupational well-being because it integrates the two separate approaches into a person-by-situation framework. Age-related changes in employee characteristics as well as personal characteristics and environmental demands may affect P-E fit both individually and in combination (Zacher et al. 2014a). Some personal characteristics and resources that help to realize P-E fit and successful aging will be discussed in more detail next.

Personal Characteristics and Resources

There is a growing body of research on the genetic dispositions and influences that contribute to indices of successful aging (Depp et al. 2010). Apart from genetic dispositions, individual characteristics and personal resources play an important role in successful aging and may serve as buffers for occupational strain, particularly in older workers. Personal resources can be defined as states, conditions, or characteristics that are valued by individuals and that may help them achieve their goals (Halbesleben et al. 2014; Hobfoll 1989). Specifically, this chapter focuses on wisdom and resilience as two personal resources. Both wisdom and resilience have shown to be positively related to successful aging and help older people to buffer some of the detrimental effects of declines in physical health (Baltes and Baltes 1990). While wisdom is associated with a positive acceptance of life circumstances, resilience buffers feelings such as irritability, sadness, anger, or fear (Depp and Jeste 2006).

Wisdom: Wisdom can be defined as a combination of cognitive, reflective, and affective qualities of a person (Clayton and Birren 1980). These three aspects of wisdom are represented by knowledge (cognitive quality), reflection of

one's own behavior and that of others (reflective quality), and a deeper understanding for the imperfections and contradictions associated with human nature (affective quality). There are several positive outcomes associated with wisdom, most importantly a positive effect on life satisfaction, physical health, and the quality of family relationships. Wise older people experience age quite realistically, while simultaneously accepting physical deterioration and the nearing of death. Wisdom is associated with satisfaction even under conditions of social and physical limitations, because a realistic understanding of things is related to a greater acceptance of negative life aspects (Blazer et al. 1991).

Resilience: Resilience can be defined as the physical and/or emotional capacity to recover from stress or adversity (Block and Kremen 1996). Resilience is associated with reduced depression, better self-rated successful aging, and life satisfaction in older people in spite of health limitations (Depp et al. 2010). Because of its positive effects on occupational outcomes such as task performance and work satisfaction (Luthans et al. 2006), resilience is an important factor for successful aging at work. Some research suggests that older workers tend to report higher levels of resilience than young workers (Patrickson and Ranzijn 2003). This higher level of resilience is associated with positive outcomes such as a positive attitude towards organizational changes (Shin et al. 2012) and greater problem tolerance (Jackson et al. 2007). These attitudes and competencies are in turn related to higher levels of performance at work.

Social support from both colleagues and supervisors is an important antecedent for older workers' resilience. Social support was found to buffer the effects of negative attitudes that older workers are exposed to. These negative attitudes range from biased thinking about older workers' productivity to negative thoughts about their physical health and stereotypes about resistance to change (Maurer et al. 2008).

Whether or not the aging process develops successfully not only depends on genetic dispositions and personal characteristics and resources. There is also a proactive perspective which

emphasizes older people's ability to actively influence their development. The proactivity model of successful aging (Kahana and Kahana 1996) describes strategies to proactively deal with and adapt to stressors associated with aging. Even more, the model also introduces several preventive actions in order to delay or minimize the number of age-related stressors. These preventive actions include health promotion, planning for the future, and maintaining a social network. Applied to aging workers, this model emphasizes the importance of planning the final career steps, cultivating social contacts outside work, and planning the transition from work to retirement.

Use of Cognitive-Behavioral Strategies in Dealing with Age-Related Changes

Apart from personal resources and characteristics that may be functional to aging successfully, older workers may apply self-regulation strategies to adapt better to the loss of resources, to fit with their work environment, and to maintain their level of well-being (Zacher et al. 2014a; Zacher and Frese 2011; Schmitt et al. 2012). As a prominent psychological approach to successful development based on lifespan development psychology, the selective optimization with compensation (SOC) model argues that the synchronized use of the three self-regulation and life-management strategies of selection, optimization, and compensation contribute to healthy and successful aging (Baltes and Baltes 1990). *Selection* occurs when individuals choose specific goals and decide on goal priorities. Selection can be determined by personal preferences or result from experiencing a loss in personal or external resources (e.g., an increase in job stress or a lack of time). *Optimization* means that people obtain, improve, and coordinate the use of personal resources to achieve their goals (e.g., learning new procedures, modeling other successful ones, and investing more time in pursuing relevant goals). *Compensation* refers to the use of alternative means to reach relevant goals and to maintain effective functioning in the face of resource losses

(e.g., asking others for help, delegating work tasks to others, or using reminders and calendar functions to compensate for deficiencies in short-term memory capacity) (Baltes and Baltes 1990; Zacher and Frese 2011).

The SOC model states that as older workers experience resource limitations, and accordingly face challenging circumstances at work, the use of cognitive-behavioral strategies for selecting and pursuing goals can enhance or maintain well-being, successful adaptation, and daily functioning (Zacher and Frese 2011; Baltes and Baltes 1990; Schmitt et al. 2012). Since these self-regulation strategies facilitate the optimal allocation of resources, maximize gains, and minimize losses, they are particularly beneficial for older people (Zacher et al. 2014a; Baltes and Baltes 1990).

Previous research shows that especially older workers in jobs with low resources (e.g., lower levels of job complexity) benefit from selection, optimization, and compensation (Zacher and Frese 2011). The use of SOC strategies facilitates the maintenance of a high focus on work opportunities for workers in low-complexity jobs. A high focus on work opportunities refers to a large amount of options, goals, and possibilities that workers believe they have in their future at work (Zacher and Frese 2011). An open-ended and future-oriented perspective in terms of a high focus on work-related opportunities has shown to provide workers with positive activating and motivational resources (Schmitt et al. 2013).

The Health-Generating Effect of Work Itself

Work itself may have a health-generating or health-maintaining function especially for older workers. This is in line with the healthy worker survivor effect, which describes a continuous selection process such that those who remain employed tend to be healthier than those leaving employment (Richardson et al. 2004). However, the strengths of the health-generating or health-maintaining effects depend on the nature of

the job. Autonomy, for example, is associated with high decision-making authority. A lack of autonomy is related to negative health outcomes such as cardiovascular diseases (Ganster et al. 2001). Moreover, it is the interplay of job demands and job resources such as autonomy that affect health outcomes. In general, jobs with high demands and low autonomy are more likely to have a negative impact in health than jobs with low demands and high autonomy (Ganster et al. 2001).

A number of studies have taken the specific situation of older workers into account, giving insight into the relevant factors for successful aging that are related to the work itself and to external influences at the workplace (Truxillo et al. 2012). For instance, there are some aspects related to ergonomic and physical factors that can help older workers to maintain their workability. The physical environment of the workplace needs to be organized in order to meet the needs of older workers (i.e., reduced physical workload and favorable ergonomic conditions) (Danna and Griffin 1999). Further, cognitive stimulation at work – such as whether an individual has access to education – provides an important resource that determines how well equipped a person is against brain pathology (Tucker and Stern 2011). The exposure to complex mental challenges at work can stimulate changes in the brain that are beneficial for cognitive functioning in terms of the generation of new dendritic branches and synapses. This assumption is also supported by longitudinal data from the Maastricht Aging Study. This study indicated that older people (average age of 61 years, ranging from 50 to 85 years) with mentally demanding jobs face lower risks of developing cognitive impairment over time. The relationship was independent of participants' intellectual abilities at baseline as well as demographic characteristics such as age, gender, or education or other factors such as smoking, physical activity, or alcohol consumption (Bosma et al. 2003). Therefore, evidence suggests that older workers benefit from the cognitive and social stimulation associated with work itself in terms of well-being and health.

Conclusion and Directions for Future Research

As the population grows older and workers retire later than they did previously, taking responsibility for the health of an aging workforce is an important issue for employers and organizations. Some prevailing stereotypes suggest that aging is primarily related to deficiencies and losses. However, this assumption cannot clearly be verified by empirical research conducted with members of the active workforce, as most health-related deficits are evident after people have retired.

Some extant research suggests that successful aging at work is also related to gains and strengths. These gains and strengths are associated with personal resources and characteristics, such as wisdom and resilience, which may buffer effects of work- and age-related strain. Further, cognitive-behavioral strategies can be used by older workers to manage and compensate for health-related problems and deficiencies. In addition, work itself in terms of cognitive stimulation, social interactions, recognition, and social support can be functional and protective against health-related complaints.

Future research is needed to develop evidence-based interventions that are related to the maintenance of health and well-being in an aging workforce and to strengthen older workers' resources and competencies (Ng and Feldman 2013; Danna and Griffin 1999). These interventions may help to reduce age discrimination in organizations over time. Specifically, to examine within-individual changes in occupational health over the lifespan and to better understand the dynamics of the fit between personal characteristics and environmental demands in predicting occupational health, more rigorous scientific research is needed in terms of longitudinal studies over the lifespan (Zacher et al. 2014a). In addition, researchers should oversample workers at the higher end of the age distribution (i.e., select more participants from the subgroup of older workers ranging from 55 to 70 years) and weigh this selection of individuals according to their actual proportion in the population (Ng and Feldman 2013). Another avenue for

future research is to study individuals' personal perceptions of the aging process (subjective aging) and relationships with occupational health and well-being. Feeling younger than one's chronological age may explain the additional variance in workers' well-being apart from their chronological age (Hubley and Russell 2009; Zacher et al. 2014a).

Definition

This entry outlines the goals, methods, and results of the Okinawa Centenarian Study, an ongoing (since 1975) study of healthy aging among the oldest old in the southernmost prefecture of Japan and well known as a “Blue Zone” due to the longevity of its citizens.

There is wide variability in disease prevalence and lifespan across populations worldwide. Past studies have suggested that while genes are important to specific diseases, the majority of the variation in overall human lifespan is environmental. Important environmental factors include dietary habits, physical activity, smoking and other risk behaviors, societal and public health practices (e.g., immunization), and basic health care.

We know from human epidemiological comparisons that some populations, such as the Japanese and, in particular, the Okinawans, who inhabit the most southwestern prefecture of Japan, have high active (“healthy” or “disability-free”) life expectancy – a measure of healthy aging. Japan is ranked first in active life expectancy, according to the World Health Organization, and Okinawa leads the Japanese rankings. Despite being the poorest prefecture in Japan, Okinawa has long been among the healthiest and longest lived. As a result, Okinawa has long had among the highest prevalence of centenarians in Japan and the world (Suzuki 1983; Suzuki 1987).

Understanding how the Okinawans achieved a markedly long healthspan and lifespan, despite socioeconomic disadvantages, has been the principal aim of the Okinawa Centenarian Study (OCS) for the past four decades. In 1975, Dr. Makoto Suzuki, a cardiologist and geriatrician, established the OCS as a population-based study of centenarians and other selected elderly persons to study genetic and environmental reasons for their healthy aging (Suzuki 1985). In 1994, Canadian twin brothers, Dr. Craig Willcox and Dr. Bradley Willcox, trained in medical anthropology/public health/gerontology and internal medicine/geriatrics/genetic epidemiology, respectively, joined the OCS team. Almost 1,000 centenarians have since been examined. This represents almost a quarter of all centenarians who have ever lived existed in Okinawa. The population-based design has limited the selection bias often seen in studies of the oldest old and provided a representative sample. Assessments of study participants include a geriatric medical exam that involves a physical and cognitive assessment, anthropometric measures, and activities of daily living. Other data collected include: sociodemographic characteristics, medical history and medication use, lifestyle habits (e.g., smoking, alcohol, diet, and physical activity), family pedigree, a blood sample, and a 12-lead resting electrocardiogram (Honma et al. 1999). Centenarian ages are validated through *koseki* (household registration) records and are reliable (Willcox et al. 2007a).

From a historical perspective, Okinawa has always led the Japanese population in longevity. Of the 47 Japanese prefectures, the Okinawans have traditionally had the lowest risk for coronary heart disease, stroke, cancer, and other major diseases linked to aging (Suzuki 1999). In the 1950s and 1960s, with the advent of public health awareness and a publicly-funded health care system, the leading causes of death at that time, infectious diseases, notably tuberculosis and gastroenteritis, were markedly reduced and Japan emerged as the world leader in longevity (Suzuki 1999). The Okinawans remained the leaders within Japan although recent decades have seen changes in the traditional lifestyle, in particular, diet and activity patterns, that have resulted in emerging health risks, such as obesity, in younger generations and slowing the growth in life expectancy (Suzuki et al. 1995; Willcox et al. 2008a). Currently, stark gender differences in health risk behaviors stand out that drive a large gap in life expectancy between men and women (Suzuki et al. 2014; Willcox et al. 2012).

Regarding the genetics of longevity, in 1985, OCS investigators performed the first extensive study of centenarian family pedigrees. This study found more long-lived siblings in centenarian families than average-lived control families. This original study was later extended and expanded to show that siblings of Okinawan centenarians had lifelong mortality advantages (Suzuki et al. 1985; Willcox et al. 2006a). The initial pedigree study was followed by the first study on the genetics of human longevity using centenarians as a study model, which showed that Okinawan centenarians had higher prevalence of specific type-2 HLA gene variants that tend to lower inflammation and favor longevity (Takata et al. 1987). Several of these findings have been replicated in other populations and inflammation has since become a major focus of studies in cardiovascular diseases (CVD), cancer, and other age-related diseases. The aforementioned studies do not address whether Okinawans have population-wide genetic advantages, which is an ongoing investigation, but rather they indicate that human longevity is influenced by genetic factors. Indeed, after the publication of these early findings, a

plethora of supportive studies has been published and two genes have emerged as the principal human longevity genes – APOE and FOXO3 – both of which are also linked to inflammation (Willcox et al. 2008b; Morris et al. 2015).

The study of environmental factors in the OCS has focused mostly on the traditional diet. The findings indicate a dietary pattern dominated by low calorie density foods with high nutrient density (Suzuki et al. 1999; Willcox et al. 2009a, 2014). The diet is suggestive of mild caloric restriction (10–15% fewer calories than usually recommended). This led to leaner more metabolically efficient bodies which favor longevity (Willcox et al. 2007a). This dietary pattern was made possible by hearty intake of low calorie foods, such as vegetables (over a kilogram per day) and legumes (mainly soybean products), and moderate consumption of fruit, fish, lean meats, and sanpin (jasmine) tea. High consumption of foods that contain compounds that mimic the biological effects of caloric restriction also occurred and resulted in fewer cell-damaging free radicals, greater insulin sensitivity, and activation of the FOXO3 longevity gene (Willcox and Willcox, 2014). Specifically, these foods include Okinawan sweet potatoes (anthocyanins), seaweed, other marine-based carotenoid-rich foods (astaxanthin), and turmeric (curcumin) (Willcox et al. 2014; Willcox and Willcox, 2014).

Eating a healthy diet is part of a traditional belief in Okinawa called *nuchi gusui* (“food is medicine”).

There is also evidence that physical activity, alcohol in moderation, avoidance of smoking, social support and health care, climate, and productive activity, among other factors, were additional environmental factors that helped optimize the odds of healthy aging and longevity in Okinawa (Robine et al. 2012; Willcox et al. 2007b). The OCS also reported that good cardiovascular health is among the most important longevity factors with exceptionally healthy CVD risk factors found, such as healthy blood pressure and very low LDL (bad cholesterol) with concomitant high HDL (good cholesterol) (Suzuki et al. 2001). In an OCS autopsy study of a “typical” centenarian there was no clinical evidence for coronary

artery disease *and* there was a complete absence of coronary calcification (an early indicator of hardening of the arteries present in the vast majority of older persons) (Bernstein et al. 2004). Other studies involving the OCS dataset and/or the OCS team found healthier blood chemistry and hematology, younger hormonal patterns, higher bone density, and better cognitive function than age-matched counterparts in mainland Japan or the USA (Nozaki et al. 1995; Chan et al. 1997; Willcox et al. 2009b). Other factors such as stress-resistant personalities, positive attitudes, and social support also may be important. These concepts are illustrated by Okinawan customs of *ikigai* (“find a reason for living”), *nan kuru nai sa* (“don’t worry, be happy”), and *yuiamaruu* (“help others”). As a whole, data were consistent a healthy lifestyle that promotes a younger biological age in older Okinawans than expected for their chronological age.

The principal findings showed that diet, physical activity, and other behavioral and psychosocial factors appear to be the major modifiable determinants of healthy aging in Okinawa. In 2002, these factors were incorporated into a lifestyle intervention plan called the “Okinawa Program.” Analysis of persons in the Honolulu Heart Study, a 50-year longitudinal study of Americans of Japanese (and Okinawan) ancestry in Hawaii, showed that persons who had similar health profiles and lifestyles as the Okinawans at younger ages had up to 19-fold increased probability of healthy aging into their 90s and 100s (Willcox et al. 2006b).

The OCS interventional program (Okinawa Program) for healthy aging was later published as an evidence-based book for the general public by Random House in the USA (Willcox et al. 2002). The major message of “The Okinawa Program” was that we can adopt the life-lengthening strategies that have served the Okinawans so well for generations. Key recommendations were based on 25 years of research into the Okinawan longevity phenomenon. The book introduces the healthy Okinawan diet and lifestyle while adapting it to modern busy lifestyles using martial arts for exercise, reducing stress using meditation, and bringing new

meaning into life by developing inner spirituality, by doing volunteer work, and by building a solid network of friends and family.

It became a New York Times bestseller and was translated into over a dozen languages worldwide. It was also nominated as “Best Wellness Book of the Year” by a panel of reviewers from Books for a Better Life, an arm of the MS Society as well as one of the “Top 50 Non-Fiction Books of the Year” by both Barnes and Noble and Amazon.com.

The OCS continues its efforts to provide scientific discoveries that can be translated into evidence-based information to help people around the world live healthier, longer lives. More information on the Okinawa Centenarian Study can be found at the OCS website (www.okicent.org).

Older Adults in the Emergency Health Care Setting

Judy Lowthian

School of Public Health and Preventive Medicine,
Monash University, Melbourne, VIC, Australia

Synonyms

Accident and Emergency room; Ambulance service; Emergency department; Emergency medical service

Definition

Older people are increasingly seeking health care from ambulance services and hospital emergency departments. The terms “emergency medical services” and “ambulance services” and “emergency rooms,” “emergency departments,” and “accident and emergency rooms” are often used interchangeably in the literature. All provide immediate health care for people who perceive the need for immediate treatment or care, which is generally provided for a short period of time. Modern emergency rooms are not designed for frail older patients who typically have special needs compared with other age groups, requiring a different approach from clinical staff.

Increasing Emergency Demand by an Aging Population

Aging of populations across developing and developed countries necessitates review of how emergency services are provided to ensure that the health and social care needs of older people are optimally managed during times of acute illness and associated stress. Older people are high users of health care in all settings; however, they are increasingly seeking care from ambulance and emergency department services. People aged 70 years or more are currently the highest users of ambulances and hospital emergency departments (Lowthian et al. 2010, 2011a). They are also more likely to re-attend an emergency department on multiple occasions within a 12-month period and more likely to be admitted to hospital, compared with people under 70 years of age (Aminzadeh and Dalziel 2002). This growth in demand for emergency care by older people is increasing at rates faster than what can be accounted for by population aging, and this is expected to continue over coming years (Lowthian et al. 2011b, 2012).

There are other numerous interrelated factors that contribute to the reasons for seeking unscheduled health care. These include increasing health awareness as a consequence of successful health promotion and public health campaigns,

and the information superhighway. Community expectations for timely specialized care are also changing; and the convenience of a “one-stop-shop” that provides a 24-h total specialist service including current diagnostic technologies cannot be ignored. Fragmentation of social support for older parents and relatives due to changes in family structures and cultural norms also affects timely access to alternative transport and alternative health care. Furthermore, changes in the organization of community-based primary care services impact the availability of such care in a timely manner.

Geriatric Emergency Care

The consequences of these intermingling factors are a growing cohort of older people seeking unscheduled health and social care from emergency departments that may be of a nonurgent and nontime critical nature. As a consequence, alongside the special needs this population has at times of acute illness and/or exacerbation of chronic illness, a new subspecialty of emergency medicine has evolved.

Geriatric emergency care is provision of health care to evaluate and/or treat medical conditions in older people at times when immediate unscheduled medical or social care is called for. While many developed countries regard older age as 65 years or more, for developing countries, the World Health Organisation uses 50 years and over to encapsulate chronology as well as changes in social roles and in capabilities. Geriatric emergency care is delivered in the prehospital setting by ambulance service personnel and/or in the hospital emergency department by emergency physicians, nurses, and/or allied health professionals.

Older People Seeking Emergency Care

Older people typically present for unscheduled care with age-related medical problems related to a high burden of chronic disease, multiple co-morbidities, frailty, and poly-pharmacy. Prominent issues relate to cardiovascular, respiratory,

musculoskeletal, neurological and abdominal conditions, adverse drug reactions, and injury (Steinmiller et al. 2015).

In addition, there is evidence that older people aged 70 years or more who present to the emergency department have a high likelihood of loneliness, social isolation, lack of social support, or feeling depressed (Lowthian et al. 2011a; Aminzadeh and Dalziel 2002). Feeling depressed is associated with higher rates of ambulance use and emergency department attendance (Rottenberg et al. 2013). Recent research identified that 56% of a community-dwelling older emergency department cohort felt socially isolated (Lowthian et al. 2013) and 24% had symptoms of depression (Lowthian et al. 2016). Loneliness, social isolation, and depression are also associated with higher rates of re-hospitalization (Mistry et al. 2001).

The consequences of undiagnosed social isolation, loneliness, and depressive symptoms in older people have far-reaching public health impacts in terms of reduced quality of life, increased burden of disease, and increased hospital use (Hawton et al. 2010). Furthermore, with population aging, it is likely that the number of older people at risk of social isolation and loneliness will continue to grow, as will their rates of emergency healthcare use.

Challenges for Geriatric Emergency Care

Emergency departments are noisy, bright, and chaotic environments that traditionally have had a key focus on the assessment and treatment of acute conditions of a sole medical nature with rapid throughput, particularly in the context of persistent demand, crowding, and time targets. This environment is not conducive to the often multimodal and complex needs of older more vulnerable patients. Furthermore, emergency physicians have typically not been trained in geriatric medicine, and many report being less comfortable when faced with managing older patients (Schumacher et al. 2006).

Importantly, for an older person, an emergency department attendance is described as a sentinel

event, associated with a number of negative sequelae, with increased risk of unplanned return to the emergency department and hospitalization, functional decline, admission to nursing care home, and death well documented in subsequent months (Aminzadeh and Dalziel 2002; Hastings et al. 2007; McCusker et al. 1997). As mentioned, older people are also more likely to experience increasingly complex psychosocial care needs that confound their medical issues in the acute setting.

Goals of Geriatric Emergency Care

Emergency health service providers in the USA, United Kingdom, and Australia have begun questioning how they can optimize the quality and safety of health and social care for this growing group of the ED population. This has led to development of geriatric-focused emergency units being established within or co-located to some hospital emergency departments. These “senior friendly” emergency departments address specific environmental issues such as provision of nonslip cushioned flooring to reduce noise, adjustable lighting, pressure reducing mattresses, assistive devices for vision and hearing, bedside commodes, and orienting aids such as clocks. Comprehensive guidelines, including *The Silver Book* in the United Kingdom and *The Geriatric Emergency Department* in the USA, have also been developed that focus on the emergency department episode with standardized recommendations for staffing, education, equipment, policies and procedures, follow-up care, and performance improvement measures to effectively improve the quality of care of the geriatric population.

A key goal of geriatric emergency care is recognition of patients who would benefit from inpatient care and the effective implementation of care and services for those not requiring inpatient resources. Another objective for optimal management of older emergency department patients includes holistic screening of their health and social care needs that inform the recommendations for discharge and care transition safely

back to the community, including appropriate referrals to community services. The aim is to hopefully reduce the risk of potential postdischarge adverse outcomes and risk of early unplanned return to the emergency department or unplanned admission to hospital. Two important areas of assessment in geriatric emergency care are cognitive impairment and depression.

Cognitive Impairment in the Emergency Department

Cognitive impairment is relatively common, with 25% of all older emergency patients presenting with medical conditions alongside one or more of the 3Ds – delirium, dementia, or depression. Therefore, cognitive screening, encompassing delirium, delirium risk, dementia, and depression, is vitally important. However, cognitive impairment is not systematically assessed in the emergency department, therefore is often unrecognized. Multiple studies report that, if tested, 25–40% of community-dwelling older adults demonstrate dementia or delirium; however, over half of these cases are neither recognized nor documented (Han et al. 2010). This has led to the recent development of emergency department-specific process and structural quality indicators to support the quality of care for older people with delirium and dementia (Schnitker et al. 2015a, b).

Delirium is an acute brain syndrome occurring as a result of an underlying condition. It may in fact be the only sign of a significant medical illness such as pneumonia, sepsis, or abdominal infection. Delirium is present in up to 10% of the older emergency department population. It can be severe and is associated with increased mortality, and the majority of patients are admitted to hospital. Approximately half of the patients in emergency department with delirium have underlying dementia as well, hence an imperative for differential diagnosis.

The four key features of delirium are an acute onset and fluctuating course; inattention with difficulty focussing or keeping on track and distractibility; disorganized thinking with incoherent

illogical rambling; and an altered level of consciousness with lethargy and drowsiness. Screening tools have been developed for quick and easy use in the emergency department, including the Confusion Assessment Method (CAM), 4AT, and RADAR.

Dementia is a chronic cognitive deficit occurring in up to 25% of older emergency attendees. Diagnosis is relevant to establishment of the discharge plan as it affects every stage of the patient's management, from obtaining a history, consent for diagnostic testing, engagement in the treatment plan, and development of a safe plan for discharge from the emergency department. Complete diagnosis of dementia is reliant on lengthy neuro-psychological assessment which does not outside the scope of the emergency department; however, screening is possible with tools such as the Six-item Screener or the Mini-Cog.

Depression is also often not fully appreciated in the emergency department environment, although it may be present in up to one-third of older patients. Because geriatric depression has features that differ from those typically observed in younger people, it may interfere with the clinical presentation of acute medical problems (Meldon et al. 1997). Depression in older people is also associated with greater numbers of emergency department attendances. A brief validated three-question tool for use in the emergency department is the ED-DSI (Depression Screening Instrument).

Care Transition from the Emergency Department to Community

Numerous models of care are implemented in many countries to support safe transition of older people from the emergency department back to the community. Core components usually include geriatric assessment by nurses or allied health professionals with community-based referral and liaison with the primary health care provider. Such care models have been shown to improve health outcomes when implemented in the inpatient setting with decreased likelihood of functional deterioration or death and increased likelihood of

living at home at 12 months following hospital discharge. However, the evidence for effectiveness when implemented in the emergency department setting is mixed regarding maintenance of functional independence in activities of daily living, unexpected death, or return to the emergency department with or without hospital admission (Lowthian et al. 2015).

Importantly, a differentiating feature in studies that report a significant reduction in early emergency department re-attendance and decreased need for nursing home admission was the use of telephone follow-up shortly after discharge from the emergency department. These telephone calls enable confirmation that emergency department discharge instructions are understood and also potentially counteract any confounding issue of poor functional health literacy. Functional health literacy is the extent to which individuals have “*capacity to obtain, process, and understand basic health information and services needed to make appropriate health decisions.*” (Institute of Medicine Committee on Health Literacy 2004). US studies indicate that 60% of older patients report not understanding their emergency department discharge information. Furthermore, it has been identified that 50% of Australians aged 65 years or older have inadequate functional health literacy. Therefore, follow-up telephone calls are a potential safety net to check the patient's comprehension of the emergency department encounter.

Implementation of “quick response programs” that provide rapid referral for home-based services immediately following emergency department discharge has also been reported to be effective in qualitative cross-sectional studies. Such programs facilitate early take-up of services recommended by emergency department clinicians.

In addition, family members and carers could be engaged to enhance emergency department community transition, but there is an absence of literature about their potential involvement. This is of particular importance where functional health literacy may be poor and in the context of admission avoidance. This calls for further research about the effectiveness of including

them in the model of care, from the point of emergency department arrival through to discharge and transition back to the community.

Population aging requires health care systems to be vigilant in their provision of integrated care across the continuum including emergency care. As such emergency care needs to be delivered safely and effectively, with a holistic approach with appropriate communication and handover to facilitate safe transition back to community following an emergency department visit.

Older People and Their Psychological Well-Being in Japan, Evidence from the Japanese Study of Aging and Retirement (JSTAR)

Hideki Hashimoto

Department of Health and Social Behavior, The University of Tokyo School of Public Health, Bunkyo, Tokyo, Japan

Definition

The Japanese Study of Ageing and Retirement (JSTAR) is a member survey of a cross-country harmonization project based on the U.S. Health and Retirement Study, to provide a comprehensive measurement of demographics, physical and psychological health, socioeconomic conditions, and social and labor participation of aged over 50 to 75 in 10 cities in Japan. The data is publicly available for research and policy purposes from the Research Institute of Economics, Trade, and Industry, Japan.

Introduction

As of 2013, Japan's life expectancy is 80.2 years for males and 86.6 for females (Ministry of Health Labour and Welfare 2014). Japan's life expectancy exceeded the OECD average in the late 1970s and has continued to extend until today.

Achievement of longevity has mixed impact on the life of older Japanese. Older Japanese people enjoy not only the longest life expectancy but also the longest healthy life expectancy in the world, though the proportion of disabled life years to total life expectancy has been increasing, especially among women (Hashimoto et al. 2010). The number of frail elderly with care needs is rising, while informal care provision by traditional family becomes less available because the proportion of older people living in single and couple household is rising (Tokunaga et al. 2014).

According to a cross-national survey by the Cabinet Office, 90% of Japanese aged 60 and over are satisfied with their current life conditions,

and 70% answered their household economy is relatively good (Cabinet Office 2010). However, recent OECD comparative data indicate the relative poverty rate among older people in Japan is about 19%, higher than among OECD member countries (OECD 2013).

Furthermore, longevity has created a social dilemma. The longevity with declined fertility resulted in a demographic change of the population; the proportion of those aged 65 and older reached 25% in 2013 and is expected to rise up to 36% in 2050 (Institute of Population and Social Security Research 2012). Sustainability of the national economy is threatened by increasing demand of social benefit for elderly healthcare and pensions, with increasing dependent ratio of the population with low fertility. As a countermeasure, the government announced a new policy to encourage active social participation and health promotion by older people themselves under community support (Cabinet Office 2014).

Japan's near future projects social issues common to developed as well as emerging economy countries that will soon pass the population dividend. How Japan responds to the situation will attract global interest among those countries that aim to achieve quality of life in people's later life, while avoiding intergenerational conflict over life chances.

To find the better way, it is very important to know what the life of older people in Japan is like. However, it is not relevant to take the older generation as a homogenous group defined simply by age. Older people are diverse in terms of health, socioeconomic, and psychological aspects of life after a life-course trajectory of experiences.

A social survey with comprehensive measurement of health, household economy, and social life in a longitudinal design is regarded as an imperative tool for capturing the various pictures of older peoples' lives. The global set of panel surveys following the US Health and Retirement Study are now available to provide a scientific platform for comparative assessment of older people across countries to learn lessons from each other. This entry provides an overview of the Japanese sister survey, Japanese Study of Ageing and Retirement (JSTAR), and some of the currently available

evidence on the psychological impact of health, socioeconomic conditions, and social participation among Japanese older people.

JSTAR Description

Details on the background and sampling strategy of JSTAR are available elsewhere (Ichimura et al. 2009). To be brief, after a pilot study in 2005, JSTAR started its first wave in 2007 in five cities across the country. JSTAR invited middle-age and old adults aged 50–75 at the time of the first contact who were probabilistically selected from municipality residential registration records. Targeted municipalities were carefully selected according to the location, demographic, and industrial characteristics to cover various pictures of the older people over the country. JSTAR intentionally chose the sampling strategy above, rather than random sampling across the whole country, because municipality local governments are responsible for implementation of policies related to long-term care and community-based public healthcare plans in Japan, and that municipality-based sampling would provide opportunities to evaluate the impact of local policy differences as a fixed effect.

JSTAR conducted computer-assisted personal interviews at the convenience of targeted respondent persons, which took about 2 h on average. JSTAR did not invite a spouse of the targeted respondent, as HRS did, though a spouse could join the interview to help the target answer the question.

The computer-assisted personal interview was originally designed following the first-wave questionnaire conducted in the Survey of Health Ageing and Retirement in Europe (SHARE) for comparative purposes. The survey was supplemented with self-administered questionnaire asking lifestyles, social participation, daily functions, household finance, and quality of life. JSTAR also included a dietary habit questionnaire to assess nutrition intake of older Japanese (Kobayashi et al. 2012).

Following HRS and other sister surveys, JSTAR followed the targeted respondent persons at 2-year intervals since the first contact. In the

wave conducted in 2009, two cities were newly invited, one of which was Naha City in Okinawa Prefecture, once known to be a centenarian island in the country. In 2011, another three cities were invited including Hiroshima City, the first civilian casualty of an atomic bomb in 1945. In 2011, one of the member municipalities, Sendai city, was hit by the East Japan Mega Earthquake and subsequent tsunami. In 2013–2014, a fourth-wave survey is ongoing in ten cities across the country.

JSTAR does not regularly include objective biomarker measurement, except for grip strength. In the second wave in 2009, measurement of blood pressure, waist circumferences, and some anthropometry (height and trunk length) was conducted. Blood tests including genome measurement have not been implemented so far.

As for psychological measurement, administered questionnaires included, in each panel interview, measurement of depression (Center for Epidemiological Studies Depression; CESD 20 items), life satisfaction and self-reported health status (5-response Likert scale), and job stress (simplified demand/control and effort-reward imbalance). Since wave 2 in 2009, quality of life measurement called CASP19 (Howel 2012), consisting of subscales on “control,” “autonomy,” “self-realization,” and “pleasure,” was included for comparative purpose. Furthermore, following HRS measurement, social preferences (risk attitude and time preference) and cognitive functions (simplified Mini-Mental State Examination, numeracy, and word recall of ten words following Alzheimer Disease Assessment Scale-Cognitive Japanese version) were measured during personal interviews. Social participation of community activities, social support reception and provision, and lifestyles related to smoking, drinking, and exercise habits were also measured in each wave through self-administered questionnaire. For details, questionnaire items are available at JSTAR homepages (<http://www.rieti.go.jp/en/projects/jstar/index.html>).

Wave 1 in 2007 included 4,163 individuals. Among them, 3,091 joined the wave 2 in 2009 (follow-up rate = 81%). The rest of this entry will provide statistics derived from data analysis of waves 1 and 2 in the original five cities.

Life satisfaction (4-level Likert scale, dichotomized into satisfied = 1 or not = 0) and depression (CESD > 16 points) were used as targeted outcomes reflecting psychological well-being. Hierarchical logistic regression was adopted to test several sets of variables added in the model, namely, demographic and socioeconomic conditions (model 1), health and functions (model 2), social relationship with family (model 3), and social relationship with nonfamily sources including social network participation in the community (model 4).

Results of Cross-Sectional Analysis in Wave 1

Table 1 shows the results on life satisfaction. In model 1, older age was significantly positively, and unemployment status was negatively associated with life satisfaction. These two characteristics were consistently and independently related to life satisfaction even after adding other predictors. Self-reported ill health and any limitation in Instrumental Activities of Daily Life (IADL) and Mobility were strong and consistent predictors of low life satisfaction (models 2, 3, and 4). Widowhood, and divorced status was negatively associated with life satisfaction, and social support from non-spousal family (e.g., children and other family members) was positively associated with life satisfaction, independently of socioeconomic and health conditions (models 3 and 4). Finally, social support provision from nonfamily sources (e.g., friends and neighborhood) was significantly and independently associated with life satisfaction (model 4).

Table 2 shows the cross-sectional model predicting depression in wave 1. Model 1 shows similar results with life satisfaction in that older age was negatively and unemployment status was positively associated with depression. In addition, higher household income was negatively associated with depression (model 1), though the significance was gradually attenuated after inclusion of health and social relationship (model 2–4). Ill health, functional limitations, widowhood, and divorced status were all significantly associated with depression, while social support from

non-spousal family and nonfamily sources showed a counter association with depression.

The results of cross-sectional analysis indicated that employment, health and independent functions, and social support from spouse, family, and nonfamily members were consistently associated with better life satisfaction and lower chance of psychological depression. However, the cross-sectional analysis does not tell much about causality and remains susceptible to reverse causation due to selection by mood disturbance on respondent's social behaviors and consequent health conditions. Besides, the explanatory power of the models was not so high, suggesting that unmeasured relevant confounders may still be left out of the model.

Results of Longitudinal Analysis Between Wave 1 and Wave 2

Table 3 exhibits the results of longitudinal analysis taking depression in wave 2 as an outcome, regressed on variables measured in wave 1 with adjustment for depression status as of wave 1. As similar with the results of cross-sectional analyses, higher age was negatively, and unemployment was positively associated with depression in wave 2, though they no more reached statistical significance. Instead, female gender turned to be significantly and positively associated with depression. As for ill health and functional limitations, they were associated with depression at wave 2, though only the limitation in mobility remained significant. As for social relationship, divorce status in wave 1 was significantly and positively related with depression at wave 2, and social support reception from nonfamily source at wave 1 was significantly and negatively associated with depression at wave 2. Otherwise, social support from non-spousal family and social participation did not reach statistical significance.

The results of longitudinal analyses were basically similar with those of cross-sectional analyses and implied that the loss of mobility function and social support from nonfamily sources was a robust predictor of depression. However, the model fitness was still limited (pseudo R-square = 0.1633).

We further conducted panel data analyses using conditional logistic regression with fixed-effect model so that we could better control unmeasured time-invariant confounders (data not shown in tables). However, since measurement of social support was differently conducted in wave 2, we could not include social support from family and nonfamily sources. Besides, changes in the depression status over survey waves were relatively rare, and the fixed model effectively included only a limited number of the sample, resulting in weak statistical power and poor model fitness. Provisional results indicated that change into retirement and homemaking status and limitation in IADL were significant predictors of depression. Differences between the fixed-effect model and the longitudinal logistic model may be caused by sample restriction, omitted variables (social support from family and nonfamily sources), and endogenous effect of unmeasured heterogeneity. The findings require further analyses with more numbers of waves and municipality participations, which should be available in the near future from the JSTAR project.

Discussion and Conclusion

This entry presented some evidence from JSTAR regarding risk factors of depression and impaired life satisfaction. However, the causal mechanisms of impaired psychological well-being among older Japanese are still to be specified, because psychological well-being is endogenously determined and determines the mode of social participation, lifestyle choices, and subsequent health and functional statuses.

A panel survey with comprehensive measurement, such as HRS and her sisters including JSTAR, is a powerful tool to scrutinize the complex mechanisms of the psychological well-being of older people who stand at a life stage with drastic change in their modes of social participation and health status. For example, a recent study used JSTAR panel data to identify the causal impact of retirement on psychological and cognitive functions (Hashimoto 2013).

Furthermore, comparable panel datasets are expected to provide the opportunities to test how external conditions such as household compositions and policies related to pension, retirement, and healthcare benefits affect the social relationships and behaviors of older people across countries. Indeed, Japan is unique in its generosity and relatively equal distribution of social benefit to older people through public pensions and healthcare provision with relatively low out-of-pocket contribution (Ikegami et al. 2011), which may crowd out the patterns and norms of private transaction within the family. Differences in culture and preferences regarding social integration and roles of senior citizens in the community can also be an interesting topic for comparative analyses. Recently, a researcher term in University of Southern California and RAND Corporation provided harmonization of HRS sister surveys to facilitate cross-panel analysis, of which details are available elsewhere (<http://www.g2aging.org/>).

Definition

This entry presents the first population-based study conducted in Portugal, the Oporto

Centenarian Study (PT100). It starts by providing an overview of the centenarian population in Portugal and then describes PT100's methodological approach (sampling, procedures, and measures) and synthesizes its main findings on three core dimensions considered to be determinants of quality of life in extreme old age (Serra et al. 2011): cognitive and physical functioning, social resources (social relationships and social activities), and personal attitude toward life (valuation of life). An outlook of current satellite projects of the PT100 is presented at the end.

Centenarians in Portugal

The phenomenon of longevity has been one of the most relevant achievements of the last century. A rapid increase in the size of the older population has been observed in Portugal, with the oldest old (individuals aged 80 and plus) representing 5.6% of the total population and 26.5% of the older population, i.e., of those aged 65 and over (INE 2011). Centenarians almost tripled over the last decade, from 589 centenarians in 2001 (95 men, 494 women; INE 2001) to 1526 in 2011 (273 men, 1253 women; INE 2011). For the year 2013, Statistics Portugal had projected the existence of 3393 centenarians (2440 women and 989 men in a characteristic gender imbalance among the oldest old), expecting an exponential growth of this population, which is likely to continue in the near future.

This aging scenario has raised several concerns and questions, with more pessimistic views suggesting that older populations will impose a growing burden on society. Most of these assumptions are based on the lack of information and real data on centenarians' status, their needs, and their capacities. Such information has been completely absent in a systematic and organized way for the Portuguese context (Ribeiro and Araújo 2012). In order to fill this gap and uncover the living conditions, functional, psychosocial, demographic, and clinical characteristics of these long-lived individuals, the first centenarian study was launched in 2012 in the second largest city in Portugal, after Lisbon, and one of the major urban areas in Southwestern Europe.

As the first Portuguese population-based centenarian study, the PT100 – Oporto Centenarian Study – aims to describe the characteristics of a sample of Portuguese centenarians and their overall personal characteristics and living arrangements using a multidimensional and comprehensive approach. Complementarily, it aims at contributing to the understanding of the longevity phenomenon, particularly the role of psychological and social resources, within a cross-cultural perspective. For this purpose, the study takes part of an international consortium with the Second Heidelberg Centenarian Study (Germany) and the Fordham Centenarian Study (USA) sharing similar methodological procedures.

Sampling

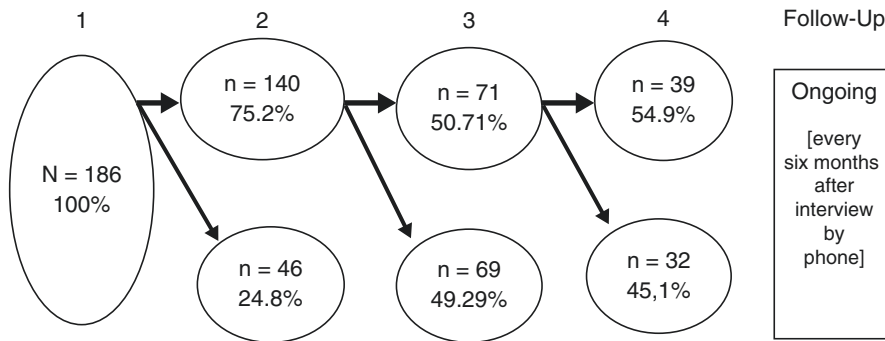

In order to obtain a representative sample of the general population, a specific geographical area was defined: approximately 60 km around Oporto, which comprised a total of 16 municipalities known as the Oporto Metropolitan Area. All inhabitants who were aged 100 years and more between December 2012 and December 2013 were identified through voter registration files after permission given by the National Commission of Data Protection. Since these files only have information on name, data of birth, and address, and a significant amount of information was outdated (i.e., many centenarians had died a long time ago), additional methods for identifying centenarians were used. Specifically, contacts with all the nursing homes listed in the Social Security Institute, parish councils, and parish churches of the Porto Metropolitan Area were made. Media announcing centenarians' birthdays were also contacted, and the project was also presented to the general public in scientific events, in the media (e.g., local newspapers), and in the web (e.g., project's site and Facebook page). In addition, during data collection, the participants who were interviewed also helped to identify centenarians or other people who knew centenarians. This snowball technique proved to be an effective complementary approach.

Altogether, recruitment procedures allowed the identification of 186 potential participants. Although all of these centenarians were contacted, only 140 were effectively face-to-face interviewed. The other 46 centenarians were excluded because they died in the interim or their relatives refused participation because of dementia, severe health problems, or lack of interest in taking part of the study.

Procedures and Measures

Information was collected during one or two sequential sessions of a structured interview protocol, directly with the centenarian and/or with proxies' respondents at their own homes, nursing homes (if institutionalized), or any other place of their convenience. Each interview session lasted on average 2 h, was conducted by two trained interviewers (psychologist and gerontologist), and was video and audio recorded. The proxies were family or friends with frequent and close contact with the centenarian. In those cases where the centenarian lived in a nursing home, complementarily information was obtained from a reference professional, often the nursing home director, who was also interviewed. Age validation was accomplished with multiple, convergent, and validated sources, such as identity card or birth certificate and crossing information on life events. An informed consent for participating in the study was obtained. This document was approved by the National Commission on Data Protection and included the authorization for taking photos and for video and audio recording the interviews.

The assessment protocol included information about the centenarians' general characteristics (e.g., sociodemographic and economic information), health (e.g., diseases, subjective health), cognition, functional capacity (e.g., daily and instrumental activities of daily living, fatigue), nutritional status and eating/drinking habits, mental health (e.g., anxiety and depression), well-being (e.g., satisfaction with life), personal resources (e.g., personality and coping strategies), social network, and support (e.g., family relations,

Oporto Centenarian Study, Fig. 1 Participation levels in the Oporto Centenarian Study

use of formal services), among several other variables. The majority of these dimensions were evaluated through the Portuguese version of well-known instruments, such as the Mini Mental State Examination (MMSE; Folstein et al. 1975), the Global Deterioration Scale (Reisberg et al. 1982), the Older Americans Resources and Services Multidimensional Functional Assessment Questionnaire (OARS, Fillenbaum and Smyer 1981), the Lubben Social Network Scale (Lubben, et al. 2006), the Valuation of Life Scale (Lawton et al. 2001), the Brief Geriatric Anxiety Inventory (Byrne and Pachana 2011), and the Geriatric Depression Scale (Yesavage et al. 1983) to name a few.

Based upon the centenarian's willingness to participate in the study and their cognitive ability to answer the assessment protocol (i.e., participants' cognitive level as assessed by the Global Deterioration Scale and the MMSE), distinct participation levels were considered (Fig. 1). By these means, from the 140 centenarians who were effectively face-to-face interviewed, almost half presented signs of having a neurocognitive disorder (49.29%); the other 50.71% had no cognitive deficits, and 39 (54.9%) were able to complete the highest participation level, i.e., to provide a fully complete assessment protocol.

Following the interest to have longitudinal information on the centenarians' health status, social/health service consumption, and death (date, location, cause), each participant is being contacted every 6 months after the interview in a follow-up basis (currently still ongoing).

Centenarians' Main Characteristics

Participants of the Oporto Centenarian Study had ages between 100 and 108, with a mean age of 101.18 (SD 1.59). The majority of the sample was female (89.3%), widowed (76.4%), and lived in the community (57.9%), as presented in Graph 1.

Regarding education and income, 45.7% of the centenarians never attended school (i.e., were illiterate) and 69.8% had a monthly income of 250–500€. Both facts are related with the Portuguese sociohistorical background (i.e., the presence of a right-wing dictatorship that lasted nearly 50 years and was characterized by a global poverty in the country and a scarce access to education) that has affected the living conditions and opportunities of the older generations.

Cognitive and Functional Status

The results of the participants' physical and cognitive deterioration are presented in Fig. 2. There is a higher concentration of centenarians on the two extremes of the Global Deterioration Scale (GDS; Reisberg et al. 1982), with 30.3% having no or very mild cognitive decline (GDS1 and GDS2), and 44.5% having severe/very severe cognitive decline (GDS 6 and GDS7). The remaining participants (25.2%) were in GDS 3–5 at the time they were evaluated.

Regarding their functional status, centenarians predictably presented greater difficulties in their instrumental activities of daily living (mean

Oporto Centenarian Study, Graph 1 Socioeconomic characteristics of PT100 participants

Oporto Centenarian Study, Fig. 2 Global deterioration scale of PT100 Participants / No cognitive decline; 2 Very mild cognitive decline; 3 Mild cognitive decline; 4 Moderate cognitive decline; 5 Moderately severe cognitive decline; 6 Severe cognitive decline; 7 Very severe cognitive decline

scores 5.58; SD = 4.49; observed range 1–14) than in their basic activities of daily living (mean scores 2.24; SD = 2.37; observed range 0–14). When analyzing the frailty phenotype in this sample, only 4% were classified as “robust,” 36% were classified as “prefrail,” and 60% as “frail” (Duarte et al. 2014).

Overall, these findings on cognition and functionality (independence) are in line with

results from other international studies on centenarians. For example, in the Tokyo Centenarian Study, 167 of 304 centenarians (55%) were classified as *frail*, exhibiting impairment of either cognitive or physical function, and 76 (25%) were classified as *fragile*, exhibiting deterioration of both physical and cognitive function (Gondo et al. 2006).

Social Networks and Loneliness

Most centenarians continue to maintain contact with other people, drawing mainly on family to have support and care. Of a subgroup of centenarians ($n = 56$) with the cognitive capacity to answer questions regarding social network and loneliness, 8.9% reported to have no regular visits and 13.6% to have no time spent in social relationships with someone they didn't live with. On the other hand, 42.9% reported at least five regular visits and 71.2% had at least two moments of social interaction in the week before the interview. As for social participation, most centenarians had stopped attending social and community activities; 79.4% had no social activity at all, 16.7% still had one activity, and 3.9% had between two and three activities, namely, volunteer work, visiting someone, or attending to church.

A substantial number of centenarians felt lonely: 54.5% of 55 centenarians reported they missed having people around them, and 61.5% (of 52) expressed feelings that they didn't see family and/or friends as frequently as they would like to. Among the oldest old, greater feelings of loneliness are often related to the lack of a spouse or partner to provide companionship and because they have health limitations that may limit their social contact. Study participants also reported that barriers resulting from the aging process contributed to the decreasing in their social participation. Also, sensory impairment (sight and/or hearing loss) was found to be a contributory factor in giving up recreational activities.

Valuation of Life

A positive mental outlook on life and aging is also an important factor for the centenarians' quality of life. The Portuguese version of the Positive Valuation of Life Scale was used as an indicator of attachment to life. The original 5-point answering format from Lawton's Positive Valuation of Life Scale (VOL, Lawton et al. 2001) was changed to three answer options: "yes," "in between," and "no," with a score range between 0 and 26 (higher scores indicate higher valuation of life and

therefore a positive personal attitude). In a subsample with sufficient cognitive capacity to answer VOL's questions ($n = 42$), the mean score of valuation of life was 14.88 (SD 5.18). When analyzing the VOL subscales (Araújo et al. 2015), centenarians present a mean of 8.54 (SD 3.35) for existential beliefs (possible score between 0 and 14) and 6.34 (SD 2.34) for personal agency (possible score between 0 and 12).

Jopp and Rott (2006) had analyzed positive valuation of life and the respective importance of self-referent beliefs and attitudes (perceived control, self-efficacy, and optimism) for centenarian's happiness and well-being and found similar results. In their study, centenarians presented high values of self-referent beliefs and attitudes, which demonstrate that these resources continue to be effective in very advanced age.

Satellite Study 1 | PT100 Beira Interior

This first satellite study from the Oporto Centenarian Study was developed between 2013 and 2014, in the inner part of the country in an area with a similar geographical extension to that of the Porto Metropolitan Area around the city of Guarda. The main objectives were to increase the available knowledge on the centenarian population in a different geographical area and living context (more rural, often isolated villages, reduced access to health services, and with overall more adverse living circumstances) from that of the Oporto study. The Beira Interior Centenarian Study used the same methodology as the PT100 main study. One hundred centenarians were interviewed.

Satellite Study 2 | Centenarians' Offspring: Intergenerational Ambivalences and Demands of Care

Due to the lack of information on the demands, challenges, and needs of these long-lived family systems, as considering the PT100 research team's experience when interviewing community-dwelling centenarians who lived with their children, a new study with centenarians'

offspring was conducted between 2014 and 2015. This second satellite study aimed to analyze the centenarians' offspring experience of caregiving and intergenerational family relations. A sample of 43 children was interviewed in depth in relation to their overall caregiving circumstances (caregiving context, costs, demands, and consequences) and to how their parent's exceptional longevity affected/affects their own aging trajectories. By means of a mixed-methods approach, information was also obtained on their valuation of life, life expectations, and attitudes toward old age. Intergenerational ambivalence was assessed by direct and indirect measures.

Satellite Study 3 | Use of Care Services in the Context of Geriatric Morbidity: A Study with Octogenarians, Nonagenarians, and Centenarians

This third satellite study emphasizes the need to timely identify the care needs of very old individuals in order to help to decrease the rate of frailty and adverse outcomes, such as institutionalization and mortality. The study is currently ongoing (2015–2018) and aims to examine care services used by the oldest old, analyzing the significance of both physical and psychosocial factors, and to examine whether certain psychosocial risks and resources are distributed differently among age groups; complementarily, a risk assessment for hospitalization, institutionalization, and death is also considered.

Conclusion

Centenarians are one of the fastest growing demographic groups of the Portuguese population. This elementary descriptive profile revealed a great heterogeneity in centenarians' cognitive and functional status, social networks and loneliness, and valuation of life, reinforcing the diversity that is to be expected when investigating the worlds of people who have lived to become the oldest old (Fry and Debats 2010; Poon and Cheung 2012).

The Oporto Centenarian Study underscores the importance of examining variation. From a theoretical perspective, the high percentages of centenarians within the high and low ends of functioning demand consider appropriate and distinct paradigms of interpretation. Successful aging and frailty paradigms coexist conceptually in the gerontological literature and are often articulated, but are opposite ends of a shared functioning continuum (Cosco et al. 2015). When studying centenarians, it is important to approach frailty domains, including exhaustion, weight loss, weakness, slowness, and low activity (Duarte et al. 2014), but also successful aging domains, including psychosocial aspects along with biomedical ones, among those centenarians who are able to maintain positive self-appraisals of their status (Araújo et al. 2016).

From a practical perspective, centenarians' health and care needs are of crucial importance and demand urgent attention. The physical and cognitive limitations so common in very advanced age call to evaluate the availability of professional services of domiciliary care provision and nursing homes, as well as to the capacity of the informal caregiving system, which have been particularly considered in the PT100 satellite studies due to its recognized public relevance. As for the social network and family relations among Portuguese centenarians, it is important to highlight that regardless of the high number of participants reporting having regular visits, most presented very low social interactions at a community level and expressed feelings of loneliness (not seeing family and/or friends as many times as they would like to). It is therefore a priority to understand the real impacts of living beyond the average of life expectancy within the social sphere and to explore what kind of strategies centenarians use to compensate the withdrawal from social roles and activities.

As in other southern European countries, in Portugal, the demographic aging of the population has increased dramatically over the last decades in a context of falling birth rates and higher average life expectancy. The oldest old population, and centenarians in particular, is becoming more common and therefore receiving greater public attention. In this context, the Oporto Centenarian Study

by assuming human longevity as a research priority plays an important role in providing information for both scientific and intervention purposes.

Oral Health in Older Adults

Rodrigo Mariño and Mike Morgan
Oral Health Cooperative Research Centre,
Melbourne Dental School, University of
Melbourne, Melbourne, VIC, Australia

Synonyms

Dental health; Mouth diseases and conditions;
dentistry; Odontology

Definitions

Oral health: “A state of being free from mouth and facial pain, oral and throat cancer, oral infection

and sores, periodontal (gum) disease, tooth decay, tooth loss, and other diseases and disorders that limit an individual's capacity in biting, chewing, smiling, speaking, and psychosocial wellbeing" (World Health Organization 2012).

Dentate: Having all or some of the natural permanent teeth.

Oral health plays an integral part in the general health of older people and should not be considered in isolation. Furthermore, oral health is a human right, an integral part of general health, and is essential for overall well-being (World Health Organization 2005). While oral health diseases are only occasionally a matter of life and death, its importance can be explained by the extent of these conditions in the society and the preventable nature of most oral health conditions and diseases. The most common threats to oral health in older adults include tooth loss, dental caries, and periodontal disease (gum disease). However, oral health is more than just having healthy teeth and gums (International Dental Federation (FDI) 2014), still, compared to dental caries, periodontal disease, and tooth loss, there is less information available on the prevalence of other oral diseases, with the probable exception of oral cancer. Clinical data demonstrates that poor oral health increases the risks to health in the same way as any disease of the body system (Kay and Locker 1998).

Similar to the rest of the body, the mouth changes with age. However, most of the changes attributed to aging actually occur due to oral diseases and conditions which may take years to develop. For example, having no teeth or teeth becoming loose is the result of the accumulation of adverse and traumatic events to the teeth and periodontium and not the direct consequence of aging. Of course, older adults have had increased exposure to those events. Furthermore, there is now increased awareness that the consequences of neglected oral hygiene are not confined to the mouth. Oral diseases and conditions can lead to systemic morbidity, increasing the risk of frailty (Kay and Locker 1998), and may precipitate or exacerbate other medical conditions, such as pneumonia, cerebrovascular and cardiovascular disease, diabetes, and nutritional deficiencies

(Cohen 2002; Australian Health Ministers' Advisory Council 2001).

Oral diseases and conditions can also cause difficulties with chewing, and swallowing, leading to impaired nutrition, and speech, which affect the way in which people look and sound, with a significant impact on self-esteem, psychological and social well-being, interpersonal relations, and quality of life (Australian Health Ministers' Advisory Council 2004). Therefore, oral health is critical to an individual's appropriate physical, emotional, and social activity and functioning.

The oral health of older people and their attendant quality of life can be improved through health promotion, self-management of prevention, and restoration by sophisticated surgical and curative techniques. In fact, evidence would suggest that new cohorts of older adults will tend to be dentate (e.g., retaining at least part of the natural dentition), even in older ages (Australian Institute of Health and Welfare 2007). Yet, for some, this trend comes too late, as they have already lost all their natural teeth.

These are important challenges to oral health providers and the wider society. Tooth retention, combined with an aging population, will undoubtedly place increased pressure on the public health system in the future (Harford 2009). However, despite the well-documented aging profile of the population and repeated calls for comprehensive geriatric assessment (Department of Human Services (Victoria) 2007), there has been little progress in addressing the oral health needs of older adults, and fewer health-care programs are specifically designed to improve their oral health. Thus, increased efforts should be directed to identifying opportunities for the development of community-based models that encourage older persons to improve and maintain their oral health as well as the economic effectiveness of these approaches (Department of Human Services (Victoria) 2007).

This chapter presents an overview of older adults' oral health. It is organized into four main sections; the first section discusses the function of the orofacial complex. The second section presents the most common oral diseases and conditions. The third part will describe some general health implications of oral health. The final section describes

areas where health providers might engage in oral health promotion and oral disease prevention with older adults. It explains the role played by health professionals in promoting oral health and the prevention of oral diseases in older adults.

Function of the Orofacial Complex

Several structures are found in the oral cavity, which have evolved to provide the individual with important physiological functions (Shay and Ship 1995). Multiple tissues have evolved to carry out the complex vital functions of the orofacial complex. Tissues and structures in the oral cavity work together to provide the individual with essential physiological functions (Shay and Ship 1995): (a) intake of food and nutrients, (b) production of speech and communication, and (c) host protection. These physiological functions are affected by conditions such as tooth loss, dental caries, periodontal disease, hyposalivation, and oral cancer.

Older adults who are edentulous, or have removable partial dentures, avoid eating certain foods such as firm meat and fresh fruits and vegetables and suffer more from problems with speech, food catching in the mouth, avoidance of smiling, and oral pain, compared to dentate older adults (Mariño et al. 2002). Also, due to retaining more of their natural teeth, the sizeable proportion of older adults in the new millennium constitute a group with diverse and complex dental needs, compared to previous older adult cohorts. Additionally, mental health and quality of life might also be affected by diminished pleasure of eating and interest in food, diminished self-esteem, and reduced enjoyment of social activities, intimacy, and companionship (Locker 1995; Mariño et al. 2008). Experiences of oral pain and problems with eating, chewing, smiling, and communication due to mouth or teeth problems tend to substantially affect well-being (Petersen and Yamamoto 2005).

Oral Disease and Conditions

The oral cavity harbors a diverse, abundant, and complex microbial ecosystem, the dental plaque

or dental biofilm, which accumulates on the hard and soft oral tissues. The dental biofilm is an important part of the natural human microflora and, if maintained in a non-pathologic state, contributes to the host defenses. When there are shifts in the balance of predominant bacterial populations, disease might occur. The two most common oral diseases (dental caries and periodontal disease), which are also the two major causes for tooth loss, are caused by this imbalance favoring pathogenic microorganisms.

Dental Caries

Dental caries is among the most common diseases in many countries. It is characterized by the decalcification and dissolution of the dental tissues (i.e., enamel and dentine), which eventually will destroy the affected tooth surface and the tooth itself. Dental caries is not just a child's disease; it can happen across all ages as long as there is a pathogenic plaque-fed fermentable diet and susceptible tooth structure. Carious lesions may begin on different parts of the tooth. Most commonly, they appear on the crown of teeth. However, older adults are at increased risk of having dental caries on the root surfaces of the teeth; these lesions are in the area of a tooth close to or below the gumline.

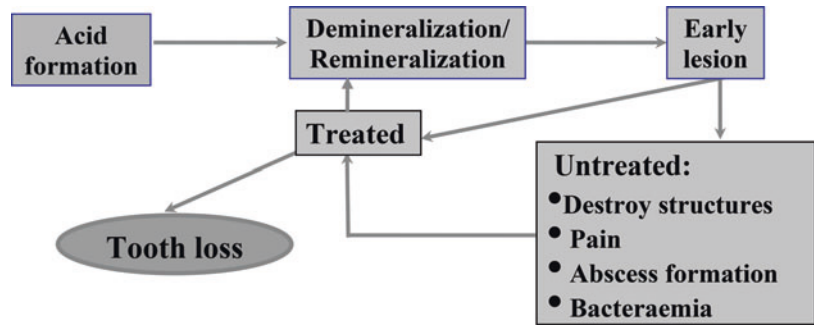

The presence of fluorides enhances remineralization of early carious lesions. Furthermore, early lesions, visible as white spots, can be remineralized and healed with the assistance of fluoride. Because older adults with natural teeth may still develop dental caries, particularly root caries, fluorides will benefit this group (see Fig. 1).

In general, drinking water and toothpastes are the most commonly used vehicles for fluorides. These vehicles, in particular water fluoridation, can reach everyone regardless of age, health status, income, ethnicity, or other sociodemographic differences. Indeed, the use of fluorides is recognized as one of the most successful measures for the prevention of disease in the history of public health (Centers for Disease Control and Prevention 1999).

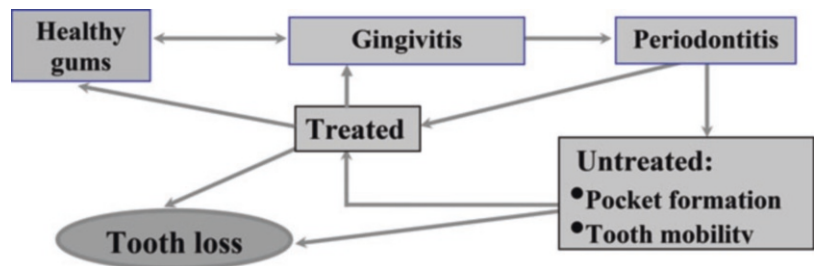

Periodontal Disease

The bacteria in biofilm can not only cause tooth decay, but also they are involved in periodontal (gum) disease. Periodontal disease is an infection

Oral Health in Older Adults, Fig. 1 Pathway of dental caries

Oral Health in Older Adults, Fig. 2 Pathway of periodontal disease and tooth loss

of the complex system that holds the teeth in place. This system includes the gums, the periodontal ligament, and the supporting bone. Periodontal health can be maintained successfully in older people with adequate oral hygiene, periodontal therapy, and maintenance.

At its early stages (gingivitis), periodontal disease is reversible and can usually be eliminated by proper daily oral hygiene care (e.g., brushing and flossing). If left untreated, the infection spreads deeply causing the gums to pull away (recede) from the teeth, and the gap between the tooth and the gums becomes deeper (pocket formation). This is due to a loss of the bone that supports the teeth. Then, gradually the tooth becomes looser and looser until it falls out or needs to be removed even though it may not be affected by dental caries. This more advanced stage of gum disease is called periodontitis (See Fig. 2).

Periodontal disease can also affect overall health. For example, there is significant evidence of the two-way link between diabetes and periodontal disease (Chapple and Genco 2013) but not well promoted. In this way, treatment of periodontal disease will help improve diabetes control (Chapple and Genco 2013). Untreated periodontal disease can also lead to other general health

problems including heart conditions and stroke (International Dental Federation (FDI) 2014).

Tooth Loss

Tooth loss is not a direct result of the aging process but is best understood as the effect of local factors acting throughout life, most of them related to social and material inequalities operating at the individual and ecological level (Bernabé and Marcenes 2011). Tooth loss could be stopped by preventing some oral diseases such as dental caries and gum disease, which are the major reasons for tooth loss (see Fig. 2).

Keeping natural teeth into old age has several advantages and some disadvantages; however, the advantages far outweigh the disadvantages. Dentures can improve oral function if one has no teeth or has lost some of one’s teeth, and it might appear that having dentures is more convenient. However, partial or complete dentures are imperfect replacements for teeth. Denture wearing has many disadvantages. Some examples of these disadvantages mentioned by participants in a study conducted in Melbourne, Australia, were difficulties when talking and social interactions, facial aesthetic and appearance, irritation to the gums, loss of self-confidence when speaking, decreased

enjoyment of food and the social enjoyment of food, difficulties in chewing and in keeping adequate nutrition, and bad breath/halitosis (Mariño et al. 2002).

Tooth mortality is an important statistic in studies of oral health status. As access to quality dental care that influences tooth retention, tooth loss could be considered as a crude estimate of access to dental care especially among older adults (Ahluwalia et al. 2010). Moreover, recent research reported number of teeth as an independent predictor of mortality among elderly populations (Österberg et al. 2008; Padilha et al. 2008). Hence, the dentate status has been commonly used as an oral health outcome to assess socioeconomic inequalities among adult populations.

Oral Mucosal Lesions

In terms of life-threatening conditions, oral mucosal lesions can be benign or malignant. Examples of benign lesions are candidiasis (angular cheilitis), denture-related conditions (stomatitis, hyperplasia), keratosis, aphthous ulcers, and traumatic ulcers. These conditions are benign but can still cause pain and can affect oral function and nutritional status. On the other hand, there are a variety of changes in the oral mucosa that might foreshadow cancer. These include white patches (leukoplakia) or red lesions (erythroplakia). Non-treated leukoplakia may turn into an invasive carcinoma, usually a squamous cell carcinoma.

In extreme cases, oral mucosal lesions may assume life-threatening proportions, such as with oral cancer. Oral cancer is one of the few life-threatening conditions in dentistry, with age among the risk factors for developing this type of cancer. Oral cancer may occur at any age but is more common over the age of 45. Oral cancer may occur in people with natural teeth or without natural teeth. Oral cancer can affect any part of the mouth, including the lip, the tongue, under the tongue, and in the internal parts of the cheeks. The most common intraoral sites for cancer are the sides of the tongue and underneath the tongue. Oral cancer frequently goes unnoticed in its early, curable stages. This is because pain is often not an early symptom. The primary causes for oral cancers are the use of tobacco, heavy alcohol use

(more than four drinks per day), combination of heavy tobacco and alcohol use, and poor diet (Petersen 2005).

Oral cancer is among the ten most common cancers in the world (International Dental Federation (FDI) 2014), but oral cancer is the most common form of cancer in India (World Cancer Research Foundation). Oral cancer is more prevalent than cancers which are heard about routinely such as leukemia, Hodgkin's disease, and cancers of the brain, bone, and ovary and melanoma of the skin (World Cancer Research Foundation 2015). Between 3% and 5% of cancer cases are oral cancers, and 2% of deaths from cancer are due to this type of cancer. There is a significant difference in the incidence of oral cancer in different regions of the world. This is due to regional differences in the prevalence of risk factors.

Xerostomia/Hyposalivation

Saliva is a fluid with multiple functions and is essential for oral health and oral function. A reduction of saliva causes dry mouth, a condition known as hyposalivation; the feeling of dry mouth is xerostomia. A dry mouth makes it hard to eat, swallow, taste, and speak. Salivary dysfunction can lead to an increased risk of dental caries and periodontal disease and eventually tooth loss, pain, decreased enjoyment of food, and decreased tolerance to prosthetic appliances and may make it harder to keep dentures clean.

Until recently, dry mouth was regarded as a normal part of aging. It is now known that healthy older adults produce as much saliva as younger adults do. Hyposalivation is more likely to be the consequence of certain diseases (Sjögren syndrome), radiation therapy, tumors and the use of medications to treat common medical problems in older adults. Hyposalivation must not be considered a trivial problem in the population. Dry mouth is common to any conditions, syndrome or chronic diseases that affect moisture-producing glands.

More than 400 medications, including medications to control hypertension, antidepressants, antihistamines, decongestants, painkillers, anti-seizure, and diuretics, may lead to salivary hypofunction. In addition, a number of over-the-counter medications (expectorants and

decongestants) can also reduce saliva flow (Walsh 2001). Thus, oral health professionals and general medical practitioners treating older adults must be aware of the xerogenic effect of medications. Some of them may be replaced by others with less xerogenic properties. Also, there is a series of measures that a person with salivary hypofunction can take (Al-Hashimi 2001). Non-pharmacological ways to reduce severity of this condition include keeping the mouth well hydrated by taking frequent sips of (fluoridated, when possible) water; pausing often to drink some water when speaking; using saliva substitutes (e.g., artificial saliva), especially during meals; avoiding alcohol and beverages with caffeine (e.g., coffee, cola drinks) and tobacco smoking to reduce their mouth-drying effects; using tooth-pastes and crèmes (such as Tooth Mousse) that help to alleviate this condition; and using mouth-washes without alcohol in them. Sugary snacks and sugar-containing chewing gums, mints, or candies to stimulate saliva flow should also be avoided. This is because the combination of lack of saliva with a sugar-rich diet increases the risk for dental caries. Instead, the use of sugar-free chewing gums, mints, or candies to stimulate saliva flow should be preferred.

Additionally, some common medication used in the treatment of chronic diseases may produce disturbances in taste (Gheezi and Ship 2000). However, any change in medications or in personal measures will only happen if health professionals are aware of this relationship and have the information to provide the correct advice to patients. Clinicians must be proactive in questioning patients about prescription and non-prescription drugs that their patients are using (Donaldson and Touger-Decker 2013). Nonetheless, despite medical practitioners being aware that some medications caused hyposalivation, it has been reported that medical practitioners identify this problem only when patients complained of xerostomia (Stacey et al. 2013). Furthermore, it was found that, even when practitioners were aware, they often gave advice that was potentially deleterious to oral health and were uncertain as to whether dry mouth would influence their prescribing (Stacey et al. 2013).

Health Implications of Oral Health

The increase of awareness of oral health as an essential part of general, and the integration of interventions for oral health in older adults into programs of general health, is being encouraged by the World Health Organization (World Health Organization 2008). Despite this, oral health is traditionally evaluated independently of other diseases and chronic conditions. This chapter has already highlighted some of the general health implications of oral diseases and conditions (e.g., diabetes, cardiovascular disease). In the same way, several general health conditions, which are more prevalent at advanced ages, interfere with care of the mouth, mastication, and use of dental prostheses; cause dry mouth and infections; and contribute to oral disease.

For example, muscular and bone conditions can cause degenerative changes in the temporomandibular joint, directly affecting the masticatory function and causing pain. Moreover, arthritis of the hand can limit mobility and the dexterity required for daily oral hygiene (i.e., to hold and use toothbrushes or to hold dental floss). When the active hand is affected by paralysis, oral hygiene practices may need to be relearned. If the paralysis affects facial muscles, it may be difficult to clean certain zones of the mouth, resulting in decay and gum disease. In addition to manual dexterity, decreased visual dexterity and difficulties of movement have a strong association with activity limitations (Chávez and Ship 2000); therefore, it impacts on obtaining the necessary clinical care, as well as for participating in health promotion activities. Diseases and conditions such as Alzheimer's disease and stroke may decrease self-care including oral health care.

Oral Health Promotion and Disease Prevention in Older Adults

As the population ages, a major challenge in the future will be to translate existing knowledge and sound experience of disease prevention and health promotion into appropriate programs. There are several ways by which health professionals might

improve the oral health of older adults, most of them related to clinical dentistry; however, goals in dentistry cannot be reached solely on the basis of providing treatment. As for any age, health promotion interventions are key to improving oral health in later life as they encourage older adults to be proactive in regard to their health.

Lifestyle modifications have been successfully implemented in the older and very old adults, provided that comorbidities are not overwhelming (Kicklighter 1991). However, although the literature includes many studies involving large samples, it does not give sufficient direction on how best to provide health promotion and disease prevention services to older adult populations (Kay and Locker 1998) and particularly rural older populations. Successful interventions include group learning sessions followed by printed material, with high participant involvement achieved when the social and learning needs of older adults are realized (Little et al. 1997). The literature also indicates that health promotion activities should include active participation by those interested in the planning, implementation, and evaluation (Mariño et al. 2004) of these activities, ensuring that they are based on the target group's own goals and needs (Dahlin-Ivanoff et al. 1998). This increases the participant's sense of program ownership, which is an important goal of health promotion.

The aim is to produce sustainable population-based interventions for older adults particularly catering to the needs of older adults. This can be achieved by creating a program together with older adults that is attractive to them rather than just helping them become users of programs designed for younger generations. However, despite the well-documented aging profile of the world population and repeated calls for comprehensive geriatric assessment, little research has focussed on the oral health needs of older adults; there are few if any health promotion programs designed to improve the oral health of these communities. Therefore, increased efforts should be directed to identifying opportunities for health promotion activities and the development of community-based models that encourage older persons to improve and maintain their oral health.

Oral Health in Older Adults, Table 1 Oral health topics covered by e-ORHIS

Oral health and aging: what to expect
Dental caries
Periodontal disease
Oral cancer
What to do with remaining teeth
Care of dentures
Dry mouth (xerostomia)
Oral health and nutrition
Use of oral health-care services
Oral health and general health

Ignoring opportunities for these activities may increase inequalities in oral health and may lead to even greater demands for curative and oral rehabilitative services in these groups.

The Melbourne Dental School, University of Melbourne, Australia, designed a study to evaluate the impact of a web-based oral health promotion program aimed at improving the oral health knowledge, attitudes, practices, and self-efficacy of independent-living older adults living in Melbourne, Australia (Mariño et al. 2016). The education program was supported by adapting for the web materials which had been developed and tested under the Oral Health Information Seminars (ORHIS) program (Mariño et al. 2013, 2016). In order to develop an e-learning environment for health promotion, the oral health intervention program, "e-ORHIS," harnessed user-friendly multimedia web technologies, to meet the oral health information needs of older adults. Oral health topics covered by e-ORHIS are presented in Table 1.

The e-ORHIS were delivered in libraries/community centers, facilitated by trained peer educators, who introduced participants to the online multimedia resources and invited them to engage actively with and contribute to these resources, both as a group and individually.

The impact of the e-ORHIS represents an extremely helpful policy approach for the design of oral health interventions. The approach was successful and largely acceptable to the participating communities and certainly sustainable with minimal external input. In the long term, this

approach represents a promising intervention aimed at increasing participants' control over their oral health and ensuring a reduction in severe oral health treatments and teeth mortality, which in turn would ensure better quality of life.

Use of Oral Health Services

Access to oral health services is critical, as it not only provides opportunities for early diagnosis, and treatment of diseases and conditions, but is also beneficial for maintenance of good oral health, health promotion, and educational awareness (Dolan et al. 1998). However, it has been demonstrated that the use of dental health services tends to decrease after retirement (Australian Institute of Health and Welfare DSRU 2001). A parallel decline in oral health status in older adult populations has also been identified (Australian Institute of Health and Welfare DSRU 2001). This may be indicative of different attitudes to concepts of health but is more likely to be due to the relative lack of access to dental care services for this population group. On the other hand, older adults are much more likely to be examined by general practitioner than dentists (Gift and Newman 1993).

Unique geography, demographics, politics, and health-care system contribute to significant inequity in access to oral health care. For example, older people living in rural and remote areas use dental services on an ad hoc basis, mostly for relief of pain (Brennan et al. 1998), with dental care received less preventive in nature and more teeth replaced by dentures, when compared to their metropolitan counterpart (Brennan et al. 1998).

Further, oral health services may not have been accessed for many reasons. Increasing the use of services will require additional efforts beyond the reduction of financial barriers. Access to oral health services among older adults is affected by many deeply entrenched sociodemographic, financial, psychosocial, and structural barriers, as well as other predisposing and enabling factors. A better understanding of factors related to oral health of older adults will need to be met with different health strategies including primary, secondary (early diagnosis and early treatment of oral

diseases and conditions), and tertiary (rehabilitation and replacement of lost dentition) prevention.

Conclusion

There is much more that needs to be understood and achieved to improve oral health in older adults, such as training and management of human resources for health. Very often the solutions depend on the collaboration of a wide range of stakeholders, such as those who train health workers, those who employ them, and those who pay for their services. The contention throughout this chapter is that oral health is part of health, and there is no health without good oral health.

Given that the proportion of dentate older adults will increase in the future, improving health professional's awareness of the prevalence of conditions and their pharmacology that may affect health and oral health becomes even more relevant. On the other hand, oral health professionals need to continue communicating the oral health preventive message and educating the public about the risks of tobacco and alcohol use or unhealthy diet, diabetes control, and blood pressure, as well as to promote healthy environments. Oral health professionals also need to be aware of, and be able to identify, risk factors for chronic diseases and verify whether patients are obtaining appropriate medication.

This situation will bring about important challenges to health-care providers. To address this challenge, health professionals will play a dual role: first as part of the health team and second as patients' advocates to put in place comprehensive policies to improve oral health and through treatment of today's older adults and to promote healthy lifestyles and healthy aging for future cohorts of older adults. Oral health programs, and oral health preventive programs, in particular, do not receive the same level of attention as medical care among policymakers. The public, policymakers, and providers may consider oral health and the need for care to be less important than other health needs.

To reach an increased number of older adults, there is a need for collaboration among the team of health professionals working with older adult patients but also with caregivers and family members, older adult organizations, and the older adults themselves. Working together will contribute to improving the oral health outcome and therefore the overall health and quality of life. For this purpose, the health-care team should be aware of this link and its extent in the community that they serve.

Oral health programs are essential for countries' ability to maximize the impact of the health sector in reaching national health objectives and/or priorities and to meet health and social challenges. It is hoped that the information from this chapter serves as an incentive to further discuss the role of oral health-care programs and in particular in reaching oral health objectives.

Organizational Climates and Age

Age configurations; Age structures; Organizational age processes and outcomes

Definition

To discuss and describe organizational climates, they have to be conceptually distinguished from the related construct of organizational cultures. In multiple disciplines, such as anthropology, sociology, and psychology, there are many definitions of the term culture (Baldwin et al. 2006). In the field of organizational behavior research, organizational culture is most commonly defined as a deep underlying system of shared meaning, i.e., collective patterns of cognition and behavior, held by the organization's members, which

distinguishes the organization from other organizations (Schein 1990). An organizational culture is a stable property of an organization. It defines the inherent rules and thus favored and rewarded behaviors within an organization and therefore provides employees with a framework and guidance.

Closely related to organizational culture is the construct of organizational climate, which depicts organizational members' shared perceptions about their organization's rather observable aspects, such as the work environment, organizational practices, and processes (Schneider et al. 2011). In contrast to organizational culture, organizational climates describe rather apparent and temporary organizational artifacts of underlying values and can thus be more consciously perceived by organizational members as well as controlled, e.g., by human resource practices. With the rise of an older and thus more age-diverse workforce, employees' perceptions about an organization's treatment of different age groups become more significant. Consequently, employees are likely to identify an age-diversity climate, i.e., the shared perception about the extent to which an organization implicitly and explicitly, e.g., through its policies, practices, and procedures, fosters and encourages age diversity and eliminates age-based discrimination (Boehm and Kunze 2015; Gelfand et al. 2005). If employees perceive their organization's actions and procedures to be unfair toward specific age groups – including older as well as younger age groups – a negative age-discrimination climate can arise (Kunze et al. 2011).

In the following sections, the underlying processes will be explained that are induced by an increasing workforce and its effects on organizational climate will be presented. Furthermore, this chapter presents recent empirical findings of the antecedents and outcomes of different age-related climates will be presented and points actions organizations can initiate to benefit from an age-diverse workforce will be pointed out.

Age in Organizations

The main source for the evolvement of age-related climates in organizations is the ongoing

demographic change in almost all Western-industrialized countries (OECD 2006). Longer life expectancies and decreasing birth rates do not only result in changing and shrinking overall population figures but also impact the workforces' compositions in many countries. Based on these developments, organizations have to deal with two main consequences: a rising age diversity and average age of their employees. From research on different levels of analyses, it is known that the individual age of employees is mostly unrelated to individual work performance (Ng and Feldman 2008), and team-based age diversity has only a slightly negative relationship to team performance (Joshi and Roh 2009; see Boehm and Kunze 2015 for a recent review of the research field). The conceptual knowledge that exists of age diversity as well as mean age and related climates on the organizational level of analysis will be summarized in the following sections.

Organizational-Level Age Diversity and Organizational Climates

Research on organizational-level age diversity has been done from two perspectives so far: an economic and an organizational behavior perspective. While the economic perspective (e.g., Grund and Westergaard-Nielsen 2008; Ilmakunnas and Ilmakunnas 2011) has used large-scale secondary data to test the relationships between distal measures of age-diversity structures of the workforces and organizational performance, organizational behavior researchers (e.g., Kunze et al. 2011) have moreover considered processes and/or context conditions, such as organizational climates that explain the link between age diversity and organizational performance. As the focus of this entry is on these inner-organizational age-based processes, the following sections it will focus on the organizational behavior findings in the following.

In line with the age-diversity findings from the team level of analysis, also the two recent organizational-level studies report negative relations between age diversity and organizational performance (Kunze et al. 2011, 2013). Both studies conceptualize a mediation model in which age

diversity leads to a shared perception of a negative age-discrimination climate, defined as a shared perception of an unfair and discriminatory treatment based on age subgroup membership (i.e., being a young or older employee), which in turn negatively impacts organizational performance. The argumentation for a positive relationship between age diversity and a negative age-discrimination climate is based on two main theoretical rationales. First, social identity and social categorization arguments (Turner 1987) might help to explain age-diversity processes on the organizational level of analysis. Based on these classical and well-validated theories from social psychology, individuals perceive and categorize themselves as well as others into social entities (subgroups) that are characterized by at least one common attribute (e.g., age). Due to its immediate visibility and high salience for many organizational processes and decisions, demographic attributes (e.g., gender, age, ethnicity) are often used for these categorization processes. As the amount of older workers within organizations increases and employees vary across different ages and generations, age becomes an especially salient attribute for employees for within-organization differentiation. In contrast, in an organization where all employees are more or less the same age, other attributes such as gender or nationality are more likely to be relevant to categorize oneself and others according to social groups. Additionally, age subgrouping processes are also spurred by the similarity-attraction paradigm (Byrne 1971) which states that individuals are most attracted by similar others. This seems to be especially relevant for age, as individuals who are alike in regard to chronological age share comparable experience from critical and historical events in their childhood and youth and thus developed like values and attitudes. In addition, same-aged employees often encounter similar life stages (e.g., having little children or being close to retirement). The resulting congruence of experience, values, and attitudes leads to higher liking, communication, and cooperation within age subgroups compared to between subgroup relations. Ultimately these mechanisms lead to a fragmented workforce, as same-aged employees across the

organization are likely to group together and enhance their own group identity by undermining other age groups. As a result, stereotypes and discriminatory behavior against dissimilar-aged workers can evolve throughout the organization which leads to a constant perception of age-based discrimination (Kunze et al. 2011, 2013). Older employees may, for example, perceive their younger supervisor's task assignments and performance ratings to be age discriminatory toward older subordinates. Additionally, younger members of the organization may evaluate human resource policies and promotional opportunities to be age discriminatory as certain career stages are required to be fulfilled with a minimum chronological age or as seniors might prefer their own age group in regard to promotions and resource allocation. If such individual experience with the organization consists over time, the individual employee forms a general perception about the organization as a whole (i.e., an age-discrimination climate).

A second conceptual argument for the evolution of a negative age-discrimination climate in age-diverse companies can be made based on the concept of organizational timetables (Lawrence 1988). This concept suggests that in all organizations, implicit norms exist, when an employee should reach a certain career. For example, to get in a first leadership role, an employee often has to reach his 30th birthday, and to become a member of the executive board, an employee has to be at least 45 years old. Increasing age diversity can be assumed to be a potential source of violation of these organizational career timetables for both younger and older employees. Older employees might, for example, perceive it as clear violation of organizational career norms if they have a younger supervisor, as classical status and hierarchy norms suggest that more experienced and older employees always possess the leading position. In contrast, younger employees might perceive a violation of age-based career norms, if usual career paths are blocked by seniors, who stay longer in the workforce due to the limited early retirement possibilities. As a result employees form the perception that promotion decisions are not based on merit and performance,

but rather on seniority-based status norms. Again, such experience can manifest in general perceptions about the organization and can spread throughout the organization, resulting in a negative age-discrimination climate, which in the end negatively affects organizational performance (Kunze et al. 2011, 2013).

What Companies Can Do to Prevent Negative Age-Diversity Climates in Organizations

Fortunately for practitioners and executives in organizations, the negative linkage between age diversity and organizational performance, through an involvement of a negative age-discrimination climate, does not necessarily happen in all organizations. In fact Kunze and colleagues (2013) have identified two contextual factors that can at least help to prevent negative consequences of age diversity for organizational climates and performance outcomes. The first tested context factor are the so-called diversity-friendly HR policies that focus on actively managing diversity and promoting diversity as an eligible organizational asset and value (Triana and García 2009), e.g., by offering trainings and leadership development programs for all age groups, fostering awareness for diversity management on executive levels. It is crucial that organizations not only adopt single HR practices aiming for a positive age-diversity climate but a bundle of aligned practices that foster all employees' (regardless of their age) skills, knowledge, motivation, effort, and opportunities to contribute to the organizational goals. This might imply age-neutral recruiting strategies as well as equal opportunities for training, promotion, and participation for all age groups – including younger as well as older workers. Such HR policies lead to employees' perception that the organization supports their employees regardless of age or other demographic attributes and that discriminatory behavior is not desired. Thus, employees are more likely to behave in line with the company's goal to foster age inclusion, which reduces the likelihood of

age-based discrimination and group formation within the organization. A second factor Kunze and colleagues (2013) identified is the role of top management's attitudes to be crucial for the involvement of an age-discrimination climate in organizations. They report that a positive relationship between age diversity and an organizational age-discrimination climate can only be found if the top managers have negative age stereotypes, whereas an absence of such stereotypes brings also the relation between age diversity and an organizational age-discrimination climate to zero. As explanation they theorize that the top executives have a focal role-modeling position to label age-discriminatory behavior as an acceptable or non-acceptable behavior in organizations. Therefore top managers should be sensitized through trainings, seminars, and coaching for their own age stereotypes and their potential impact on organizational processes.

Yet these currently validated context factors can only help to prevent negative consequences from age diversity on organizational climates and performance. In particular from a practitioner perspective, it is relevant to gain knowledge on context factors that might even turn the relationship between age diversity and an organizational age-discrimination climate into something positive to reap the benefits of age diversity. One promising factor for such a reversal of the current age-diversity effects is a positive age-diversity climate, as introduced and validated by Boehm and colleagues (Boehm et al. 2014). Defined as "organizational members' shared perceptions of the fair and nondiscriminatory treatment of employees of all age groups with regard to all relevant organizational practices, policies, procedures, and rewards" (Boehm et al. 2014, p. 671), such a climate has been shown to relate positively to collectively perceived social exchange relationships with an organization, which in turn affect company performance and collective turnover behavior (Boehm et al. 2014). Additionally from an antecedent perspective, age-inclusive human resource practices (i.e., all HR practices that create an age-inclusive workforce) were reported to shape the pro-age-diversity perceptions within

organizations. It can be speculated that in organizations with an age-diverse workforce, such a pro age-diversity climate can be particularly useful to create a workplace in which employees from multiple age groups do not form age-based subgroups to increase mutual age-based discrimination, but rather combine their joint experience and knowledge for the joint benefit of the organization.

The Emerging Role of Subjective Age for Organizations

The second trend that has been identified in the introduction is the rising mean age and its relation to organizational climates and outcome. Compared to age diversity even fewer research exists on the organizational level of analysis. Again some economists have considered and tested direct linkages between mean age and organizational performance (e.g., Backes-Gellner and Veen 2013), but almost no study has researched the evolvement of organizational climates based on the average age of the workforce. However, recent research has shown that not the chronological mean age of the employees but subjectively perceived age identities (i.e., how old the employees perceive to be) shape the collective behaviors and processes in organizations (Kunze et al. 2015). In a large-scale multicompany sample, the authors are able to show that what they label as relative subjective age (i.e., how on average the employees perceive their age in comparison to their chronological age) is the focal predictor of company performance, whereas the chronological age per se does not show any statistically relevant interrelation with organizational performance. These findings are in particular relevant from a practical perspective. While currently many organizations are focused on the chronological age structure of their workforces and can only react on their drastic transformation (i.e., a steady rise of the average ages), the subjective age identities of their employees are something that they can actively influence. For example, the study by Kunze and colleagues (2015) identified the average perception of whether the organizational members perceived

their job as meaningful and purposeful as a statistical relevant antecedent of the average relative subjective age in organizations (i.e., employees felt on average younger, when they perceived to have a meaningful job). Beyond meaningfulness, numerous factors, including the pro age-diversity climate and human resource management practices discussed above, might also function as factors that create an organizational environment for a lower relative subjective age in organizations. In consequence the research on subjective age identities in organizations is a very promising future avenue for research on aging in organizations.

Organizational Strategies for Attracting, Utilizing, and Retaining Older Workers

Matt Flynn

Centre for Research into the Older Workforce (CROW), Newcastle University, Newcastle upon Tyne, UK

Synonyms

Ageing workforces; Age management; Age diversity; Generations

When discussing challenges and opportunities relating to an older workforce, many terms are used which, strictly speaking, are not synonyms, but are often used interchangeably.

Aging workforces shift the focus of human resource management (HRM) toward a recognition that, owing to increased longevity, declining birth rates, and extended educational careers which are delaying the entry of young people into the labor market, the balance between older and younger people in the workforce is shifting in the formers' direction. This fact increases the imperative on employers to have HR policies in place to manage retirement of staff so as to retain skills and experience.

Age management, *age diversity*, and *age inclusivity* are all terms which concern effective strategies for managing workers of different ages – not just older ones. Age management focuses on workforce planning and, from an HRM perspective, can be somewhat directional: having HR policies and processes in place to mitigate negative consequences of ageing (e.g., reduced physical capacity) while maximizing the positive aspects (e.g., experience and tacit knowledge). One of the most notable examples is BMW's redesign of its factories to ensure that they are fit for design for ageing car workers (Loch et al. 2010). *Age inclusivity and diversity* both focus on the barrier which older and younger workers face in finding, maintaining, and

excelling in work. Such barriers may be formal (e.g., mandatory retirement ages or last in/first out redundancy arrangements) or informal (e.g., ageism and stereotypes) (Bytheway and Johnson 1990). While age diversity focuses on the value of a multiaged workforce, age inclusivity concerns how to make use of such a range of talents, for example, by developing age-mixed work teams, mentoring (whereby a more experienced worker supports the development of a newer member of staff), or reverse mentoring (where a younger employee supports an older one in embracing new technology).

Finally, the concept of *generations* may sometimes be used as a signal for age. The premise of generation is that people who were born within a certain time period (and therefore go through different life stages like education, marriage, first job, etc. simultaneously) share orientations and perspectives with regard to work, family, and community (Parry and Urwin 2009). There are certainly events which shape people's perspectives, and this kind of an impact can show patterns within an age cohort. Many Europeans and Americans born in the 1920s would have seen the start of their careers delayed by the Second World War, while those born in the 1970s will have been entering the labor market just as the personal computer was being introduced. Such major events can affect how our lives and careers unfold and shape our perspectives. However, three notes of caution should be made: first, while generations may be an important cohort signifier, there are many others such as gender, race, nationality, and social class that are equally important in influencing how we work and what opportunities are available to us. Social media may be an important way in which "Generation Y" communicate, but over a quarter of young Europeans lack access to the daily use of the Internet. Second, life course may take multiple trajectories, so it is not necessarily true that people pass through life stages at the same time. Many people have more than one marriage or partnership throughout their lifetimes, raise children at the same time as caring for grandchildren, and make a midlife transition from one career to another. It is therefore difficult to identify patterns in how people of the same

generation experience life events. Finally, it is important when identifying shared characteristics of people within a similar generation not to use terms which are a signal for ageism. Attributing an aversion to new technology among baby boomers is not too different from characterizing older people as reluctant to adapt. Both can be exclusionary, inhibiting people in their 50s and 60s from making use of new work opportunities.

Definition

Managing an older workforce concerns HRM policies and processes for attracting, retaining, and making best use of older workers. Such interventions overlap those focused on work-life balance (e.g., phased retirement to enable older people to combine work with retirement activities), lifelong learning, diversity and inclusion, and talent management. While the immediate focus of employers who are concerned with ageing workforces is how to manage the transition from work to retirement, a growing network of academics and practitioners are more concerned with how employers can maximize the use of talents and experiences of older people and finding ways to make late career work fulfilling and something which older people value.

What HRM Policies Can Enable Employers to Make Better Use of Their Older Workers' Skills and Talents?

HR policies and practices to support age diversity can be broadly categorized into the following areas, taking definition according to Eurofound (Naeyele and Walker 2006), the ILO (2009), and the United Nations (2006), as well as age diversity good practice guides which have been distributed by governments (DWP 2013) and stakeholder organizations such as employer groups, trade unions, and age advocacy groups:

- *Flexible working hours*: the opportunity to adjust working hours in order to improve work/life balance, accommodate

caring responsibilities, or participate in voluntary work or other retirement activities. This is the most common form of workplace adjustment. In the UK, a third of people 50 and over work part-time, a figure which doubles after the age of 65. Ninety percent of employers report offering at least one form of flexible working to employees (CIPD 2005). Several EU countries offer older employees the right to flexible working as they approach retirement. In some countries like the UK, the USA, and Japan, people who work past retirement age can reduce working hours while topping up their pay with pension entitlements (OECD 2011).

- *Lifelong learning*: the opportunity to improve one's skills through training, especially employer-sponsored workplace training. One way in which generational differences may play out is in terms of access to education. Older workers are less likely than younger ones to have received formal qualifications through higher education, although in the West, this difference is reducing as baby boomers who have benefited from expansion of education become older workers. Employers believe that older workers are reluctant to train in order to keep their skills up to date. On average, older workers are less likely than younger ones to take part in training, partly though not exclusively because they are also less likely to be offered learning opportunities by their employers. Older workers usually feel that their skills are sufficient for their jobs and find ways to compensate for skill deficiencies. Training programs are usually not designed with an eye toward older people who are looking for shorter programs which build on the skills and experience which they already have (McNair 2010).
- *Job rotation*: the opportunity to adjust job content through promotion, lateral transfer, or winding down toward retirement. This can also include measures such as experienced workers engaging in skill transfer, for example, by mentoring younger workers. Changing work content is rarer than changing working hours by older people. Part of the reason is because employers tend to

channel development opportunities to younger employees. However, older workers are also often reluctant to seek a job change even when they are eager for a new challenge. Moving from a secured job which one is good (or at least adequate) at to a new job in which your abilities are unknown is a risk which older workers are rarely willing to take close to retirement. As noted below, older job seekers are out of work on average longer than younger ones, and job security is a priority.

- *Healthy working*: interventions to improve health and well-being and to address physical and mental health risks associated with work. There has been growing attention to how employers can adapt workplaces to manage changes in physical capacity with age. For example, Finland has seen a doubling of its 60–64 year-old worker participation rate in part because of a comprehensive program of health interventions organized by the Institute of Occupational Health known as the Work Ability Index (Ilmarinen 2007). The program involves periodic checks throughout the life course to identify risk factors which could lead to early exit. It is important, however, to remember that while age-related changes to physical capacity are universal, it is not uniform. Many 60-year-olds can do the work of people decades younger than them. Further, evidence shows that mental capabilities to manage work do not reduce, at least up until 65 (there have been few studies beyond 65) (Meadows 2004). While the speed of mental processes may decline with age, older people are able to compensate with experience and crystallized intelligence (Warr 1995).

Why Is the Older Workforce an Issue and Who Is It Affecting?

Populations are ageing around the world. In fact, the United Nations World Population Ageing report suggests that populations are becoming older in all but 18 countries (mostly in sub-Saharan Africa). Demographic change is having different implications across nations.

Europe and North America have passed through the “demographic window” in the latter half of the twentieth century, a period in which government, employers, and unions used early retirement as a way to manage job attrition resulting from organizational and labor market restructuring. The demographic window is defined as the time period in which a society’s working age population is growing as a proportion of the overall society. In agrarian-based economies, families are often large so that manual work can be distributed among a large number of children, and parents can depend on their children to care for them as they age. The nonworking age population dominates because children outnumber adults even though the number of older people is low. As the economy shifts from agrarian to manufacturing to service and high technology, families become and the working age population grows as a proportion of the overall population. As society becomes healthier and people live longer, the proportion of the population above retirement age (and thus nonworking) then begins to grow. The demographic window is the “once in a lifetime” opportunity in which labor supply is maximized and government, employers, and other stakeholders can prepare for ageing populations.) This has been called a “collusion towards early retirement” (Ebbinghaus 2001) since, in the short term, encouraging older workers to bring forward their retirements in order to make way for younger ones was seen as an easy way to manage industrial and workplace change. In reality, there is a wealth of evidence to suggest that shrinking the older workforce exacerbates youth unemployment because economies need full employment in order to grow. For Western economies, the focus at both the public policy and organizational levels has been reversing the collusion toward early retirement to one which promotes active ageing and longer periods of economic activity (Muller-Camen et al. 2011). This is done through policy instruments which could be described as sticks (raising pension ages, closing off early retirement routes) as well as carrots (improving opportunities for older workers to pursue fulfilling careers). While Western economies are having to retrofit economies designed for lower retirement ages but not

having to provide for ageing populations, they are doing so with well-developed welfare states and employment regulatory systems.

Middle-income and less-developed welfare states are younger than Western economies, with most not yet reaching, or still passing through, the demographic window. For some, ageing is imminent. China, for example, will pass through its demographic window in 2016. While these economies can focus on older workforce policies before their working age populations start to proportionally shrink (and they can learn lessons from the experiences of old societies), almost all of them are still in the process of developing their welfare states to ensure that the elderly are cared for, and there is a heavy reliance on the family, including older people still in work, to care for those in need. Even in the well economically developed Tiger economies, welfare states are in the process of shifting from favoring social provision to some groups toward more universal models. As a consequence, most developing economies are having to prepare for ageing populations while at the same time expanding social welfare provision – a scenario akin to running up and down the escalator.

Are All Older Workers the Same?

Not at all. While ageing populations are a global phenomenon, the older workforce is heterogeneous. As people age and follow different trajectories, their experiences as well as perspectives diverge. Approaches to managing older workers need to take into account the diversity of the older population. Three examples can demonstrate this diversity, although many others also exist:

- Social class, education, and income: These three factors correlate highly, with those at the higher end of all three spectra having more opportunities both in work and retirement (McNair et al. 2004). They are more likely to have sufficient pensions and savings to retire at a date of their choosing. Those who “live to work” also have more opportunities to tailor their work arrangements to fit in with

their lifestyles. Because they depend on it as a larger proportion of their retirement income, low-income older workers are harder hit by changes to state pensions such as a rise in the age at which people can draw a full pension. They are also more likely to be in physically and mentally demanding jobs ill-suited to longer working lives (Lain 2012).

- **Gender:** Workforce participation trends of older men and women have taken divergent paths in the West. For men in their 50s and 60s, participation declined in the 1970s and 1980s as a shift from manufacturing to service-based economies shrank the availability of low-skill-/high-paid blue collar work, and both the state and employers encouraged early exit with financial incentives. Now that the number of white-collar older male workers is rising, participation rates are also going up (Hirsch 2003).

Older women's participation rates start from a lower rate but have not gone through the dip as experienced by men in the third quarter of the twentieth century. Older women's participation rates have risen not only because of changes in family structures (i.e., a rise in the number of two-earner families) but also an increase in the number of flexible but precarious work which tends to be female dominated like social care (Arthur and Rousseau 2001). Many older women also find themselves having to delay retirement because of changes to family circumstances like divorce or widowhood, and welfare states are still in the process of catching up to changes in family structure (Cohen 2013). For example, the US Social Security system still does not credit years of full-time caring responsibilities toward state pension provision.

- **Self-employment:** Self-employed people in most countries retire later than those who work for an employer. There are both intrinsic and extrinsic reasons why this may be the case. Intrinsically, self-employed people may have more of their identities and value invested in their businesses and be reluctant to give up an important aspect of their lives. Extrinsically, the self-employed are less likely to have access to occupational pensions than the employed

and therefore may not be able to afford to retire. It can also be a challenge for the self-employed who want to retire to find a buyer to whom to sell their business (Platman 2003). Correspondingly, economic migrants often find themselves in self-employment not necessarily through choice but because language, skills, and documentation status close off opportunities for them, and "neighborhood enclaves" are the only opportunities for work (Rhee et al. 2013). As they age, precarious work histories, as well as limited savings and pension contributions, make them particularly vulnerable to poverty in retirement.

- **Unemployment:** Finally, and perhaps most importantly, it is important to remember that the experiences of those who are seeking work can be harsher than both younger job seekers and older workers who are seeking to extend working life (Ball 2010). In the UK, 43.8% of job seekers over 50 have been out of work for over a year (by comparison 26.2% of job seekers under 30 in the same circumstance). Ageism is a significant barrier facing older job seekers with employers seeing them as more expensive, less willing to adapt, and more difficult to manage than younger ones. Employers also often assume that an older job applicant will be dissatisfied with a job, especially if it is entry level or requires being managed by a younger person. This perception is usually false, as people making a mid to late career change are likely to stay longer with their new employers than a younger person would. Ageism affects people in work as well as jobseekers. However, older workers who are in work usually know their managers well, and their managers know their skills, abilities, and career ambitions. They are therefore able to overcome some of the ageist perceptions which create barriers to work. It is also important to remember that there are relatively few formal state and employer initiatives to help older job seekers find and sustain work. A recent innovation however is Barclaycard which is seeking to attract mid-career job changers by offering apprenticeships for older job seekers.

What Is Driving Businesses to Adapt to Aging Workforces?

Just as there is diversity within the older workforce, there are also different drivers for employers to adopt HRM policies and practices. What constitutes good practice for one organization might be ill-suited for another. Governments as well as business groups have presented age exemplars – organizations which have developed innovative approaches to managing age. For example, the UK DIY retail chain has had an HR strategy since 2004 of recruiting at least 60% of their shop floor staff among older people (Duncan 2003). The policy has earned the company recognition for providing job opportunities for the older unemployed, particularly former tradespeople who have been forced out of work for health reasons. There are tangible business reasons for the company's recruitment policy: retail firms in the UK face high turnover but can offer flexible work arrangements which suit people who are close to or at retirement age. Many other retailers offer "snowbird leave" for people who want to work part-year in order to be able to afford extended vacations the other part. The UK supermarket chain has a program for offering both training and a guaranteed job interview to long-term unemployed people when they open new stores in regeneration areas. Shops benefit from having local people within their workforces which can attract neighbors to shop in the locality (Flynn et al. 2013).

Some employers are driven to adapt workplace HRM practices by the fact that their own workforces are currently older, and large groups of workers are scheduled to retire at the same time. This was one of the most significant drivers for a landmark collective agreement on age in the German steel sector (Dribbusch 1996) which included healthy living programs, ergonomic redesign, and a demographic fund to support retraining. Similarly, the UK telecoms company BT introduced several phased retirement options for the large cohort of pre-privatization employees who are scheduled for retirement (McNair and Flynn 2005).

Many organizations find synergy between the desires which older workers have with regard to work and retirement and business demands. BAE Systems, for example, introduced a phased retirement option for engineers and factory workers in 1990 (Flynn 2014). The option was originally part of a negotiated arrangement to changes in the pension system, but offering flexibility in how and when older workers retire turned out to be an effective management tool for the firm to manage peaks and troughs in labor demand.

Finally, it is worth noting that small- and medium-sized businesses can benefit in managing age in ways different from large organizations even though most good practice guides are targeted to the latter. SME's tend to be at a disadvantage against large businesses when recruiting younger talent. Younger people are looking for opportunities for promotion and career development opportunities. SME's need employees who are flexible "all rounders" who have the skills to do more than one job. While university leavers tend to be specialized, older workers have a wealth of experience to enable them to perform multiple tasks (Flynn 2015).

Conclusion

Managing age and work is a challenge facing employers not only in Europe and the USA but also worldwide. Extending opportunities not just for work but for fulfilling work is an essential part of ensuring sustainable retirement regimes as older populations grow. However, extended working life is not just a challenge but also an opportunity for both employers and older workers themselves. Adjustments, often modest, to how older workers work can enable both to make better use of skills and experience longer.

Organizational Wisdom and Aging

Bernard McKenna

The University of Queensland, Brisbane, QLD, Australia

Synonyms

Phronēsis; Prudence

Definition

The capacity developed from knowledge, life experience, reflection and emotional regulation, and empathy to make sound judgments that produce virtuous and efficacious outcomes.

The paradox inherent in organizational wisdom and aging is that while wisdom is widely considered to come with aging, aging members of an organization are often under pressure to leave.

Nonetheless, with an aging population and workforce, more positive attitudes are beginning to emerge. In the organizational and management literature, the notion of wisdom is slowly working its way into theory but is more prominent in leadership theory. Compared with the rapid advances in wisdom and life-span psychological development (Baltes et al. 2002), research into wisdom in an organizational context is relatively immature and theoretical rather than empirically based. Wisdom and aging in organizations is considered from two perspectives: individual and organizational. At the individual level, people can have degrees of personal wisdom (PW), self-related wisdom in which a person shows insight into their own life, and general wisdom (GW), which shows insight into wider aspects of life. Importantly, GW and PW are substantially correlated (Mickler and Staudinger 2008). At the organizational level, members' wisdom will influence the organizational climate, the aggregated perceptions of how the work environment is perceived to impact on individual well-being, and organizational culture, the normative beliefs, and shared behavioral expectations, or system norms, in an organization.

Key Principles

An important distinction needs to be drawn between the objective notion of getting older as a chronological accumulation of years and aging within a particular social context. Clearly, as one enters the third (young-old) and fourth (old-old) age, many physiological and psychological variables deprecate such that at a certain point, usually the fourth age, people become increasingly dependent on others and lose their independence. When considering the role of older people in organizations, cultural differences need to be considered. In general terms, it might be said that many Western cultures have a more negative orientation to older people than do Eastern cultures. This orientation is manifest in the widespread cultural beliefs about older people, particularly in terms of respect for older people and acknowledgment of their past and present contributions to family

and society. The cultural orientation is also determined by the degree to which utilitarian and economic factors are considered salient, which can be a negative factor in Western organizations.

Although wisdom is an elusive concept to describe, and even more difficult to measure, a consensus is emerging. At the core of wisdom is virtue if one adopts the Aristotelian approach. Central to this is the teleological goal of *eudaimonia* or "human flourishing." Attaining *eudaimonia* requires the proper use of certain intellectual, esthetic, and moral virtues that is driven by a deep humanity. According to Aristotle, applying virtue, intelligence, and reason to life's problems enhances the person and the lives of those around them. Psychological evidence shows that "there is a kind of deep and enduring happiness that is impossible without virtue," according to Nancy E. Snow. Emerging from this Aristotelian tradition is the distinction between *episteme* (factual or disciplinary knowledge), *technē* (applying this knowledge to produce a good or service), *sophia* (abstract reasoning), *phronēsis* (experience, insight, intuition, creativity), and *prudence* (judgment, including moral judgment and emotional intelligence). Organizational wisdom literature is oriented toward the notion of *phronēsis* and virtuous, thoughtful judgment.

Defining and Measuring Wisdom

Recent psychological research into wisdom emerged in the 1980s very much from gerontology studies, particularly by Paul B. Baltes, and contemporaneously in the United States, by Clayton and Birren. Although attempts to define and measure wisdom have been diverse, certain common elements emerge. Ardel (2003) uses the three dimensions first devised by Clayton and Birren: cognitive, reflective, and affective. Although all three dimensions need to be present for wisdom, the reflective dimension is regarded as "crucial." Webster (2003) identifies five dimensions: experience, emotional regulation, reminiscence, and reflectiveness, openness, and humor. Wisdom requires the synthesis of at least two of these skill sets. Greene and Brown's (2009) Wisdom Development Scale (WDS) uses eight

dimensions: self-knowledge, altruism, leadership, judgment, life knowledge, life skills, emotional management, and willingness to learn. An alternative to these self-assessed scales is the Berlin wisdom paradigm, which began with the work of Baltes et al. (1992). Their explicit theoretical approach sees wisdom as an aspect of the cognitive pragmatics of intelligence in a “dual process” model of intelligence. According to them, intelligence comprises cognitive mechanics (processing speed, recall capability) and cognitive pragmatics, which is derived over one’s life through reflexivity, problem-solving, and critical thinking skills. Wise people display “expert knowledge in the fundamental pragmatics of life that permits exceptional insight, judgment, and advice about complex and uncertain matters” (Pasupathi and Staudinger 2001). More specifically, pragmatics incorporate rich factual knowledge, rich procedural knowledge, life-span contextualism, relativism, and the capability to deal with the uncertainty of life’s contingencies.

In a large study conducted by Jeste et al. (2010), 60 experts in wisdom used a Delphi method to determine what they considered wisdom to be. The initial survey of this group evaluated items from existing wisdom measures including Ardel (2003), Baltes and Staudinger (Baltes et al. 1992), Brown and Greene (Greene and Brown 2009), Webster (2003), and Sternberg (Sternberg and Hedlund 2002) but added items to deal with skepticism and spirituality. Although extremely worthwhile, the study can be criticized for its imbalance in terms of gender (37% women), culture (73% North American and most of the others European), and to a lesser extent, discipline (predominantly gerontology, psychology, and psychiatry). Notwithstanding this, concept differences among wisdom, intelligence (with a slight overlap), and spirituality (sharing prosocial attitudes and behaviors) were significant. Further, wisdom differed from intelligence and from spirituality on most items. Reduced to the three metacomponents of cognitive, reflective, and affective domains, the experts agreed on seven cognitive items, eight reflective items, and three affective items. Four other items were

considered descriptive of wisdom: emotional regulation, openness to new experience, a sense of humor, and maturity gained with experience. The experts also considered resilience and successful coping strategies to be significantly more important than intelligence and spirituality. Finally, they agreed that wisdom, unlike high intelligence and spirituality, is rare and that it is positively associated with aging.

Plainly, such studies are intended to define and measure individual wisdom. However, very little work has been completed on organizational wisdom. One attempt by Limas and Hansson (2004) has not been adopted in other research. In the first of a two-part study, they developed an instrument that considered the components of wisdom within a work context. The scale used the five criteria of the Berlin model as well as Sternberg’s (Sternberg and Hedlund 2002) three domains of reasoning ability, sagacity, and judgment. The study showed that of the four factors that account for wise organizational practice, being broadly integrative in perspective accounted for the largest variance. Wise people in an organizational context were identified as “highly observant, balanced, and strategic in their interactions in the organization. They consider many points of view, are fair in their judgments, and have learned from experience” (Limas and Hansson 2004, pp. 91–92). Other factors identifying wisdom in an organizational context included respect for human diversity, practical political acumen, and sensitivity to organizational culture. The second study, which looked for organizations that are most appropriate for wise leadership, found that the most supportive organizational cultures are those that value supportiveness and a team orientation, and the least supportive are those that value precise applications to rules, aggressiveness, and predictability.

Wise Organizational Members

To be a wise organizational member, one must use their intelligence, creativity, and experience to produce a common good, according to wisdom researcher Robert Sternberg (Sternberg and

Hedlund 2002). Thus, an ethical dimension based on the common good is essential for organizational wisdom. Organizationally wise people extend their range of vision by balancing their own and institutional interests over the long and short terms and by making genuine efforts to understand other people's points of view and incorporating them into one's thinking.

Wisdom and Intelligence

While intelligence is crucial to wisdom, the distinction between fluid and crystallized intelligence (Horn and Cattell 1967) is crucial. Fluid intelligence, the capacity to think in the abstract, is largely inherited. Crystallized intelligence, according to Sternberg, is practical intelligence based on experience that is used to solve everyday problems in one of three ways: purposefully adapting to, shaping, or selecting new environments. Of significance here is the temporal aspect of crystallized intelligence, which is increasingly used throughout life. That is, as one ages, the potential for developing crystallized intelligence obviously increases provided other factors discussed below are present. Also of importance in considering fluid and crystallized intelligence is the relationship of wisdom with highly intelligent people. It has been found that although there is a correlation between PW and fluid intelligence for those with higher fluid intelligence levels, there is an inverted-U-shaped relationship. This means that those scoring in the top 15% produced a marginally negative relationship with PW when controlled for age (Mickler and Staudinger 2008). While it is generally accepted that fluid intelligence begins a steady decline from our thirties, crystallized intelligence remains stable into old age: in fact, it is suggested that fluid intelligence is transformed into crystallized intelligence over time (Schaie 2005). A crucial element, with critical relevance to aging, is that there is a link between openness to experience, fluid intelligence, and crystallized intelligence. More specifically, openness to experience might explain some of the age-related differences in fluid and crystallized intelligence.

Concepts

Given the importance of cognitive capability, affect, and moral reasoning as core components of wisdom, these are discussed in relation to aging. Because personality can affect the disposition for wisdom, this is also discussed before considering the notion of generativity in older people.

Cognitive Capability

An excellent summary of the effect of age on cognition by Salthouse (2012) provides a clinical foundation. Although some studies, such as that by Hunt in 1995, estimated dramatic declines in fluid cognition, other studies confirm the decline but at a more moderate rate. Salthouse's (2012) own studies on more than 3,000 adults aged between 20 and 70 years indicated a decline in fluid cognition of about 0.02 of a standard deviation. These results were largely unaffected by education, self-rated health, depression and anxiety, SES, or levels of job complexity. The inverted U of cognitive functioning in relation to age revealing a rapid rise peaking at around age 30 followed by a gradual decline is now well established. While this is largely true across different disciplines and historical periods, it seems to be most pronounced where novel problem solving is important (e.g., lyric poetry, pure mathematics, and theoretical physics) with one study finding that whereas the peak age for mathematicians was 26.5, for historians, it was 38.5.

An emerging area of interest is the notion of neuroplasticity. Advances in neuroscience are considering how the brain physically responds to neural deterioration caused by aging. Results indicate that the brain can develop neural scaffolding to regulate cognitive function. Cognitive training has been shown to increase neural volume; however, it is uncertain whether this is the result of strategy change rather than neural plasticity (Park and Bischof 2013). Clearly, such findings have important implications for most organizations because seniority and experience is indubitably correlated with age.

These findings may seem gloomy. However, six other factors need to be taken into account in an organizational context. The first factor, which is elaborated more thoroughly below, is that while sound to strong cognition is important, wisdom is best understood not just as a late stage of cognitive development in a Piagetian sense but also necessarily incorporating a synthesis of dialectical thinking based on knowledge of self, others, and the world, as well as a combination of intrapsychic systems of cognition, emotion, and motivation (Kunzmann and Batles 2005). The other five factors specifically relate to an organizational context and are largely drawn from Salthouse (2012). The second factor to consider is whether productivity declines as one ages because in their later career, people are more likely to be involved in supervisory, mentoring, and collaborative work. A third factor to consider is the different information obsolescence rates in fields: e.g., bioengineering compared with the law. A fourth factor is that in some (perhaps most) professions, high reasoning ability is best tempered by experience. One study, for example, shows that about 53 is the peak age for favorable financial decisions. With experience, novel problem-solving capability may be increasingly superseded by the capacity to retrieve prior solutions. A fifth factor is the possible positive contribution to a positive organizational culture. For example, when considering the life-span relationship of traits and age (below), older workers may contribute strongly to corporate citizenship, a vague but important component of organizational functioning and wise culture. Among the positive attributes of an older organizational worker may be positive aspects of personality, particularly conscientiousness which tends to increase with age, emotional intelligence, practical intelligence (which is related to experience-based tacit knowledge), and process/analytic ability. In other words, an excessive focus on cognitive decrement can blind us to the many other factors that positively impact work performance (Sternberg and Hedlund 2002), particularly in old age. It is reasonable to surmise that these factors promote wise personal and cultural practices. This disagreement about the relationship between age and job performance, especially

in complex jobs, raises the question about the relevant criterion variables to be considered. The sixth and final factor that may limit the impact of age-related declines is the various forms of accommodations (e.g., restricting exposure to deficit-revealing situations, moving from excessively difficult jobs, and reducing the domains of expertise) that people use over time to adjust into an appropriate organizational role.

Limitations of Rationality. Before leaving the topic of cognitive capability, it is worth noting that there is considerable epistemological debate about the nature of contemporary knowledge, particularly that which is valorized in dominant social and organizational discourses. According to philosopher Nicholas Maxwell in his (1984) *From Knowledge to Wisdom*, the philosophy of wisdom is needed to overcome the damage caused by the rationality that inheres in the philosophy of scientific knowledge. Such knowledge is limited because it is the outcome of rational enquiry that falsely claims to be objective. In contrast, while wisdom incorporates knowledge, it goes beyond these rational answers to include values. The orientation of science must vitally deal with the pressing issues of poverty and injustice, says Maxwell. This inherent limitation may be overcome by a set of competencies understood as *wisdom meta-competencies* that are related to wisdom and complement and enhance knowledge activities.

Affect

Because emotional regulation is an important component of wise action, the relation between affect and aging is another important consideration. From the broad perspective of socio-emotional selectivity (Carstensen et al. 1999), it is argued that the individual's perception of time strongly influences the selection and pursuit of social goals. If time is perceived as open-ended, then we tend to pursue knowledge acquisition goals, but if time is seen as limited, we tend to pursue emotional goals. The crossover occurs in middle age. The implication of this for organizational decision-making is that calculating gains and losses is likely to be influenced by individual temporal frameworks that, in turn, prioritize

knowledge or emotional goals. The work of Eva-Marie Kessler and Ursula Staudinger is particularly pertinent in supporting the importance of age in affect regulation in difficult situations. They found that, although the Big Five personality factors and health significantly reduces the effect of age on affect, age still has explanatory power over and above these variables. As a result, older participants' displayed greater efficiency in increasing positive affect in difficult situations and reducing negative affect after negative events and failures. Older people are more flexible in deploying problem-solving strategies in which emotion regulation is a part of the contextual features of a situation. The entry by Scheibe, Wisse, and Schulz in this volume identifies positive features of affect and emotion regulation in aging workers with outcomes such as lower burn-out, more favorable job attitudes, and satisfaction with the supervisor.

Moral Reasoning

Moral reasoning is a core function of wisdom from both an Aristotelian perspective and most contemporary psychological accounts. Because of its core role, it is important to consider whether age impacts on moral reasoning. However, the research is inconclusive as to whether moral development, in the Kohlbergian sense, plateaus, develops in earlier adulthood, or declines in later adulthood. For example, a review of the *Journal of Business Ethics*, which is perhaps best aligned with moral reasoning in an organizational context, provides virtually no empirical work in this area since Ruegger and King's 1992 study. A study by Pasupathi and Staudinger (2001) showed that moral reasoning was positively associated with wisdom-related performance. Of note is that the association was mediated by personality, intelligence, and other factors. In relation to age, it was found that higher age was associated with higher levels of wisdom-related knowledge and judgment for those with high moral reasoning or cognitive capability.

Personality

Although the positive personality traits of emotional stability, openness to experience,

agreeableness, and conscientiousness spike sharply between roughly 15 and 25, they also incrementally rise with age, with an optimum age of about 55 (Roberts et al. 2006). Three features are noteworthy in relation to aging and personality traits in the workforce. First, agreeableness appears to spike again at around age 45 with slight increments from 55. Second, conscientiousness spikes dramatically from age 20 and continues to rise strongly to age 65 before plateauing. These two features, along with optimum levels of emotional stability from 55 to 65, point to the potential positive organizational cultural influence of older workers. Agreeableness, conscientiousness, and emotional stability produce balance in humans and, of course, in their place of work. Balance is also evident in theories of wisdom ranging from Aristotle's notion of the mean (much misunderstood as the center between extremities) to Sternberg's (Sternberg and Hedlund 2002) Balance Theory of Wisdom. For Sternberg, balance that is likely to produce wise outcomes includes consideration of the common good in the intrapersonal, interpersonal, and extrapersonal domains. The third feature is less positive: that is, openness to experience tends to decline from the mid 50s. Given the importance of openness to experience in predicting wisdom, this is one variable that could potentially reduce the wisdom of older people.

Generativity

Generativity, a concept first introduced by Erikson in 1950, has proved to be a robust concept that is strongly associated with successful aging, although there is no clear point at which it begins. Longitudinal aging researcher George Vaillant concludes from decades of research that mastering generativity is strongly correlated with successful adaptation to old age. The psychological features of generativity, according to McAdams and St. Aubin, are a personal inner desire to support the next generation based on the motivation of a conscious concern for their welfare and is associated with belief in human goodness. In an organizational context, a positive relationship between leader age and leader generativity was identified.

This same research (Zacher et al. 2011) also showed that leader generativity moderated the relationships between leader age and all the criteria of leadership success, the implication of which is that leaders who are high in generativity are better able to maintain high levels of leadership success at higher ages than leaders low in generativity.

Generativity is an important consideration in understanding the wisdom potential of older workers in an organizational context. A mentor is an older person who freely takes on responsibility for developing less experienced organizational members in three ways. First, mentors provide practical, experience-based advice related to applying professional knowledge in a field and by helping younger people build confidence to find their place within the profession. Second, successful mentoring provides moral guidance in difficult situations or where wider considerations (long-term perspective or relevant stakeholders) should be taken into account. Third, mentors, particularly given their heightened emotional regulation and conscientiousness, help to develop an appropriate disposition by dealing artfully and thoughtfully with highly charged situations or novel situations for the less experienced person.

Applications

Turning the focus now to organizational wisdom reveals considerably less inquiry than there is on the relationship between aging and wisdom in an organizational context. Notwithstanding this paucity, a number of factors are generally agreed upon: the role of knowledge, reflexiveness, balance, and experience.

It is agreed that wisdom does not necessarily come with aging. Rather, there must be openness to experience; experience itself (see, e.g., Nada and Andrew Korac-Kakabadse's work) and reflexiveness. As explained above, the trait of openness to experience is strongly correlated with wisdom because it might explain the process by which fluid intelligence over time is reconstrued as crystallized intelligence. Providing the potential for wisdom from experience is

reflexiveness. The notion of reflexiveness in organizational theory and practice is not new: Donald Schön's reflection-in-action and Henry Mintzberg's reflexive practice are well established. However, as Keith Grint points out, practical wisdom that leads to positive humane outcomes combines reflection, action, and lived experience. This notion of lived experience lends itself to another emerging aspect of experience-based wisdom that philosopher Paul Ricoeur calls reflective mediation. A more useful recent development in this regard has been the emergence of the phenomenological perspective that considers the relationship between somatic experience and consciousness through a process of embodiment. This notion is extensively developed in the work of Wendelin Küpers, who understands the wise phenomenological practitioner as dynamically interrogating situated experiences and one's perceptions, receptive affectedness, emotions, cognitions, and actions. Thus, wisdom is understood in the broadest sense as not only knowing but doing within a moral universe.

Given the importance of knowledge, some organizational wisdom theorists such as Jennifer Rowley and Bierly, Kessler, and Christensen took up Ackoff's data-information-knowledge-wisdom (DIKW) "knowledge hierarchy" to elaborate the important distinction between knowledge and wisdom. Such a distinction resembles the distinction that Aristotle in *Nicomachean Ethics* made between *epistēmē*, *technē*, and *phronēsis*. *Epistēmē* is the theoretical knowledge needed to be a craftsperson or professional in a particular domain. Thus, early career-organizational members would demonstrate this level of knowledge; indeed, they may even have acquired new knowledge that older organizational members do not have. *Technē* involves the application of that knowledge to produce a good or service, as well as the capacity to explain the process of production in terms of that knowledge. However, *technē* is not directed to purposive social change; it merely reproduces existing practices and outcomes. Thus, a technically competent person is not necessarily a wise person. *Phronēsis*, on the other hand, according to Aristotle in his *Eudemian Ethics*, is not a form of knowledge but

an excellence that produces virtuous outcomes. It is an intellectual and an ethical virtue that is directed to living well, the eudaimonic existence that is selflessly directed to the greater good of all.

Phronetic leadership has become widely developed in the literature of management and leadership particularly since Bent Flyvbjerg introduced the notion of phronetic planning. Importantly, wisdom theorists such as Haridimos Tsoukas and Robert Chia incorporate moral capacity. For Tsoukas, phronetic leaders intuitively identify salient features in complex situations to produce responses that promote the common good. Chia sees *phronēsis* as a form of resourcefulness that produces appropriate responses that meet the common good. A vital element of this process is *sophia*. According to Richard Hawley Trowbridge, *sophia* incorporates intuitive knowing and a sense of cosmic unity. A wise person who incorporates *sophia* into their deliberative processes is not bound by the sensory awareness that produces established knowledge, and they admit intuitive understandings as a valid aspect of consideration. They also perceive the interrelatedness of all things, assuming a cosmic unity or total union with the infinite, according to Trowbridge. Thus, above knowledge are various meta-competencies including metacognitions and ethics that integrate to produce practical wisdom, according to Intezari and Pauleen (2013).

Future Directions

Management, organizational, and leadership theory is increasingly adopting wisdom principles into its research and practice. The first significant instance of this was Eric Kessler and James Bailey's (2007) edited *Handbook of Organizational and Managerial Wisdom*. Rooney, McKenna, and Liesch's (2010) *Wisdom and Management in the Knowledge Economy* provided five characteristics of wisdom and applied these to various business subdisciplines such as strategy and international business. In applying wisdom principles to HRM, they looked at the potential wisdom value of an aging work force. Kinsella and Pitman's

(2011) *Phronē as Professional Knowledge* attempts to redress the instrumentalism of professional practice and the valorization of particular forms of knowledge by introducing *phronēsis*. Thompson and Bevan's (2013) edited volume *Wise Management in Organisational Complexity* includes a critique of the Global Financial Crisis as well as providing Chinese philosophical perspectives. Küpers and Pauleen's (2013) *A Handbook of Practical Wisdom* provides a range of theoretical orientations including phenomenology, Buddhism, and transcendence to guide practical wisdom in contemporary times.

Despite this growing trend in organizational wisdom theory, there is little that specifically deals with aging and wisdom in an organizational context. Clearly, there is much that can be done from psychological, sociological, and phenomenological approaches. While the concept of wisdom is not agreed, there are core features of cognitive and affective capability, reflectiveness, and an ethical commitment to the common and longer-term good. Thus, research on how these features vary, if at all, with age, will provide useful information about wisdom and aging. Because aging is biocultural, the sociology of older workers in the workplace would also shed light on organizational wisdom. Thus, the following questions would be of particular interest.

- Do cognitive decrements impair older workers' capacity for wisdom in an organization?
- Is intuitive knowledge largely built on experience?
- Does reflexive experience over time provide replicable heuristics to solve complex problems?
- Do older people, because of life-stage characteristics, help to produce a wise organizational disposition?
- Given the importance of the trait of openness to new ideas and to experience, what processes as well as personal and cultural changes would arrest the tendency for a decline of openness in older people?
- Are there new configurations of work patterns that would allow older people to provide wise mentorship and to pass on tacit knowledge?

Pain and Pain Management

Thomas Hadjistavropoulos
Department of Psychology and Centre on Aging
and Health, University of Regina, Regina, SK,
Canada

Definition

The International Association for the Study of Pain (IASP) defines pain as “an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage.” Pain of short duration is considered acute pain, while pain that has persisted longer than the normal healing period is considered to be chronic (Turk and Okifuji 2001). Chronic pain is often operationalized as pain lasting longer than 3 months.

Pain in Old Age

The prevalence of pain in older persons is high (Charlton 2005). Specifically, estimates of pain prevalence range from 25% to 65% of community-dwelling older adults and are as high as 80% for seniors residing in long-term care facilities. Of the older adults who report pain, 25% describe their pain as severe and 60% describe it as moderate (Langley 2011). This high prevalence of pain is largely due to a variety

of health conditions that become more frequent with aging (e.g., osteoarthritis, cancer, osteoporosis, postherpetic neuralgia, spinal stenosis, fractures) as well as injuries due to falls. As the list of conditions that increase with aging implies, older persons are affected both by nociceptive (i.e., pain resulting from activation of the nociceptors which are sensory neurons that respond to noxious tissue stimulation) and neuropathic (i.e., pain due to nervous system damage) pain. Examples of the former type of pain include musculoskeletal injury pain and osteoarthritis. Common sources of neuropathic pain in older adults include central poststroke pain as well as various neuralgias (e.g., herpetic neuralgia). Cancer pain can be neuropathic or nociceptive depending on the nature of the specific illness.

Persistent pain has negative consequences for quality of life and is often associated with negative mood states such as depression, anxiety, sleep disturbances, and increased use of mental health services (Hadjistavropoulos 2015). In the case of seniors with dementia and neurocognitive disorders (e.g., Alzheimer’s disease, vascular dementia, frontotemporal dementia), pain can also be associated with increased behavioral disturbance which can lead to pain patients being treated with psychotropic rather than analgesic medication.

Despite their high prevalence, pain problems are often undertreated in older individuals (Hadjistavropoulos 2015; Morrison and Siu 2000). This pain undertreatment has been attributed to a variety of factors including, but not

limited to, prevalent myths that pain is a normal part of aging and, as such, must be endured. While pain problems are frequent in old age, they are not normal but result from pathology that needs to be managed irrespective of a person's age. In the case of seniors who have dementia and limited ability to communicate due to cognitive impairment, pain undertreatment is often associated with challenges in effectively assessing pain in this population who have difficulty self-reporting their subjective experiences. Moreover, insufficient health-care staff education about effective approaches to the assessment of pain in dementia also contributes to pain undertreatment with pain problems often going undetected. In addition, despite good will, fiscal and resource challenges in many long-term care residential facilities have interfered with the implementation of adequate regular pain assessment/management programs.

The literature has also examined the possibility of pain threshold and tolerance changes as a function of old age, given the variety of age-related neurobiologic and psychosocial changes that occur. The results, however, have not been perfectly consistent across studies. Although, for example, some laboratory research has shown an age-related increase in pain thresholds, this effect has not been found consistently across a variety of pain stimuli (Hadjistavropoulos et al. *in press*; Gibson and Farrell 2004; Lautenbacher 2012). Studies of pain tolerance as a function of age tend to show the opposite effect. That is, pain tolerance appears to decrease with age (Hadjistavropoulos et al. 2014; Gibson and Farrell 2004).

Results on the effects of dementia in pain perception also vary across studies with inconsistencies possibly due to differences in the patient samples and/or methodologies. It has been, nonetheless, suggested that severe dementia may impair pain perception although more research is needed before such a conclusion can be reached with confidence (Hadjistavropoulos et al. 2014). That said, much of the research on pain threshold and tolerance utilizes psychophysical principles, and the age- and dementia-related changes shown in the laboratory may not have substantial clinical

significance. In fact, it has demonstrated that patients with dementia, compared to peers without dementia, often react with more vigor to painful stimuli in clinical settings (Hadjistavropoulos et al. 2000).

Pain Theory and Conceptualization

The gate control theory of pain (Melzack and Wall 1965) is the most comprehensive and well-supported theory of pain. It postulates that a gating mechanism at the dorsal horn of the spinal cord modulates the ascending sensory inputs from the body. Ascending transmissions from large diameter fibers, representing sensory neural pathways (transmitting sensations such as touch), tend to close the gate by inhibiting competing potentially painful messages transmitted by smaller diameter fibers. As a practical example, rubbing a painful area may reduce the level of pain experienced through activation of large diameter fibers. More importantly, from a psychological standpoint, the theory postulates that descending cortical input (e.g., arising from cognitive and attentional processes) can also open and close the gate. Consistent with the gate control theory, the biopsychosocial model of pain elaborates on the manner in which biological, social, and psychological parameters interact with the pain experience. Indeed, the important role of psychological (e.g., catastrophic thinking about pain, coping strategies) and social parameters (e.g., social support) in the pain experience of older individuals is supported (e.g., Benyon et al. 2013) although the biopsychosocial model has been primarily investigated with younger persons.

Pain Assessment

Effective pain management must be preceded by effective pain assessment. A comprehensive assessment of pain would not only include evaluations of pain intensity but also of a variety of other domains (e.g., functional ability,

psychological functioning, coping skills, physical pathology, etc.) (Hadjistavropoulos et al. 2007). Given the multidimensional nature of a comprehensive pain assessment, interdisciplinary approaches are often considered optimal. A variety of tools, validated for the pain assessment (and related domains such as functional ability and psychological sequelae) in samples of older adults, are often used by psychologists. For example, pain intensity can usually be assessed effectively using unidimensional scales including 0–10 numeric rating scales (NRS, anchored by polar opposites such as “no pain” and “pain as bad as it can be”) and/or verbal rating scales (VRS, involving the use of verbal descriptors such as “mild,” “moderate,” “severe,” etc.). VRS verbal descriptors can correspond to numeric ratings (e.g., “no pain” = 0; “extreme pain” = 10). Other dimensions of pain, including psychological sequelae, can be assessed through a wide variety of tools such as the Brief Pain Inventory, the Geriatric Depression Scale, the Multidimensional Pain Inventory, the Coping Strategies Questionnaire, and others [see Hadjistavropoulos et al. (2007) for more details on these assessment tools].

Seniors with mild to moderate dementia can often self-report pain using unidimensional rating scales (e.g., NRS or VRS). However, as dementia progresses, patients often become unable to effectively self-report pain. The American Geriatrics Society (AGS) recommended that the following domains be evaluated when assessing pain in dementia patients: (a) facial expressions, (b) verbalizations and vocalizations, (c) body movements, (d) changes in interpersonal interactions, (e) changes in activity patterns and routines, and (f) mental status changes. A variety of observational pain assessment tools have been validated for the assessment of the patient with dementia. These tools include items such as grimacing, rubbing the affected area, paralinguistic vocalizations (e.g., moaning and screaming), changes in sleep patterns, and others. Specific examples of observational tools include the Pain Assessment Checklist for Seniors with Limited Ability to Communicate (PACSLAC) and

PACSLAC-II, the Pain Assessment in Advanced Dementia (PAINAD), the Doloplus-II, the Abbey Pain Scale, and others (see Hadjistavropoulos et al. (2014) for a review and more complete listing of such tools). Clinicians can evaluate the extent to which specific observational pain tools allow for the assessment of the domains recommended by the AGS. Tools that can assess psychological dimensions of the pain experience of older adults with severe dementia are also available (e.g., Cornell Scale for Depression in Dementia, Alzheimer’s Disease-Related Quality of Life [ADRQL]; see Hadjistavropoulos (2015) for a more detailed discussion). These tools are reliant on caregiver report given the communication limitations that are frequent in patients with severe cognitive impairments.

Clinical approaches to the assessment of the older adult with and without dementia have also been described in the literature (Hadjistavropoulos et al. 2007, 2010). For example, in the case of the observational assessment of pain for seniors with severe cognitive impairments, an individualized approach to assessment has been recommended whereby pain behaviors are monitored over time (with assessments conducted across similar situations). Fluctuations from the regular pattern of a patient’s scores could be indicative of changes in pain levels requiring further investigation. Regardless, results of observational pain assessment should always be considered within the context of patient history, medical examination and test results, caregiver reports, and related information. Observational assessment tools are for screening and should not be considered, in and of themselves, to be definitive indicators of pain.

Pain Management

Given the multidimensional nature of pain, its optimal management involves an interdisciplinary approach (e.g., psychology, medicine, physical therapy, pharmacy, nursing, occupational therapy). Psychologists, working within interdisciplinary and interprofessional treatment teams,

can offer psychological therapy to clients in an effort to improve quality of life (e.g., improve mood, reduce anxiety, increase social engagement) despite a person's pain condition. Cognitive behavioral therapy (CBT) approaches show some promise when used with older persons (Hadjistavropoulos 2015) and involve a variety of techniques including challenging maladaptive cognitions related to pain, encouraging appropriate pacing of activities, enhancing coping skills, behavioral activation, relaxation training, psychoeducation, and others. While CBT methods are also used in the treatment of younger persons, CBT tends to have a somewhat different focus with older individuals. Although CBT programs with younger chronic pain patients often have a return-to-work focus, for example, return to work is not an issue with retired older persons. Moreover, the types of stressors that older adults bring into therapy tend to be different (e.g., widowhood in late life, empty nest syndrome) as compared to other populations who may be more concerned about the pain problem's impact on ability to support a young family and related responsibilities. CBT with older adults may also focus on myths that may contribute to pain undermanagement (e.g., an older person not seeking physical therapy for pain because of the false belief that pain is normal and inevitable in late life). In addition, the nature of the psychoeducation may be different depending on the age of CBT patient (e.g., metabolic and other physiological changes that accompany aging may have an impact on how the body metabolizes medications). Recently, evidence has begun to emerge on the usefulness of acceptance and commitment therapy (ACT) for older persons with pain (McCracken and Jones 2012). ACT emphasizes acceptance of one's symptoms (rather than efforts to control them) and incorporates mindfulness (e.g., meditation-like) techniques.

In the case of seniors with advanced dementia, CBT and ACT pain management approaches would, generally, not be feasible. Long-term care staff continuing education in pain assessment and management has been shown to increase knowledge of best practices, although the extent to

which this increased knowledge translates to widespread clinical application is less clear (Gagnon et al. 2013). For changes in clinical practices to occur, change in facility policies and management support (e.g., changes in resource allocation) may be needed. Research has shown, however, that implementation of regular pain assessment in long-term care facilities leads to improved pain management practices (Fuchs-Lacelle et al. 2008). In addition, in terms of pharmacological management, the AGS has produced specific recommendations (American Geriatrics Society (AGS) 2009). Finally, psychosocial and behavioral programs (e.g., pleasant activity scheduling) to improve dementia patient mood have shown some promise (Teri et al. 1997).

Self-management approaches for pain in older persons have also been developed (Hadjistavropoulos 2012). These approaches vary with respect to the extent that they incorporate health professional support (e.g., facilitators) with some approaches involving regular group meetings with a health professional and other approaches involving less direct health professional support (e.g., use of a detailed pain self-management manual that encourages patients to consult with health professionals as necessary). Self-management programs offer psychoeducation, coping skills training, mood management approaches, pacing techniques, and other related methods. The results on the effectiveness of self-management approaches are generally mixed although programs specifically focused on people with arthritis seem to be especially promising (Hadjistavropoulos 2012; Du et al. 2011).

Future Directions

Further investigation is needed to systematically clarify and explain the inconsistencies in studies of age-related changes in pain threshold and tolerance. A longitudinal approach to these types of investigations may be the most fruitful avenue. Given the limited access to services that many seniors have, either due to reduced mobility or because they live in rural areas, more research in

the delivery of pain management approaches via internet or other telemedicine and e-health initiatives is needed. In the area of pain assessment, more research is needed on the specificity of observational pain assessment tools for seniors with severe dementia and limited ability to communicate. While we know that such tools are quite sensitive to the identification of pain, their ability to discriminate pain from other distress states has not been studied adequately. Moreover, future research, including public policy research, should address the issue of barriers to widespread implementation of effective pain management programs for older persons and especially for individuals who reside in long-term care facilities.

Palliative Care

Julia E. Kasl-Godley¹ and Kysa M. Christie²

¹Palo Alto VA Health Care System, Palo Alto, CA, USA

²Boston VA Healthcare System, Boston, MA, USA

Definition

Palliative care is a broad term that refers to care provided at *any stage* of a serious illness to alleviate physical, psychosocial, or spiritual suffering; enhance quality of life; effectively manage symptoms; and offer comprehensive, interdisciplinary support to the patient and family throughout the course of illness, regardless of stage of disease (Dahlin 2013).

Palliative care ideally begins at the point of initial diagnosis of a serious, potentially life-limiting illness and can be delivered concurrently with other therapies that are intended to cure a disease or prolong life (see Box 1 and Fig. 1). If disease-directed therapy stops working, palliative care can become the main focus of care. Although the primary focus is enhancing quality of life, palliative care may even extend life. Individuals with advanced or terminal illness may face a myriad of treatment decisions such as choosing not to start life-prolonging interventions; withdrawing or discontinuing life-prolonging treatments; or completing advance directives. Individuals may be overwhelmed with the entire process and need a sounding board.

Box 1 Who Is Appropriate for Palliative Care?

Any one of the following situations may be sufficient to consult palliative care:

- *Surprise.* You would not be surprised if the patient died within 12 months.
- *Frequent admissions.* Repeated admissions for the same condition within several months.

(continued)

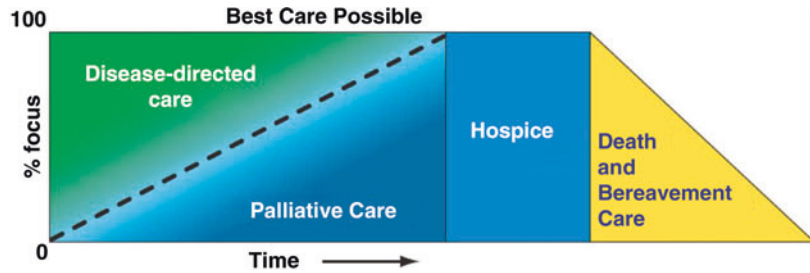

- *Complex symptoms.* Admission for difficult symptoms or psychological need.
- *Complex care requirement.* Functional dependence or complex home support needed.
- *Failure to thrive.* Decline in functional status, weight, or ability to care for self.
- *Advance care need.* No history of completing an advance care directive or having a discussion about end-of life care preferences (e.g., do not resuscitate, do not intubate (DNR/DNI).
- *Limited social support.* Family stress, chronic mental illness, lack of caregivers.
- *Limited prognosis.* Metastatic or locally advanced cancer, hip fracture with cognitive impairment, or out-of-hospital cardiac arrest.

Excerpted from Weissman and Meier (2011)

Palliative care aims to help patients and families make difficult medical decisions that enable them to work toward their goals, especially as outcomes become more uncertain. These advance care conversations can include offering basic information about illness and the dying process, identifying medically ill persons' and their families' values and goals for living and dying, clarifying treatment options, obtaining advanced directives, and evaluating factors that can influence decision-making and decisional capacity (e.g., depression, pain, religiosity, value of quality of life, fear of dying process, cognitive impairment, and the influence of family members).

Palliative care also includes "end-of-life care," which might involve referral to a formal hospice program, as well as support of the family through the bereavement period. In the USA, hospice care is often linked to the specific programs offered under the Medicare Hospice Benefit and Medicare is the primary source of payment for hospice care. Individuals receiving hospice care must typically forgo active disease-directed therapy for the

Palliative Care,
Fig. 1 Model of Palliative
 Care

terminal illness, though interventions intended to maximize quality of life are continued and individuals can receive disease-directed treatment for medical problems other than the terminal illness under Medicare. Furthermore, if an individual's condition stabilizes or improves, he or she can disenroll from hospice care and return to regular Medicare coverage. In addition, a new pilot program called the Medicare Care Choices Model allows Medicare beneficiaries who qualify for coverage under the Medicare hospice benefit and dually eligible beneficiaries who qualify for the Medicaid hospice benefit to receive palliative care services and disease-directed care simultaneously.

The overall number of patients and families served by hospice has increased over the years, as have the proportion of individuals served with noncancer diagnoses and those living in skilled nursing homes.

Palliative care can occur across the entire continuum of care: the treatment-intensive hospital setting, long-term care facilities, outpatient specialty medical clinics, and home-based programs. In addition, hospice services can be provided in the home, nursing homes, residential facilities, or inpatient units. However, few hospitals offer specialized outpatient Palliative Care services, and when they exist, providers are typically part time and focused primarily on cancer care, despite the growing evidence that outpatient palliative care can improve satisfaction with care, improve symptom control/QOL, reduce care utilization, and lengthen survival (Rabow et al. 2013). Similarly, although nursing homes may provide hospice/palliative care, the focus may be on end-of-life care, through a contract with community hospice agencies, rather than embedded throughout the fabric of care.

Who Provides Palliative Care?

Palliative care can be provided as a specialty consult service or as part of basic primary medical care. Ideally, both primary care practitioners and specialists who care for seriously ill patients can provide basic palliative care (e.g., basic pain and symptom assessment and management, advance care planning) in the routine course of providing health care to patients at all stages of serious illness. In reality, not all medical providers are trained to provide even basic palliative care, although this situation is slowly changing. In cases where symptom management or family dynamics are more challenging, patients and/or family members frequently require the added services of palliative care specialists. Specialist palliative care providers are those clinicians who have received formal specialty training and appropriate credentialing in the field and whose work is primarily involved with palliative care. At present, physicians can be board certified in hospice and palliative medicine, and nurses can be certified in hospice and palliative nursing. Social workers and chaplains can obtain specialty credentials in hospice and palliative care. In the USA, to date, there is no formal certification for specialty practice in palliative care for psychologists, although there are a small number of postdoctoral fellowships that offer advanced training for psychologists in this area.

Most commonly, specialty palliative care is provided in hospital settings by palliative care consult teams composed of a physician, nurse/nurse practitioner, social worker, and chaplain, though the teams may be expanded to include a wider range of professionals or, in contrast, be reduced depending on resources and patient volume. For example, programs in nonhospital

settings or in smaller medical centers may have relatively few disciplines represented and are much less likely to include psychologists. Palliative care consult teams assist the primary treatment team with goals of care discussions, treatment planning, symptom management, emotional and spiritual support, and communication among and between medically ill individuals, family members, and health care providers. The palliative care consult team also may help initiate referrals with community hospice or home care agencies depending on treatment goals.

Beneficial Outcomes of Palliative Care

Palliative care is associated with increased patient and family satisfaction with care; reduced symptom burden, improved bereavement adjustment; and sometimes longer lives than similarly ill patients who do not receive Palliative Care. Palliative Care also is associated with cost savings which are achieved through earlier intervention, reductions in emergency department visits, ICU stays, and hospital readmissions (Higginson and Evans 2010).

Despite these outcomes, many individuals do not experience comprehensive hospice and palliative care. This result is a function of financial disincentives, a fragmented care delivery system, time pressures that limit communication, lack of service coordination across programs, and limited training (Institute of Medicine [IOM] 2015). These issues can result in frustration among professionals at the mismatch between their training and the complex needs of patients; a high, escalating financial price, which includes costs for interventions that many people near end of life do not want; and a perception that the health care system is not designed to meet individuals' most pressing needs and priorities, many of which involve not medical care but social services.

Areas of Focus in Palliative Care

Physical Symptoms

Pain. Adequate pain control is one of the greatest concerns of seriously and terminally ill patients, and fortunately, effective pharmacological

interventions exist. However, despite concerns about unmanaged pain, patients may be hesitant about pain control. Individuals may have particular beliefs about pain that affect its management, such as it should be experienced and tolerated because it is retribution for past misdeeds, a characterological deficit if one cannot bear it, or simply an indication of if/how the illness is progressing. In addition, physicians may underestimate pain, if there is a history of pain and/or substance use which can increase medication tolerance. Alternatively, physicians may overestimate the contribution of psychological factors to pain and thus undertreat pain. Non-pharmacological interventions seek to decrease individuals' perception of pain by reducing pain intensity and increasing tolerance, building self-efficacy and perceived control in managing pain, and decreasing anxiety. Effective interventions include exercise and positioning, massage, education, cognitive-behavioral therapy, mindfulness-based stress reduction, and meditation.

Dyspnea. Patients with dyspnea describe feeling like they are being smothered or suffocated, that their chest feels tight, their breathing is rapid, and they cannot get enough air or stop thinking about their breathing. The course of dyspnea fluctuates such that patients can have periods of increased or decreased difficulty breathing, and it is a symptom of chronic lung diseases (COPD), heart failure, advanced cancer, as well as diseases with significant muscle loss such as multiple sclerosis and amyotrophic lateral sclerosis.

Opioids are the most well-studied and used pharmacological treatment to manage dyspnea, and the evidence is largely supportive of their efficacy (Kamal et al. 2011). Nonpharmacological interventions also are effective. Using a fan to provide a cool breeze on a person's face reduces dyspnea. Psychoeducation about the feeling of suffocation compared to physiological risk of suffocating can be helpful. Cognitive interventions aimed at identifying and managing automatic thoughts related to suffocation that arise during periods of dyspnea, as well as relaxation strategies, particularly breathing retraining, can reduce the distress caused by breathlessness.

Fatigue, Decreased Energy, Weakness. Fatigue is characterized by weariness or exhaustion resulting from physical or mental exertion. It can cause emotional distress both from the significant functional changes and limited ability to engage in daily activities but also from the meaning attributed to the symptom – e.g., that one’s disease is progressing, that one is helpless and useless and no longer capable of doing anything one once did. Strategies to accommodate fatigue can focus on pacing activities, alternating physical activity with rest, trying to reduce the demands of everyday living, and modifying pleasurable activities or identifying new ones that can provide the same function with less physical demands.

Delirium. Delirium is a disorder of consciousness which presents as hyperactivity (increased arousal, agitation, hallucinations, day-night reversal), hypoactivity (withdrawal, lethargy, reduced arousal), or mixed. Delirium can be distressing for the individuals themselves, their family members, and treatment providers. Agitation can be particularly troubling to families, yet they may feel ambivalent about aggressively managing this symptom if it means sedating individuals and eliminating the possibility of meaningful communication.

Terminal delirium is highly prevalent in the advanced stages of dying and typically is refractory to intervention, which may be a function of nonreversible causes such as tumor burden, renal/hepatic failure, or vascular complications. However, the etiology of delirium often is multifactorial, and potentially reversible causes should be considered such as urinary tract infections, constipation, pain, or medications (e.g., opioid toxicities). Even in terminal delirium, delirious individuals may continue to have periods of relative lucidity, and family should be encouraged to take advantage of that time.

Nonpharmacological interventions include maintenance of structure/routine, presence of familiar belongings or people, reduction or elimination of noise or excess stimulation, and reassurance (e.g., that the patient is safe, being well cared for, not challenging or minimizing delusions or hallucinations).

Psychosocial-Spiritual Symptoms

Loss and Grief. Individuals with advanced or terminal illness often experience a myriad of losses – loss of health, function, independence, autonomy, control, predictability, mental clarity, sense of purpose or meaning, status in the family, future hopes and dreams, and a sense of normalcy. Grief over these losses is normative and can manifest in waves of emotion, including anger, sadness, irritability, and distractibility. How individuals make sense of loss is critical to adjustment. Medically ill individuals and their families may benefit from exploring the meaning and impact of current or anticipated losses in order to help them create new meaning in the face of adversity. Even if new meaning cannot be found easily, sharing one’s sorrow and loss lessens the isolation of the experience.

Bereavement. Palliative care supports individuals and their family members throughout the disease process and into bereavement. Individuals may experience normal grief responses as distinguished from complicated or Prolonged Grief. Prolonged Grief is characterized by distressing and functionally disabling symptoms including intrusive thoughts and images of the deceased person; painful yearning for his/her presence; and some combination of shock and emotional numbing, mistrust, anger, diminished sense of self and meaning in life, difficulty accepting the loss, or avoidance of reminders of the loss. Risk factors for prolonged grief include secondary stressors (e.g., financial strains); multiple, concurrent losses; circumstances of the death such as lack of preparation or hospital death; interpersonal factors; and psychological vulnerabilities. Interpersonal factors encompass the degree to which family members feel close to, or dependent on, or define themselves by their relationship to, the ill person, or experience unresolved family issues. Factors that can be protective against complications in bereavement include an ability to make sense of loss, find personal meaning or compensatory benefit in the experience, an ability to regulate one’s emotional state, spirituality, and general resiliency characteristics such as self-esteem, hardiness, and positive expectancies.

Psychoeducation and support for normative grief (for those individuals seeking support) and referrals for specialized treatment when individuals experience complications in bereavement are helpful. Approaches include Complicated Grief Disorder treatment (Shear et al. 2005), narrative-based interventions (Neimeyer 2001), cognitive behavioral therapy (Boelen et al. 2007), grief therapy (Worden 2008), and Family Focused Grief therapy (Kissane and Bloch 2002).

Existential issues. Often as a result of the multitude of losses, individuals' basic sense of who they are is threatened. Many individuals with advanced illness experience a diminished sense of dignity, believe they are a burden to others, or express a waning will to live and a growing desire for death. Perceived burden is associated with loss of dignity, suffering, depression, and a desire for hastened death (McPherson et al. 2007). Individuals can experience spiritual or existential angst, crisis of faith or hopelessness, questions of meaning, or guilt. Medically ill individuals' tasks (which can be facilitated) include identifying aspects of their identity that transcend the illness or physical decline and seeing themselves for the individuals they have been, rather than the disease with which they live. Fruitful areas to explore include religious/spiritual beliefs, evaluations of self-worth, sources of meaning and purpose, ways to continue to contribute that accommodate the illness, things that the ill person values, and one's legacy. Ethical wills or legacy documents – a document in which the individual communicates personal values and beliefs, life stories and lessons and advice with the intention of passing them on to another generation – can be particularly useful to this end. Therapeutic approaches such as Life Review, Acceptance and Commitment therapy, Meaning-Centered Group Psychotherapy, and Dignity Therapy also can be useful. See LeMay and Wilson (2008) for a comprehensive review of treatments for existential distress in advanced illness.

Family Systems

In palliative care, the family, defined as anyone with whom the patient shares strong emotional ties, whether or not they are biologically or legally

related, is the unit of care. Illness impacts families along the disease continuum, from diagnosis to death, and members must integrate the experience of the patient's illness into their ongoing lives. Illness can trigger changes in roles, relationships, communication, and finances, and family members may experience conflict over these changes. In addition, families may struggle with how to assist the ill person in maintaining his or her identity and place within the family system while also accommodating the individual's shifting roles and needs. Family members may have difficulty making sense of treatment, may have difficulty tolerating the ambiguity and uncertainty regarding prognosis, and may be avoidant of planning for life after the person dies. Moreover, families vary in their ability to communicate effectively about distressing issues, to make decisions collaboratively, and to remain committed to one another through transitions and crises. Some families are prone to conflictual patterns of interaction due to long-standing problems such as substance abuse, physical/sexual abuse, or untreated mental illness. These long-standing conflicts may be exacerbated by the stress of serious, life-limiting illness.

Palliative care often involves facilitating family meetings, and psychologists should be familiar with how to facilitate them. Palliative care requires being able to identify areas of conflict for the family, to discern the family's ability to tolerate and resolve conflict, and to modulate chronically conflictual patterns of interaction that may prevent the family from participating productively in collaborative medical decision-making on behalf of the patient. Family-centered treatment approaches such as Medical Family Therapy and Family Focused Grief Therapy, which capitalize on evidence-based family assessment in order to help families develop coping resources in the face of illness-related changes in the family, can be helpful.

Families also may be stressed by unfinished business – both practical – such as wills that are not updated, final arrangements that are incomplete – or emotional – such as unrepaired relationships or limited legacy-building activities. Individuals with advanced, life-limiting, or

terminal illness and their families can be assisted with saying what they still need to say and doing what is important to them. Byock (2004) offers a helpful framework for this work, building on the fundamental tenet that while people cannot undo the past, they can express forgiveness, gratitude, and affection, thereby increasing the likelihood of healing and reconciliation.

Psychopathology

Mood and Anxiety. Major Depressive Disorder among persons with advanced disease ranges from 5% to 15% and varies depending on the patient population, type and severity of physical illness, and method and timing of assessment (Hotopf et al. 2002; Walker et al. 2013). When including clinically significant depressive symptoms or Adjustment Disorders, the rates increase to 20–50% among patients in palliative and hospice settings (Derogatis et al. 1983; Rayner et al. 2011).

Treatment of mood disorders at the end of life should include aggressive management of the underlying medical illness and associated physical symptoms as well as the mood disorder. The overarching goals are to manage the psychiatric symptoms, strengthen coping with the disease and associated changes, reduce helplessness and hopelessness, promote meaning-making, and improve quality of life. Cognitive-behavioral therapy (CBT) has been found to reduce depressive symptoms in patients with advanced cancer (Williams and Dale 2006) as has Supportive-Expressive therapy (Kissane et al. 2007). Cognitive therapy also has been found to reduce depressive symptoms as well as fatigue, insomnia, and anxiety in women with metastatic breast cancer (Savard et al. 2006). Mindfulness-based stress reduction meditation seems to be a useful approach in managing depressive symptoms in people with cancer (Garland et al. 2007).

Prevalence of anxiety disorders in individuals with advanced and terminal illness ranges from 2% to 30% (Kadan-Lottick et al. 2005; Roth and Massie 2007). Medically ill individuals often experience anxiety in response to symptoms of the disease as well as uncertainties and fears inherent in living with life-limiting or terminal illness.

They may fear medical interventions, treatment, or particular symptoms and may worry about their capacity to cope with those symptoms. They may fear incapacity, dependency, or disfigurement and may have specific fears about dying, engendered in part from past experiences with the death of significant others. They may fear past transgressions and being rejected or abandoned. They may be concerned about how their loved ones will cope after they are gone. They may worry about financial, legal, and practical matters and fear not having time to complete their affairs. They may fear nonexistence or the afterlife.

Assessment of anxiety in individuals with advanced or terminal illness is complicated by the fact that physical causes of anxiety can be difficult to distinguish from psychological ones. Physical symptoms used to diagnose anxiety and panic may be present as a part of the normal dying process. In addition, anxiety symptoms may reflect a diagnosable disorder, normative fears, or existential suffering and are likely to co-occur with depression and/or delirium. As with depression, it may be helpful to focus on cognitive symptoms such as derealization, depersonalization, and fears of going crazy, generalized worries or worries about future panic attack. Treatment of anxiety disorders includes aggressive management of symptoms associated with the underlying physical illness as well as anxiety. Cognitive restructuring, relaxation training, and coping skills rehearsal have been associated with reduced anxiety and psychological distress in individuals with advanced cancer. Supportive therapy and psychoeducation also are effective in reducing anxiety symptoms.

Post-Traumatic Stress Disorders (PTSD). Individuals diagnosed with a life-threatening illness may be at increased risk for developing PTSD, with estimates ranging from 0% to 35% (Kangas et al. 2002). PTSD can impinge on factors important to hospice and palliative care – emotional and practical support, communication, life review, and unfinished business. Many individuals with PTSD are used to being isolated and detached and are wary of interpersonal relationships, particularly those with people in positions of authority. They have a high need for control and are avoidant of

trauma reminders. They may have difficulty communicating with care providers as direct, clear communication requires effective affect regulation and trust of others, both of which are difficult for persons with PTSD. The normal process of life review and attending to unfinished business for persons with PTSD at the end of life may induce anxiety, guilt, anger, or sadness when key memories are trauma related. Thus, individuals with PTSD may avoid the life review process in order to avoid or suppress reminders or feelings.

Standard treatments for PTSD have limitations for individuals at the end of life, particularly length of time both in terms of duration of treatment and length of individual sessions (e.g., prolonged exposure) and the likelihood of increasing distress in the short term when individuals may have only a relatively short time to live. Pilot studies of prolonged exposure with older adults look promising but have not been replicated with individuals with advanced illness (Thorpe et al. 2012). A model proposed by Hyer and Woods (1998) for treatment of PTSD in older adults and adapted by Feldman (2011) also has potential application to the treatment of PTSD at the end of life. In this multistage model, treatment begins by addressing short-term concerns, then proceeds to longer-range concerns should the medically ill persons live long enough to benefit from addressing such issues. Supportive-expressive therapy in combination with psychoeducation has been associated with reductions in traumatic stress symptoms and mood disturbance in women with advanced breast cancer (Classen et al. 2001).

Psychotherapeutic Approaches

Evidence-based psychotherapies for common mental health disorders (e.g., depression, anxiety, PTSD, substance abuse) are appropriate, but often the evidence available regarding the effectiveness of these approaches in palliative and hospice care settings is limited. Nonetheless, the evidence base supporting the use of Motivational Interviewing (e.g., Benzo et al. 2013; Brodie et al. 2008), Life Review (e.g., Ando et al. 2010),

Cognitive-Behavioral Therapy (e.g., Sage et al. 2008), and Acceptance and Commitment Therapy (e.g., Feros et al. 2013) in palliative care is building. Acceptance and Commitment Therapy is especially fitting given its focus on values-based living and living fully in the midst of suffering. Palliative care providers often find themselves needing to sit with and validate individuals' suffering while raising the possibility that life still can have meaning in the midst of suffering. Sometimes providers' greatest intervention is to bear witness to the suffering, validate the experience, and affirm the individual's humanity – complete with flaws, regrets, failings, goodness, resiliencies, and fundamental worth to others. Trying to "fix" or lessen the feeling can be invalidating in many circumstances.

Mental health providers will want to know about treatment approaches that address issues common to living with a life-threatening or advanced illness, such as existential distress (e.g., LeMay and Wilson 2008). Two promising approaches developed specifically for individuals with advanced illness to promote meaning-making, a sense of purpose, and a sense of self-worth are Meaning-Centered Group Psychotherapy and Dignity Therapy. Meaning-Centered group psychotherapy is based on the principles of Viktor Frankl's Logotherapy and seeks to enable individuals to make the most of whatever time they have remaining through an enhanced sense of meaning and purpose using a combination of didactics, discussion, and experiential exercises. Participants are assigned readings and homework tailored to specific meaning-centered themes. Dignity Therapy seeks to promote individuals' desire to go on living in the face of impending death by helping them identify and share meaningful, important aspects of their past and current lives, their hopes and wishes for their loved ones, and their life values and future goals. The content of sessions is recorded, transcribed, edited, and eventually compiled into a document that is then bequeathed to an identified loved one.

In addition to familiarity with specific psychotherapeutic approaches and the associated evidence base, psychologists also will want to be aware of some of the more unique or salient

aspects of providing psychotherapy with individuals with advanced or life-limiting illness. Psychotherapy typically demands cognitive flexibility, high distress tolerance, and a high tolerance for ambiguity. The pace can be rapid, and the manner in which issues unfold can be unpredictable. Rather than waiting to develop a therapeutic rapport with a patient, providers need to be comfortable “seizing the moment” and tackling difficult issues even when they have no prior relationship with a patient. Psychologists need to be able to critically evaluate and modify their practice to accommodate their patients’ medical status (e.g., fatigue, cognitive impairment, pain) and to help colleagues of other disciplines do the same. Like other forms of psychotherapy in medical settings, psychotherapy as part of palliative care will rarely follow the typical 50-min outpatient model in which individuals are self-referred and requesting assistance. Psychotherapy also may involve a greater pull for self-disclosure, though the guidelines for self-disclosure in the service of the patient still apply, and the potential for stronger emotional and countertransference responses is important to recognize. Psychotherapy in this setting necessitates reflective practice and a high degree of self-awareness, particularly because dying and death is a universal experience that evokes complex feelings in patients, families, and providers alike. See Qualls and Kasl-Godley (2010) for a discussion of psychotherapy at the end of life in the context of a broader discussion of roles for psychologists in end-of-life care.

Interdisciplinary Teams, Consultation, and Professional Self-Care

Palliative care requires interdisciplinary collaboration, consultation, and good self-care. The needs of individuals with advanced, life-limiting, and terminal illness often are extensive and can exhaust the expertise and training of any one discipline. Thus, palliative care is interdisciplinary care. Providers need knowledge of types of teams – multidisciplinary, interdisciplinary, transdisciplinary – and models of team

development. It also helps to know about the function, structure, context, process, and productivity of these teams (Heinemann and Zeiss 2002).

Conflict is a normal aspect of interdisciplinary team function that must be brought to the surface and negotiated for the team to work effectively. Conflict can result from a variety of larger systems factors including scarcity of resources, the stress of large caseloads, and poorly managed organizational change. It can be exacerbated by problematic team dynamics such as deficiencies in team leadership, poor communication, or ambiguous team roles and responsibilities. If there is not adequate team communication, patients’ family dynamics can influence team dynamics, and vice versa, such that teams can unwittingly mirror or amplify family conflict.

Conflict can be negotiated effectively when providers have skills in managing team dynamics (Heinemann and Zeiss 2002) and knowledge about the factors that affect team organization, such as stages of team development, type of health care setting and its resources, professional training models and interdisciplinary roles, and attitudes toward palliative care and mental health. For example, when providers misunderstand each other’s qualifications and skill sets, or try to inappropriately constrain colleagues’ professional responsibilities, the team context (e.g., experience on the team), process (e.g., communication, navigating stressful situations), and productivity (e.g., coordinating patient care) often suffer. Another challenge for interdisciplinary teams is how to cover the salaries of all team members, especially in fee-for-service, noncapitated systems. Reimbursement for all services provided may not be possible, as not all members of a team may be able to bill for their work and having separate billing/reimbursement practices for every individual on the team is not viable.

In addition, palliative care providers need to be self-reflective, self-aware, and establish self-care practices; otherwise, they will not be able to sustain the work. Acting in ways that are inconsistent with values or having a chronic mismatch between providers’ expectations or needs and their work settings (e.g., regarding workload, control, values, fairness, interpersonal relationships)

may be a particular risk for burnout. Equally important is awareness of ways to maintain psychological health such as self-compassion and mindfulness/meditation practices.

Summary

Palliative care is specialized care for people with a serious illness. It can be provided at any point in the trajectory of a serious illness and ideally begins when a serious illness is diagnosed. Palliative care also includes end-of-life care, which might involve referral to a formal hospice program, as well as support of the family through the bereavement period. Throughout the course of illness, the focus of palliative care is to alleviate physical, psychosocial, and spiritual suffering; enhance quality of life; manage symptoms; and offer comprehensive, interdisciplinary support to the patient and family.

With physical, psychosocial, and spiritual symptom relief at the heart of palliative care, it is imperative to understand trajectories of common diseases and symptoms experienced by palliative care patients (e.g., pain, fatigue, dyspnea, delirium) and be aware of approaches to symptom management, both medical and psychological. In addition, common psychosocial and spiritual challenges range from normative sadness about loss and change to existential angst about meaning and purpose to development or exacerbation of psychopathology, including major depression or anxiety. In addition to reducing distressing symptoms, palliative care also promotes well-being, through mobilization of support, resilience, perspective-taking, and meaning-making.

The comprehensive focus on patient, family, and medical and emotional symptoms leads to greater patient and family satisfaction with care, reduced symptom burden, improved bereavement adjustment, and sometimes longer lives than similarly ill patients who do not receive palliative care. Palliative care also is associated with cost savings which are achieved through earlier intervention, reductions in emergency department visits, ICU stays, and hospital readmissions.

A Privileged Responsibility

Palliative care offers unique opportunities to change lives for the better, including our own. By helping seriously ill individuals and their families find connection and healing in the midst of medical suffering, we ourselves are privileged to find deeper meaning in our own lives, personally and professionally. We need to recognize the importance of establishing core competences in basic palliative care with the understanding that knowledge and skills are not enough. We must ask ourselves, "In what ways can we be a part of the change that we want to see happen?". "What can we do, in our respective disciplines, as researchers, clinicians, educators and policy advocates, to shape the field of palliative care such that reliable, accessible, quality palliative care is universally available?".

Intergenerational relationships; Kids; Retirees; Withdrawal from employment; Work role exit process

Definition

This contribution focuses on the role that children play in their parents' retirement processes. The central question is: To what extent and how do children affect the retirement processes of their parents? Theoretical approaches, empirical research findings, and potential directions for future research on children-retirement linkages are discussed.

Introduction

The aging of populations in many developed countries and its consequences for public finances, pension systems, labor markets, and organizations has put the topic of retirement high on both policy and scientific agendas. Labor market policies in numerous countries are nowadays focused on mobilizing available labor reserves and prolonging the working lives of older individuals: “Live longer, work longer” is a commonly used expression (OECD 2006). In light of these developments, insights are needed into the factors that affect retirement-related decisions and experiences. Why do some people retire early and others continue working until – or even beyond – the public pension age? How do individuals experience this transition? Why is adjustment to retirement highly difficult for some and fairly easy for others?

The current contribution focuses on the role that children play in the retirement processes of their parents. Generally, two ways can be distinguished in which children can be of influence (Szinovacz 2012). Firstly, the life situations of children may serve as anchor points for the retirement decisions and experiences of their parents. For example, parents may decide to delay their retirement until their children are no longer financially dependent. Secondly, children may be actively involved in the retirement processes of their parents, thereby shaping their parents' decisions and experiences. Children could, for instance, talk with their parents about retirement or provide support in other ways to ease the transition into retirement. Even though children are important members of the social networks of older individuals, the role of children has only received limited attention in retirement research thus far.

This entry will start with a general discussion about retirement research, in which attention will be paid to the definition and conceptualization of retirement and its predictors. After that, the two ways in which children may influence retirement processes – i.e., because of their life situations or by being actively involved in these processes – will be discussed in separate paragraphs. Thereby, attention will be paid to both theoretical approaches and empirical research findings. The entry will

Parents' Retirement Processes, Role of Children, Fig. 1 Schematic representation of the retirement process (Based on Shultz and Wang (2011))

conclude with a discussion of potential directions for future research.

Understanding Retirement Processes

Retirement research is a multidisciplinary study field. Research on retirement has been reported in the economic, demographic, gerontological, psychological, and sociological scientific literature. The definition and measurement of retirement differs largely between studies and disciplines. As Ekerdt (2010) described in a recent overview of the literature, the “designation of the retirement status is famously ambiguous because there are multiple overlapping criteria by which someone might be called retired” (p. 70). Retirement can refer to receipt of retirement income, leaving the labor force completely (or partly) during late careers, leaving one’s main employer, self-assessment of being retired, or combinations of these various characteristics (Denton and Spencer 2009). Most researchers would agree, however, that retirement “relates to withdrawal from the paid labour force” (Denton and Spencer 2009, p. 64).

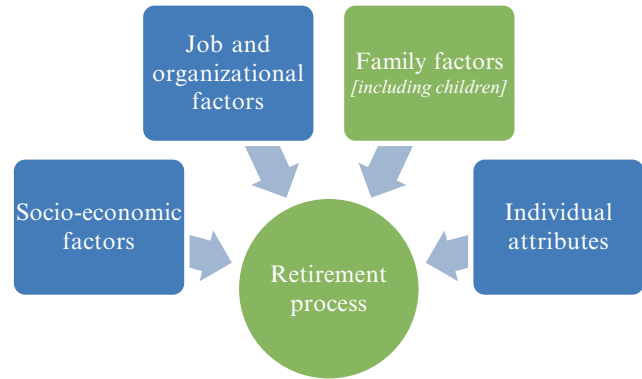

Generally, retirement is conceptualized as being a process taking place over a longer period of time (see Fig. 1). The retirement process starts with a rather distal preretirement planning and preparation phase, in which individuals start thinking, talking, and reading about retirement. After that, if retirement comes closer, older individuals start the retirement decision-making process, in which they decide how and when to retire. Finally, after making the transition into retirement, there is the postretirement adjustment process, in which individuals have to deal with the loss of the work role and need to develop a satisfactory postretirement lifestyle (Shultz and Wang 2011). Even though the consensus is that retirement is a longitudinal process, empirical studies often focus on just one aspect

of the retirement process. Where economic, demographic, and sociological studies often focus on explaining differences in retirement-related behaviors and states (e.g., actual retirement timing), psychological and social-gerontological studies often focus on more subjective processes surrounding the act of retirement (e.g., adjustment to retirement).

Traditionally, for understanding variation in retirement processes, retirement research has focused on older individuals’ own characteristics. For example, it is well known that the financial resources of older individuals and their health situation are crucial factors shaping retirement decisions (Jex and Grosch 2012). Increasingly, however, contextual factors are taken into account as well, which are related to the growing popularity of the “life course perspective” in the gerontological literature. The life course perspective proposes that life transitions – such as retirement – are contingent upon the social contexts in which the transitions occur (Settersten 2003). It takes a multilevel perspective on the individual life course: historical time and place, social norms, the lives of other individuals (i.e., “linked lives”), and earlier life experiences are all proposed to be contextual factors that shape life transitions and experiences. A recent review of the empirical retirement literature by Wang and Shultz (2010) detects – in addition to individual attributes – three central groups of empirically examined precursors of retirement processes: macrosocioeconomic factors (e.g., economic conditions, social security system, social norms about retirement), job and organizational factors (e.g., job characteristics, job attitudes, age stereotypes), and family factors (e.g., marital status, partner support, dependent children). The current entry focuses on this last group of factors – family factors – and more specifically on the role that children play in their parents’ retirement processes (see Fig. 2).

Parents' Retirement Processes, Role of Children,

Fig. 2 Predictors of the retirement process (Based on Wang and Shultz (2010))

Impact of the Life Situation of Children on Their Parents' Retirement Processes

The first way in which children may affect retirement processes of their parents is by their life situations. Both states in the lives of children (e.g., being financially dependent) or events in the lives of children (e.g., having children themselves) might be of importance. To what extent and how can differences in retirement processes of parents be explained by the life situation of their children? Even though the life course perspective points out that children may affect retirement processes, it offers few concrete theoretical expectations about how or why this might be the case. Therefore, research on predictors of retirement often – either implicitly or explicitly – applies a rational choice or resource perspective to formulate hypotheses.

Theoretical Perspectives

From a rational choice perspective, individuals are assumed to make decisions regarding work and retirement based on information they have about their current situation and their expected future situation in retirement. Simply said, it means that “people will attempt to make decisions in such a way that they will maximize their long-term outcomes while minimizing their costs” (Jex and Grosch 2012, p. 275). The individual’s financial situation, health, work context, leisure activities, and also the family situation (including children) can all form important “costs” or “benefits” that either push individuals away from work or pull them into retirement. Also for explaining differences in adjustment to retirement, these various groups of resources can be expected to play

a role. From a resource-based dynamic perspective, the ease of adjusting to retirement is hypothesized to be the direct result of the access individuals have to resources and changes in these resources over time. The more resources older individuals have to fulfill the needs they value in retirement, the fewer difficulties they will experience adjusting to retirement (Wang et al. 2011).

Having children and events in the lives of children may shape the resources of their parents surrounding retirement. On the one hand, children might affect the financial situation of their parents and consequently their retirement decisions and experiences. Having children might negatively affect the acquisition of pensions over the life course – especially among women – and might therefore limit the financial opportunities to retire relatively early. Moreover, having financially dependent children during one’s late career might affect retirement processes, because it limits the financial leeway individuals have to make retirement decisions and to shape their lives in retirement in their preferred way. Financial dependence of children can therefore be expected to result in a delay of retirement timing, to make adjustment to retirement more difficult, and to increase the likelihood of engagement in bridge employment (i.e., paid work after retirement from a major/longer-term job).

On the other hand, the situation and events in the lives of children might shape the social situation of their parents during late careers, which could also affect retirement decisions and experiences. For instance, having relatively young children in the household might make adopting a

retiree identity not yet feeling appropriate and therefore might result in a delay of retirement timing. Becoming a grandparent can rather be expected to increase the relative attractiveness of retirement. Having grandchildren at a younger age might make individuals feel older than their peers without grandchildren, making the retiree identity more appropriate and attractive. Moreover, spending time with one's grandchildren might form an attractive outlet for activities in postretirement life. If early retirement options are present, care for grandchildren might therefore be a motivation for grandparents to leave the labor force relatively early.

Empirical Findings

In empirical studies aiming to explain differences in terms of retirement timing, adjustment to retirement, or bridge employment, the role of children has only received limited attention thus far. Children's characteristics are often – if they are taken into account – included as control variables, especially in studies focusing on men. In studies on the retirement of women, children have traditionally received more attention, which is related to the traditional gender role division where paid work was central in the lives of men, and housework and care tasks were central in the lives of many women. Given the popularity of the life course perspective in the social-gerontological literature, attention for the role of children in retirement processes seems to be growing. Increasingly, for instance, the relationships between fertility histories and retirement also receive attention in studies including men (Damman et al. 2011; Hank and Korbmayer 2013).

The measures that have been used to incorporate information about children in the statistical models are rather diverse. Next to basic measures of whether the studied individuals have children, or their number of children, also whether older individuals have dependent children, or children still living at home, are factors that are frequently taken into account. More detailed measures of fertility histories, such as the timing of having a first child in the life course, are factors that recently have received more consideration in the empirical literature. Findings from these studies

are, however, still rather fragmented and difficult to compare and yield conflicting conclusions (Szinovacz et al. 2012). Another factor that also recently started to receive more attention in the retirement literature is the transition into grandparenthood. Also here, empirical insights are still rather scarce, and more research would be needed to draw general conclusions.

The most consistent finding with regard to the impact of children on retirement processes concerns the role of dependent children. Having dependent children has been found to affect retirement processes in many different studies and country contexts, and it appears to influence diverse aspects of the retirement process. Recent reviews of the literature show that not only retirement timing is influenced by having dependent children (Wang and Shultz 2010) but also the ease of adjustment to retirement (Wang et al. 2011) and engagement in bridge employment (Wang et al. 2014; Beehr and Bennett 2015). Having dependent children has generally been found to decrease the likelihood of retiring early, to have a negative impact on retirement adjustment quality, and to be positively related to the decision to take on bridge employment. This is an important finding, particularly given the trend that the transition into parenthood has increasingly been postponed during the last decades and having relatively young dependent children in one's fifties and sixties is no longer unusual.

Involvement of Children in Their Parents' Retirement Processes

The second way in which children may affect retirement processes of their parents is by being actively involved in these processes. For example, by talking with their parents about retirement or by offering emotional support in the transition to retirement, children could shape their parents' retirement decisions and experiences. To what extent are children involved in the retirement processes of their parents and how can potential differences be explained?

Theoretical Perspectives

In the literature on retirement, limited attention has been paid to the involvement of children in

the retirement processes of their parents and its potential predictors. In the literature on intergenerational relationships, however, theoretical starting points can be found regarding the exchange of support between parents and their adult children, which is often referred to as “functional intergenerational solidarity.” Provision of support can be instrumental/practical (e.g., helping with household work), financial, or emotional in nature. Two central theoretical perspectives can be distinguished that have been used to provide insights into the question why parents and children provide each other with support: one based on altruism and another based on exchange (Kalmijn 2014).

In the first theoretical perspective, based on the principle of *altruism*, it is assumed that within families, individuals are willing to provide support to each other, in case the other is needing support. The well-being of the other is perceived to be a benefit that is taken into account by the individual who is providing support. By assuming that “meeting another person’s need makes that other person happier” (Kalmijn 2014, p. 392), it is expected that children will respond to the need for support of their parents. When applying this notion to the case of retirement, it can be hypothesized that the more support parents need surrounding their retirement transition, the more support they will receive from their children. Older individuals might differ, however, in the amount of support they need. For example, factors like retiring involuntarily and not having a partner to share the retirement transition with, have been shown to make postretirement adjustment more challenging (Wang et al. 2011). This might increase the need for emotional support of the children surrounding retirement and consequently can be expected to be related to a higher level of support received.

The second theoretical perspective is based on the principle of *exchange*. This theoretical perspective starts with the assumptions that (a) engaging in social relationships involves both costs and benefits for the individual and that (b) what individuals do in social relationships is motivated by the balance of these costs and benefits. Generally, it is argued that “the costs of

supporting someone else – in terms of time and energy – are compensated by the benefits of receiving support in return” (Kalmijn 2014, p. 390). The norm of reciprocity reduces uncertainty and ensures that individuals will receive something in return for the support they have given. This “payback” does, however, not need to take a similar form and does not need to take place immediately. When applying this theoretical perspective to the context of retirement, it can be expected that the more support parents provide to their children (e.g., by frequently taking care of the grandchildren), the more support they will receive from their children surrounding retirement.

Empirical Findings

Empirical insights on intergenerational support regarding retirement are limited. There are a few studies focusing on changes in terms of social contacts between parents and children surrounding retirement (Szinovacz and Davey 2001). Research that specifically focuses on the involvement of children in the retirement processes of their parents is still virtually absent, though. Data of the NIDI Work and Retirement Panel could, however, provide some insights regarding the extent to which parents talk with their children about retirement and perceive their children to be a major support in their retirement processes.

The NIDI Work and Retirement Panel is a three-wave panel study conducted in the Netherlands. Older individuals who were working in three private sector organizations and for the Dutch national government in 2001 were followed in their retirement processes over a period of 10 years. During this period, the majority of participants retired from work. In 2011, all fully retired participants who have at least one child – about 700 persons in total – were asked to respond to four statements about the role of their children in their retirement processes. The responses to these statements could provide an indication of the extent to which children are involved in the retirement transitions of their parents. It should be noted, though, that these responses only reflect the perceptions of parents in this respect. The mean age of the participants

Parents' Retirement Processes, Role of Children, Fig. 3 Involvement of children in the retirement processes of their parents, responses of fully retired parents, *N* = 697 (percentages) (Source: NIDI Work and Retirement Panel 2011)

Parents' Retirement Processes, Role of Children, Fig. 4 Involvement of children in retirement processes, level of agreement with four statements by gender, partner

status, and voluntariness of retirement (percentages) (Source: NIDI Work and Retirement Panel 2011)

was 65 in 2011, and they were on average (early) retired for 5.5 years.

To what extent are children involved in the retirement processes of their parents? In short, only a minority of the studied retirees talk with their children about their retirement or experience their children as an important source of support in retirement. Figure 3 shows that only about 10% of the studied retirees have talked a lot with their children about life after retirement. A somewhat larger share, 13%, indicate that their children often ask about their experiences exiting the work role. About 22% of the retirees agree with the statement “My children are a great support for

me, now that I do not work anymore,” and one out of five retirees expects that life after retirement would have been more difficult if they did not have children. When combining the answers to the different statements, a similar conclusion can be drawn. Figure 4 shows the percentages of respondents that agree with none, one, two, or three/four of the statements. Only 6% of retirees agree with three or all four statements. About 61% did not agree with any of the statements, suggesting they do not receive much support of their children in their retirement processes.

Retirees appear to differ quite a lot in terms of the support they receive from their children in the

Parents' Retirement Processes, Role of Children, Fig. 5 Involvement of children in retirement processes, level of agreement with four statements by frequency of

taking care of grandchildren, and helping with practical chores (percentages) (Source: NIDI Work and Retirement Panel 2011)

transition from work to retirement. How can these differences be explained? Interestingly, the amount of support received does not seem to differ much between men and women. What appears to play a role is whether the parent has a partner. Retirees who do not have a partner on average report a higher level of involvement from their children compared to parents who have a partner, as could be expected based on altruism theory. It might be the case that parents who do not have a partner need more support surrounding their retirement transition and that children respond to these needs. Other potential indicators of need for support surrounding retirement, such as involuntary retirement, are, however, not associated with involvement of children in their parents' retirement processes (see Fig. 4).

Additionally, as expected based on exchange theory, retirees who regularly take care of their grandchildren, or who often help their children with practical chores, are relatively likely to receive support of their children when transitioning into retirement (see Fig. 5). Especially retirees who are babysitting the grandchildren on a weekly basis report a higher level of involvement of the children regarding retirement as compared to those retirees who never

babysit. The differences between the other groups are relatively small, suggesting that babysitting only plays a role if it is done frequently. For practical chores, the responses also show the expected pattern: The more often parents help their children with household work or practical chores, the more likely they are to receive support in their retirement processes. It should be mentioned, however, that these results do not necessarily reflect the exchange principle. They can also be explained by other underlying factors such as the contact frequency between parents and children, family norms, or relationship quality.

Overall, this research example suggests that only a minority of retirees receive support from their children in the transition from work to retirement. It might be the case that children are not aware of the fact that retirement is an important life transition in which their parents might need some support. Alternatively, it might be the case that parents do not need much support during their retirement processes or do not need support from their children. They might rather search for support among individuals in a similar life phase, such as their partner, siblings, or friends. Further research is needed in this respect.

Future Directions

The life course notion of “linked lives” proposes that close others in the social network of individuals – such as one’s partner, siblings, and children – will play an important role in shaping retirement processes. Whereas the role of the partner has received considerable attention in retirement research, the “field needs additional research about family-retirement linkages that extend beyond the marital unit” (Szinovacz et al. 2012, p. 480). To what extent and how do children affect the retirement processes of their parents? With regard to this question, retirement research has largely focused on the role of basic characteristics of children (e.g., having dependent children). Little is known about the active involvement and support of children in retirement processes. In this paragraph, four potential directions for future research will be discussed.

Firstly, the role of attitudes of children regarding retirement of their parents needs further examination. Even though prior studies have shown that feelings of the partner and the supervisor are important for understanding differences in retirement timing and the way in which retirement is experienced (i.e., being voluntary or involuntary), the feelings of children have received limited attention in empirical studies thus far. How do attitudes of children with regard to the retirement timing of their parents affect the retirement processes of the parents? And does this impact differ between parents who have children that still live at home, as compared to parents who have children that live on their own?

Secondly, the extent to which children are actively involved in the retirement processes of their parents requires further study, as well as its consequences in terms of postretirement adjustment and well-being. The empirical data of the NIDI Work and Retirement Panel suggest that only a minority of retirees talk with their children about retirement or receive emotional support from their children in the transition from work to retirement. Children seem to be likely to support their parents if support is exchanged and only seem to react to a limited extent to potential indicators of need for support surrounding retirement.

To what extent and how do the principles of altruism and exchange apply to intergenerational support provision during retirement processes? Further disentangling this puzzle in other research samples would be a valuable direction for future research.

Thirdly, the impact of the social context deserves more attention. The role that children play in retirement processes might, for example, differ between retirees that live alone or live with a partner, between individuals from different socio-economic groups, and between country contexts. Countries differ notably, for example, in the role that children play in retirement systems and cultures (Velladics et al. 2006), and therefore we should be careful with generalizing results from one specific country to other countries. Recent initiatives like the SHARE data (i.e., Survey of Health, Ageing and Retirement in Europe) offer opportunities to make between-country comparisons in terms of the role of children in retirement processes.

Fourthly, children might not only influence the retirement processes of their parents, but the retirement processes of the parents might affect the relationships with children as well (Szinovacz 2012), raising several questions for future research (Szinovacz et al. 2012). To what extent and how does retirement of the parents change the contact and quality of the relationships with their children? Do the expectations that children have about the support that parents provide to them (e.g., expectations about taking care of the grandchildren) change when their parents retire? Studying these questions would require a longitudinal and multiactor research design, in which older workers and their children are followed over a longer period of time.

Retirement is an important transition in the lives of older individuals, which “does not occur in a social vacuum” (Szinovacz 2012, p. 167). It can be influenced by the family and social network context and may shape the individual’s family context and social network too. Overall, research has shown that including family-related factors in models predicting retirement does not largely diminish the effects of well-established correlates of retirement but

rather improves model predictions (Matthews and Fisher 2012). For achieving a better understanding of retirement processes, children might therefore be important network members to take into account.

Parkinson's Disease

Sarah E. Cook
Duke University, Durham, NC, USA

Parkinsonism is a clinical syndrome involving problems with voluntary motor function, including development of a resting tremor, muscle rigidity, and slowed down motor movements. Parkinsonism as a syndrome can be present in multiple different neurological diseases. It can also result from the use of certain medications. Parkinsonism, when idiopathic or not due to any other cause, is called Parkinson's disease (PD), which will be the major focus of this entry.

While Parkinson's disease (PD) can develop in mid- to late adulthood, age of onset peaks around age 60 (Gunzler et al. 2011). PD affects approximately 1 out of 100 individuals over the age of

65 (Noyce et al. 2012). A meta-analysis of risk factors for developing PD conducted by Noyce and colleagues (2012) concluded that family history of PD confers the greatest risk, with history of pesticide exposure also increasing risk. This meta-analysis also suggested that history of smoking tobacco, consuming coffee, and consuming alcohol may reduce the risk of PD, although the mechanism by which they protect against PD is not well understood.

This entry will provide a broad overview of Parkinson's disease for nonphysician health service providers. First, the relevant pathology will be discussed briefly, including neuroanatomy, neurotransmitters, and neural circuitry involved in the clinical presentation of PD. This will provide a framework for understanding the common clinical presentation of PD, including both the neurological and cognitive signs and symptoms, which will be presented in the second and third parts of this entry, respectively.

Parkinson's Disease Pathology

Structures in the Basal Ganglia

Dysfunction of the basal ganglia, and to a lesser extent the cerebellum, is implicated in producing the neurological signs and symptoms associated with Parkinson's disease and other movement disorders that present with parkinsonism. The basal ganglia is a set of gray matter structures deep within the brain (i.e., subcortical), including the striatum (including the caudate nucleus and putamen), the globus pallidus (which is further divided into the globus pallidus interna and globus pallidus externa based on their position within the brain), the substantia nigra (which is further divided into the substantia nigra pars compacta and substantia nigra pars reticulata), nucleus accumbens, ventral pallidum, and subthalamic nucleus (Gunzler et al. 2011).

There is a typical order in which pathological central nervous system changes occur in individuals with PD (Williams-Gray et al. 2009), starting with subcortical changes and then cortical changes occur much later in the disease process. The initial noted change is loss of dopaminergic

neurons in the substantia nigra. This process is slow and according to Galvan and Wichmann (2008) may develop over the course of decades, with dysfunction of the substantia nigra projections to the putamen likely to occur prior to changes in the connections to other association areas. This progression may mirror the clinical presentation, as motor changes occur prior to non-motor changes, which will be described in more detail in the next section of this entry.

Other Neuropathological Findings in Parkinson's Disease

In addition to the noted changes in the substantia nigra, there is also deposition of Lewy bodies in subcortical and brainstem structures, including the substantia nigra, locus ceruleus, nucleus basalis of Meynert, dorsal medial nucleus of the vagus nerve, and hypothalamus. However, the presence of Lewy bodies is not specific to PD, as Lewy bodies can be present in asymptomatic individuals (i.e., individual passed away prior to any clinical manifestation) and co-occur in 10–40% of individuals with pathologically confirmed Alzheimer's disease, and importantly some patients with PD do not have Lewy body deposition (Gelb et al. 1999). In addition, there are changes in the amount of available acetylcholine in the brain due to alpha-synuclein accumulation in the basal forebrain and ascending cholinergic pathways, which interferes with cognition and has been shown to be associated with onset of dementia in PD discussed in more detail in the last section of this entry (Kehagia et al. 2010).

Function of the Basal Ganglia

Many of the basal ganglia structures are part of multiple important parallel neural circuits connecting different parts of the cortex; some of its function includes the initiation of and control of voluntary motor movement. This entry will only review in depth the motor circuit, which is involved in motor control and provides a framework for understanding the pathological changes that cause the clinical presentation of PD. Galvan and Wichmann (2008) and Wichmann and DeLong (2015) provide much more detailed summaries about the connections along with helpful

figures of the motor circuits, neurotransmitters, and structural issues related to PD if more comprehensive information is desired.

In the motor circuit, the putamen and caudate nucleus (striatum) receive excitatory inputs via glutamate from the cortex (primary motor cortex, premotor cortex, and the supplemental motor areas in the frontal lobes). There are two functionally distinct circuits at this point, the direct and indirect pathways. In the direct pathway, the projections from the caudate and putamen are inhibitory via γ -aminobutyric acid (GABA) and head to the globus pallidus pars interna and subthalamic nucleus pars reticulata which further project to the thalamus via GABA and back to the motor cortex via glutamate. The net effect of this is excitation, or an increase in motor activity, in a healthy individual. However, if there is a lack of dopaminergic neurons in the substantia nigra pars compacta firing excitatory dopamine on the striatum (caudate and putamen), as is the case in PD, the net activity in the direct pathway is reduced and therefore causes a reduction in motor activity (Wichmann and DeLong 2015).

In the indirect pathway, the projections from the caudate and putamen are inhibitory via GABA and head to the globus pallidus externa, then have inhibitory projections to the subthalamic nucleus via GABA, and then go to the globus pallidus pars interna and subthalamic nucleus pars reticulata with excitatory glutamate which further project to the thalamus via GABA and back to the motor cortex via glutamate. The net effect of this pathway is a reduction of motor activity in a healthy individual. However, if there is a lack of dopamine excitation in the substantia nigra firing on the striatum due to PD, the effect of the indirect pathway is an increase in activity in the indirect pathway, meaning *increased reduction* in motor activity. Taken together, the result of losing the excitation from dopamine in both the direct and indirect motor circuits causes the hypokinetic symptoms seen in PD, such as slowed movement (bradykinesia; 7).

While the motor circuit dysfunction provides understanding of what causes the slowed motor movements in PD, the two other parallel circuits that have projections to the striatum and

substantia nigra are responsible for the non-motor features of PD. The disruption of the prefrontal circuit is responsible for the cognitive changes, including problems with attention, working memory, and sequencing. The disruption of the limbic circuit is what can lead to problems with emotional regulation including impulsivity, compulsive behavior, and mood changes (Wichmann and DeLong 2015).

Neurologic Presentation of Parkinson's Disease

Diagnosis

While the pathological features of PD are loss of dopaminergic cells in the substantia nigra, the cardinal clinical features of PD include akinesia/bradykinesia (absent or slowed voluntary movement), resting tremor, muscle rigidity, and eventually postural instability later in the disease course (Gelb et al. 1999). There are some other characteristic motor signs that frequently are present in individuals with PD, including hypophonia (very soft voice), masked facies (blank or reduced facial expression), micrographia (small handwriting), shuffling gait, absence of arm swing when walking, and stooped posture (Gunzler et al. 2011). Clinical symptoms often appear only after a very large proportion (50–80%) of dopaminergic neurons is lost. Onset of symptoms is often asymmetrical, typically in an upper extremity, but usually eventually spreads and becomes bilateral. However, it should be noted that the asymmetric onset is not sensitive or specific for PD as other movement disorders can present this way (Gelb et al. 1999). In addition to the motor symptoms, there are non-motor symptoms that often occur in PD as well, including symptoms of depression or apathy, cognitive changes, autonomic disturbance, and/or sleep disturbance. The course of PD is slowly progressive but individually variable, with younger patients often seeing slower progression (Gunzler et al. 2011). Severity is often gauged by neurologists with one or both of the standard rating scales, the modified Hoehn and Yahr Scale or the Unified Parkinson's Disease Rating Scale (UPDRS).

Clinical diagnosis is made with history as well as physical and neurological examinations, usually by a neurologist. Careful attention to exclude any alternative explanations for the parkinsonism is necessary, as there are many other conditions that can present with parkinsonian features, including cortical basal degeneration (unilateral apraxia and reflex myoclonus often present), multiple system atrophy (prominent autonomic symptoms and ataxia), progressive supranuclear palsy (problems with vertical eye movement, falls early in disease course), Wilson's disease (dystonia, liver disease, Kayser-Fleischer rings in the eyes are present), and Huntington's disease (choreiform movements and family history). Once PD is suspected and treatment begins, confidence in diagnosis often increases, as idiopathic PD responds well to typical (levodopa) treatment, while symptoms often do not remit in conditions mimicking PD (Gelb et al. 1999).

In addition to these neurologic syndromes that can present with parkinsonism, patients may present with the same symptoms only to later discover that the symptoms are functional (i.e., psychogenic) and do not have a physiological cause, such as a somatoform or conversion disorder (Gunzler et al. 2011). Parkinsonism can also be drug induced by dopamine antagonists (drugs that block the action of dopamine), including neuroleptics. Many drugs that are used to treat psychotic disorders, such as clozapine (Clozaril) and quetiapine (Seroquel), can cause parkinsonism, with about half of cases showing symptoms in the first month of being exposed to the drug. It occurs more often in older adults and more likely in women than men. Drug-induced parkinsonism is more likely to present with bilateral symptoms rather than the typical asymmetrical onset, and most often symptoms will not progressively worsen as in the case with idiopathic PD. In drug-induced cases, the majority of individuals recover once the offending medication is stopped, although the time to recovery is variable and may take more than a year (Sustatia and Fernandez 2009).

Definitive diagnosis has traditionally only been available with examination of the brain post-mortem to look for the characteristic neuropathological changes described earlier. According

to Seifert and Wiener (2013), only about 80% of individuals with a clinical diagnosis of PD are found to have the diagnosis confirmed by post-mortem examination. In very recent years, the development (and US Food and Drug Administration approval) of an imaging technique has shown to be particularly useful in the differential diagnosis of movement disorders. The imaging technique is called DaTscan, a dopamine transporter single-photon emission computerized tomography (SPECT) scan in which I-123 ioflupane is injected which binds to dopamine. During the scan, the amount of transporter present in the striatum is visualized. As outlined in Seifert and Wiener (2013), there is a strong relationship between an abnormal scan and autopsy confirmed parkinsonian syndromes. However, while it has been proven to be useful in distinguishing essential tremor and drug-induced parkinsonism from PD (as there is not a loss of dopaminergic neurons in either), the DaTscan does not differentiate between the parkinsonian syndromes (e.g., PD, multiple system atrophy, progressive supranuclear palsy).

Treatment

The gold standard treatment for PD is medication, which provides symptom relief but does not reverse the pathological changes that have already occurred (substantial loss of dopaminergic neurons in the basal ganglia) or prevent further deterioration. Medication is sometimes not started until PD symptoms, often tremor, begin to significantly interfere with functioning and quality of life as some individuals with PD develop dyskinesia (abnormal involuntary writhing movements) with long-term use of levodopa, the most commonly used class of medications for symptomatic relief of PD. However, recent research by Parkkinen and colleagues (2011) has concluded though that there is not a relationship between chronic use of levodopa taken during life and number of dopamine neurons found in the substantia nigra post-mortem, nor was there a relationship between levodopa and amount of Lewy body pathology. Therefore the medication is not suspected to increase or hasten the pathological process.

Several classes of medications are used to treat PD, including dopamine agonists (which increase the level of available dopamine in the brain, such as levodopa, ropinirole, pramipexole), beta blockers (propranolol), catechol-O-methyltransferase (COMT) inhibitors (which block the metabolism of levodopa, such as entacapone, tolcapone), and MAO-B inhibitors (which block an enzyme in the brain that breaks down levodopa, such as selegiline, rasagiline) (Gunzler et al. 2011). Further discussion regarding medication selection for particular symptoms is beyond the scope of this entry, but it is important to know that each type of medication class confers at least some physical side effects that can impact functioning (e.g., constipation, sedation, sleep problems, hyperkinetic movements such as dyskinesias or choreiform movements). Many also have psychiatric side effects. Most notably, the dopamine agonists can cause significant problems with impulse control (such as gambling or compulsive sexual behavior) and/or cause psychotic symptoms (hallucinations and/or delusions) (Gunzler et al. 2011). On the other hand, some of these medications can have a positive impact on cognition, which will be discussed more in depth in the last section of this entry.

Over time with disease progression, individuals with PD often find that their medication(s) is not providing the same benefit. Despite individuals with PD often having to take medication every few hours due to the short half-lives of many of the common drugs used to treat PD symptoms, usual complaints include wearing off of medication causing increasingly prolonged off periods between doses, sudden on/off changes in motor symptoms, and problems with hyperkinesia (e.g., choreiform movements, dyskinesias) during peak dose times (Gunzler et al. 2011; Massano and Garrett 2012). Due to these issues that disrupt functioning and quality of life, regimens may need to be frequently updated to increase symptomatic relief.

There have been non-medication approaches to PD treatment as well. Back in the mid-1900s, some ablative techniques targeting the basal ganglia were explored, and later thalamic targets were used. In more recent decades, for individuals

with PD who no longer gain adequate symptom relief with traditional medications and/or experience rapid wearing off of medications, the possibility of deep brain stimulation (DBS) surgery is often considered. DBS is a neurosurgical procedure that was approved by the US Food and Drug Administration in 2002 for treatment of PD in which the patient has an electrode that provides continuous electrical stimulation placed either unilaterally or bilaterally in the subthalamic nucleus or globus pallidus interna that is connected to a device implanted in the chest used for programming. This has been a favorable evolution in treatment as it is a less invasive treatment than ablations and can be modified as needed based on patient response; however, it does not appear to modify disease progression (Gunzler et al. 2011; Bronstein et al. 2011).

However, not all individuals with PD who have disabling symptoms that are treatment refractory with traditional medications will be deemed an appropriate candidate for DBS. Extensive research in recent decades has assisted with understanding what factors are important for good clinical outcomes, which has informed patient selection for DBS surgery. In a recent consensus statement on DBS (Bronstein et al. 2011), experts in this field agreed that a multidisciplinary approach to patient selection is indicated, including neurology, neurosurgery, neuropsychology, internal medicine, and sometimes psychiatry and/or other specialties. Those with the best outcome have advanced PD whose symptoms have responded very well to levodopa (dopamine agonist), are of younger age (but an exact age cutoff has not been established), are not cognitively impaired (presence of dementia is the most frequent exclusion criterion, but no exact test battery or score cutoffs have been established as guidelines), and have no or well-controlled psychiatric symptoms.

Outcomes of DBS are not universally positive. Some research has found differential outcomes depending on site of electrode, with patients having DBS implanted within the subthalamic nucleus (STN) demonstrating more problems than those with globus pallidus interna implants. According to the consensus review (Bronstein

et al. 2011), individuals with STN DBS have increased falls and can worsen speech. Apathy and impulsivity may worsen with STN DBS. In addition, verbal fluency and executive efficiency may be differentially worse in those with STN DBS, although the research to date has been equivocal (Massano and Garrett 2012). Furthermore, the benefit gained from DBS may not be permanently sustained even with regular programming adjustments because DBS does not alter the disease course, although Bronstein et al. (2011) suggest that multiple studies have generally shown effects for up to 5 years.

Neuropsychological Presentation of Parkinson's Disease

Due to replacing dopamine with medication, some individuals with PD who consistently take levodopa may see mild cognitive benefit. Such research has compared newly diagnosed drug naïve and individuals with PD that are treated with dopaminergic medications or by temporarily withdrawing randomized patients from their medication regimens. Skills that have been shown to benefit from medications that increase available dopamine include cognitive efficiency, thinking flexibly, holding information in mind while manipulating it (i.e., working memory), and inhibiting a prepotent response. Other cognitive skills seem resistant to the effects of increasing dopamine (Kehagia et al. 2010).

Mild Cognitive Impairment in Parkinson's Disease

Despite the potential cognitive-enhancing benefit of dopaminergic medications, many patients with PD complain about problems with focusing attention, multitasking, and sustaining attention over long periods. As the disease progresses, individuals with PD can experience increasing attention and memory problems which become more evident to those around them. As noted earlier, such changes are likely related to the neuropathological changes in PD. Specifically, the dopaminergic dysfunction leads to a dysexecutive syndrome while cholinergic changes can lead to changes in

memory and visuospatial skills (Kehagia et al. 2010).

One issue with defining criteria for cognitive deficits in PD is that as a group, the clinical presentation is heterogeneous, with often very little findings in those earlier in the disease, but then some have mild impairments and some have a clear dementia. Furthermore, assessment and interpretation of findings of individuals with PD is complicated by disease- and medication-related effects. For example, individuals with PD very often present with slowed motor movements (bradykinesia) and/or upper extremity tremor that impacts performance on speeded tasks, more so for motor responses, but also can be present for verbal speeded responses as well. Some medications used to treat PD can have sedating effects or have negative cognitive side effects, such as amantadine or the benzodiazepines. As discussed earlier, there are also non-motor features that individuals with PD can present with that could negatively effect cognition, including psychiatric features (such as depression or apathy) and/or sleep disturbance. It is optimal to have individuals with PD complete neuropsychological testing while in their usual medicated state, and therefore careful watch of the time by the neuropsychologist is necessary so that medications are taken as usual to attempt to prevent testing during an "off" time (Litvan et al. 2012). York and Strutt (2015) provide an excellent review of the common assessment measures used in the neuropsychological evaluation of individuals with PD.

While there has been some controversy regarding the use of the term mild cognitive impairment (MCI) for individuals with PD, the Movement Disorder Society (MDS) convened a task force in 2010 to discuss cognition in PD, which led to a systematic review of the literature (Litvan et al. 2011) as well as a set of criteria for what they termed PD-MCI (Litvan et al. 2012). The task force developed inclusion and exclusion criteria for PD-MCI so that there is a uniform criterion to assist with provider communication, patient care, and clinical trial outcomes research. Once the PD diagnosis has been formally established, the task force recommends formal neuropsychological evaluation early in the course

of the disease to establish a cognitive baseline. With that resulting data, the deficits can be examined to determine where on the continuum of cognitive status the individual patient falls.

In order to meet the criteria for PD-MCI, the individual with PD must have a noted gradual decline in cognition either by self-report, other reports, or observed by the health provider. Cognitive deficits on formal testing must be present. If only a brief cognitive screening was complete (e.g., the Montreal Cognitive Assessment or MoCA), the individual with PD must score in the impaired range. If a formal, comprehensive neuropsychological evaluation was completed, the individual with PD must demonstrate impairment on at least two tests, either both in one cognitive domain or at least one test in multiple cognitive domains. The definition of impairment is rather liberal, defined as either 1–2 standard deviations below same age peers, significant decline demonstrated on serial (longitudinal) evaluation, and/or significant decline from estimated level of premorbid functioning. Patients are excluded from PD-MCI if the cognitive impairment is likely best explained by another factor, such as delirium, stroke, depression, brain injury, or medication effects. Further, the neuropsychologist must determine that PD-associated features (e.g., bradykinesia, severe depression, fatigue) did not significantly interfere with performance on the neuropsychological evaluation (Litvan et al. 2012).

Individuals with PD are twice as likely to develop mild cognitive impairment (MCI) as healthy older individuals, with up to about 50% expressing mild cognitive deficits within the first 5 years after diagnosis (Kehagia et al. 2010). There has been a dearth of research examining cognition longitudinally in a well-characterized PD sample. From the review of the literature by the MDS task force (Litvan et al. 2011), there were only eight studies that met the inclusion and exclusion criteria that were included in the review. The mean cross-sectional prevalence of mild cognitive deficits was 26.7% with a range of 18.9–38.2%. This work also showed that the frequency of cognitive impairment increased with age and disease duration. Other research has also

demonstrated that there is a relationship between PD-MCI and late onset of disease as well as lower educational level. The search for biomarkers for cognitive impairment in PD is still in an early stage, although one study did find that the tau MAPT H1/H1 genotype was found to be a risk factor for PD-related dementia (Litvan et al. 2011).

Dementia in Parkinson's Disease

Not surprisingly, having mild cognitive impairment in PD is a risk factor for later development of PD-related dementia. PD-related dementia is considered when significant cognitive deficits occur in two or more cognitive domains, and the deficits cause significant interference in everyday activities. Accompanying the significant cognitive changes, there can be problems with visual hallucinations (which may be a sign of more rapid cognitive decline and may have associated visuospatial and perceptual deficits on formal testing), depression or apathy, or anxiety (Kehagia et al. 2010). Dementia in PD is now more widely accepted as part of the disease process. However, dementia preceding motor changes or very early in the disease process should alert the clinician that another diagnosis should be considered (Aarsland and Kurz 2010), particularly with dementia with Lewy bodies on the differential.

A study by Janvin and colleagues (2006) found that 62% of PD-MCI patients converted to dementia within the 4-year follow-up compared to 20% of individuals with PD that did not have cognitive impairment at baseline. Sixty-nine percent of those with single-domain, non-amnesic cognitive impairment converted to dementia, while only 40% of those originally with an amnesic impairment alone converted. They also found that increased severity of depression was a risk for later development of PD-related dementia. In a review on the epidemiology of dementia in PD, Aarsland and Kurz (2010) conclude that the point prevalence of dementia in PD is about 30%, with incidence about four to six times that of healthy controls. Notably, they also suggest that the cumulative prevalence suggests that about 75% of those with PD who survive 10 years will develop dementia.

In one population-based longitudinal study examining incidence of cognitive impairment in PD (Williams-Gray et al. 2009), the authors concluded that posterior cortical neuropsychological findings were more related to PD-related dementia, while more frontal-striatal neuropsychological findings were not related to dementia. This implies that there could be two distinct cognitive phenotypes in PD with possibly unique features including etiology, pathology, and/or disease course. Kehagia and colleagues (2010) reported that in neuroimaging studies, compared to controls, individuals with PD and PD-MCI have reduced cerebral glucose uptake in the temporal lobe and occipitoparietal junction. In those with PD-related dementia, there is also cerebral atrophy in the frontal, temporal, and occipital cortices, as well as changes in the subcortical structures. The visual hallucinations that can be seen in PD-related dementia were associated with Lewy body accumulation predominantly in the temporal lobe as well as loss of cholinergic neurons in the basal forebrain (Kehagia et al. 2010).

In terms of treatment of cognitive symptoms in PD, there has been some research investigating cholinesterase inhibitors (e.g., donepezil) and NMDA receptor antagonists (e.g., amantadine, memantine). There has been modest benefits identified (Kehagia et al. 2010), but as with any drugs, the risks and benefits need to be weighed for each individual patient. For example, amantadine can cause hallucinations and confusion and thus may not be the best choice for all patients. In addition to pharmacotherapy, some individuals with cognitive impairment secondary to PD may benefit from a therapeutic intervention. Some neuropsychologists and speech therapists specialize in providing such interventions aimed at identifying specific problems in daily life as a result of cognitive impairment and teaching ways to compensate for the specified deficit in very concrete ways.

Dispositional traits; Individual characteristics; Life stories; Personal action constructs; Self-narration; Self-regulatory processes; States

Definition

The construct of personality encompasses individual characteristics as well as the active processes of the individual's interactions with the environment. This includes relatively enduring characteristics of one's thoughts, feelings, and actions (i.e., traits), as well as dynamic interplays of social-cognitive processes (i.e., personal-action constructs, self-narration). Under a lifespan developmental approach, research on personality now involves both personality stability and change, growth and decline and recognizes the heterogeneity of development due to processes of adaptation across the lifespan.

Overview

Throughout the aging process, individuals encounter unique age-related challenges that have stimulated a myriad of health-related investigations from lifespan researchers in the last 50 years. Incorporating the study of personality

development within the realms of gerontology has provided valuable insight on the interactions between individual characteristics and health-related behaviors expressed throughout the lifespan. Studying one's personality can reveal, on multiple levels of analysis, the particular behaviors that are of importance to optimal aging (e.g., social support, coping strategies, exercise, and nutrition). Personality research has tremendous value in gerontology because of the capability for aspects of one's personality to demonstrate positive growth in late adulthood (Bolkan et al. 2009). The integrative and comprehensive approaches taken today highlight the value of studying personality in aging research, and this historical review underscores the essential progress made throughout the years that have brought the field to where it is now.

The Early Years

In 1890, William James, founder of American psychology, argued that "personality is set like plaster by age 30" (James 1981, p. 126). Sigmund Freud's work marked the beginning of theorizing about personality development by supporting James' claim with his theory on psychosexual development. However, Freud's theory limited the stages of development to childhood and adolescence. It was not until major theoretical frameworks from Carl Jung and Erik Erikson that the focus of personality development was broadened to be studied throughout adulthood as well. Self-preoccupation and self-discovery are two essential age-appropriate developmental tasks of Jung's theory that extend beyond childhood. In Erikson's theory of psychosocial development, age-related tasks and resolutions of their corresponding psychosocial crises are thought to arise throughout the lifespan in an eight-stage model. Erikson also pioneered the investigation of adults' concern for and commitment to supporting the well-being of future generations, creating the now well-known term of *generativity* (Bolkan et al. 2009).

Bernice Neugarten provided empirical evidence for why personality theories explaining adult development and aging must not be based

on studies of children alone. She became a pioneer in the study of personality and aging through her work with the Kansas City Studies of Adult Life, a set of studies she launched with Robert Havighurst. Results from this project denounced the idea that there is no change in adult personality. Instead, Neugarten argued for more investigation into the relationships between heterogeneity and age which paved the way for future research to focus on processes of both stability and change, and person-environment fit, throughout the lifespan (Bolkan et al. 2009).

Controversies Dividing the Field

Before the integration of stability and change was generally accepted, these distinct views separated the field into either arguing for internal processes or environmental forces directing behavior. The psychodynamic perspective can be seen in Freud's argument for personality structure's stability due to behavior in early childhood being governed by internal struggles from contradicting drives. Behavioral theorists opposed these claims by arguing for the plasticity of personality across the lifespan. In the 1970s, these critics stimulated the field's divide by positing environmental factors influence personality variables, thus explaining human behavior. This debate exposed the limitations of the existing theoretical accounts, which dampened public interest in personality science (Bolkan et al. 2009).

In addition to these opposing views, personality in general is a broad and abstract construct that has historically been difficult to define. Over the decades, researchers have defined the elusive construct in various ways – applying different theoretical frameworks and utilizing various research methods. This led to dozens of different definitions and little communal agreement on what constituted an individual's personality and how it should be measured. Difficulty in interpretation and understanding of research findings can result from this uncertainty. With this definitional inconsistency and a lessened interest in personality science threatening, little advancement occurred until the reinvigorating contributions from

dispositional trait researchers. The empirical evidence from studying personality traits united the field and may arguably be one of the most substantive contributions of personality science (Bolkan et al. 2009).

The Power of the Trait Framework

The trait level of one's personality involves a structural approach to studying the relatively enduring characteristics of one's thoughts, feelings, and actions generally known as personality traits. These traits are the most fundamental features of an individual and are the foundation of individual differences across the lifespan. The trait framework of personality rose to prominence after multiple factor analytic studies revealed five main traits that were thought to best define personality. At the heart of this research epoch were widely accepted models known as the "five-factor" and "Big Five" models of personality (Goldberg 1993; Costa and McCrae 1992) The "Big Five" model, for example, identifies openness to experience, conscientiousness, extraversion, agreeableness, and neuroticism (OCEAN) as the five main traits of personality (McAdams and Olson 2010). These models provided clarity and a universal language among personality researchers.

While traits are known to be generally consistent over time and context, there is considerable fluctuation in traits based on gene-environment interactions, age, and ways in which researchers measure change. Temporal stability, or the rank-order consistency of individual differences in traits, generally increases from adolescence until a peak in middle adulthood, followed by a slight decline in older adulthood. Mean-level changes, or actual increases or decreases in a trait over specific ages and time periods, show more personality change across the lifespan compared to rank-order consistency (Roberts et al. 2013). Mean-level changes in traits from adolescence to middle adulthood include increases in conscientiousness and agreeableness, and decreases in neuroticism and extraversion. This patterning of socially desirable traits, known as the "maturity

principle,” is influenced by both *genes* and *context* presumably through an increase in responsibilities related to an increase in social roles in family, the work place, and community engagement (McAdams and Olson 2010).

This maturity principle peaks in middle adulthood and is followed by increases in neuroticism and decreases in agreeableness in older adulthood, though studies on very late adulthood are relatively sparse. According to the lifespan developmental perspective, the decreased capability of proficient biological plasticity results in age-related declines in the physical, cognitive, and social dimensions of health. As a result, older adults face challenges in their ability to sustain the positive characteristics displayed in middle adulthood. Increases in depression, neuroticism, and negative effects from stress suggest the possibility of a decline in the positive aspects of personality traits with aging (McAdams and Olson 2010).

While the power of the trait framework is elegant in its simplicity, it is limited in its coverage of the dynamic nature of personality and investigation of differences within the individual, known as intraindividual variability. Ways in which personality predicts various outcomes in aging populations is best understood when taking a holistic approach that involves both personality traits and processes (Hooker and McAdams 2003).

Traits Predict Many Outcomes

Personality traits are related to countless intra- and interpersonal outcomes across the lifespan and are fundamental pieces in establishing and maintaining healthy or unhealthy trajectories in life. In aging populations, particular interest is placed upon the traits that predict physical and mental health, well-being, longevity, cognitive ability, and meaningful engagement in society amid age-related declines and mortality risks. Each trait from the “Big Five” model, especially conscientiousness and neuroticism, and other dispositional characteristics have primary and moderating roles in age-related outcomes in older adults (Friedman and Kern 2014).

Being conscientious, defined as dependable, organized, dedicated, and sensible, is instrumental in creating healthy trajectories across the lifespan. Higher levels of conscientiousness have been related to lower mortality risk due to consistent healthy behaviors and decision-making. Individuals high in conscientiousness pursue environments that promote health and well-being rather than place them at greater risk. For example, conscientiousness has been related to less smoking, better diet, seat belt compliance in cars, pursuit and achievement of education goals, marriage stability, and personal friendships at home and the workplace with other conscientious individuals. In union with these healthy lifestyle patterns, conscientious individuals assess health problems with better coping strategies and other studies have found relationships with the trait and reduced disease development and less symptoms. Possessing conscientious qualities may be important for cognitive health as well, as some research has found low levels of the trait to predict cognitive impairment and diseases such as Alzheimer’s disease (Friedman and Kern 2014).

Having high levels of conscientiousness can also moderate the unhealthy trajectory high levels of neuroticism predicts across the lifespan. Neuroticism is characterized by being insecure, emotionally unstable, worrisome, and anxious, and predicts negative feelings, health complaints, higher stress, and lower levels of subjective health. Being conscientious may reduce these trait expressions amid health problems through effective emotion regulation strategies that help individuals recover from detrimental emotional stressors (Friedman and Kern 2014). There has been conflicting evidence related to neuroticism, with some studies showing neuroticism levels predicting higher mortality risk, some showing lower mortality risk, and some report no substantive prediction of mortality risk. The lowered mortality risk association with neuroticism seems to be characteristic of “healthy neuroticism,” defined as individuals who utilize worry and concern in beneficial ways (e.g., going to the doctor’s office for a checkup). This inconsistency in the literature brings a greater awareness to the importance of studying multiple personality traits

together to see if other factors are contributing to symptom expression or health trajectories (Friedman and Kern 2014).

Lower levels of neuroticism and higher levels of agreeableness, extraversion, conscientiousness, and openness to experiences have been related to lower risks for various diseases and possessing a greater sense of purpose in life, which is associated with positive outcomes such as life satisfaction and self-esteem. Personality traits provide a way to better understand what contributes to healthier lifestyles in older adults, and intervention research is growing with aims to increase healthier trait expressions across the lifespan (Friedman and Kern 2014).

Personality Disorders and Aging

In addition to general health-related outcomes, aging may play an important role in symptom expression of personality disorders. The DSM-5 generally defines a personality disorder as “an enduring pattern of inner experience and behavior that deviates markedly from the expectations of the individual’s culture, is pervasive and inflexible, has an onset in adolescence or early adulthood, is stable over time, and leads to distress or impairment” (American Psychiatric Association 2013). Organized into three clusters, there are ten types of personality disorders (PDs): Cluster A (odd) includes paranoid, schizoid, and schizotypal; Cluster B (dramatic or erratic) includes antisocial, borderline, histrionic, and narcissistic; and Cluster C (anxious or fearful) includes avoidant, dependent, and obsessive-compulsive. Personality disorder not otherwise specified can be diagnosed when symptoms do not fit within a specific type. An alternative approach to classification is featured in the DSM-5 as well. Based on personality functioning and the individual’s pathological personality traits, this emerging model is an attempt to address the existing approach’s shortcomings of unclear diagnoses based on individuals showing symptoms of multiple PDs (American Psychiatric Association 2013).

The median prevalence for any type of PD ranges approximately from 10% to 14% of the

general population (Oltmanns and Balsis 2011). This approximation is most likely an underestimate of the true number due to invalid diagnostic criteria for older adults, as criteria are based on young adults, which may result in missed diagnoses in an older population (Edelstein and Segal 2011). Convenience samples of young adults and lack of longitudinal studies or valid measures for older populations create a need for more appropriate methodology. Utilizing lifespan approaches that incorporate later life environmental demands and an openness to the variability of symptom expression in different age groups may provide a clearer understanding of PD in older adults (Oltmanns and Balsis 2011).

Due to limited longitudinal research on PDs in aging populations, age-related changes in PD symptom expression are not well understood. Cross-sectional analyses comparing prevalence of PD in younger and older adults limit developmental interpretations, but provide some valuable information. There is some support for Cluster A (paranoid, schizotypal, and schizoid PDs) and Cluster C (dependent, avoidant, obsessive-compulsive PDs) increasing in prevalence or remaining stable, with Cluster B (narcissistic, histrionic, borderline, and antisocial PDs) decreasing in prevalence into later adulthood (Oltmanns and Balsis 2011). Recognizing specific age-related stressors is key to examining why symptom expression and traits of PDs may change with aging. Factors to consider include physiological and mental decline, social dynamics (e.g., smaller networks, death of peers, caregiving responsibilities), and life events (e.g., adjustment to retirement, divorce, surgeries, and hospital stays; Oltmanns and Balsis 2011).

PDs have shown comorbidity with other mental and physical health outcomes such as anxiety, depression, substance, and eating disorders (Clark 2007). Borderline PD has been related to greater risk of obesity and diabetes, and schizoid, avoidant, and obsessive-compulsive PDs have been related to coronary heart disease (Oltmanns and Balsis 2011). Treatment programs can be successful if the treatment plan is considerate of the specific qualities of each individual’s diagnosis and involves a comprehensive approach of the structure of personality. Unfortunately,

individuals with PDs very rarely seek treatment for themselves because they generally possess a lack of introspection and concern for societal aid. There is no medication that specifically treats PD, but medications are used to lower comorbid symptoms like anxiety and depression (Segal et al. 2011).

Toward a More Integrative Approach

Dispositional trait research has brought the field to a much greater understanding of personality development and health-related outcomes across the lifespan. However, trait research alone does not fully capture the dynamic nature of personality. Individuals cannot be simplified to the embodiment of their expressed traits. Researchers should aim to analyze individual characteristics as well as the active processes of the individual's interactions with the environment. In this way, a more *whole*, accurate depiction of the individual's personality can be examined. Researchers recognized the importance in this and have called for a more comprehensive framework to apply to these aims (Hooker and McAdams 2003). The study of personality in recent years has adopted a general lifespan developmental approach as a result of this need. Personality theorists now study both personality stability and change, growth and decline, and recognize the heterogeneity of development due to processes of adaptation across the lifespan (Bolkan et al. 2009).

Instead of researchers fueling old debates over "stability versus change," the field has accepted the two can coexist in tandem, with longitudinal evidence for the concurrency of the two conceptually and empirically independent aspects of personality. This shift in understanding requires new personality models that incorporate both stability and change. Hooker and McAdams aimed to answer this need with their *six foci of personality* model of personality development (Hooker and McAdams 2003). Integrating both personality structures and processes in a three level framework, this model enables researchers to study stability and change in personality structures and processes simultaneously. By incorporating multiple trait and social-cognitive approaches, this model examines

the entire complexity of personality. The person as a dynamic *whole* is able to be studied as an individual embedded within relationships and social institutions throughout time and space. In line with lifespan developmental psychology, this model is founded in Developmental Systems Theory, with assumptions including plasticity, multidirectionality, and the organizing characteristics of the individual (Bolkan et al. 2009).

The Six Foci Model of Personality Development

Incorporating literature from lifespan development and personality psychology, Hooker and McAdams identified six essential indicators, or foci, of personality and personality development (Hooker and McAdams 2003). These six foci include *dispositional traits*, *personal action constructs (PACs)*, *life stories* rooted in trait approaches, *states*, *self-regulatory processes*, and *self-narration* rooted in social-cognitive approaches. Each focal point represents a crucial element of either a personality *structure* (i.e., traits, PACs, life stories) or *process* (i.e., states, self-regulatory processes, self-narration) in linked pairs (i.e., traits and states, PACs and self-regulatory processes, life stories and self-narration) that correspond with each other on distinct analytical planes (i.e., one on the structural plane and one on the processes plane).

The structure-process pairs represent the three levels of analysis this model integrates and demonstrates a personality framework that features both idiographic and nomothetic approaches. Together, the model suggests that *all* individuals can be placed upon a continuum of a relatively universal set of traits (Level I); that *some* individuals may find specific goals and developmental tasks important (Level II); and that life stories are *unique* among all individuals (Level III; Bolkan et al. 2009; Hooker and McAdams 2003).

Level I: Traits and States

As noted earlier, the structural construct of dispositional traits accounts for broad patterns of behavior across time and different situations. The parallel process construct of states accounts

for the intraindividual processes that explain dynamic change (e.g., emotions, mood, hunger, fatigue). Since states are transient processes that involve short-term change and significant variability, researchers utilize rigorous, repeated measurement designs to capture the intraindividual variability. Together, traits and states explain the individual differences between and within individuals (Bolkan et al. 2009).

Level II: Personal Action Constructs (PACs) and Self-Regulatory Processes

Personal action constructs are specific goals, developmental tasks, and motivations that are uniquely contextualized by time, place, and social roles. These constructs can be various strategies, plans, and defenses employed by an individual aimed to attain or avoid a particular outcome. Different person-environment interactions throughout one's lifespan can reveal substantial variability in PACs that expose dynamic interplays between cognition, emotion, and the environment. The investigation of *possible selves* or the individuals' ideas of what they would like to become (*hoped-for selves*) and what they are afraid of becoming (*feared selves*) has been a rich area of study in PAC research. For example, across the lifespan, younger adults exhibit possible selves related to occupations and older adults exhibit more possible selves related to health. Through research in PACs such as possible selves, researchers have found a potential for growth in older adults who find ways to selectively optimize and compensate for normative age-related declines (Bolkan et al. 2009).

PACs are parallel with self-regulatory processes that individuals must invoke to reach their goals, such as self-efficacy and sense of control. These processes are typically investigated in particular domains such as work or family and demonstrate how people actively control their own lives. Research has shown an association between mortality rates in institutionalized older adults and sense of personal control. In addition, possessing a sense of mastery has been related to successful stress reduction strategies employed by adults amid midlife challenges. Clear age differences can be seen when studying processes associated with resilience, such as self-evaluation, emotion

regulation, and goal setting. This is due to individuals typically improving in maintenance of subjective well-being and adjustment to life tasks as they age, as well as the use of compensatory strategies and adaptive behaviors amid age-related loss (Bolkan et al. 2009).

The maintenance of self-regulatory processes across the lifespan can be explained through the SOC model of lifespan developmental psychology. In short, the three processes of selection, optimization, and compensation make up the universal principles of developmental regulation. An individual selects goals or outcomes, optimizes the means to achieve the goals or outcomes, and compensates for loss so that the goals or outcomes remain attainable. An example of the SOC model in older adults' goal processes toward social relationships was presented by Baltes and Carstensen (1999). Older adults tended to select goals related to preserving family relationships. They optimized these goals by devoting more time in family relationships compared to other relationships. Finally, they compensated for the loss of friendships by maximizing their most important family relationships (Baltes and Carstensen 1999).

Adults encounter potential resource gains (e.g., practical knowledge, material possessions) and potential resource losses (i.e., physical decline) with increased age. Therefore, incorporating PACs and self-regulatory processes are critical when studying personality in aging populations because researchers must be aware of the selection and pursuit of goals that maximize gains and minimize losses. Including an individual's personal goals and desires and the ways in which they are attained are vital to the study of personality development and optimal aging.

Level III: Life Stories and Self-Narration Processes

Life stories can be defined as the constantly evolving narrative understanding of one's self. A life story is made through remembering the past and anticipating the future with a sense of meaning, unity, and purpose. Middle-aged and older adults have life stories with themes of "giving birth to" a new generation and overall qualities of generativity. These life stories featuring

generativity aid in creating the individual's identity. Being able to preserve a positive view of oneself amid age-related changes is critical for optimal aging (Bolkan et al. 2009).

The parallel process of self-narration can be defined as the social cognitive processes employed while constructing a life story, such as remembering, reminiscing, and storytelling. Age differences can be seen in autobiographical memories or subjective depictions of an individual's past. For example, older adults tend to retain self-relevant and emotionally intense memories compared to younger adults. In this third level of analysis, the structural life story and the parallel self-narration processes shed light on the individual's uniqueness and ways in which personality identity is constructed across the lifespan.

Summary of the Six Foci Model of Personality Development

This model has provided the field of personality development a comprehensive and dynamic framework that can examine stability and change concurrently across multiple foci of personality. The integrative nature of the levels in the model speak to its value in the fields of personality development and aging. For example, traits and states can manifest in infancy (but can change throughout adulthood), while PACs and life stories manifest in later childhood and adolescence and continue to develop throughout the lifespan (Hooker and McAdams 2003).

Staudinger and her colleagues have written about positive personality functioning following two trajectories: growth and adjustment (Staudinger and Kessler 2009). A structure and process approach is also presented in this framework, and the authors draw on the lifespan developmental literature to identify indicators of adjustment and indicators of growth or maturity along structure and process dimensions.

Structures and Processes in Today's Research

The integration of the structures and processes of personality in the Six Foci model is a foundational

stepping stone toward today's research studying the underlying mechanisms that drive dispositional traits. The trait framework has been instrumental in identifying the traits that predict important outcomes across the lifespan, but it does not extend into the explanatory processes that are responsible for these trait-outcome associations. Under a lifespan developmental perspective, today's research features integrative analyses and elaborate methodology aimed to better understand personality in its entirety. This involves investigating not only if personality traits predict certain outcomes but identifying the processes responsible for personality's contribution to individual and interpersonal outcomes in specific contexts across the lifespan (Hampson 2012).

Personality processes are typically identified as either a moderating factor indirectly influencing an outcome known as reactive personality processes or a mediating factor directly influencing an outcome known as instrumental or self-regulative processes. In both types of processes, these mechanisms influence the trait-outcome associations and provide clearer explanation for why certain relationships exist (Hampson 2012). Both moderating and mediating processes have been identified for specific traits including neuroticism, anger, extraversion, happiness, and conscientiousness.

Typically, individuals with higher trait levels of neuroticism and anger are more emotionally reactive. It is the negative emotional responses to situations that moderate the relationship between having higher levels of neuroticism and more adverse consequential outcomes. Extraversion moderates social activity's relationship with happiness such that individuals taking part in social activity will report greater happiness if they are more extraverted than individuals who are less extraverted. Conscientiousness has been found to moderate many predictors and health outcomes by either decreasing or increasing the magnitude of relationships. Specifically, individuals who exhibit conscientiousness are typically making direct efforts to inhibit responses and produce healthier behaviors (Hampson 2012).

Mediating processes have substantive value in intervention research, as these processes require

direct effort. Health behaviors and niche selection are two mediational pathways found in neuroticism's relationship with different outcomes. Happiness' relationship to extraversion is mediated by social participation, although other mediating processes for happiness and extraversion remain to be understood. Further, various health behaviors mediate the relationship between conscientiousness and health outcomes (Hampson 2012).

Each of these processes aids in understanding what characteristics are most beneficial under what context. Researchers can utilize personality processes to put behaviors in context and follow developmental patterns depending on the situation. This is made possible through better longitudinal methodology, including efficient daily diary and measurement burst study designs that can follow various processes in each context experienced. Further, technological advancements have made it possible to unite personality dispositions and processes with brain mapping equipment to follow corresponding brain region activation. Uniting structural traits and various personality processes in today's research provides the field a more comprehensive understanding of the ways in which personality impacts the aging process throughout the entire lifespan (Hampson 2012).

Conclusion

The historical underpinnings of personality and aging, the transitional migration into more integrative approaches, and the current investigations into the comprehensive *whole* of an individual's personality across the lifespan have been reviewed. Studying personality under a lifespan developmental approach and integrative framework allows researchers to uncover optimal aging strategies and the potential for growth in older adults amid age-related declines. By acknowledging the concurrency of personality stability and change and the dynamic nature of personality, researchers can continue to extend the field's understanding into the many roles personality plays across the lifespan.

Character; Nature; Disposition; Temperament; Make up; Persona; Psyche; Identity; Inadequate; Maladaptive; Coping

Introduction

Older adults are growing in numbers and meet a higher age as well as a better quality of life. We all have a certain personality with its strengths and limitations. It is however hard to see where an adaptive personality transforms into a maladaptive personality or even a personality disorder. From a clinical perspective, the presence of personality disorders in older adults is typically manifested through a complex presentation of symptoms as well as a complicated course of symptoms and increased risk of relapse, challenging both assessment and treatment.

Definition and Synonyms

A personality disorder can be defined as an enduring pattern of inner experience and behavior that deviates markedly from the expectations of the individual's culture, is pervasive and inflexible, has an onset in adolescence or early adulthood, is stable over time, and leads to distress or impairment. Frequently used synonyms of personality (disorders/pathology) are character, nature, disposition, temperament, makeup, persona, psyche, identity, inadequate, or maladaptive coping.

Personality

Personality can be defined as a stable pattern of feeling, thinking, and acting as a form of adaptation to the environment. In general it is assumed that personality characteristics can be explained by hereditary, upbringing, and the interaction with the surroundings. There are various psychological theories which describe personality due to changes in different domains of psychological and physical functioning in older adults. Sigmund Freud was one of the most influential persons of the twentieth century, and his legacy still has a great influence on the view of personality. Freud explored the human mind more thoroughly than anyone before him. His contributions to the concept of personality are vast. Freud believed that when we explain our own behavior to ourselves or others (conscious mental activity), we seldom give a true account of our motivation. This is not because we are deliberately lying. Human beings can be great at deceiving others; they are however even more adept at self-deception. The rationalizations of our conduct are therefore disguising the real reasons. Freud's lifework was dominated by his attempts to find ways of penetrating this often subtle and elaborate camouflage of the hidden structure, thoughts, and processes of personality. Freud was an id psychiatrist. Another theory on personality (which stems from Freud's ideas) comes from Erikson who was an ego psychologist. He emphasized the role of culture and society and the conflicts that can take place within the ego itself. Freud on the other hand emphasized the conflict between the id and the superego. According to Erikson, the ego develops as it successfully resolves crises that are distinctly social

in nature. The idea was to establishing a sense of trust in others, developing a sense of identity in society, and helping the next generation to prepare for the future (Erikson 1959). A theory from the eighties comes from Botwinick who described personality as a way to see things more in perspective with aging which may lead to more pragmatic solutions instead of purely rational thinking and problem solving (Botwinick 1984). The Big Five personality traits, also known as the five-factor model (FFM), is a widely examined lexical approach of five broad dimensions used by psychologists to describe personality. The five factors have been defined as openness to experience, conscientiousness, extraversion, agreeableness, and neuroticism (acronyms: CANOE and OCEAN). Beneath each proposed global factor, a number of correlated and more specific primary factors are claimed. In a literature review, the stability of the Big Five personality domains of Costa and McCrea (1988) (Costa and McCrae 1988) was evaluated. The mean-level stability revealed a concave curve for neuroticism with an increase seen after the age of 80, a decrease for extraversion, and an increase for agreeableness (Debast et al. 2014). Personality can thus be defined in various ways. Some of the described theories show the occurrence of changes during the course of life. The relationship between personality and aging is complex due to the interactions between biological, psychological, and social aspects of aging such as cognitive changes (memory and attention abilities), changes in the role or purpose, impulse regulation, loss of health, relationships, and autonomy. The importance of each aspect usually varies within the different phases of life. The described personality theories however share the common view that personality consists of the combination of unique and stable aspects over various situations over time.

Personality Disorders

The clinical concept of a personality disorder has changed dramatically over the last 60 years. In the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5), a personality disorder has been defined as “an enduring pattern of inner experience and behavior that

deviates markedly from the expectations of the individual’s culture” (American Psychiatric Association 2013). There are only a modest number of studies that have focused on personality disorders in adults aged 65 years and older. This indicates a limited scientific interest in late-life personality disorders which can be seen as a discrepancy with the high prevalence rates and the negative impact on quality of life as well as the successful treatment of psychiatric and somatic disorders. The suitability of the DSM-5’s definition of personality disorders is limited for older adults. There are personality criteria which focus on work and relationships that are often not or limited present in the older adults’ life. Besides, the late-onset personality disorders and the personality disorder due to another medical condition raise some questions which will be discussed later in this chapter. Although the DSM-5 criteria have been subject to debate in literature (Agronin and Maletta 2000; Segal et al. 2006), this psychiatric classification model is still frequently used in the clinical field of geropsychology. We will discuss the assessment and treatment of personality disorders as well as medical options and close with some recommendations to pay more attention to the specific characteristics of older adults with personality disorders which will become even more important given the global aging.

DSM-5

In the DSM-5 (American Psychiatric Association 2013), there are four core defining aspects of personality disorders which are:

1. Distorted thinking patterns
2. Problematic emotional responses
3. Over- or underregulated impulse control
4. Interpersonal difficulties

These four aspects are common to all personality disorders. Before a diagnosis is made, a person must demonstrate significant and enduring difficulties in at least two of those four core aspects. These four core aspects combine in various ways to form ten specific personality

disorders identified in the DSM-5. Each disorder lists a set of criteria reflecting observable characteristics associated with that disorder. In order to be diagnosed with a specific personality disorder, a person must meet the minimum number of criteria established for that particular disorder. To meet the diagnostic requirements for a psychiatric disorder, the symptoms must cause functional impairment and/or subjective distress. This means the symptoms are distressing to the person with the disorder and/or the symptoms which makes it difficult for them to function well in society. The ten different personality disorders can be grouped into three clusters based on descriptive similarities within each cluster (see Table 1):

Cluster A (the “odd, eccentric” cluster)

Cluster B (the “dramatic, emotional, erratic” cluster)

Cluster C (the “anxious, fearful” cluster)

Personality Change Due to Another Medical Condition

The former DSM-IV (American Psychiatric Association 1994) incorporated “Personality change due to another medical condition” under the section “Psychological Disorders due to Another Medical Condition.” In the DSM-5, however, this disorder appears in the “Personality Disorders” chapter of section II (Diagnostic Criteria and Codes) under the subheading “Other Personality Disorders.” However, the general criteria for a personality disorder in the same chapter assert; it is confusing that personality change due to another medical condition should be excluded in order to diagnose a personality disorder. A point of concern is that there seems to be a confusion between two constructs, a personality disorder and a change in personality. A change in personality can be defined as a permanent behavioral change due to a direct pathological consequence of the medical condition (e.g., cancer, Huntington disease). The personality changes are persistent behavioral (often negative) changes like apathy or sexual oriented behavior. These medical and neurological conditions, however, have a different etiological construct compared to the etiology of

personality disorders which derive from complex biological, psychological, and social aspects into adulthood. The treatment methods for these personality changes are also very different compared to personality disorders. The treatment of behavioral problems such as disinhibited behavior as a result of a brain compromising disease can, for example, be conducted in a medical rehabilitation center, for example, where the family will be included in a treatment program. Behavioral Problems, such as impulsivity as an essential feature of the borderline personality disorder, can be treated with introspective psychotherapy. It is arguable whether the next edition of the DSM-5 may remove the personality change due to another medical condition from the chapter of personality disorders.

Late-Onset Personality Disorder

In the DSM-IV and the DSM-5, the chapter on personality disorders argues that a personality disorder can worsen later in life: “A personality disorder may be exacerbated following the loss of significant supporting persons or previously stabilizing social situations.” The experimental DSM-5 model for personality disorder however emphasizes the “relative stability” in the general criteria for a personality disorder. Expert opinions point to the existence of late-onset personality disorders. They present the idea that an underlying personality constellation and coping limitations can lead to the development or manifestation of a personality disorder for the first time later in a person’s life. Looking more closely to the late-onset personality disorders, it shows that later in life, changes in the individual’s living circumstances may lead to a decrease in adaptation due to aging (loss of physical fitness, retirement, loss of spouses and friends). The coping limitations and personality maladaptive functioning then become more manifest. An example from the clinical practice is the loss of role and appraisal among previous narcissists when losing their job and appraisal. Another example is the loss of control due to physical or mental decline which can increase rigidity among older adults with pre-morbid obsessive-compulsive traits. Some of the specific criteria of the aforementioned

Personality Disorders in Older Adults, Table 1 DSM-5 personality disorders

Cluster	Personality disorder	Description
A	Paranoid personality disorder	The paranoid personality disorder is characterized by a pervasive distrust and suspiciousness of other people
A	Schizoid personality disorder	The schizoid personality disorder is characterized by a pervasive pattern of social detachment and a restricted range of emotional expression. For these reasons, people with this disorder tend to be socially isolated
A	Schizotypal personality disorder	Persons with schizotypal personality disorder are characterized by a pervasive pattern of social and interpersonal limitations. They experience acute discomfort in social settings and have a reduced capacity for close relationships
B	Antisocial personality disorder	The antisocial personality disorder is characterized by a pervasive pattern of disregard for the rights of other people that often manifests as hostility and/or aggression
B	Histrionic personality disorder	Persons with histrionic personality disorder are characterized by a pattern of excessive emotionality and attention seeking. Their lives are full of drama (so-called drama queens)
B	Narcissistic personality disorder	People with narcissistic personality disorder have significant problems with their sense of self-worth stemming from a powerful sense of entitlement. This leads them to believe they deserve special treatment and to assume they have special powers, are uniquely talented, or are especially brilliant or attractive
B	Borderline personality disorder	Borderline personality disorder is one of the most widely studied personality disorders. People with borderline personality disorder tend to experience intense and unstable emotions and moods that can shift fairly quickly. As a result, they frequently have angry outbursts and engage in impulsive behaviors such as substance abuse, risky sexual liaisons, self-injury, overspending, or binge watch and eat
C	The avoidant personality disorder	The avoidant personality disorder is characterized by a pervasive pattern of social inhibition, feelings of inadequacy, and a hypersensitivity to negative evaluation. People with this disorder are intensely afraid that others will ridicule them, reject them, or criticize them. This leads them to avoid social situations and to avoid interactions with others. This further limits their ability to develop social skills
C	Dependent personality disorder	The core feature of the dependent personality disorder is a strong need to be taken care of by other people. This needs to be taken care of, and the associated fear of losing the support of others often leads people with dependent personality disorder to behave in a “clingy” manner and to submit to the desires of other people
C	Obsessive-compulsive personality disorder	Persons with obsessive-compulsive personality disorder are preoccupied with rules, regulations, and orderliness. This preoccupation with perfectionism and control is at the expense of flexibility, openness, and efficiency. They are great makers of lists and schedules and are often devoted to work to such an extent that they often neglect social relationships
Other personality disorders	Personality change due to another medical condition	A persistent personality disturbance that represents a change from the individual’s previous characteristic personality pattern. This disturbance is the direct pathophysiological consequence of a medical condition, such as temporal lobe epilepsy, head trauma, and cerebrovascular disease
	Other specified personality disorder	When people do have a personality disorder, however, they do not meet the criteria for any specific personality disorders mentioned in clusters A, B, or C The clinician chooses to communicate the specific reason that the representation does not meet the criteria of any specific personality disorder
	Unspecified personality disorder	In contrast with the category of “other specified personality disorder,” the clinician chooses not to specify the reason that the criteria are not met for a specific personality disorder because of insufficient information

AXIS II personality disorders show an overlap with AXIS I disorders, as well as other personality disorders and changes due to (normal) aging. The 11th edition of the *International Statistical Classification of Diseases and Related Health Problems* (expected 2018) may include the diagnosis of late-onset personality disorder (Tyrer 2013).

Epidemiology

Prevalence, Course, and Etiology

The prevalence rates of personality disorders in later life are very diverse because of the different methods, tools, and resources used in research. An integrative review on late-life personality disorders shows that the prevalence of one or more personality disorders among older adults in the general population ranges from 3% to 13% (Van Alphen et al. 2012a). These wide ranges are partly explained by the fact that almost one third of the DSM criteria for personality disorders are not applicable for older adults. In the largest study on the prevalence of personality disorders in later life, data was drawn from the National Epidemiologic Survey on Alcohol and Related Conditions (NESARC), focusing on a large subsample of 8205 adults aged 65 years and older. Among these community-dwelling older adults, the prevalence rate of at least one personality disorder was 8% (Schuster et al. 2013). The highest rates were found for the obsessive-compulsive personality disorder. Analyses showed that personality disorders were highly associated with disability as well as medical and mental disorders. For the decline in the prevalence of cluster B personality disorders with advancing age, the explanation that aging is accompanied by a decrease in expressive, impulsive, and aggressive behavior is often given. The idea of temporal stability of personality disorders and personality traits is less than an original thought (Debast et al. 2015), particularly for the borderline, antisocial, narcissistic, and histrionic personality disorders (cluster B); a higher degree of improvement and even recovery was reported while aging. Unhealthy life choices, violence, and addiction results in a shorter life expectancy among older

adults with cluster B personality disorders. Unfortunately, there are limited course studies in older adults. An item response theory (IRT) analysis among almost 37,000 respondents aged between 19 and 98 years in the general population showed that in older persons, fewer diagnostic criteria of the DSM-IV personality disorders were identified compared to younger persons. A second IRT analysis on this sample revealed measurement errors in 29% of the diagnostic criteria of DSM-IV PDs (Balsis et al. 2007). Although the most common etiologies for personality disorders are multifactorial, these conditions may also be secondary to biologic, developmental, or genetic abnormalities. Personality disorders can be aggravated by stressors, external or self-induced. In clinical practice it is shown that stressful situations (e.g., loss of a loved one or physical decline) can result in decompensation, revealing a previously unrecognized personality disorder. Also the loss of a social role, relational problems, and existential worries can play a role in a late-life personality disorder. Informant information (e.g., spouse or children) often shows a pattern of premorbid vulnerability and/or maladaptive coping strategies.

Assessment

The assessment of personality disorders consists of patient information including a medical history, autobiography, self-description, informant information (to complete and/or verify patient information), behavioral observation by the clinician, and preferably the use of (semi-) structured interviews or personality questionnaires. The use of (semi-) structured interviews and personality questionnaires among older adults is however subject to a number of limitations. The main problem is the often lacking normative data for the various population groups of older adults. Due to generational beliefs, the introspective abilities of older adults are often limited. The (often cluttered) layout of self-report score sheets and the use of small fonts can lead to problems particularly among adults aged 75 and over who have to deal with physical decline. In the recent years, a few personality measures have been validated for

Personality Disorders in Older Adults, Table 2 Validated personality tests for older adults

Type	Test	Validated in older adults	Remarks
Self-report	NEO-PI-R	✓	Psychometric data for clinical populations of older adults are lacking
	NEO-PI-3	✓	–
	NEO-FFI	✓	–
	NEO-PI-R-SF	✓	–
Informant report	HAP	✓	–
Screeener	GPS	Sensitivity specificity patient version around 70%	Sensitivity and specificity informant version are somewhat lower

older adults which can be divided into three categories: self-report questionnaires, informant-report questionnaires, and screening instruments. The self-report questionnaires that are validated among older adults are Neuroticism Extraversion Openness Personality Inventory Revised (NEO-PI-R), NEO Personality Inventory 3 (NEO-PI-3), and two abbreviated versions, the NEO Personality Inventory Revised Short Form (NEO-PI-R-SF) and the NEO Five Factor Inventory (NEO-FFI) (Rossi et al. 2014). These tests are mostly useful for assessing adaptive personality traits among older adults in the general population. The HAP (a questionnaire for family members or caregivers to assess maladaptive personality traits of the patient) is an example of an informant questionnaire for use in older adults in mental healthcare and nursing home residents. In order to try to prevent bias resulting from a current psychiatric condition or somatic comorbidity, the HAP retrospectively tries to map the patient’s personality features. Another 16-item screening instrument for personality disorders among older outpatients in mental healthcare as general practice has been validated named the Gerontological Personality disorder Scale (GPS) (Van Alphen et al. 2006). The GPS contains a patient and an informant version. Age-neutral measurements are necessary to derive valid and reliable conclusions of the presence of personality disorders across different age groups. An age-neutral instrument implies that items work the same for different measured age groups. A number of studies have examined the age neutrality of personality questionnaires: the Assessment of DSM-IV Personality Disorders (ADP-IV), the NEO-PI-R, the

Personality Disorders in Older Adults, Table 3 Differential item functioning

Test	DIF ^a	Differential test functioning
ADP-IV	4.3%	–

YSQ	3%	Entitlement scale
PID-5	13.6%	Withdrawal, attention seeking, rigid perfection, unusual beliefs

^aDIF differential item functioning

Young Schema Questionnaire (YSQ), and the PID-5 (Rossi et al. 2014) (see Tables 2 and 3). The age neutrality of test and specific items and its implications are still in progress. Studies have been often conducted in either the general population or highly specific clinical populations which limits generalization to the older adult populations.

Treatment

Treatment Levels

Research of the treatment of personality disorders in older adults is still at its infancies. The number of publications on this subject is also very limited. This may come from decades of therapeutic nihilism regarding the treatment results of personality disorders in older adults. Looking at treatment that focuses a distinction between (1) personality-changing, (2) adaptation-enhancing, and (3) supportive-structuring treatments can be made (Videler et al. 2015):

1. **Personality-changing treatment:** At this level, the therapy focuses on changing the dysfunctional aspects of the personality. This is usually a lengthy therapy. Examples of personality-changing treatment are schema-focused therapy (SFT), dialectical behavior therapy (DBT), mentalization-based treatment (MBT), and transference-focused therapy (TFT). (Meta-) cognitive behavioral therapy, brief psychodynamic therapy, and marital therapy are situated at the transitional level of personality-changing and adaptation-enhancement treatments.
2. **Adaptation-enhancement treatment:** This kind of treatment is for older adults who are motivated for treatment, yet are limited in their abilities to change, for example, because of limited introspection and empathy. Treatments in this category include interpersonal psychotherapy, social skills training, or other brief psychotherapies specifically addressing the interpersonal functioning of the patient such as relational therapy or cognitive behavioral therapy. A promising adaptation-enhancing therapy is the problem-solving therapy (PST) which consists of limited (six to eight) sessions where older adults learn to break down problems that affect well-being and develop strategies to address them (Gustavson et al. 2016). The treatment shows a more directive approach to change the critical environmental circumstances.
3. **Supportive-structuring treatment:** When a patient is not able to change; or cannot benefit from direct psychological treatment because of severe cognitive disorders, interventions such as supporting the patient and advising him how to make the best of his environment. Also mediation interventions, such as psychoeducation of the patient's informal or formal (i.e., professional) care providers and social support system.

See Table 4 for (contra)indication criteria for personality-changing, adaptation-enhancing, and supportive-structuring treatment of personality disorders in older adults (Van Alphen et al. 2012b).

Treatment Studies

It was long thought that personality-changing psychotherapy was not feasible in older adults. Clinical evidence is slowly growing for the treatment of personality disorders. There have been four promising treatment studies published that have examined personality-changing therapy in older adults (Table 5). Two of these studies however were conducted without proper personality assessment in older adults with depression. Although a significant proportion of the patients with depression in mental healthcare institutions suffers from personality disorders, these two studies can only indicate that the measured dialectical behavioral therapy (DBT) and schema-focused therapy (SFT) are feasible in older patients. Two studies have examined personality-changing psychotherapy in older adults with (features of) personality disorders and/or long-standing mood disorders. Despite small and heterogeneous populations, these studies, one on SFT and one on DBT, showed promising results among older patients. The SFT study that showed a medium treatment effect on the reduction of depressive symptoms, dysfunctional schemata, and schema modes was found, which was comparable to results previously found in adults (Videler et al. 2014). The DBT showed that antidepressant combined with DBT was significant superior with respect to improvement on interpersonal sensitivity and on interpersonal aggression at both posttreatment and 6-month follow-up compared to antidepressants alone. Addition of DBT did not significantly improve the depressive symptoms in comparison with antidepressants alone (Lynch et al. 2007). These results may suggest that the diagnosis of the personality disorders has been confounded by the comorbid depression (Van Alphen et al. 2015). The two studies suggest that the effectiveness for older adults with severe mood and personality disorders are comparable with younger age groups; given the small and heterogeneous study populations, the generalizability is limited. Up until today, there are no effect studies on MBT and TFT in older adults. Treatment studies should focus more on the added value of “geropsychological topics”

Personality Disorders in Older Adults, Table 4 (Contra-) indication criteria for personality-changing, adaptation-enhancing, and supportive-structuring treatment of personality disorders in older adults

Indications	Contraindications
Personality-changing treatment	
The individual is willing to enter a therapy focused on complaints originating from the personality disorder, or there is some estimate that this willingness will emerge during the initial phase of the treatment The individual possesses sufficient discipline and persistence to participate in therapy The personality issues are the primary factors causing and/or maintaining psychological and/or relational problems The individual is capable of self-reflection on a reasonable level The individual is able to tolerate the disorganizing effects which can derive from the treatment	Moderate to serious cognitive disorder Florid psychotic disorder Serious depressive episode Unstable bipolar disorder Serious inability to achieve a therapeutic alliance. Drug abuse demanding detoxification. Presence of acute psychosocial or somatic factors which are the exclusive focus of the individual's attention
Adaptation-enhancing treatment	
The involved individual has (some degree of) willingness to change his or her behavior or feels enough pressure enter treatment Especially the age-specific factors in interaction with personality issues lead to psychological complaints and/or social dysfunctioning The involved individual is not willing or not able to enter a long-term therapy focused on changing personality aspects	Moderate to serious cognitive disorder Florid psychotic disorder Serious depressive episode Unstable bipolar disorder Drug abuse demanding detoxification
Supportive-structuring treatment	
Serious inactivity Exceptionally limited social support system Overloaded (professional) support system	Noncompliance with nearly all kinds of care

Personality Disorders in Older Adults, Table 5 Summary of outcomes of personality-changing treatment studies

Author	Year	Country	N	Mean age	Treatment method ^a	Mood disorder	PD assessed	Outcome
Lynch TR	2003	USA	68	66	DBT	Depression	No	DBT is feasible in older adults
Kindynis S	2013	FRA	51	75	SFT	Depression	No	SFT is feasible in older adults
Lynch TR	2007	USA	37	61	DBT	Depression	Yes: SCID-2	Medication + DBT significantly improve outcome 6 months later
Videler AC	2014	NLD	31	67	SFT	Depression	Yes: SCID-2	Change in dysfunctional schemas

^aDBT dialectical behavior therapy, SFT schema-focused therapy

like the loss of health and autonomy, generational cohort beliefs, sociocultural context, missing out on the digital evolution, and changing life perspectives.

Case Vignettes

The following three case vignettes describe the aforementioned treatment approaches (personality changing, adaptation enhancing, or

supportive structuring) from a specific clinical geropsychological perspective.

Personality-Changing Treatment:

Schema-Focused Therapy (SFT)

Mr. X, a 76-year-old man, was referred by his general practitioner with a depressive episode. He was diagnosed a decade ago with traits of an avoidant and dependent personality disorder but only treated for his mood disorder. At the start of the therapy, Mr. X reported he was inactive again and felt depressed. Mr. X was diagnosed with a major depressive episode and also with avoidant and dependent traits. In the recent years, Mr. X lost his wife and also a good friend and neighbor. His anxiety about losing another loved one was still tangible. The deaths activated his suppressed core cognitions "I will lose everyone, I can't do it alone." The loss of his wife and other loved ones activated and manifested maladaptive cognitive schemata. From these core cognitions, Mr. X avoided intimacy with others, which maintained his depression. Mr. X was motivated to overcome his depression, but more so he wished to work on the underlying relapse risk factors. Mr. X showed the motivation to invest in personality-changing psychotherapy. Because of the significant invalidating core beliefs, SFT was started. The goal of SFT is to change the dysfunctional core belief, or so-called early maladaptive schemata, about the self into a functional core belief. After 41 weekly sessions and five follow-up sessions, Mr. X no longer met the criteria for avoidant and dependent personality disorder, and his depressive mood was in remission. He started to do charity work which gives him a new purpose in life as well as a daily routine where he met other people.

Adaptation-Enhancing Treatment:

Problem-Solving Therapy (PST)

Mrs. B, a 70-year-old woman, developed a panic disorder with agoraphobia after her daughter and her family moved to another country. The patient reports that her daughter was her main support person. Since the daughter went to live elsewhere, Mrs. B reports being unable to do normal daily

activities such as preparing a meal. Mrs. B reported problems in going grocery shopping or visiting friends. In addition, she reported feeling depressed and had been neglecting her usually nice appearance. She complains of depressed mood and indicates that there is little reason for her to continue to live. Mrs. B was, in addition to the panic disorder, diagnosed with a late-onset avoidant personality disorder. Although she had functioned relatively well in life as a librarian, after interviewing the husband and daughter, it was shown that the daughter had to drive her mother to her work for years, because Mrs. B was too afraid to take the bus. Adaptation-enhancing treatment was selected and given by means of PST. This relatively brief PST treatment, which took eight weekly sessions and two follow-up sessions, led to an improvement in her daily functioning. After a view practice sessions together with the nurse, she now goes grocery shopping every weekday and started to do voluntary work in a nearby nursing home. She now speaks regularly with her daughter and grandchildren via social media. Note that the treatment of the personality disorder itself is not the goal of adaptation-enhancing treatment.

Supportive-Structuring Treatment: (Mediation)

Behavioral Therapy

Mr. F, who was 87 years old, was referred because of suicidal behavior after the loss of his spouse 6 months earlier. On the one hand, Mr. F longed for rest and wanted to be admitted to a nursing home. He also was very negative whether he could be treated and often expressed his wish to die. Mr. F disposed of many belongings that reminded him of his wife in order to avoid thinking about her. According to one of Mr. F's brothers, Mr. F was described as vulnerable and often claiming others' attention and then dismissing them. The brothers had stopped having contact decades ago after a dispute but stayed in touch after the funeral of Mr. F's wife. Mr. F was diagnosed with a borderline personality disorder and a depressive disorder with agitation. Mr. F lacked activities and was suicidal; his older brother was worried but limited in his resources. Mr. F was not

motivated to engage in any kind of therapy. The only option was to try a supportive-structuring treatment. Goals of the treatment were to prevent suicidal behavior and to acquire some rewarding activities. In addition, his brother was given psycho-education of the borderline PD and support. The supportive-structuring treatment led to a better relationship between the two brothers. The personality disorder in itself was not treated. However, as a result of the behavioral changes of the brother and the support Mr. F received, the suicidal and agitated behavior declined which made it possible for Mr. F to mourn the loss of his wife.

When assessing behavioral disorders as a personality disorder in older adults, differential diagnostics show that similar behavioral disorders can also derive from a cognitive impairment (i.e., due to a delirium). Assessing older adults implies a broad approach in which biological, psychosocial, and somatic (comorbid) disorders have to be considered.

Pharmacological Treatment

There is some preliminary evidence that medication may be of value in the treatment of personality disorders. In these studies, there are many methodological uncertainties. The studies of the borderline personality disorder are the most promising, although it is one of the most difficult personality disorders to disentangle whether enduring (i.e., trait) versus potentially short-lived (i.e., state) changes to the symptoms have been made. There is reasonable evidence that antidepressants, especially the serotonin reuptake inhibitors (SSRIs) and monoamine oxidase (MAO) inhibitors, have beneficial effects independent of antidepressants. There is also some less favorable evidence that antipsychotic drugs and mood stabilizers may be of some value. Specific drug effects are difficult to identify in the studies of personality disorders because of the high comorbidity rates. The effects found can only indicate that medication can have a place in the treatment of personality disorders (Newton-Howes and Tyrer 2003).

Future Challenges

A patient can be diagnosed with more than one personality disorder. The experimental model for understanding personality disorders (section III, “Emerging Measures and Models”), proposed for further study in the DSM-5, focuses on reducing this overlap among personality disorders by using a dimensional approach versus the present categorical one. Six prototypes of personality disorders (schizotypal, borderline, antisocial, narcissistic, avoidant, and obsessive-compulsive) were maintained to address diagnostic overlap, based on two criteria. Criterion A refers to the significant disturbances in personal and interpersonal functioning and criterion B to the presence of one or more of the five pathological defined personality traits (negative affectivity, detachment, antagonism, disinhibition, and psychoticism) and the 25 facets associated with these traits. Today there have been only two empirical studies on the dimensional DSM-5 model conducted in older adults, both focusing on criterion B using the personality inventory for DSM-5 (PID-5) (Van den Broeck et al. 2013, 2014). Research in older populations is essential for the further development of especially section III of the DSM-5. This is in order to limit the risk, as was seen in the previous editions of the DSM, that the criteria remain inadequate for older adults (Van Alphen et al. 2015).

Conclusions

Older adults with personality disorders are a relatively large and vulnerable growing group with a high healthcare consumption. The assessment and treatment process is complicated because of the limited studies and age-neutral items and questionnaires. With regard to the clinical practice, (DSM-5) personality questionnaires and interviews used in adult care must be adapted and validated for the diverse older patient populations. Especially for the hospitalized older populations in mental healthcare centers or nursing homes, studies are needed.

Definition

Personality traits are relatively enduring patterns of thoughts, feelings, and behaviors, which are expected to remain stable over time and consistent across situations. Theories and research, however, demonstrated that personality traits could change over longer time periods across the lifespan into old age.

Old Age and Personality Trait Change

This contribution gives an overview of theoretical and empirical work on personality trait change in old age. Old age is a unique period of the lifespan that is characterized by environmental changes in the primary social contexts and social roles such as loss of the spouse or other important interaction partners. Old age is also characterized by complex individual changes and processes in multiple domains of functioning such as declines in cognitive and physiological functioning and ultimately physical health or inclines in chronic illnesses. Regardless of these changes in old age, individual differences exist in how older adults move through the later years of life. As a result of diverse and specific environmental experiences, individual abilities and competencies, and a

variety of adaptive processes and behaviors to maintain or improve well-being and health, each individual may demonstrate unique patterns of developmental change in old age.

Understanding the malleability of personality traits in old age is important for several reasons. First, personality trait change may predict a variety of important life outcomes in old age. For example, research demonstrates the ability of personality trait change above and beyond the trait level to predict mortality and other health-related aspects (Mroczek and Spiro 2007). Second, personality traits may be changed or modified by age-related environmental and individual changes in old age. For example, research suggests that a specific functional impairment such as hearing impairment may affect socially oriented personality traits because it reduces the capability to participate in social activities (Berg and Johansson 2014). Third, environmental and individual changes in old age require adaptive dynamic regulation processes to maintain or improve individual and social well-being and health. Personality traits may contribute to these processes either in adaptive or maladaptive ways. For example, research suggests that older adults tend to engage in strategies and processes that optimize positive social experiences and minimize negative ones by avoiding conflicts and showing greater willingness to forgive others (Fingerman and Charles 2010). In sum, changes in personality traits can be conceptualized and studied as predictors, mechanisms, or consequences of the aging processes.

This contribution focuses on four primary topics when discussing the past literature on personality trait change in old age. The first part defines personality traits and developmental change by considering several meanings of change. The second part discusses the cross-sectional and longitudinal research literature on personality trait change in old age. Specifically, it focuses on normative and differential perspectives of personality change. Normative change refers to change based on group averages, whereas differential change means that there are interindividual

differences in individual change. The third part discusses several mechanisms of personality trait change. The final section discusses the important future directions with respect to the role of personality traits in the aging process.

Defining Personality Traits and Developmental Change

Personality traits are relatively enduring patterns of thoughts, feelings, and behaviors that are relatively consistent across a wide variety of situations and contexts. Traits describe the most basic and general dimensions upon which individuals are typically perceived to differ. These individual differences are often organized within the prominent conceptual frameworks of the Big Five or Five-Factor Model and include five broad traits (see John et al. 2008): neuroticism, extraversion, openness to experience, agreeableness, and conscientiousness. Briefly, neuroticism, or conversely, emotional stability, contrasts even-temperedness with the experience of anxiety, worry, anger, and depression. Extraversion refers to individual differences in the propensity to be sociable, active, assertive, and to experience positive affect. Openness to experience refers to individual differences in the proneness to be original, complex, creative, and open to new ideas. Agreeableness refers to traits that reflect individual differences in the propensity to be altruistic, trusting, modest, and warm. Finally, conscientiousness reflects the propensity to be self-controlled, task and goal directed, planful, and rule following.

In general, personality traits are thought to be relatively stable over time, and thus they are not assumed to change at a rapid rate but rather reflect slow processes. Studying personality change in old age thus requires longitudinal data over longer periods of time to capture the long-term developmental processes. In contrast, one can study more dynamic and fluctuating manifestations of traits such as states over shorter time periods. Unlike traits, states reflect more dynamic processes of personality that show temporary changes in response to internal aspects such as motives and

goals and external situations such as stress in a given situation (Hooker and McAdams 2003). States reflect the ways how individuals think, feel, or behave in a given situation. In other words, states are the manifestations of the traits. They are transient and involve change and variability over short periods of time. In other words, a person with a high average level of emotional stability may still demonstrate a neurotic behavior in a given situation such as on a day when he or she faces a difficult challenge. Typically though, an individual thinks, feels, or behaves in ways consistent with that person's average standing on the trait level. Studying personality dynamics in old age requires (very) intensive longitudinal data over short periods of time to capture the short-term processes in daily life and the fluctuations over short time intervals. Such an approach provides information about the underlying processes of change or maintenance as they occur in addition to longer developmental change processes. This contribution does not further discuss empirical evidence for age-related changes in personality dynamics in old age (see Nofhle and Fleeson 2010, 2015 for details).

There are several ways to define developmental change. Each way offers a unique perspective on change. This article focusses on four conceptually and statistically different forms of change (see Roberts et al. 2008 for other forms). First, differential or rank-order change implies that individuals change their relative standing on a trait dimension relative to others over time. Second, mean-level change implies that the average level of a personality trait changes over time and/or across different ages. Third, structural change refers to change of the patterns of correlations among traits, or items on a personality scale. Structural change implies that the associations between the traits change over time and/or across different ages. Fourth, individual differences in change refer to the fact that although the average level of a personality trait may change over time, not every individual demonstrates the same amount of change. Some individuals may increase, whereas others decrease over time, or even show stability. This perspective holds that personality change is itself an individual-differences variable. In sum, there are several

conceptually and statistically distinct ways of framing and answering questions about the malleability of personality traits.

Current Evidence for Personality Trait Change in Old Age

There are two common research designs to address personality trait change, and each design provides unique information. Cross-sectional designs consist of at least two samples of different ages drawn from different cohorts and measured simultaneously. They provide information about age-group differences or interindividual differences but cannot easily separate the effect of age from the effects of belonging to a particular age cohort. Longitudinal designs consist of at least a sample of participants of a given age and from a given cohort that are followed through time. They provide information about age-related changes or interindividual differences in intraindividual change. The next paragraph discusses empirical evidence for age differences and age-related changes in personality traits.

Cross-Sectional Evidence

Evidence for age differences in personality traits in old age comes from cross-sectional studies. Several large-scale, cross-sectional lifespan studies with broad age ranges included older adults aged 65 years and older, whereas some studies contrasted older with younger adults and other studies focused exclusively on samples of older adults and the oldest olds. These relatively recent investigations observed age effects in personality traits in terms of mean levels even during older adulthood, when most researchers in the past thought there was not much possibility for change in later life. For example, mean-level age differences in all of the Big Five traits from ages 16 to the mid-80s were observed using two large national datasets from Britain and Germany (Donnellan and Lucas 2008). In the two countries, there is evidence that older adults were less extraverted and open to experience but they were more agreeable than younger age-groups. Average levels of conscientiousness were either highest

for middle-age participants or even showed an increase up to old age. The results were more mixed for neuroticism. Substantial nonlinear age effects from ages 15 to 99 were observed in a methodologically sophisticated study using a large nationally representative dataset from Britain (Marsh et al. 2013). The big picture of the results has led Marsh and his colleagues to suggest a “*dolce vita effect*” of personality traits in old age. Specifically, in later years, individuals become happier (more agreeable and less neurotic), more self-content and self-centered (less extroverted and open), more laid back and satisfied with what they have (less conscientious, open, outgoing, and extroverted), and less preoccupied with productivity. Due to the cross-sectional nature of the findings, though, it is possible that age and cohort effects are confounded.

In contrast to cross-sectional lifespan studies like these, which typically include a large number of younger adults in comparison to older adults, Weiss and colleagues included a significant sample of participants in their 80s and older in their investigation of personality trait trends (Weiss et al. 2005). Specifically, they examined age differences in personality traits in Medicare patients aged 65–100 years and divided the sample into a young-old group (65–79 years) and an old-old group (80–100 years). With the exception of higher levels of agreeableness in the oldest-old as compared to the young-old group, this study found little evidence for age differences among those in the last decades of life.

Whereas age differences were repeatedly observed for personality traits across the lifespan into old age at the mean levels (with some exceptions), the results for structural change show a different picture. Previous research demonstrates relatively high levels of structural stability in personality traits across different age-groups (Allemand et al. 2008a). For example, in large national datasets of individuals aged 25–74 years from the United States, equal factor correlations between the traits were found in 10 age-groups comprising equivalent age bands of 5 years, implying a stable factor structure across adulthood into old age (Zimprich et al. 2012). These findings are in line with the conclusion that, at least

cross-sectionally, the Big Five personality structure seems to be invariant at different ages. In sum, evidence from cross-sectional studies suggests age differences in personality traits in old age with respect to mean levels but rather stability with respect to the structure. However, studies focusing on older and very old age-groups are still rare, and it is unclear whether the structure is stable in very old age or in older adults with declines in cognitive and physiological functioning and physical health.

Longitudinal Evidence

Evidence for age-related change in personality traits in old age comes from an increasing number of longitudinal studies. However, previous longitudinal work differs with respect to the targeted age-group and the time intervals. Several longitudinal studies with broad age ranges also included older adults aged 65 and older and followed these individuals over several years and decades. In addition, a few studies focused exclusively on personality trait change in old age. The general picture of this work suggests that while personality trait change may not be as dramatic in older adulthood as it is in infancy, childhood, and emerging adulthood, there is evidence that even during the later years subtle changes in personality can occur that are not simply error of measurement. However, the different ways of defining developmental change offer distinct answers to the question of whether and to what degree personality traits change in old age.

First, personality traits tend to become more stable with age. A meta-analytic review summarized 3,217 test-retest correlations for a wide range of personality traits reported in 152 longitudinal studies on differential change of personality traits (Roberts and DelVecchio 2000). They used statistical methods to equate the different test-retest correlations to a common interval of about 7 years. This allowed them to compare results from studies of differing lengths of time because not all studies followed participants for the same interval of time. The main finding was that differential stability increased with age. The correlations increased from 0.31 in childhood to 0.54 during the college years to 0.64 at age 30 and

reached a plateau around 0.74 between ages 50 and 70. The finding of differential stability in old age also illustrated that the degree of stability does not prevent changes occurring within personality traits as age progresses. A study with older adults observed relatively high levels of differential stability in two older age cohorts, indicating that instability engendered by aging processes does not necessarily affect older adults' standing within an age cohort (Möttus et al. 2012). In contrast, other work found decreases in the rank-order stability of the Big Five traits after the age of 60 except for conscientiousness (Specht et al. 2011).

Second, personality traits are malleable in old age. A meta-analytic review (Roberts et al. 2006) summarized the results of 92 longitudinal studies to provide meta-analytic overview of mean-level changes in personality traits at various ages across the lifespan. The general results were that average levels of social dominance (a facet of extraversion with attributes that are linked to self-confidence and independence), agreeableness, and conscientiousness appear to increase with age, whereas neuroticism appears to decrease with age. Openness also declines with age, especially after mid-life. These changes are often viewed as positive trends given that higher levels of agreeableness and conscientiousness and lower levels of neuroticism are associated with desirable outcomes such as greater success in work and family and better health and longevity (Roberts et al. 2007). However, less is known about personality trait changes in older adults and the oldest-old.

Third, regarding personality structure, previous longitudinal work on structural change in personality traits converges with cross-sectional findings and demonstrates a stable personality structure in older adults over a few years (e.g., Small et al. 2003). However, a study with older adults (Allemand et al. 2008b) reported these patterns of correlations among the Big Five traits to be less stable over longer time periods in old age. As such, it is an open question whether and to what degree structural stability declines in old and very old age.

Fourth, personality trait change in old age is characterized by significant individual differences

in change. Regardless of typical mean-level changes in old age, several studies evidenced significant interindividual differences in individual personality trait change, implying that not every individual demonstrates the same amount of change; some individuals may increase, whereas others decrease over time, or even show stability (e.g., Allemand et al. 2008b; Mroczek and Spiro 2003). Hence, older adults may demonstrate unique patterns of developmental change in the patterns of thoughts, feelings, and behaviors as they move through the later years of life. Individual differences in change could be the result of diverse environmental experiences, age-related physical changes, and a variety of adaptive processes and behaviors that older adults utilize to maintain or improve well-being and health. In sum, evidence from longitudinal studies suggests age-related changes in personality traits in old age. This implies that personality traits are malleable even in old age. However, compared to younger ages, less is known about personality change in old and very old age.

Mechanisms of Personality Trait Change in Old Age

Given this potential for malleability, the next question to consider is: what leads older adults to differ in their patterns of personality development? Though old age may be characterized more by stability than change, further research is needed to understand what catalyzes trait change in older adulthood. On this front, it may prove valuable to consider previous theoretical work on the mechanisms influencing adult personality development, which point to the importance of considering social role investments and expectations (e.g., Roberts et al. 2008).

The adult years are characterized by transitions in and out of culturally framed social roles. These roles come with clear duties and expectations, which in turn can influence individuals' daily actions and responsibilities, allowing them new contexts for self-reflection and personal change. In turn, research suggests that adults who commit to socially prescribed roles often tend to report

higher levels on personality traits deemed socially preferable, such as agreeableness, conscientiousness, and emotional stability (Lodi-Smith and Roberts 2007). Though researchers often focus on the transition into the workplace, marriage, and community early in adulthood, it is equally important to consider the influence of transitions *out* of these roles later in life. One particularly important role transition for older adults is the decision, forced or voluntary, to retire from work. The years following retirement are among the most vulnerable for health concerns of any point in the lifespan (Moon et al. 2012) and appear to coincide with a diminished sense of purpose for older adults. Similarly, it appears that retirement coincides with a greater likelihood for declines in conscientiousness compared to unretired adults (Specht et al. 2011).

Another important transition in older adulthood is how married individuals deal with the increasing potential for losing a spouse. Given that the death of a family member (e.g., child, spouse) is one of the most stressful life events one could experience during the life course, this event also might influence personality development. Indeed, widowers appear to score lower on openness to new experiences (Specht et al. 2011). Interestingly, this research also suggests that males and females appear to react differently to the death of spouse, insofar that it may lead to declines on conscientiousness among females but actually *increases* for males. One possibility is that widowed males are now required to take on more of the responsibilities within the home, which may require them to become more conscientious with time.

Though this literature is relatively nascent, it bodes well for considering social role commitment and decommitment as influences on personality later in the lifespan. As noted earlier, additional research though is needed that provides intensive longitudinal assessments with multiple measurement occasions, which would allow researchers a better idea of how transitions in and out of social roles and relationships influence trait change for older adults. Theories point to the enhanced value of intimate social relationships during old age (e.g., Carstensen et al. 1999), which only further underscores the potential for social roles to provide

important mechanisms of change. Indeed, recent research does suggest that older adults who perceive greater social support appear more likely to gain in conscientiousness over time (Hill et al. 2014). Further work though is needed to fully examine the rationale behind these potential social role effects, particularly given the importance of personality trait change during older adulthood.

Implications of Personality Trait Change and Future Directions

Even modest changes in personality traits clearly have strong implications across the lifespan, given the known potential for traits to predict a wide variety of important life outcomes (Roberts et al. 2007). As noted earlier, research even points to the possibility that trait changes can influence mortality risk (Mroczek and Spiro 2007). Given this point, in old age, personality trait changes could hold profound consequences, exacerbating or attenuating the health risks conferred by the aging process. However, research is still needed to understand why and when trait changes hold health consequences for older adults, in order to best determine whether interventions should target promoting increases on seemingly positive traits or to scaffold personality stability during older adulthood.

Another important consideration returns to the prominence placed on intimate social ties by older adults. People prefer friendships with individuals higher on socially adaptive traits (e.g., more conscientious, agreeable, and emotionally stable). As such, changes away from these desirable characteristics could prove particularly deleterious for older adults, given their emphasis on maintaining social relationships (Carstensen et al. 1999). Future research is needed though to better understand whether personality trait changes in old age lead to poorer relationships with close others or if such intimate relationships, given their generally longer duration, are more resistant in the face of presumptively negative trait changes.

Finally, though the factor structure of the Big Five appears relatively consistent across adulthood (Allemand et al. 2008b), further work is

needed to understand whether researchers should revisit the item content of common Big Five inventories when sampling older adults. Researchers may wish to write additional items or edit existing inventories to better address how personality traits manifest in the contexts relevant to older adults. For instance, conscientiousness scales often discuss actions in the workplace implicitly or explicitly, which may make responding to these items more difficult for retired adults. Similarly, inventories may need to account for the potential that older adults are dealing with physical and cognitive limitations, which can attenuate their capability to manifest dispositions such as openness to new experiences. Investigations along this front can help researchers more accurately capture the trait changes that do exist later in life. Just as research has begun to demonstrate the potential for traits changes in old age, studies also need to better account for how the contexts in which traits manifest differ during this developmental period.

Conclusion

Old age is an important developmental period in the lifespan. The goal of this article was to discuss the role of personality traits in the context of aging processes and to give an overview about theoretical and empirical work on changes in personality traits in later life. First, personality traits are enduring characteristics that describe individual differences in behavioral, cognitive, and emotional patterns. Several conceptual and statistically distinct ways define developmental change. Second, current empirical evidence suggests both change and stability in personality traits in old age partly on the definitions of developmental change one considers. However, research on personality trait change in old and very old age is underrepresented in the literature. Third, different mechanisms are responsible for individual differences in personality trait change in old age. One important approach to investigate mechanisms of change relates to social transitions in old age. Finally, changes in personality traits may have important consequences for older adults.

Definition

Tom Kitwood, a UK academic, was a key figure in the theoretical development of person-centered approaches in dementia during the 1990s. He developed Dementia Care Mapping (DCM) as an observational tool to test his theories empirically and as a means of improving care practice. Kitwood died at the age of 61 in 1998 just as his theories (and DCM) were really beginning to gain traction in Europe, North America, and Australia. In this chapter the origins and relationship between person-centered dementia care and DCM are explored. DCM is described in detail alongside more recent developments around person-centered care.

Personhood and Person-Centered Dementia Care

It is nearly 30 years since the late Professor Tom Kitwood first used the term *person-centered*

approaches in relation to the long-term care for people living with dementia. In an attempt to move away from a reductionist medical model, the term was first used to bring together ideas and ways of working that emphasized communication and relationships. The term was intended to be a direct reference to Rogerian psychotherapy with its emphasis on authentic contact and communication. Kitwood's work was part of the ground swell of psychosocial approaches to dementia during the 1980s and 1990s. Writing throughout this period, Kitwood published a continuous stream of articles in prominent journals, bringing these ideas together in 1997 in his most well-known book *Dementia reconsidered: The person comes first* (Kitwood 1997).

Kitwood focused on the maintenance of personhood as being central to person-centered care. He defined personhood as “A standing or status that is bestowed upon one human being, by others, in the context of relationship and social being. It implies recognition, respect and trust” (Kitwood 1997, p. 8). Kitwood proposed that people living with dementia have the capacity to experience relative well-being and ill-being and that their behavior has meaning. He proposed that high levels of challenging behavior, distress, or apathy would occur more commonly in care situations that are not supportive of personhood. It would also follow that when personhood was supported then a greater preponderance of well-being and social confidence would be observed. Kitwood's view of person-centered care for people with dementia was that it took place in the context of relationships. He theorized that as verbal abilities are lost, the importance of warm, accepting human contact through nonverbal channels become even more important than before. With the onset of dementia individuals are vulnerable to their psychological defences being radically attacked and broken down. It becomes increasingly important that the sense of self is held within the relationships that the person with dementia experiences. These relationships are a key part of the social psychological milieu. He described personhood as being undermined when individual needs and rights are not considered, when powerful negative emotions are ignored or

invalidated, and when increasing isolation from human relationships occurs.

Kitwood described the various common ways that he had observed personhood being undermined in care settings, coining the phrase *Malignant Social Psychology (MSP)* as an umbrella term. MSP includes episodes where people are intimidated, outpaced, not responded to, infantilized, labeled, disparaged, blamed, manipulated, invalidated, disempowered, overpowered, disrupted, objectified, stigmatized, ignored, banished, and mocked. Kitwood was at pains to say that episodes of MSP are very rarely done with any malicious intent. Rather, this way of responding becomes interwoven into the care culture. New staff members learn how to communicate with people with dementia from existing staff. If the staff communication style is one that is characterized by the infantilization and outpacing of people with dementia, then the new member of staff is likely to follow their lead. The malignancy in MSP is that it eats away at the personhood of those being cared for and it also spreads from one member of staff to another very quickly. Kitwood also coined the term *Positive Person Work* to describe different forms of interaction that would maintain personhood. These included recognition, negotiation, collaboration, play, stimulation (engagement through the senses), celebration, relaxation, validation, holding, and facilitation.

The Origins and Development of DCM

DCM was developed as an observational tool that could test this theory empirically and to assess the impact of the social and psychological environment for people living with dementia. The method and coding system were developed through ethnological observations of many hours in nursing homes, hospital facilities, and day-care in the UK. Kitwood described DCM as “a serious attempt to take the standpoint of the person with dementia, using a combination of empathy and observational skill” (Kitwood 1997, p. 4).

DCM has been through a number of changes since its inception. The current version DCM8

was launched in 2005 following a period of systematic international development and validation against DCM 7th edition (Brooker and Surr 2006). DCM training has been available in the UK since 1991. The worldwide spread of DCM has been remarkable. This growth necessitated a need to have formalized structures around DCM to maintain quality, led by the University of Bradford in the UK, who hold the copyright of the method. The DCM tool is only available through undertaking a registered course delivered by licensed trainers using standardized training methods. Those undertaking the basic DCM training course do not need any formal qualification although the complexity of the method requires reasonable numeracy and literacy skills. Worldwide there are currently 13 centers that have a Strategic Partnership with the University of Bradford to provide DCM training. The DCM tool and training materials have been translated into ten different languages. It is estimated that up to 12,000 practitioners have been trained in DCM since the early 1990s.

The DCM8 Tool and Process

DCM training covers the tool itself and also the process by which the tool can be used to improve practice. This process involves five phases.

1. *Briefing/preparation*: During the briefing phase the trained DCM users (mappers) meet with staff in the facility (ward, care home) where the DCM process (mapping) will be implemented. They explain what the mapping process will involve and answer any questions or concerns staff may have about what this entails.
2. *Mapping Observation*: In the observation phase each mapper observes usually up to five people with dementia (participants) continuously over a time period. The period of observation chosen will depend upon the purpose of the map. It may, for example, include maps of 30 min to an hour at certain times of day over a few days (e.g., if the focus is on improving the mealtime experience, or

participant well-being in the hour after lunch), or for longer periods of 4–6 h or more on one or more days (e.g., if a picture of the waking day is required). Observation only takes place in communal areas of care facilities and personal or private care is never observed. Guidelines are provided during training about how to observe in a way that does not increase the ill-being of people with dementia. The observations are divided into continuous time periods (time frames) of 5 min. At the end of each 5-minute time frame two codes are used to record the experience of each participant. The Behaviour Category Code (BCC) describes the participant behavior that has occurred, from a choice of 23 alphabetical codes. To accompany each Behavior Category Code a judgment is also made about the participant's relative state of mood and engagement called the Mood/Engagement Value (ME Value). This is coded using a 6-point scale ranging from -5 (extreme negative state) to $+5$ (extreme positive state). ME values are averaged over the mapping period to produce a well- and ill-being score (WIB score), which gives an index of relative well-being for a particular time period for an individual or a group. Two additional data items are recorded as and when they occur. Personal detractors (PDs) and Personal Enhancers (PEs) are staff behaviors that have the potential to undermine (Malignant Social Psychology) or enhance (Positive Person Work) the personhood of those with dementia respectively. There are 17 types of PEs and PDs, which are coded according to their type and degree of severity.

3. *Data Analysis*: The analysis phase involves processing the raw DCM data into a format that can be used in a feedback session with staff. At a most basic level this involves showing the percentage of time spent in each BCC or ME and showing the numbers and types of PDs and PEs recorded. However, further processing of the data can produce indicators of agitation, distress, engagement, occupation, and social engagement. Once processing of the data is complete, the mappers produce a

feedback report, which will be used in the feedback phase with staff.

4. *Feedback to staff*: The feedback phase involves holding at least one feedback meeting with the staff team to share with them the findings of the map, to identify examples of good practice and areas for practice development.
5. *Action planning and quality improvement*: Following on from the feedback session a series of action plans and points is developed by the staff team for them to implement over an agreed period of time. This practice development cycle is repeated on a regular basis (every 4–12 months) to monitor progress and identify new action plans.

The Efficacy of DCM as a Practice Development Tool

Practitioners use DCM in many different settings, for many different purposes, primarily because they report that DCM provides an effective vehicle for systematically moving dementia care from a task-focused, custodial model into one that focuses on the experience and well-being of people living with dementia. There are very few other tools that fulfill a similar purpose or that have been shown to be effective in doing so. There is no data available regarding how many care providers actually use DCM in practice, or how many of those trained in the method use it regularly as a practice development tool. However, anecdotal feedback, surveys of DCM users (Douglass et al. 2010), and formal intervention studies (Chenoweth et al. 2009) have all highlighted implementation difficulties for DCM following training, with rates of use reported as being between 30% and 60%. Formal surveys (Douglass et al. 2010) report that attendance at DCM training is a transformative experience that leaves those trained feeling empowered and inspired to make positive change back in their workplace. Feedback suggested that even those who had never used the tool felt that attending the training alone had had a positive impact on their own practice. However, both surveys were

based on small samples (<150 respondents) and their recruitment methods mean there was potential for bias. They were also conducted only in the UK and USA and therefore it is unclear how representative these figures are of the actual picture of DCM implementation worldwide. The most commonly cited difficulties for practitioners in implementing DCM are a lack of time and management support (Douglass et al. 2010). This is a serious barrier to widespread use in an increasingly resource-impooverished field.

Whether DCM has had a sustained impact on practice is difficult to assess and there still remains a fairly limited body of robust evidence about its efficacy as a tool for practice change over time (Chenoweth et al. 2009). Practice implementation studies report the benefits of DCM include the improvement of well-being for the person with dementia and helping staff to understand the perspective of the person with dementia, and to use this to develop evidence-based action plans that motivate staff and increase their confidence in implementation of person-centered care. However, these studies have a number of methodological weaknesses (Brooker 2005). To date only a handful of studies have examined the benefits of using DCM for improving clinical outcomes for people with dementia using robust designs. These pilot or full cluster randomized controlled trial studies conducted in care home settings report several benefits of DCM compared to usual care control homes. Such benefits include reduction in resident agitation, anxiety (Chenoweth et al. 2009; Chenoweth and Jeon 2007; Rokstad et al. 2013), falls (Chenoweth et al. 2009), depression (Chenoweth and Jeon 2007), neuropsychiatric symptoms (Rokstad et al. 2013), improved resident quality of life (Rokstad et al. 2013), improved quality of staff interactions with residents (Chenoweth and Jeon 2007), and reduced emotional exhaustion and staff burnout (van de Ven et al. 2013).

There is very limited available evidence on the cost-effectiveness of DCM as a practice development tool. A Dutch randomized controlled trial in nursing homes (Van de Ven et al. 2014) found that in the DCM intervention group, significantly lower costs associated with hospital outpatient

use were observed, but no other overall cost differences were seen between DCM intervention and usual care control. They concluded that DCM is a cost-neutral intervention. However, an Australian study (Chenoweth et al. 2009), comparing implementation of DCM to implementation of a staff training intervention in person-centered care and to usual care, found that DCM cost more than four times the amount than implementation of person-centered care training per site. Thus they concluded that DCM may be too costly in terms of funding training and then the additional staff time required for conducting mapping cycles, for many care homes to implement.

DCM has received criticism for not being suitable for gaining a detailed understanding of the experiences of people with very advanced dementia, with multimorbidities, or those who may be at end of life (Perrin 1997). The length of the time periods for coding (5-min) and restrictions of using DCM only in public areas can result in production of data that lacks the richness needed to plan care for those with very high levels of dependency. Alternative observational tools such as PIECE-dem (Brooker et al. 2013) have been developed specifically for people with advanced dementia and so may be used alone or alongside DCM when conducting practice development or research with this population. Dementia care staff are sometimes concerned that DCM observations may in themselves diminish the quality of life of people with dementia by making them feel intimidated. However, much of the content of the training in DCM provides various ways to ensure that the process of DCM is inclusive both of the people living with dementia and the care staff so they do not feel marginalized or intimidated.

DCM has also provided the foundations for an observational tool designed specifically for inspection and regulation of health and social care (Brooker et al. 2007). The Short Observational Framework for Inspection (SOFI) was developed in England as an observational component to the inspection toolkit used by the Care Quality Commission in its regulation of health and social care services. SOFI, like DCM, collects data on the experience of care from the point of view of the person using the service and gathers

information about service user mood, engagement, and the quality of interactions with staff. This information is triangulated with other data to help inspectors/assessors form judgments about care practices. SOFI is now being used in Wales, Scotland, Australia, and the Netherlands in the regulation of health and/or social care services.

DCM in Research

A recent review of the psychometric properties of DCM as a research tool (Cooke and Chaudhury 2012) concluded that it has acceptable face validity but unclear content validity particularly in terms of recommended length of observation periods and numbers of participants included. Nevertheless, published studies and reviews of DCM as a research tool suggest that it is acceptable for use as a research outcome measure, providing careful consideration is given to its applicability to the study aims and outcomes, and to its implementation within the research through careful study design and method development. A number of studies have examined the psychometric properties of DCM as a research tool.

Validity as a Quality of Care and Quality of Life Measure

There is limited published evidence for the concurrent validity of DCM as a quality of care measure, but there is available evidence exploring its concurrent validity as a quality of life measure. Evidence suggests DCM appears to have the same biases as proxy rated measures, compared to self-report (Cooke and Chaudhury 2012). However, one of the key features of DCM is that it aims to help assess the quality of life of people who would otherwise be unable to provide this information via self-report. Therefore, it may provide an additional, alternative measure to proxy staff/carer evaluations, where self-report is not possible, and a complimentary rather than alternative measure, where self-report is possible. A number of studies report correlation between higher dependency levels and lower well-being in people

observed using DCM, suggesting DCM is measuring dependency-related factors rather than quality of life (Brooker 2005). However, this is not universal to all studies and one US study comparing DCM to quality of life measures reported that dependency levels accounted for less than 12% of the variance in well-being/quality of life (Edelman et al. 2005). This suggests DCM may measure additional components of quality of life that are not captured by other quality of life measures.

Reliability

There is insufficient evidence to draw conclusions regarding internal consistency and test-retest reliability (Brooker 2005; Cooke and Chaudhury 2012). A number of studies have reported on the inter-rater reliability of DCM that indicate it is possible for mappers to achieve acceptable levels of inter-rater reliability for use of the tool in both practice (above 70% concordance) and research (above 80% concordance) situations (Brooker 2005). However, other studies have reported issues with consistent achievement of inter-rater reliability between mappers (Cooke and Chaudhury 2012). It is not possible to be confident in the inter-rater reliability of DCM across or between studies, or between mappers on a national or international level, as there are currently no approaches to ensuring inter-rater reliability for DCM observations beyond local concordance checks.

The VIPS Model of Person-Centered Dementia Care

Since Kitwood's early writing there has been a significant change in how people with dementia are treated in their relation to being active agents in their own lives. The right to be aware of diagnosis and treatment options have come to the forefront. The recognition that the voice of the person with dementia needs to be heard directly in shaping and developing services has become an accepted way of working. More and more direct accounts of what it is like to live with dementia are

available. Self-advocacy groups are becoming more prominent in the Alzheimer charities. Even in long-term care facilities, where people have significant cognitive impairments, their voice is now frequently heard in qualitative research reflecting directly on their perspective.

The concepts in person-centered care are not easy to articulate in a straightforward manner. In a review of definitions of person-centered care (Brooker 2004) it was noted that person-centered care was being interpreted as meaning individualized care, and that the emphasis on relationships that Kitwood promoted had been lost. In addition, since Kitwood's original writing, there is a stronger recognition that the societal and organizational context in which care is delivered impacts upon the quality of care. If care is to shift from task-focused to person-focused, then society and care providers need to prioritize the human rights of those living with dementia. Changing the skills of front-line care workers is not enough in itself.

The VIPS definition of person-centered care (Brooker 2004) is an attempt to introduce the notion of organizational responsibility while maintaining the sophistication of Kitwood's original work. Put simply, the VIPS definition of person-centered care encompasses a **value** base that asserts the absolute value of all human lives (**V**); an **individualized** approach, recognizing uniqueness (**I**); understanding the world from the **perspective** of the person living with dementia (**P**); and the promotion of a positive **social psychology** in which the person living with dementia can experience relative well-being (**S**).

The VIPS definition has been used in the English NICE/SCIE Guideline on Dementia (NICE/SCIE 2007) as the underpinning value base for best practice and defined the principles of person-centered care as asserting the human value of people with dementia, regardless of age or cognitive impairment, and those who care for them; the individuality of people with dementia, with their unique personality and life experiences among the influences on their response to the dementia; the importance of the perspective of the person with dementia; and the importance of

relationships and interactions with others to the person with dementia, and their potential for promoting well-being.

In addition to DCM, complementary tools for assessing person-centered care delivery and services have been developed, which draw on contemporary definitions of person-centered care and provide a richer picture of the elements a service needs in place to provide person-centered care. For example, the VIPS definition was used as the structure for the evidence base for developing a tool to assess good practice in person-centered care (Brooker and Latham 2016), which provides a set of concrete indicators that care providers can benchmark their services against. Around 50 care providers and service user organizations worldwide arrived at a detailed description of what a person-centered care provider should have in place. This list of 24 indicators is grouped around the 4 elements of the VIPS definition and has become known as the *VIPS framework*. Person-centered care requires sign-up to working in this way across the whole care provider organization if it is to be sustained over any length of time. Particular elements require leadership at different levels (i.e., from those responsible for leading the organization at a senior level, from those responsible for setting care standards and procedures within the organization, and from those responsible for day-to-day management and direct provision of care). The data gathered through use of DCM can provide evidence toward assessment against a number of the indicators within the VIPS framework. These are next provided:

V: Does this service actively show that the experiences of people with dementia and their families are valued and respected?

1. Is the service actively welcoming to people with dementia and their families?
2. Is the service valuing of good-quality direct care for people with dementia and their families? Is there a management ethos that fosters the best direct care?
3. Is the staff empowered to act in the best interests of people with dementia and their

families? Is there a management ethos that empowers staff to act in this way?

4. Is the workforce skilled in person-centered dementia care at all levels from frontline to leaders?
5. Generally are the physical and social service environments designed to be easy for people with dementia and their families to use?
6. Does the service know about and act upon the needs and concerns of people with dementia and their families?

I: Are systems in place to enable staff to get to know the person, to provide continuity of care, and to ensure the person feels like a unique individual?

1. Do staff know each person's strengths and needs across physical, social, and psychological domains?
2. Are staff alert to changes in these strengths and needs over time?
3. Do staff know what personal possessions and relationships are important to each person to help them feel calm?
4. Do staff know each person's likes and dislikes and preferred everyday routines and are these utilized in everyday care?
5. Do staff know each person's history and key stories and are these utilized in everyday care?
6. Do staff know how to engage each person in enjoyable activities?

P: Is care taken to understand the perspective of the person with dementia and their family?

1. Do staff check out preferences, consent, and opinions using verbal and nonverbal means?
2. Can staff empathize with how each person is feeling and show this in their everyday care?
3. Do staff regularly ensure that the physical environment is as comfortable as possible for each person?
4. Is the staff vigilant about physical health needs that the person may not be able to tell them about directly?
5. If the person is showing "challenging behaviour" do staff try to understand why

and what the person may be trying to communicate?

6. Do staff treat the rights of the individual with dementia as important as the rights of other people?

S: Does this service provide a Supportive Social Psychology to enable the person with dementia to feel socially confident and that they are not alone?

1. Do staff help the person feel included and not "talked across"?
2. Do staff treat each person respectfully and not use a "telling-off" tone or derogatory labels to describe people?
3. Do staff come across as warm and caring and not cold and indifferent?
4. Do people know that staff take their fears seriously and that they won't be left alone for long periods in emotional distress?
5. Do staff help people to be active in their own care and activity as far as possible and not just do things to people without communicating with them?
6. Do staff facilitate to help the person keep important relationships and make sure that they stay in touch with people and activities they value?

In the USA, the VIPS framework was utilized to develop a series of workshops on improving communication skills of care workers in a large for-profit long-term care facility (Passalacqua and Harwood 2012). The VIPS framework has been adopted as a means of internally benchmarking the person-centeredness of practice within a number of service settings, particularly within the care home sector. Baker (Baker 2014) describes utilizing VIPS as an organizing principle for an internal quality improvement program in a large "for-profit" care homes provider in the UK. In Norway, Røsvik and colleagues have developed the VIPS Practice Model as a means of improving quality of care for care-home residents (Røsvik et al. 2013). Rokstad et al. examined the impact of the VIPS Practice Model and DCM when compared to usual dementia education sessions and found that nursing home residents who were cared

for by teams using the VIPS practice model showed significantly less depressive symptoms over time.

Conclusion

The development of person-centered dementia care and DCM are intertwined. Both have continued to develop as drivers for improving dementia care internationally. Person-centered care has developed into a set of guiding principles to help care providers support personhood. It is not necessary to undertake DCM in order to deliver person-centered care. DCM as a practice development tool may help to evidence whether person-centered care is occurring and can highlight ways in which practice can be developed. It can therefore serve as an evidence-based driver for person-centered practice change. DCM was developed in an era when it was thought that people with dementia could not provide reliable accounts of their own experience. The motivation for its development, however, was so that the standpoint of the person with dementia was represented. The development of DCM and subsequent guidance for its use in practice and research has emphasized the centrality of people with dementia in this process and has thus helped to drive forward the central tenet of person-centered care – the primary focus on the experience and needs of the individual with the condition.

Observational methods such as DCM provide the opportunity to provide the perspective of those who cannot speak out for themselves. DCM provides evidence of what happens to people with dementia in communal areas of formal care settings. DCM provides evidence of how people spend their time, their observed well-being, and how they are treated by staff and professionals. When people are very dependent on care services, quality of life becomes inextricably linked with quality of care. Within more advanced dementia, quality of life may be the most important goal. As dementia progresses, the ability of individuals to secure help in their own right or to assert their best interests in the face of poor service quality becomes increasingly difficult. Unless the person

with dementia is blessed with a strong family support structure they may have very few advocates who will act solely in their best interests. Because of this, their citizenship rights are easily violated. This renders them extremely vulnerable to abuse – be it financial, physical, sexual, or psychological. Individuals living with dementia are likely to find it difficult to complain directly about poor quality of care because of the nature of cognitive disability that is part and parcel of dementia. In addition, many family members are worried that if they complain services will be taken away from them or that there will be repercussions for their loved ones.

Evidencing quality from the perspective of the person living with dementia is complex both conceptually and practically. There is an inherent tension in providing standardized measures of quality of life and quality of care for such a heterogeneous group of people living out their lives in a multiplicity of ways. Yet unless there are standardized measures of these important outcomes and processes then practitioners, regulators, researchers, and policymakers will continue to rely on the easy-to-measure such as cognitive status or compliance with health and safety regulations.

As evidenced by this review, there are many questions unanswered about the efficacy of DCM to change practice and sustain change over time. Person-centered dementia care is not an easy or trivial process and, in some respects, this is reflected in DCM. Person-Centered Care continues to evolve as more evidence is learned about how services maintain personhood. Whether DCM remains a practical driving force within this will depend on its own ability to evolve so as to remain relevant to progressive definitions and frameworks describing contemporary person-centered care.

Synonyms

Exercise, wellbeing, health, successful ageing,
 healthy ageing, active ageing

Definitions: Physical Activity, Exercise, Inactivity, and Sedentary

Physical activity is any bodily movement produced by the skeletal muscles that requires energy expenditure. Physical activity can occur in a range of contexts such as work (e.g., carrying and lifting), households (e.g., gardening, cleaning), travel (e.g., walking or bicycling to get to and from places), and leisure (e.g., sport, recreational walking). Exercise is a specific type of physical activity that is planned, structured, and repetitive, with the aim to improve or maintain one or more components of fitness, such as balance, strength, or endurance.

The words “inactive” and “sedentary” are sometimes used interchangeably to describe a lack of physical activity or exercise. Contemporary practice is, however, that “inactive” implies a lack of physical activity or exercise and “sedentary” describes behaviors of low energy expenditure that are done in a sitting or reclining posture, such as lying down to watch television and sitting to use a computer or travel in a motor vehicle. This distinction highlights that sedentary behavior and physical activity are not mutually exclusive lifestyle components. A person can have high levels of sedentariness (i.e., sitting 8–10 h/day) and also exercise daily, or have low levels of sedentary behavior and do no exercise.

Health Benefits of Physical Activity

Inactivity is the fourth leading risk factor for global mortality and a leading cause of years lost due to poor health, disability, or premature death (World Health Organization 2010). Inactivity is estimated to be the main cause for approximately 25% of breast and colon cancers, 27% of diabetes, and 30% of ischemic heart disease burden in the general population including older adults (World Health Organization 2010).

Data from Sweden indicate that physical activity is the strongest factor associated with longevity among adults aged 75+ years, with regularly active people living on average 2 years longer than those inactive

(Rizzuto et al. 2012). Activity has a positive impact on many of the concomitants of aging. Sufficient and regular physical activity:

- Reduces the risk of high blood pressure, coronary heart disease, stroke, type 2 diabetes, breast and colon cancer, falls, depression, functional and role limitations, and premature death
- Improves bone health, cardiorespiratory and muscular fitness, physical functioning, performance of activities of daily living, balance, health-related quality of life, and life expectancy
- Is a key component of energy balance and weight management

Benefits for well-being. Physical activity can enhance well-being and health-related quality of life, and prevent and help manage poor mental health among older adults. Potential benefits include stress management, improved mood, mental alertness, competence, self-esteem, self-worth, and social connectedness (Franco et al. 2015). Physical activity may also provide specific psychological benefits that are associated with emotional well-being, such as enjoyment and fulfillment; time-out and distraction; a sense of accomplishment, mastery, and control; enhanced energy; and reduced fatigue and tension. A Taiwanese study with older adults demonstrated that leisure time physical activity was positively associated with psychological, social, learning, growth, and independence dimensions of well-being, both currently and over the following 3 years (Ku et al. 2014). Those who did frequent walking, gardening, or group exercise had higher levels of life satisfaction as they aged over 8 years, even after accounting for health, depression, and cognitive decline: this association was stronger for the oldest group aged 80+ than those aged 70–74 years (Ku et al. 2015). Regular exercise and physical activity can also reduce the severity of depression and improve well-being in older adults (Bridle et al. 2012; Windle et al. 2010).

Physical activity reduces the risk of cognitive decline by approximately 35% and the risk of dementia by approximately 18% (Blondell et al. 2014) and can help maintain or enhance

cognitive function in older adults with or without mild cognitive impairment (Carvalho et al. 2014). Among those with dementia, exercise may help improve some activities of daily living (Forbes et al. 2013).

Benefits for healthcare service use. Physically active older adults have fewer general practitioner visits, hospitalizations, emergency and outpatient visits, and extended hospital stays; and lower overall healthcare costs than those who are inactive (Sari 2011). Data from Jerusalem demonstrated that the proportion of older adults with emergency room visits was 37% for active people and 16% for those inactive at age 78 years, and 51% for active people and 31% for those inactive at age 85 years, after allowing for functional dependence, cognitive impairment, depression, body mass index, smoking, and conditions such as diabetes and heart disease (Jacobs et al. 2013). The proportion of older adults with hospitalization was 11% versus 17% at 78 years and 22% versus 38% at 85 years for those active versus inactive (Jacobs et al. 2013). *Initiating* physical activity in late adulthood resulted in a similar lower likelihood of emergency visits and hospitalization as being consistently active, and *ceasing* activity and *never* being active were associated with increased emergency visits and hospitalization (Jacobs et al. 2013).

Exercise, including walking, can be more cost-effective than medical interventions for some health conditions (Sari 2011). In the US general population including older adults, insufficient physical activity is estimated to account for 9–11% of healthcare expenditure, with a mean annual expenditure difference per capita of 30% between inactive and active adults and 15% between those doing some activity and those doing none (Carlson et al. 2015). Inactivity is the cause of more than 15% of annual costs of major noncommunicable diseases in China (Zhang and Chaaban 2013).

How Much Physical Activity?

General recommendations. Recommendations on how much physical activity to do for good health have been produced by a range of organizations

across the world, e.g., national heart associations, public health institutes, sports medicine associations, and government departments of health. Countries with physical activity recommendations include Australia, Belgium, Canada, Chile, Denmark, England, Fiji, Finland, France, Ireland, Jamaica, Japan, the Netherlands, New Zealand, Norway, Singapore, Spain, Sweden, Switzerland, the United Kingdom, and the United States.

For people aged 65+ years, the World Health Organization (World Health Organization 2010) recommends:

- At least 150 min of moderate-intensity physical activity or at least 75 min of vigorous-intensity physical activity or an equivalent combination of moderate- and vigorous-intensity activity throughout the week
- For additional health benefits, people should increase to 300 min of moderate-intensity physical activity, or 150 min of vigorous-intensity activity, or an equivalent combination of moderate- and vigorous-intensity activity throughout the week
- For those with poor mobility, physical activity to enhance balance and prevent falls on at least 3 days per week
- Muscle-strengthening activities involving major muscle groups on at least 2 days a week
- When older adults cannot do the recommended amounts of physical activity due to health conditions, they should be as physically active as their abilities and conditions allow

Focus of activity recommendations. The lower recommendation (150 mins/week moderate, 75 mins/week vigorous) is for *general* health benefits, such as good physical functioning and a lower risk of cardiovascular disease. The higher recommendation (300 mins/week moderate, 150 mins/week vigorous) reflects that more activity is needed for other benefits such as reducing the risk of some cancers and preventing weight gain (Brown et al. 2014). *Specific* goals, such as managing an injury or health condition, or improving a select aspect of physical functioning, may require a different amount or specific types of physical activity.

Older adults with disability or health concerns may benefit from professional advice on adjustments to physical activity recommendations, based on individual capacity, risks, and limitations. Screening tools that assess health history (Australian Government Department of Health and Ageing 2005; Balady et al. 1998) can provide pre-participation guidance on potential risks and if a medical consultation is advisable. Because many of these tools screen for medication use or conditions often prevalent among older adults, they can yield a high rate of recommendations for medical consultation (Whitfield et al. 2014). Screening tools specific to older adults (Resnick et al. 2008; Cardinal et al. 1996) may, therefore, be advantageous.

Physical activity intensity. The intensity of physical activity reflects the effort and energy involved. With moderate-intensity activity (e.g., brisk walking, slow bicycling, general gardening), there is some difficulty talking, and heart rate is at 50–70% of the maximum. When doing vigorous-intensity activity (e.g., jogging, aerobics), it is difficult to say more than a few words without stopping to take a breath, and heart rate is at 70–85% of the maximum. High-intensity activity (e.g., running, jumping rope) is at more than 85% of the maximum heart rate. Maximum heart rate depends on age, can change with physical activity type, and may be lowered by some medications. While there are some simplistic informal means to estimate maximum heart rate based on mathematical formulae (e.g., a set number – your age), formal determination is based on exercise testing.

Activity recommendations are lower for vigorous- than moderate-intensity activity because vigorous-intensity activity expends more energy. However, *both* types of activities provide benefits. Vigorous-intensity activity may provide benefits at a slightly higher level more rapidly, but may be difficult or undesirable for some older adults to do. People can, therefore, mix types of physical activities depending on their ability, preference, and opportunities.

Most research on the health benefits of physical activity focuses on moderate- to vigorous-intensity physical activity. Notably, light-intensity activities – such as slow walking,

stretching, and light gardening/housework – can also provide some health benefits for older adults and may be more acceptable and tolerable for some people (Loprinzi et al. 2015). Emerging research is suggesting that light-intensity activity can have a positive impact on blood glucose, cholesterol, metabolic health, self-rated health, weight indicators, and mood.

Physical activity types. Activities that enhance balance typically involve balancing movements e.g., tai chi, yoga, dancing, and specific exercises (e.g., standing on one foot). Muscle-strengthening activities involve weight-bearing – this can include actual weights (e.g., carrying loads, lifting/pushing weights, weights on the wrists or ankles) or body weight (e.g., stepping, jumping, push-ups, sit-ups). Major muscle groups are the legs, back, abdomen, chest, shoulders, and arms.

Physical activity thresholds. These physical activity recommendations represent a threshold at which there is a *majority* of general health benefit. It is important to note, however, that physical and psychological benefits can be derived from smaller amounts of activity. Doing at least 30 min of activity 1–2 times a week can significantly reduce the risk of all-cause mortality (Wu et al. 2015). The reduced risk of mortality in older adults is 22% for activity less than recommendations compared to no activity, and 28% for activity recommendations compared to not meeting recommendations (Hupin et al. 2015). Low levels of activity – such as 40–75 min/week walking – have been associated with current emotional well-being and a reduced risk of depression and anxiety symptoms after 3 years among older women (Heesch et al. 2011). Often the greatest benefit to health is to change from doing no activity to do some.

How Active Are Older Adults?

How to measure physical activity. There is a range of ways to assess physical activity. Questionnaires, logbooks, diaries, and interviews can be done face to face and by mail, telephone, or online. These methods rely on individual reports of how much physical activity was done in a set

time period, e.g., past day/week/month. People may be asked to report on frequency, duration, or specific types or intensities of physical activity in different settings. This assessment is, however, vulnerable to error, as it can be difficult to recall physical activity accurately, particularly if it was incidental (e.g., climbing stairs), during a time period with atypical behavioral patterns, or over a long period (e.g., during the past year). Errors can also arise if people want to present themselves in a positive manner.

Other types of assessment involve the use of instruments to measure the biomechanical or physiological consequences of physical activity. Pedometers and accelerometers are electric or electromechanical devices that detect motion. Pedometers count steps and accelerometers assess speed and intensity. These small devices are commonly worn at the waist or wrist, and some are worn on the ankle or thigh. Some personal devices, such as a watch or mobile phone, have an integrated pedometer or accelerometer and provide physical activity information on a visual display or relay data to a computer. This approach to assessment is less vulnerable to reporting errors and includes incidental physical activity that can be difficult to keep track of, such as short walks to do errands. However, some of these devices are not suitable to wear in water or to detect activities unrelated to walking and therefore cannot assess activities such as swimming, bicycling, yoga, and weights. Other types of instruments, e.g., monitors to assess heart rate, focus on energy expenditure as a reflection of the amount of activity done.

How many are meeting activity guidelines? The proportion of older adults meeting recommendations to do at least 150 mins/week of moderate- to vigorous-intensity activity varies markedly by country and method of measurement. The majority of reports range from 20% to 60%, with higher prevalences in Cyprus, Brazil, rural China, Columbia, Sweden, and Switzerland: when domestic activity is included: among men than women; and for younger than older age groups (Sun et al. 2013). There is mixed evidence on trends over time, although low- and middle-income countries may have decreasing levels of physical activity with the increasing

availability of mechanical and technological devices that reduce the need for physical exertion (Sun et al. 2013).

Pedometer-based health promotion messages for adults often recommend 10,000 steps each day. Benefits for older adults are, however, apparent from at least 4500 to 5500 steps/day for health-related quality of life, body weight, cholesterol, physical functioning, mobility and balance, blood glucose, and mood (Ewald et al. 2014; Tudor-Locke et al. 2011). Healthy older adults average 2000–9000 steps/day, which reflects the natural diversity of ability associated with age, illness, and mobility (Tudor-Locke et al. 2011). Those with illness or disability, but not limited to older adults, average 1200–8800 steps/day (Tudor-Locke et al. 2011). Data from the United States suggest an average of 4240 steps/day among older adults, generally with men accumulating slightly more steps than women, and a decreasing step count/day with increasing age (Tudor-Locke et al. 2013).

Barriers and Enablers of Physical Activity

Among older adults, there is a range of potential barriers and enablers of physical activity; these relate to sociodemographic, personal, social, and environmental contexts.

Demographic and personal factors. Major demographic and personal factors that can help or hinder activity participation among older adults include affordability, activity habits, physical and psychological health, and activity-related attitudes (Franco et al. 2015). Affordability may be an issue in late adulthood because of a change in financial circumstances or priorities after leaving the paid workforce, or among those with socioeconomic disadvantage. Past habits regarding sedentary or physically active leisure pursuits may influence behavior in late adulthood, because of positive/negative experiences and established opportunities and networks. Physical limitations can reflect poor health; pain; discomfort; breathing difficulties; or concerns associated with falling, injury, musculoskeletal disorders, or urinary incontinence. Stress, psychological difficulties

(e.g., depression, anxiety), low mood, and negative reactions to life events (e.g., bereavement) may be a barrier. Personal attitudes relating to the perceived value of physical activity, activity competence and confidence, competing time priorities, independence, and apathy can also influence activity participation.

Social factors. Key social influences of physical activity among older adults relate to interactions, confidence, and support (Franco et al. 2015). Positive social interactions from seeing familiar people, from group-based activities, or with activity instructors can enhance motivation. Low social confidence or concerns with group diversity may be a barrier to group-based activity options. Some cultural or religious contexts may require specific social conditions, such as gender segregation. Social support for activity includes verbal encouragement and informational and practical assistance, e.g., advice, transportation, and equipment. Constraints may come from competing time demands from family or care responsibilities for, e.g., a partner or grandchildren. Some older adults may be discouraged from activity by overprotective or critical significant others worried about injury or exacerbation of a preexisting condition. Ageist stereotypes, from others or among older adults themselves, may constrain participation and reflect beliefs that exercise is unnecessary or potentially harmful, or that age-related decline is inevitable. Professional advice (e.g., from a trusted health practitioner) to do physical activity and supervised instruction may be particularly valued by older adults with vulnerabilities, and can enhance feelings of safety during participation.

Environmental factors. Salient environments for older adults' physical activity include pedestrian infrastructure (e.g., continuous unobstructed dedicated paths), crime-related safety (e.g., friendly people, lit areas), traffic-related safety (e.g., street crossings, safe drivers), accessible and appropriate opportunities (e.g., age-oriented options, walking destinations) and amenities (e.g., rest areas, public transport, toilets), aesthetics (i.e., well maintained, attractive, natural scenery), and environmental conditions (e.g., moderate weather, quiet, peaceful, minimal pollution) (Moran et al. 2014).

Promoting Physical Activity for Older Adults

Interventions to improve or maintain physical activity in older adults can involve a variety of contexts and methods. Physical activity may be the single focus or integrated with other intervention components, e.g., healthy eating. Types of activity can include conventional exercise, walking, sports, or more novel applications such as dance or exergaming.

Individual-level approaches. These strategies focus on individualized delivery or small groups. Programs can be home-based or in other settings, e.g., exercise facility, church, health service, and aged care. The format may be individual- or group-based and supervised or unsupervised and, if supervised, led by peers, lay people, or professionals across a range of disciplines. Participant contacts can be face to face or remote using print materials, telephone, text messaging, or online resources. Programs may involve direct exposure, e.g., exercise training and instruction, or aim to enable independent engagement in physical activity, e.g., providing social support, advice, resources, or motivational counseling.

Individual-level physical activity interventions with older adults living in the general community can be effective, with an average improvement of 620 steps/day or 73 min/week and greater effects among more healthy people (Chase 2015). Position statements and best practice guidelines on physical activity in older adults identify multicomponent programs, low-risk and safety through graduated intensity, and behavioral change strategies (Toto et al. 2013).

Behavioral change strategies. Individual activity programs may be more successful if they combine cognitive and behavioral strategies, include motivational components that promote independent change, and incorporate problem-solving techniques and barriers management (Chase 2015). Cognitive strategies address activity-related attitudes and beliefs, e.g., perceived value, understanding of risks vs. benefits, and building confidence. Behavioral strategies include goal setting, action planning, self-monitoring, modeling (i.e., demonstrations and opportunities to rehearse),

and contingent rewards. Motivation for physical activity can be extrinsic (e.g., wanting to please significant others) or intrinsic (e.g., pleasure) and reflect interests in health and fitness, social and emotional benefits, weight management, enjoyment, improved appearance, and other gains. Importantly, the personal salience and meaning of these motivators will differ among older adults. Exploring and resolving ambivalence toward physical activity is a key component of counseling-based approaches to enhance motivation, and is based on the premise that there are different stages of readiness for change. Problem solving and barriers management can include self-regulation strategies on how to manage disruptive thoughts and feelings, strategies to enhance social support for physical activity, and coping planning on how to manage distractions, setbacks, and relapses.

Community-level approaches. These strategies target large groups or whole populations. Communication-based strategies use audiovisual materials and persuasive messages to promote e.g., awareness of the value of physical activity, recommended activity levels, and strategies for change. Signage can highlight opportunities for physical activity, e.g., the number of steps to a destination, using the stairs. Mass media campaigns are an appropriate part of community-wide activity campaigns but have uncertain effectiveness as a stand-alone strategy (Hawkins et al. 2007). Despite some initial low Internet confidence, older adults can successfully engage with online physical activity interventions (Ammann et al. 2013; Irvine et al. 2012).

Health and community-based services can enable staff to promote physical activity and can enable activity opportunities for older adults, e.g., staff training in physical activity counseling, organized activity groups, and supported access to community-based activity providers. Primary care may be a useful setting to reach older adults: activity interventions in this context need more evaluation but show promise (Stevens et al. 2013; Neidrick et al. 2012). Walking groups that target older adults are more effective in increasing physical activity than groups that target younger adults (Kassavou et al. 2013). Mass physical activity

participation events can attract and involve older adults (Stevinson and Hickson 2014).

Environmental approaches focus on enhancing the natural or built settings for physical activity. Large shopping malls may provide a safe, accessible, and affordable walking environment for older adults, redressing barriers of personal security and poor weather (Farren et al. 2015). Local government partnerships can develop more “walkable” neighborhoods characterized by pedestrian infrastructure, high residential density, mixed development (which provides destinations), high street connectivity, aesthetics, green space, and optimized safety (e.g., adequate street lighting) (Kerr et al. 2015). People living in high walkable communities accumulate an average of 766 steps/day more than those living in low walkable areas (Hajna et al. 2015). Exercise equipment and resources can be provided in local parks, aged care residences, and other settings accessible to older adults.

Economic incentives for physical activity include cash/gift vouchers or cost subsidies for older adults to access activity opportunities/resources, taxation strategies to promote active transport, and insurance returns or credits for ongoing activity participation. Government, worksite, and other groups can develop physical activity policy to identify behavioral targets; organizational goals, resources, and implementation plans; as well as organizational, political, and public opportunities, e.g., urban design and land use (Rutten et al. 2012).

Future Directions

Directions for future enquiry on older adults’ physical activity include:

- Quantifying what intensity, frequency, mode, and duration of physical activity is most beneficial for enhancing different aspects of aging (physical, psychological, cognitive, social) and the benefits from low levels of activity
- Establishing and maintaining surveillance studies, in particular in low- to middle-income countries, to understand the patterns and trajectory of participation

- Assessing the relative importance of personal, social, and environmental determinants
- Identifying the most effective promotional strategies, at the individual and community level
- Exploring how physical activity can be enabled among older adults with specific needs, e.g., socioeconomic disadvantage, ethnic diversity, poor physical/psychological health, cognitive decline, frailty, physical limitations, in residential care, in regional, and remote areas
- Understanding how improvements in physical activity can be maintained over time

Summary and Conclusion

Physical activity is about movement and includes behavior across a range of contexts. Inactivity is a leading cause of poor health, disability, and premature death. Regular and sufficient activity provides multiple benefits including cardiovascular, metabolic, respiratory, and musculoskeletal health; physical functioning; psychological and social well-being; cognitive functioning; and quality of life. For older adults, physical activity is the strongest factor associated with longevity. Current recommendations are for adults aged 65+ years to engage in at least 150 min/week of moderate-intensity activity and activities to promote balance and strengthen muscles. Importantly, benefits can be obtained from lower levels and intensity of physical activity, so people should be as physically active as abilities allow. There are a range of potential sociodemographic, personal, social, and environmental barriers and enablers to physical activity among older adults – these factors can inform individual- and community-level strategies to promote physical activity. Key components of successful individual-level programs to promote activity include a combination of strategies to address attitudes, self-directed behavior change, motivation, and problem-solving techniques and barriers management.

Physical activity requires minimal resources, provides physical and psychosocial benefits across a diverse range of aging experiences,

and reduces health service use and associated costs. It is never “too late,” with some benefits from initiating physical activity in late adulthood comparable with being consistently active. There is strong evidence and consensus that a physically active lifestyle, comprising non-exercise activities and moderate- to vigorous-intensity exercise, is an important component of optimal aging.

Physiotherapy

Definition

Physical therapy is the health science of improving physical function and mobility through reducing pain, increasing strength and flexibility, and improving posture and balance. The American Physical Therapy Association defines their vision through recognizing that physical therapists diagnose, intervene, and prevent impairments and activity and participation limitations related to movement and function. Based on assessment and clinical judgment, physical therapists decide, in conjunction with the older person, whether a functional limitation can be rehabilitated or requires adaptation of the task or the environment. Rarely does physical therapy consider the psychosocial aspects of health for older people in isolation, yet many aspects of physical therapy impact a person's psychosocial well-being. This entry will explore the role of physical therapy in

psychosocial well-being, through the lens of building and/or maintaining functional capacity, and thus independence of older people.

Introduction

Health is defined as “a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity” (CSDH 2008). The World Health Organization (WHO) developed a framework, the International Classification of Functioning, Disability, and Health (ICF), which fits with the definition of physical therapy above, with its focus on activity and participation. Linking in with this too are the WHO Rights to Health: that all people are entitled to available, accessible, acceptable, and quality healthcare services (CSDH 2008). Older people across the world experience challenges to their physical health, with reduced capacity for improvement in function related to physiological, sensory, and cognitive changes as they age (WHO 2015). There is a decline in muscle mass and subsequent reduced strength, reduction in bone density, and changes to joint cartilage all impacting musculoskeletal function and movement (WHO 2015). Physical health challenges are often related to chronic disease, such as osteoarthritis and low back pain, complicated by multi-morbidity, with situations of conflict and natural disasters exacerbating existing chronic conditions such as hypertension and diabetes. Physical therapy is only one of a multitude of medical and allied health services that can support older people to regain their physical health but play a unique role in assisting older people to regain and/or maintain physical functional capacity.

Functional capacity can be defined as the ability to perform life skills under optimal conditions, essentially what a person is capable of doing (Bowie et al. 2006). Interestingly, functional skills can also be viewed through the lens of functional performance, what a person *actually* does, which is complicated by physical and cognitive abilities, motivation, and environmental factors such as social support (Bowie et al. 2006). Within Australia, recent aged care reform recognized the need

for capacity building of older people, to maximize preventive and restorative care, aiming to improve independence, quality of life, and social participation (Lewin et al. 2013). These reforms followed the vision for social care set out in the United Kingdom, premised on all people making a positive contribution to society and having the right to control their lives (Department of Health 2005). A reduction in functional capacity has the potential to impact in three key areas: at an individual older person level, for their caregiver and/or family, and at the level of health services more broadly. For an individual, independence is tied with quality of life and social connectedness. An example is an event such as a fall for an older person leading to curtailment of activity in up to 55% of people, subsequently leading to functional decline, reduced social participation, and decreased quality of life with institutionalization a looming threat (Kendrick et al. 2014). For the caregiver and/or family, there may be worry and concern for the older person with ongoing stress related to caring for someone with reduced functional capacity perhaps signaling the need for respite care services. For the health system more broadly, addressing the needs of an older person with reduced functional capacity requires healthcare services to be available and accessible but also, more importantly, suitable for individual needs and preferences and coordinated with other required services. Physical therapy plays an integral role in supporting the functional capacity of an older person.

To support the functional needs, and subsequently the psychosocial needs, of an older person and their caregiver/family, healthcare services should ideally be available, accessible, acceptable, and of high quality (CSDH 2008). Available physical therapy services include the type of physical therapy offered, such as exercise, manual therapy, postural control, and the provision of assistive devices. Available services for the older person ideally incorporate the need for neurological, orthopedic, and cardiothoracic rehabilitation as well as specialist services relevant, but not exclusive, to older people such as falls prevention, rheumatology, chronic pain, continence, and amputee management. Accessibility of physical

therapy services must account for metropolitan, regional, and remote locations; delivery of services through hospital, community, and residential care settings; and cost of services. Acceptability of services draws on the philosophy of person-centered care, with services provided free of prejudice and stereotype, acknowledging an individual's preferences and desires. High-quality healthcare services rely on the adequate undergraduate and ongoing training of physical therapists, of the ability of physical therapists to work as part of a multidisciplinary coordinated team.

Physical Therapy Services for the Older Person

Physical therapy is concerned with movement disorders, with numerous services potentially available to ensure optimal physical functioning, such as neurological, orthopedic, and cardiothoracic rehabilitation and specialist services. Physical therapists are well positioned to assist with the increasing needs of older people related to health conditions such as cardiovascular disease, arthritis, and stroke to maintain optimal levels of functional capacity and reduce future demands on the health system (Australian Physiotherapy Association 2012).

Neurological rehabilitation focuses on regaining and/or maintaining physical function related to stroke, spinal cord injury, dizziness, or other diseases such as Parkinson's disease and multiple sclerosis. Most commonly, the link with psychosocial well-being is the impact of limited mobility on independence and social participation. For example, Parkinson's disease is a progressive disease leading to difficulties with gait and balance, ultimately leading to decreased independence as a result of inactivity and social isolation (Tomlinson et al. 2013). Current evidence suggests that physical therapy is of benefit for improving transfer ability through cognitive movement strategies, improving gait through cueing strategies, and improving strength, balance, and flexibility through exercise, yet there is limited evidence that explore how pain and fatigue

can impact an individual's well-being (Tomlinson et al. 2013). A further example is the link between stroke and depression, with an association found between depression and the physical disability, stroke severity and impairment in cognition resulting from the stroke (Hackett and Anderson 2005). Physical therapists are encouraged to identify and seek assistance for those with depression given that it affects rehabilitation participation and adoption of treatment strategies.

Orthopedic rehabilitation relates to the musculoskeletal system, the rehabilitation of muscles, bones, joints, and ligaments, resulting from trauma, degeneration, or congenital conditions. Most commonly for older people, injury and conditions are related to falls, osteoarthritis, and overuse. For example, vertebral fractures are a complication of falls and are related to increased morbidity, due to resulting pain and reduced quality of life (Giangregorio et al. 2013). Exercises are often prescribed for an older person with a history of vertebral fractures, with resulting benefits of reduced pain and improved function and quality of life, but this evidence must be treated with caution as high-quality studies are not yet available (Giangregorio et al. 2013). Distal radial fractures, resulting from a fall, are a common clinical problem in older people with osteoporosis. Rehabilitation is designed to improve hand function, yet little evidence exists for the effectiveness of a home exercise program (Handoll and Elliott 2015). Education prior to surgery, such as for hip and knee replacements (often due to osteoarthritic changes in the joints), is an important consideration in physical therapy practice. Major surgery is stressful for people, and, while the evidence is not strong, it is hypothesized that the provision of education to improve knowledge and health behaviors will reduce postoperative anxiety and pain and improve function and quality of life (Handoll and Elliott 2015).

Cardiothoracic rehabilitation incorporates rehabilitation following myocardial infarction and heart, lung, or vascular surgery or related to chronic pulmonary disease. Cardiac rehabilitation programs are designed to improve function, quality of life, and well-being of people with heart disease through exercise, education, and

psychological support (Anderson and Taylor 2014). Cochrane systematic reviews, although not specific to older people, but showing a mean age of 46–87 years across studies, showed high-quality evidence for supporting exercise-based cardiac rehabilitation in addition to education and psychological interventions following heart attack or cardiac surgery or for those who have chronic heart failure (Anderson and Taylor 2014). Pulmonary rehabilitation is considered a key recommendation for people with chronic obstructive pulmonary disease also comprising exercise, education, and psychosocial support (McCarthy et al. 2015). Improvements have been noted in quality of life and in domains of shortness of breath and fatigue, with enhanced sense of mastery over their condition and emotional function (McCarthy et al. 2015).

More specialist physical therapy services available for older people relate to management of falls, amputation, rheumatology, chronic pain, and continence. Each of these areas benefits from individual consideration, linking to psychosocial outcomes, as outlined below.

The prevention of falls is a major public health issue, with one in three older people falling each year, leading to escalating hospital-related costs (Gillespie et al. 2012). Physical therapy can assist through the provision of lower limb strengthening exercises and challenging balance activities, which have been shown to reduce falls rates (Gillespie et al. 2012). A recent Cochrane review suggests that both group and home exercise programs for community-dwelling older people reduce the rate and risk of falls, but that education alone is inconclusive (Gillespie et al. 2012). Exercise programs may have the specific goal of reducing fear of falling given the serious physical and psychosocial consequences for older people. Exercise interventions appear to have short-term beneficial effects on fear of falling, through improvements in strength, gait, balance, and mood (Kendrick et al. 2014).

For those living with limb loss, the main cause is vascular disease most commonly related to diabetes and trauma (Veteran Affairs Employee Education System 2008). Amputee rehabilitation considers several domains, with physical

therapists being one of a number of health professionals involved in the multidisciplinary team. The domains include: postoperative pain, including residual limb and phantom limb pain; physical health related to balance, strength, and endurance; function related to transfers, mobility, reduced activity limitation, and improved quality of life; and psychological and social support for associated comorbidities of depression and anxiety and return to home and community and recreational participation (Veteran Affairs Employee Education System 2008). The multidisciplinary team is critical for pain management, managing comorbidities, psychological assessment, and prosthetic training.

Rheumatological conditions cover a broad spectrum of joint-, muscle-, and bone-related conditions such as osteoarthritis, rheumatoid arthritis, fibromyalgia, and osteoporosis. Functional capacity is impacted through pain and swelling of the joints, stiffness, and limited mobility. Best practice recommendations are for multidisciplinary team management, incorporating medications, exercise, nutrition, assistive devices, and management of emotions and fatigue. Physical therapists are often involved in education for people with osteoarthritis, encouraging people to take an active role in the management of the disease, in addition to usual physical therapy techniques. A recent Cochrane review concluded that there is limited evidence to suggest that self-management programs are beneficial for reducing pain and improving quality of life and function, but it is acknowledged that active and positive engagement in life are unknown effects and program delivery should be closely assessed to ensure health equity for recipients (Kroon et al. 2014).

Chronic pain is a global term for pain that lasts beyond the usual time for expected healing, often correlated with psychological outcomes (Pain Australia 2015). Chronic pain can lead to depression, anxiety, physical deconditioning, and social isolation (Pain Australia 2015). In Australia, the National Pain Strategy is currently under way with recommendations including a coordinated multidisciplinary assessment and management, of which physical therapy plays a role in

addressing the physical domains of chronic pain management (Pain Australia 2015). Cognitive-behavioral therapy (CBT) is used as a means to address chronic pain, through an individualized program to healthy habits unhelpful thoughts and behaviors to be replaced with healthy habits (Monticone et al. 2015). CBT is designed to reduce the impact of pain, thus allowing physical therapy to be of greater benefit, and reduce physical and psychosocial disability. A Cochrane review assessing the effects of CBT on chronic neck pain found it to be effective for short-term pain reduction and improved quality of life, with a small effect on reducing the fear of movement (Monticone et al. 2015). Multidisciplinary biopsychosocial programs for chronic pain emerged from the United States and have growing support and evidence in many other areas across the world (IASP 2012). Program elements of medication management, exercise, and cognitive behavioral therapies are central, with service availability and length of waiting lists highly variable, potentially impacting quality of life and psychological well-being (IASP 2012).

Urinary incontinence is a common impairment in older age, particularly among women, and is a strong predictor for the need for community and/or residential care (WHO 2015). From a physical therapy perspective, exercise programs can be implemented to strengthen pelvic floor muscles, in turn contributing to enhanced quality of life for the older person. One of the profound consequences of incontinence is stigma, with many people not even seeking health professional advice (Garcia et al. 2005). It is suggested that stigma arises from the strong cultural expectation of managing bodily fluids, something people are taught to do from a very young age (Garcia et al. 2005). People who are stigmatized feel devalued and have their self-esteem threatened, but interestingly, health professionals can also avoid discussing incontinence for fear of being seen as biased (Garcia et al. 2005). Providing advice on healthy diet and lifestyle habits, management techniques including continence aids, and pelvic floor exercises can assist with reducing stigma, allowing people to lead a positive and active life (Garcia et al. 2005).

Through all of these examples, it can be seen that the assessment and treatment of physical dysfunction through the provision of exercise, use of manual therapy, and assistive devices can enhance the functional capacity and independence of an older person. The availability of services, however, is not sufficient to ensure that older people take up the options available to them. Issues related to accessibility also need to be taken into account and are addressed in the next section.

Accessibility to Physical Therapy Services

Accessibility to services includes the physical, economic, and educational ability to access health services and information (CSDH 2008). Physical therapists are found in hospital, community, and residential care settings, variably within metropolitan, regional, rural, and remote areas. The World Confederation for Physical Therapy currently represents 350,000 physiotherapists globally, through 111 member organizations, supported by the World Health Organization to promote access and provide quality rehabilitation services (World Confederation for Physical Therapy 2015).

Physical Accessibility

The need for acute physical therapy services is often related to trauma or sudden-onset medical conditions. Acute services are found in the hospital sector, with physical therapists a key player in treating people within hospital and then ensuring efficient discharge processes. Acute physical therapy services allow older people to regain mobility and strength and thus independence, albeit most likely in a supported manner with gait aids as required and potential assistance in the home. Discharge planning is critical in ensuring that an older person is supported in their transition from hospital to home (with community based services as required). Lack of coordination and person-centered planning can lead to poorer outcomes, including possible readmission to hospital, with collaboration a key ingredient to ensure understanding and mutual respect of the person and their caregiver (NHS Wales 2008).

Sufficient resources and skills are required to ensure successful discharge which, in practice, means that there is successful negotiation between hospital and community services to ensure adequate physical and social support (NHS Wales 2008).

Community-based physical therapy services cover the spectrum of community health centers and in-home aged care support, both of which are government subsidized, and private practice. In-home aged care support occurs through short-term services, specifically designed to provide support following an acute hospital stay. Longer term aged care support is provided on an increasingly more frequent consumer-directed basis, in line with providing choice and flexibility in the services that are provided to older people. Allied health services are a component of this support, with a focus on preventive and restorative care based on improving/maintaining functional capacity and independence (Lewin et al. 2013).

Physical therapy services within residential aged care facilities are generally provided by external organizations or, rarely, employed directly by the residential care facility. Physical therapists assess the physical needs of the residents; equip people with gait aids or other aids such as hip protectors, as required; and ensure staff are capable of assisting the mobility needs of the residents. Again, providing a sense of independence and autonomy to residents in an often disempowering environment is a goal of physiotherapy, but there is only limited evidence for the benefits of activity and exercise in this setting due to intervention and dependency differences (Cameron et al. 2012).

Ensuring physical accessibility to services extends to the uniquely challenging environment of rural and remote areas. In Australia, rural zones are classified as between 10,000 and 100,000 people, while remote areas are <10,000 people. Classification differs, for example, in Canada, with rural areas classified as <1,000 people, with a density of <400 people per square kilometer. The provision of physical therapy services in rural and remote areas is complicated by recruitment and retention rates of health professionals,

correlating with poorer health status of residents in these areas (Campbell et al. 2012). Lack of access to professional development opportunities, sufficient supervision, and inclusion are responsible for some of the barriers to retaining allied health in these communities, but autonomy and connection with the community are considered incentives (Campbell et al. 2012). From an individual older person's perspective, accessing services has been enhanced through the use of telemedicine, with promising results for chronic disease management and Internet-based physical activity/exercise interventions (Ekeland et al. 2010).

Financial Accessibility

Acute and community physical therapy services vary considerably from a financial accessibility perspective. Financial commitment for a client is highly variable with fee schedules dependent upon prevailing market conditions of a particular country, with clients entitled to understand anticipated costs for service prior to undertaking treatment (World Confederation for Physical Therapy 2015). The financial circumstances of the older population vary substantially from being active participants in the workforce through to requiring support from family and/or the provision of pensions or other welfare (WHO 2015), impacting their ability to access healthcare services. Physical therapy services should reflect the economic variability of nations, as well as the complexity of conditions as outlined within this entry.

Information Accessibility

Information accessibility is an important consideration to ensure that older people have access to information from which to make informed decisions about their healthcare. Shared decision making is the process of health professionals involving the person themselves in understanding options for treatment and how the person can choose care that meets their needs and reflects their values and preferences (Legare et al. 2014). There is currently low-quality evidence for shared decision making, but certainly interventions that target both the health

professional and the person themselves show more promise than individual interventions (Legare et al. 2014).

Acceptability of Physical Therapy Services

Acceptable services should be respectful of the diversity of older people, acknowledging their unique needs and preferences in a manner free of bias and prejudice. A report commissioned by the United States Congress highlighted that inequity in healthcare for people from culturally diverse backgrounds actually resulted from structural health service issues related to bias and prejudice, impacting equity in healthcare *greater* than failing to address personal needs and preferences (Smedley et al. 2003). This report shines a light on the need to focus on a person-centered approach, through shared decision making and partnerships in healthcare, with adequate communication for inclusive healthcare required to address structural bias, moving beyond the bare minimum of provision of health information in different languages (Smedley et al. 2003).

Quality of Physical Therapy Services

Quality of physiotherapy services is predicated on adequate training and ongoing professional development. The World Confederation of Physical Therapy recognizes differences in education and health system models internationally but recommends university-level studies of a minimum of 4-year duration, including competencies necessary for a professional career (World Confederation for Physical Therapy 2015). Only qualified persons may practice physical therapy and, if legislative requirements prevail, be licensed or registered, ensuring ethical conduct and the maintenance of professional development (World Confederation for Physical Therapy 2015). The style of learning within the Australian system is problem-based, the experience of learning using open-ended problems. This style allows for a holistic approach to the

management of movement disorders and has the potential to incorporate psychosocial considerations. The World Confederation of Physical Therapy recognizes the diversity of social, political, and economic environments in which physical therapists must work; hence, standards of practice should reflect prevailing conditions and the changing needs of the local community (World Confederation for Physical Therapy 2015).

A holistic approach allows for multidisciplinary team involvement. Quality physical therapy services often depend on the involvement of other health professionals such as general practitioners (GPs), medical specialists, practice/district nurses, pharmacists, allied health professionals, and community aged care workers. For example, strong evidence exists for the reduction of falls risk with physical therapists addressing lower limb strength and balance, pharmacists and/or GPs providing a medication review, and an optometrist conducting a regular visual assessment (Gillespie et al. 2012). Quality services should also ensure that they are coordinated, with smooth transitions through the various sectors, as mentioned above through effective discharge planning. Older people often have numerous health professionals involved in their care, in addition to physical therapists, and value their expectations and needs respected (NHS Wales 2008). The “passing the baton” metaphor from the National Health Service (UK) guidelines succinctly sums up the need for older people to receive the right care at the right time and in the right place and supported by the right people (NHS Wales 2008).

Conclusion

As mentioned in the opening paragraph, physical therapy has not traditionally focused on psychosocial outcomes for older people. It is now clearer, however, that the physical domain of functional capacity cannot be separated from psychosocial outcomes. Physical therapists need to rise to the challenge of incorporating behavior change techniques and identifying meaningful goals in

collaboration with older people and facilitate active participation in the rehabilitation process. Through this, older people and their physical therapists can effect person-centered change toward building and/or maintaining functional capacity and independence.

Synonyms

Chronic condition; Chronic disease; Cognition; Cognitive function; Cognitive impairment; Dementia; Medical disease; Health condition

Definition

Medical diseases are closely associated with cognition. Medical conditions prevalent in older people include hypertension, diabetes mellitus, and obesity. Cognition encompasses cognitive function, such as memory and executive function, and pathologic states, such as cognitive impairment and dementia. In this entry, health conditions commonly observed in late life, including cardiovascular disease, type 2 diabetes, obesity, HIV, and frailty, and their relationship with cognition are presented.

Introduction

The notion that physical conditions are related to cognitive health has gained prominence in recent years. The “brain–body connection” is intuitive, especially in late life, in that medical conditions are often accompanied by cognitive disorders, with health conditions often presenting as cognitive signs and symptoms. The prevalence of both multimorbid chronic conditions and dementia rises exponentially with age. It is estimated that about 10% of Alzheimer’s disease worldwide is attributable to midlife hypertension, type 2 diabetes, and midlife obesity (Norton et al. 2014). Deterioration or improvement in one affects the other,

with both sharing common risk factors and underlying pathophysiology.

Examining the relationship between health conditions and cognitive function is important in that it helps to identify modifiable risk factors and populations at risk of developing cognitive decline and to understand the underlying biologic mechanisms that, in turn, can lead to the development of preventive and therapeutic strategies for cognitive impairment and dementia. In this entry, several common diseases affecting older adults and their effects on cognitive function are presented. Potential mechanisms and critical pathways known to contribute to cognitive manifestations of physical conditions are described.

Cardiovascular Disease

Cardiovascular diseases (CVD) are prevalent in older people and include hypertension, atrial fibrillation, coronary artery disease, and heart failure. Hypertension, defined as systolic/diastolic blood pressures of 140/90 mmHg or higher, raises the risk of cerebrovascular events, affecting both the macro- and microvascular structures in the brain (Launer 2013). Cerebral macrovascular disease includes clinical stroke, causing focal or diffuse impairments, and small vessel disease (SVD). SVD manifests as lacuna, focal lesions in the white matter, or deep white matter hyperintensities, resulting from ischemia. Cerebral microvascular disease includes cerebral microbleeds and microinfarcts. Coronary artery disease (CAD) is caused by atherosclerosis, formation of plaques within the vessel walls, leading to the narrowing of the arteries supplying blood to the heart. Acute myocardial infarction may result as atherosclerotic plaques clog the coronary arteries. Heart failure occurs when the heart is unable to pump sufficient amount of blood and oxygen to meet the body’s demand.

There is consistent evidence that midlife hypertension is associated with late-life cognitive impairment and dementia (Abete et al. 2014). Elevated levels of blood pressure primarily affect executive function, but hypertension is also reported to influence verbal and nonverbal

memory domains and can increase the risk of amnesic and multiple-domain mild cognitive impairment (Launer 2013). However, the relationship between late-life blood pressure and cognition is still controversial. Treatment of midlife hypertension has the potential to curb the projected increase in the number of people with dementia. However, there is insufficient evidence as to the benefits of treatment of hypertension in reducing the risk of cognitive impairment or dementia.

An elevated systolic blood pressure appears to be a prominent predictor of cognitive decline and impairment (Gąsecki et al. 2013). Alternatively, an increased diastolic blood pressure, because of its effect on small arteries, has been found to be related to cognitive impairment. Moreover, a U-shaped association has been observed between blood pressure and cognitive function (Abete et al. 2014). Not only hypertension but low blood pressure in late life may increase the risk of cognitive impairment and dementia. It has also been postulated that an age-related increase in systolic blood pressure and decrease in diastolic blood pressure, leading to a high pulse pressure, may predispose to large artery stiffness that contributes to decline in cognitive function.

Atrial fibrillation has been found to be associated with cognitive decline, cognitive impairment, and dementia (Jefferson and Thompson 2013). Global cognitive functioning and multiple cognitive domains have been reported to be affected, including visual and verbal memory, abstract reasoning, and executive function (Eggermont et al. 2012).

CAD has been reported to be associated with declines in global cognition, with reduced visual memory, visuoconstruction, verbal fluency, and psychomotor speed (Abete et al. 2014; Eggermont et al. 2012). CAD has also been found to increase the risk of non-amnesic mild cognitive impairment. Further, coronary artery bypass grafting (CABG), used to treat the condition, has been implicated in increasing the risk of dementia (Jefferson and Thompson 2013). Atherosclerosis and myocardial infarction have been found to increase the risk of cognitive impairment.

Heart failure, especially of compromised ejection fraction, has been linked to lower cognitive performance, including verbal memory and executive function (Eggermont et al. 2012). Adverse effects on attention, learning ability, delayed recall, working memory, and psychomotor speed have been reported (Abete et al. 2014). However, less is known about its effect on visuospatial and language domains. Reduced cardiac output and clinically manifested heart failure have been found to increase the risk of cognitive impairment and dementia (Jefferson and Thompson 2013).

Although the specific cause of cognitive changes due to CVD is still unknown, embolic stroke and chronic cerebral hypoperfusion appear to play a key role (Abete et al. 2014). CVD may induce reductions in cerebral blood flow, compromised cerebral autoregulation, blood–brain barrier dysfunction, and inflammation, contributing to Alzheimer’s disease pathology, microvascular abnormalities, and neurodegeneration (Jefferson and Thompson 2013).

Elevated blood pressure increases the risk of cerebrovascular disease and can also accelerate neurodegeneration, causing brain atrophy (Launer 2013). Vascular damage due to hypertension is considered to be brought on by multiple factors, such as hypoxia, thrombosis, inflammation, oxidative stress, and atherosclerosis. Elevated blood pressure is also believed to promote beta-amyloid deposition in the brain. These vascular and neurodegenerative changes are thought to interact to negatively influence neuropsychologic function.

In atrial fibrillation, reduced cardiac output and cerebral blood flow, increased risk of thromboembolism and clinical stroke, and enhanced amyloidogenesis due to chronic cerebral hypoperfusion are considered to lead to cognitive impairment (Launer 2013). Also, cerebrovascular disease appears to mediate the link between atrial fibrillation and cognitive decline.

Atherosclerosis can have adverse effects on the brain through chronic inflammation, promoting endothelial dysfunction and stroke, shared genetic factors, and oxidative stress (Jefferson and Thompson 2013). Myocardial infarction may induce arrhythmogenesis, microembolism, and

reduced cerebral blood flow. CAD patients who manifest cognitive impairment have an elevated platelet activity that could trigger perivascular inflammation and cerebral vasoconstriction, contributing to dementia progression (Abete et al. 2014). Moreover, CAD itself may lead to atrial fibrillation and heart failure.

The primary mechanism thought to account for cognitive decline among individuals with heart failure is cerebral hypoperfusion due to reduced cardiac output (Jefferson and Thompson 2013). Moreover, acute strokes caused by thromboembolism may ensue due to left ventricular dysfunction and cardiac dilation, endothelial dysfunction, and activation of coagulation cascades (Abete et al. 2014).

Type 2 Diabetes

Diabetes mellitus, or type 2 diabetes, is a common metabolic condition, caused by insulin resistance and pancreatic beta cell dysfunction (Koekkoek et al. 2015). The prevalence of type 2 diabetes increases with age. Type 2 diabetes can lead to serious chronic complications, such as cardiovascular disease, nephropathy, peripheral neuropathy, and retinopathy.

Patients with type 2 diabetes exhibit lower cognitive abilities, compared with those without the condition (Koekkoek et al. 2015). Multiple cognitive domains, including memory, processing speed, and executive function, tend to be affected. Cognitive decline starts in prediabetic stages with slow decrements in cognitive performance with age, but the speed of cognitive decline may be accelerated than that of normal cognitive aging. The risk of amnesic and non-amnesic MCI is elevated among those with type 2 diabetes. Compared with those without diabetes, people with type 2 diabetes demonstrate higher conversion rates from MCI to dementia. Type 2 diabetes also increases the risk of both vascular and Alzheimer's dementia. About 6–7% of all dementia is attributable to type 2 diabetes. Midlife rather than late-life diabetes has been found to be particularly predictive of cognitive decline and impairment in late life (Feinkohl et al. 2015).

Several mechanisms have been proposed to explain the relationship between type 2 diabetes and cognitive deficits (Umegaki 2014). Chronic hyperglycemic state has been found to induce impaired neurogenesis and exert neurotoxic effects on the brain due to oxidative stress. Diabetes can also trigger disruption of the blood–brain barrier (BBB) integrity brought on by structural changes in the cerebral microvessels. Impaired neurovascular functioning due to diabetes-related structural and functional deficits in the cerebral vasculature may further contribute to impaired neural activity, BBB dysfunction, and reduced amyloid clearance from the brain. Moreover, chronic inflammation, amyloidogenesis, and insulin resistance appear to be common underlying mechanisms in the pathogenesis of both type 2 diabetes and dementia.

For those with type 2 diabetes, vascular, metabolic, and psychological factors may contribute to an increased risk of cerebrovascular damage (Feinkohl et al. 2015). Consistent findings point to poor glycemic control, hypoglycemia, microvascular disease, inflammation, and depression among diabetic patients to act as risk factors for cognitive decline. The role of dyslipidemia, hyperinsulinemia, and hypertension as risk factors for cognitive decline among type 2 diabetes, however, is less clear. Although blood glucose control has been reported to be of benefit in preserving cognitive function, recurrent episodes of treatment-associated hypoglycemia appear to increase the risk of dementia (Umegaki 2014).

Obesity

The prevalence of obesity is increasing worldwide and poses a global threat to public health. Obesity increases the risk of cardiovascular disease, type 2 diabetes, and various forms of cancer (Prickett et al. 2015). Obesity is an accumulation of excess adipose tissue, often defined by a body mass index (BMI) of 30 kg/m² or greater, with overweight having a BMI in the range of 25.0–29.9 kg/m². However, BMI tends to underestimate body fat with aging due to a progressive loss of muscle and bone mass (Whitmer and Gustafson 2013).

Waist circumference or waist–hip ratio has been used as a measure for central obesity, reflecting visceral and subcutaneous adipose tissue. Other techniques used to assess adiposity include anthropometry, bioelectrical impedance analysis, dual-energy X-ray absorptiometry (DEXA), computed tomography (CT), and magnetic resonance imaging (MRI).

The relationship between obesity and cognition has been studied across the life course, with consistent findings of cognitive deficits, especially of executive function, in children, adolescents, and adults who are obese (Smith et al. 2011). In obese children, global functioning, short-term memory, attention, and verbal ability have been reported to be affected. In adulthood, higher BMI is found to be associated with poorer performance in global cognitive function, memory, language, and motor skills. It is known that obesity predicts cognitive decline, but changes in weight do not reliably predict changes in cognitive ability.

Studies examining late-life obesity and its association with cognitive function are rather contradictory. In the Baltimore Longitudinal Study of Aging, higher BMI was associated with poorer performance in global function, memory, and language (Whitmer and Gustafson 2013). However, higher BMI was not associated with worse executive function but associated with better performance in attention, psychomotor speed, and visuospatial ability. In contrast, higher BMI was associated with a more rapid decline in global function, executive function, and memory. Obesity in late life as it relates to changes in cognition is also conflicting. Obesity predicted not only cognitive decline but also less decline and even better performance in some instance. Weight loss in late life, however, has been found to strongly predict poorer cognitive performance.

Epidemiologic studies have provided consistent evidence that obesity in midlife raises the risk of dementia and Alzheimer's disease (Whitmer and Gustafson 2013). Moreover, the relationship between BMI and cognition may be nonlinear, as underweight in midlife also poses a significant risk for dementia in late life (Bischof and Park 2015). Weight loss also appears to increase the

risk of dementia, reflecting either a prodromal phase or worsening severity of the disease. However, studies that have examined the association between late-life obesity and dementia risk have produced mixed results. Higher weight in late life appears to lower the risk of dementia in the short term but may increase its risk in the long term.

It has been hypothesized that the greater predictive value of midlife than late-life BMI on cognition may be due to higher BMI reflecting greater skeletal muscle mass which has been shown to be protective of cognitive function (Bischof and Park 2015). Other explanations center on BMI being a poor measure for evaluating adiposity, selective attrition of obese middle-aged adults due to early mortality, survival bias of the older respondents, and long prodromal phase of dementia (Whitmer and Gustafson 2013; Bischof and Park 2015).

Alternatively, central adiposity may be a more important indicator of cognitive deficits as it is tied to cardiometabolic risk (Bischof and Park 2015). Even among the normal weight by BMI, central obesity has been reported to be associated with higher dementia risk (Whitmer and Gustafson 2013). More recently, obesity as part of the metabolic syndrome, including hypertension, type 2 diabetes, and dyslipidemia, was recognized to act synergistically to raise the risk of cognitive impairment and dementia (Bischof and Park 2015). Although metabolic syndrome appears to affect cognition in global cognition, memory, and executive functioning, its association with cognitive decline may be age dependent, with the young–old (≤ 70 years) but not the old–old (> 70 years) demonstrating significance (Siervo et al. 2014).

There are multiple potential mechanisms that could explain the link between obesity and cognition. Obesity increases the risk of other cardiometabolic conditions mentioned above, and this could engender cognitive dysfunction. The adverse effects on cognition may be mediated by increased neural structural challenges, such as reduction in brain volume, amyloid accumulation, changes to macro- and microstructure of white matter, cortical thinning, and dopamine depletion, brought on by obesity (Bischof and Park 2015).

Adipose tissues secrete adipokines, causing pro-inflammatory state that induces chronic inflammation, contributing to the development of insulin resistance and endothelial dysfunction, resulting in impaired synaptic function (Whitmer and Gustafson 2013; Bischof and Park 2015). Also, genetic predispositions to total obesity and visceral obesity have been reported to be associated with cognition.

HIV

Human immunodeficiency virus (HIV) is a lethal virus that compromises the immune system. HIV infection is now recognized as a chronic illness as people with HIV survive longer, with the development of combined antiretroviral therapies (Wendelken and Valcour 2013). The neuropsychologic manifestations by HIV have been termed HIV-associated neurocognitive disorder (HAND). HAND is defined as impairment in two or more cognitive domains and is further classified according to the presence and severity of limitations in activities of daily living, as mild neurocognitive disorder (MND) and HIV-associated dementia (HAD).

Early signs of HAND are mental slowing and impaired information retrieval, gait disturbances, and decreased manual dexterity, with general signs of apathy and depression (Wendelken and Valcour 2013). Working memory and executive function can also become impaired, but semantic and visuospatial abilities are usually spared. HAD, the most severe form of HAND, manifests as progressive subcortical dementia, with loss of attention and concentration, motor slowing, impaired verbal fluency, and behavioral problems, resulting in death within a year with no treatment (Clifford and Ances 2013). In the era of combined antiretroviral therapy, the manifestation of HAND has changed to a more cortical than subcortical dysfunction, with impairments in memory, learning, and executive function being predominant, more similar to that of Alzheimer's disease.

More recently, with the aging of the population, chronic HIV infection has attracted attention. Older adults with HIV are at an increased risk of

developing cognitive impairment (Wendelken and Valcour 2013). Older adults with HIV are cognitively vulnerable in that, compared to the young, they tend to manifest higher rates of cognitive impairment at the same detectable HIV levels in the cerebrospinal fluid. Moreover, genetic predispositions related to APOE ϵ 4 allele for Alzheimer's disease have been reported in older adults but not the young (Clifford and Ances 2013).

HIV can infiltrate the brain by crossing the BBB via a number of different pathways, such as by trafficking on infected monocytes and T cells that in turn infect microglia and astrocytes (Hong and Banks 2015). This results in the release of inflammatory cytokines that further compromises BBB integrity and facilitates transmigration of HIV, eventually leading to neuronal death. Aging may accelerate HIV pathogenesis due to the chronic exposure to HIV and interaction with other age-dependent neurologic diseases. The effect of age on HAND may also be due to comorbid conditions, such as metabolic and cerebrovascular diseases. Coinfections, such as herpes virus, cytomegalovirus, and hepatitis C, may further contribute to severe complications and poorer cognitive performance.

Frailty

Frailty is a distinct syndrome highly prevalent among the geriatric population with increasing age. Frailty is defined as a reduced ability to respond to stressors that increases vulnerability to adverse outcomes, such as disability and mortality (Robertson et al. 2013). Although no consensus exists on the operationalization of frailty, one way proposed is to define it as an accumulation of deficits. The other more commonly used concept is the phenotype model, defined as the presence of three or more of the five key components: poor grip strength, slow walking speed, low levels of physical activity, exhaustion, and unintentional weight loss.

Numerous epidemiologic studies have reported that physical frailty is closely associated with cognitive function. Frailty has been found to

predict cognitive decline and incident dementia (Robertson et al. 2013). The relationship appears bidirectional, as cognitive impairment has been reported to also predict frailty. Among the frailty components, gait speed and grip strength have been found to be most commonly associated with cognitive function. Other studies have also reported unintentional weight loss and low physical activity to be significantly associated with poor cognition. More recently, a new term, cognitive frailty, has been proposed to define cognitive impairment, excluding dementia, that accompanies physical frailty that is potentially reversible (Ruan et al. 2015).

Although multiple cognitive domains have been reported to be affected by frailty, executive function and attention have been found to be the most consistently associated (Robertson et al. 2013). Further, perceptual and processing speed, dual-attention processing, orientation, and reasoning have been reported to be affected in frail individuals. However, memory, though relatively worse in frail older adults, does not appear to be significantly deteriorated.

Physical frailty and cognitive impairment may share common underlying mechanisms (Halil et al. 2015). Reduced blood flow and impaired vascular dysfunction, hormonal dysregulation, altered immune mechanism and inflammation, and nutritional deficiency have been suggested to be linked to both frailty and cognitive impairment. Cardiovascular risk factors may play a role in the development of both frailty and cognitive impairment (Robertson et al. 2013). Increased levels of frailty have also been found to be associated with AD pathology. It has been suggested that reduced testosterone levels and insulin resistance are potential mediators in the development of frailty and cognitive impairment. Chronic inflammation can affect both brain and muscle function and has been linked to frailty and cognitive decline. Malnutrition and low protein intake can lead to sarcopenia, loss of muscle mass, and poor functional performance, which has been linked to both frailty and cognitive impairment. Depression has also been implicated in elevating the risk of both frailty and cognitive decline.

Conclusion

Medical conditions prevalent in late life are associated with poor cognitive performance and increase the risk of cognitive impairment and dementia. Multiple mechanisms and pathways, such as vascular damage, neurodegeneration, inflammation, and insulin resistance, are responsible for changes in brain structure and function. Cardiometabolic diseases share common risk factors and may also act synergistically to adversely affect cognition in late life. An increased life expectancy is also predisposing older people to extended periods of morbidity and increased vulnerability. Identification of risk factors and proper management of medical conditions have the potential to lessen the cognitive burden in the older population.

²Network Aging Research (NAR), Heidelberg University, Heidelberg, Germany

Synonyms

(Behavioral) malleability; Changeability; Making use of reserve capacity

Definition

Generally defined, plasticity describes capacity for change, i.e., an individual's capability and reserve capacity to react to demands of the environment by means of cognitive, behavioral, or any other kind of reorganization. The core of plasticity is thus the potential for and amount of intraindividual change, driven by changing conditions in one's natural ecology or by means of training or experience. Given all the experiences and changing challenges an individual is facing across long-term developmental trajectories, plasticity is an important construct in life-span developmental psychology. Plasticity may appear at various levels (e.g., brain structure, behavior) and can be related to different domains (e.g., cognitive plasticity, behavioral plasticity, personality plasticity).

Introduction

Aging has long been seen as the outflow of a strongly genetically driven program and age-related disease occurrences that may be hard to modify by means of external stimulation and enrichment. Encouraging research on plasticity, particularly cognitive plasticity which has appeared since the 1970s in geropsychology (e.g., Baltes 1973), has contributed much to correcting this rather rigid view of the aging process toward a more dynamic understanding of what remains developmentally possible even late in the human life-span. Life-span developmental psychology also has put strong emphasis on the plasticity of development and aging from its inception (e.g., Baltes et al. 1980). The major argument has been that development is not fixed at any phase of the human life-span and thus always malleable via changing conditions in one's environment or planned interventions. That is, plasticity points to unused or underused reserve capacities of individuals that may be released (or not) depending on respective environmental constellations. In this sense, the concept of plasticity also has important relations to ongoing discussions on successful aging (e.g., Rowe and Kahn 1997; Wahl et al. *in press*), because it points to still unknown potentials of aging that may only unfold under optimal enriching external conditions in the future.

In this work, we concentrate on the now classic area of cognitive plasticity and respective differentiations, such as distinguishing between normal versus pathological cognitive aging.

Cognitive Plasticity

The kind of plasticity that has received most conceptual and empirical attention so far is cognitive plasticity. Cognitive plasticity describes the capacity for changes in the possible range of cognitive performance (Lövdén et al. 2010), i.e., the amount of increase in cognitive performance that is achievable under optimal circumstances by environmental support (e.g., via training). It thus

refers to cognitive “potential” or malleability as opposed to current cognitive performance.

The degree to which cognitive abilities are “plastic” across the life-span has been extensively investigated by previous research. We will first review empirical evidence on lifestyle effects on cognitive plasticity, before summarizing recent findings on training-induced malleability of cognitive performance in old and very old age as well in individuals with cognitive impairment. We will also briefly discuss the potential of physical and combined physical-cognitive interventions regarding late-life cognitive outcomes.

The Role of Mental and Social Activity for Cognitive Plasticity

Cognitive plasticity is not only observable via intervention approaches but may also become manifest through lifestyle factors, (leisure) activities, and environmental “cognitive enrichment” (Hertzog et al. 1999, 2008; Kramer et al. 2004). Activity engagement may even, to some extent, reduce the prospective dementia risk (Hertzog et al. 2008; Karp et al. 2006). Despite some supporting empirical evidence for this “use it or lose it” perspective (e.g., social participation as a protective factor against perceptual speed decline in very old age; Lövdén et al. 2005), opposing findings have also been reported (Mitchell et al. 2012), and underlying mechanisms of the activity-cognition associations are still not well understood (Bielak 2010). Moreover, there is still a lack of studies convincingly demonstrating a lasting attenuating effect of activity engagement on mental aging (Salthouse 2006). Therefore, Hertzog et al. (1999) rather cautiously conclude that “Older adults, like anyone else, should do crossword puzzles and other activities if they find them entertaining and enjoyable. Whether they should consider such activities to be the analog of aerobic exercise for their cortex, and therefore solve puzzles in order to foster maintenance of their cognitive functioning, is still very much a matter of debate” (p. 533). Similarly, Salthouse (2006) recommends that “people should continue to engage in mentally stimulating activities because even if there is not yet evidence

that it has beneficial effects in slowing the rate of age-related decline in cognitive functioning, there is no evidence that it has any harmful effects” (p. 84).

Moreover, even if there is a relationship between activity engagement, cognitive ability, and late-life cognitive decline, activity is probably not a major determinant of cognitive ability, whose stability with age is mostly mediated by genetic factors (Briley et al. 2015), and the potential of activity engagement to prevent or alleviate age-associated cognitive changes may be limited: “To put it crudely, no one expects a cognitively active and engaged lifestyle to make an Einstein out of a used car salesman, nor would one expect one active and one inactive identical twin to show radically different profiles of cognitive ability” (Hertzog et al. 2008, pp. 169–270).

Cognitive Plasticity in Later Life: A Janus Face Situation

As a means to operationalize cognitive plasticity, many cognitive interventions have employed a “Testing the Limits” approach (Baltes and Kliegl 1992; Kliegl et al. 1989), i.e., individuals received training until their maximal performance was achieved and no further training gains were observable. A major and replicated encouraging finding of such cognitive interventions with different age groups is that older adults benefit from these trainings and thus exhibit cognitive plasticity. However, compared to younger adults, training gains in older adults are usually smaller, indicating an age-associated decrease in cognitive plasticity (Baltes and Kliegl 1992; Kliegl et al. 1989; Baltes and Lindenberger 1988; Brehmer et al. 2007, 2008; Verhaeghen et al. 1992) and resulting in an increased posttraining performance difference between younger and older adults as compared to the pretraining, baseline difference. According to P. B. Baltes (1997), such findings indicate the “incomplete architecture of human ontogeny,” characterized by age-related loss in biological (brain) plasticity as well as by a reduced efficiency of cultural input and support (such as educational interventions or trainings) with advancing age. Baltes and Lindenberger (1988) used the term

“Janus-like character [of cognitive aging]” to describe the phenomenon of “continued plasticity accompanied by increasing limits to plasticity” (p. 283).

Given that – according to the conception of the incomplete architecture of human ontogeny (Baltes 1997) – the “need for culture” or for environmental support increases with age, whereas the efficiency of culture and also of intervention decreases, most intervention studies may lack this efficiency by not offering an extensive training exceeding days or weeks. The observation of age-associated decreases in training gains may thus be due to intervention formats that are too superficial in terms of training effort, intensity, and duration. A recent cognitive training program, the COGITO study, has addressed this criticism by investigating and comparing cognitive plasticity in younger and older adults via an impressively extensive intervention with an average of 100 daily practice sessions (Schmiedek et al. 2010a). Despite the finding of medium to strong training gains and reliable positive transfer effects to untrained tasks in both age groups over the 100-days training period, a decrease in cognitive plasticity with advancing age was still found (Schmiedek et al. 2010b; Noack et al. 2013). It thus seems unlikely that still longer or more intensive cognitive training programs will not lead to findings of significantly reduced cognitive plasticity as people age. On the other hand, it has to be acknowledged – and this is certainly good news – that cognitive plasticity is a life-long phenomenon that can be reactivated to a large extent by training and life-style factors (Hertzog et al. 2008).

Such a view is supported further by an ongoing large field trial, according to which cognitive training improvements can be enduring and also affect stability and change in functional ability: Results from the extensive ACTIVE study (Ball et al. 2002; Jobe et al. 2001) suggest that cognitive training has a positive long-term effect on cognitive abilities, with training gains continuing up to 10 years after onset of the intervention, and also attenuates to some extent late-life declines in cognitive and functional abilities (Willis et al. 2006; Rebok et al. 2014).

Cognitive Plasticity in Very Old Age

At the conceptual level, advanced old age (or fourth age) has been described as possibly the most vulnerable phase of the human lifespan, a life period of “dilemmas” characterized by accumulating disease occurrences, functional losses, and nearness to death (Baltes and Smith 2003). According to Baltes (2006), the oldest-old are manifesting “a new level of biocultural incompleteness, vulnerability, and unpredictability in their everyday behavior” (p. 33). In addition, compensatory means at the brain (e.g., efficiency of neurocognitive scaffolding; Park and Reuter-Lorenz 2009) as well as the behavioral level (e.g., use of mnemonic strategies; Singer et al. 2003), although still available, are assumed to be underused and, in addition, low in magnitude and efficiency. Hence, limits in cognitive plasticity become particularly apparent in very old age. Singer et al. (2003) trained participants of the Berlin Aging Study (BASE) aged between 75 and 101 years in a mnemonic skill and found overall modest performance gains. Notably, the authors also observed substantial heterogeneity regarding the amount of training gains, and these interindividual differences in plasticity were significantly predicted by prior 6-year change (decline) in perceptual speed. Moreover, most individuals (85%) were not able to further enhance their memory performance during adaptive practice (i.e., practice sessions that were tailored to each study participant’s prior performance), which implies that there are substantial restrictions in very old adults’ cognitive plasticity.

However, the amount of available cognitive plasticity in very old age may also be a matter of the specific cognitive function that is considered and trained. Sutter et al. (2013), for example, offered a telephone-based verbal fluency training for adults aged between 64 and 92 years and observed an improvement in cognitive performance in the intervention group which exceeded the improvements in an active control group. Similarly, Yang et al. (2006) compared cognitive plasticity in young-old (mean age 74.4 years) and old-old individuals (mean age 84.0 years) by means of a self-guided retest paradigm and

observed that learning occurred across all tests and in all samples, although age-associated reductions in learning were observed as well.

Cognitive Plasticity in Older Adults with Cognitive Impairment

Cognitive plasticity has also been investigated in older adults with cognitive impairment (mild cognitive impairment [MCI] and dementia). It seems that these “cognitively vulnerable” individuals primarily benefit from cognitive interventions regarding their subjective memory beliefs, whereas only minor intervention effects on their objective cognitive performance can be achieved (Rapp et al. 2002). However, there are also some more promising findings suggesting that cognitive plasticity still persists when cognitive impairment sets in (Calero and Navarro 2004), though to a lesser extent compared to cognitively healthy individuals (Schreiber and Schneider 2007), and that cognitive interventions in older adults with MCI can produce training gains (e.g., Brum et al. 2009). However, regarding the efficacy of memory trainings in both cognitively healthy and MCI older adults, Martin and colleagues (2011) conclude based on their review that “there is currently little evidence on the effectiveness and specificity of memory interventions for healthy older adults and individuals with mild cognitive impairment.”

In demented individuals, dual task trainings have been shown to be efficient for decreasing combined cognitive-sensorimotor “dual task costs” (Schwenk et al. 2010). Moreover, cognitive trainings seem to improve certain cognitive functions in patients with Alzheimer’s disease (Sitzer et al. 2006), but effects are rather specific and do not extend to neuropsychological functioning and general dementia severity (Davis et al. 2001).

Notably, cognitive plasticity may also have an important diagnostic function by revealing a prospective validity in terms of predicting later mental status (Baltes and Raykov 1996), thus potentially facilitating early detection and diagnosis of dementia (Baltes and Kühl 1992; Baltes et al. 1995) and of mild cognitive impairment (Sales-Galán et al. 2013). Higher cognitive plasticity (i.e., larger training gains) in individuals

with MCI has indeed been found to be associated with less marked cognitive decline (Calero and Navarro 2004). In addition, Boron et al. (2007) report that reasoning training gains prospectively predict later mental status/dementia status in a sample of older adults. Quantifying an individual's amount of cognitive plasticity may thus be an important avenue for early detection of dementia risk as well as early diagnosis of cognitive impairment in general.

The onset and manifestation of pathological cognitive aging itself, particularly dementia, seems to be a matter of "cognitive reserve," a concept closely related to cognitive plasticity: Findings suggest that the correlation between degree of brain damage (i.e., dementia neuropathology) and its clinical outcome (i.e., cognitive performance) is far from deterministic (e.g., Stern 2009). There are individuals who, despite progressing neuropathology, exhibit fairly "normal" cognitive performance until a certain point in time and who thus are able to "delay" the clinical manifestation of cognitive pathology. These individuals are assumed to be the ones with a higher cognitive reserve. Factors which are discussed as constituent determinants of the cognitive reserve are (early) education as well as lifestyle factors such as dietary habits or workplace complexity (e.g., Richards and Sacker 2003; Whalley et al. 2004).

Physical Interventions and Cognitive Plasticity

Interestingly, increasing empirical evidence suggests that physical interventions, particularly aerobic exercise, are more promising and beneficial than cognitive trainings regarding enhancement of different cognitive functions and positive transfer effects (e.g., Colcombe and Kramer 2003). In their meta-analysis based on 18 intervention studies, Colcombe and Kramer (2003) found that largest cognitive training gains occurred for executive-control processes. Moreover, they observed that training effects were largest for interventions combining strength and aerobic training (rather than offering aerobic training alone), for long-term trainings (continued over 6 months and longer), and for mid-old (66–70 years), rather than for young-old or old-old

training participants. The efficacy of these physical interventions may be due to mechanisms which are more direct and more efficient than the respective mechanisms of cognitive interventions. These mechanisms are neurogenesis and improvement in brain plasticity (Colcombe et al. 2004), increase in brain volume (Colcombe et al. 2006), and reduction in brain tissue loss (Colcombe et al. 2003).

Moreover, the approach of combining both physical and cognitive interventions has been found to be promising regarding cognitive outcomes (Oswald et al. 2002). Physical-cognitive dual task trainings have been found to improve performance in dual task settings, in which limits of and age differences in plasticity usually become particularly evident (Beurskens and Bock 2012; Lindenberger et al. 2000). These dual task training formats indeed seem to be more promising and beneficial for improvement of dual task performance than offering only single task (i.e., physical or cognitive) training (Schwenk et al. 2010; Theill et al. 2013). As pointed out before, even "resource-poor," demented individuals benefit from such interventions (Schwenk et al. 2010).

However, not all studies, reviews, and meta-analyses reported strong effects of physical interventions (e.g., Snowden et al. 2011; Jedrzejewski et al. 2007). More research based on interventions with longer study intervals is needed to evaluate the efficacy of physical interventions as well as to identify the specific underlying mechanisms and the most beneficial activity type, duration, and intensity.

Discussion and Outlook

In this chapter, we addressed the issue of plasticity of aging by focusing on cognitive plasticity. Cognitive abilities seem to be modifiable across the entire adult life span, although cognitive plasticity becomes increasingly limited with advancing age, consequently reaching its minimum in very old age.

Beyond the factors we described through which plasticity manifests itself, namely lifestyle

factors and interventions, the role of society and societal change may need additional consideration. For example, the so-called Flynn Effect, stating that over the twentieth century, each successive generation has exhibited higher IQ scores than the respective previous ones, has found empirical support across multiple cultures and nations (Flynn 1987), although cohort trends may vary according to the time interval and the specific cognitive domain considered (Schaie et al. 2005). It seems that the Flynn effect also applies for old and very old age, with later-born cohorts of old and very old adults showing better cognitive performances than earlier-born cohorts (Christensen et al. 2013; Gerstorf et al. 2011, 2015). In addition, later-born cohorts have been found to reveal less steep age-associated late-life cognitive declines (Gerstorf et al. 2011). However, this phenomenon, which may be termed “cross-cohort cognitive plasticity,” does not hold into the terminal life phase; rather, cognitive declines as a function of distance to death have become steeper across successive cohorts (Gerstorf et al. 2011), also when comparing earlier- and later-deceased cohorts rather than birth cohorts (Hülür et al. 2013). It thus seems that progress in education and in health care has caused improvements in cognitive abilities and attenuated age-associated cognitive declines across cohorts, but mortality-associated biological processes causing terminal cognitive decline may be too powerful to be counteracted by these societal changes.

We acknowledge that our focus on cognitive plasticity is somewhat narrow. For instance, recent empirical work has explicitly addressed the extent of *personality plasticity* across different phases of the life span (e.g., Terracciano et al. 2006; Mühlig-Versen et al. 2012; Allemand et al. [in press](#)). Generally, empirical findings do not support the original “plaster hypothesis” (Costa and McCrae 1994; James 1890) stating that personality remains stable after age 30. Rather, personality plasticity is observable across the whole life span, with ongoing differential personality changes in middle adulthood, old age, as well as very old age (Allemand et al. 2007; Möttus

et al. 2012; Wagner et al. 2015; Billstedt et al. 2014). Moreover, late-life personality has been found to be modifiable via (cognitive, therapeutic, and other) interventions (Mühlig-Versen et al. 2012; Jackson et al. 2012; Chapman et al. 2014) which clearly supports the notion of late-life personality plasticity.

In addition, motor performances seem to reveal some extent of plasticity. For instance, the fact that gait speed of very old adults has improved across successive cohorts (Christensen et al. 2013) and that older adults – even the “resource-poor” ones with dementia – benefit from motor trainings (Hauer et al. 2012) may be seen as evidence for late-life “*motor plasticity*.” Moreover, improvements in functional ability across very-old cohorts (Christensen et al. 2013) as well as declining disability rates across successive cohorts of older adults (Fries et al. 2011) may be regarded as positive evidence for “*health plasticity*.” Plasticity in other areas, such as social and emotional behavior or well-being, may also be considered. However, so far most research on plasticity of aging has indeed been dedicated exclusively to cognitive abilities. Future plasticity research thus needs to broaden its focus beyond aspects of cognition.

Finally, the construct of plasticity also requires critical consideration and additional refinement in the future. Specifically, plasticity has been criticized as a “vague and overused concept” (Lövdén et al. 2010, p. 659) whose specific underlying mechanisms and whose distinctiveness from other concepts are still not well understood. Indeed, cognitive plasticity and cognitive reserve have so far often been treated as synonyms. Similarly, a clear-cut differentiation, both based on conceptual consideration as well as on an empirical basis, between plasticity and related concepts such as learning, resilience, compensation, and adaptation is needed. Therefore, we agree with Lövdén et al. (2010) who point out that “it is necessary, now more than ever, given the different meanings of the plasticity concept in modern science, to operationally define the term and to sharpen its conceptual distinctiveness in relation to the more encompassing notion of change” (p. 660).

Positive Emotion Processing, Theoretical Perspectives

Kimberly M. Livingstone and Derek M. Isaacowitz
 Department of Psychology, Northeastern University, Boston, MA, USA

Synonyms

Positive affective processing; Positive emotional processing

Definition

Age differences in positive emotion processing refer to the differential processing of positive and negative emotional stimuli and experiences among younger and older adults, proposed as one mechanism for explaining emotional well-being in older adulthood.

Introduction

Older adults report surprisingly positive affective experience, with most studies finding older adults reporting equally positive and less negative affect than their younger peers (Isaacowitz and Livingstone 2014). Such findings raise questions about how such a positive age-related trajectory in affective experience can be possible, especially in light of well-documented negative age-related changes

in physical and cognitive functioning. Given the recent focus throughout psychological science on cognitive processes in emotional experience and emotion regulation, much of the theory and research on age differences in affective experience has, not surprisingly, centered on possible cognitive pathways. A number of conceptual and empirical approaches to understanding this age difference in affective experience have considered how emotional material is differentially processed by younger and older adults. For example, prioritization of positive emotional goals (Carstensen et al. 1999), shifts in emotion regulation (Urry and Gross 2010), and cognitive (Labouvie-Vief et al. 2007) and brain (Cacioppo et al. 2011) changes leading to greater positivity have been identified as possible mechanisms underlying older adults' positive affective experience. In this entry, these cognitive pathways to potential affective outcomes are referred to as "positive emotion processing" (Isaacowitz and Blanchard-Fields 2012).

This entry reviews the primary cognitive approaches that have been proposed to explain potential age differences in affective experience. Whether emphasis is placed on shifting motivation, emotion regulation strategies, compensation for declining cognitive complexity, or changes in the aging brain, each places important causal weight on cognitive processes. In light of this, we consider each approach to potentially reflect "positive emotion processing," although some approaches may fit this terminology better than others. Notably, the term "positive" here encompasses stimuli and emotions that are explicitly positive, as well as those that are less negative in comparison to other alternatives (Reed and Carstensen 2012).

Positive Emotion Processing as Motivated Cognition

The most well-established conceptual explanation for why older individuals report such positive affective experience probably comes from socioemotional selectivity theory (SST) (Carstensen et al. 1999), which suggests that in

older age, motivational shifts related to more limited time perspective influence prioritization of current emotional state over other possible goals. Therefore, one reason why older adults may experience maintained or enhanced emotional well-being is that they value this positive experience to a greater extent than younger adults.

Carstensen and colleagues further refined the theory to address possible cognitive mechanisms – "age-related positivity effects" in attention and memory – that may assist older adults in pursuing hedonic goals and achieving the goal of feeling good (Mather and Carstensen 2005). Though the descriptive work on age differences in positivity effects is important, findings on age differences in attention and memory are only one component of any attempt to use cognitive mechanisms to explain age differences in affective experience. Two central but distinct questions regarding age differences in positive emotion processing in emotion are: (1) To what extent do older adults show positivity effects – focusing more on positive and less on negative material? (2) To what extent are these positivity effects an explanation for age differences in affective experience (Isaacowitz and Blanchard-Fields 2012)?

One method that can be used to investigate age differences in positivity in attention is eye tracking. Eye tracking involves presenting stimuli on a computer screen and recording visual fixation to the material presented on the screen in nearly real time. Positivity effects can be assessed by measuring age differences in relative visual fixation toward positive, negative, and neutral stimuli. Several descriptive studies have used eye tracking to assess visual attention to emotional stimuli among younger and older adults. Overall, findings from these studies are consistent with age-related positivity effects in visual attention: Older adults attend relatively more to positive stimuli and relatively less to some types of negative ones (Isaacowitz et al. 2006). These patterns were originally observed with static images, but later studies observed similar patterns using video stimuli (Isaacowitz and Choi 2012). These patterns do not seem to be side effects of more general age-related changes in cognitive or perceptual functioning

(Isaacowitz et al. 2006). This work supports the idea of age-related positivity effects as well as the broader idea that there are age differences in positive emotion processing.

The descriptive pattern of older adults looking more at positive stimuli and less at negative ones is referred to as “positive looking.” After establishing this pattern, the next step was to determine whether age differences in looking relate to emotional experience, as would be expected given SST’s assertions about age-related shifts in prioritizing positive emotional experience. One study found that age differences were most likely to emerge among those in a negative mood state before eye tracking, compared to positive or neutral moods: After a negative mood induction, older adults displayed more positive looking, whereas younger adults looked relatively more at negative material (Isaacowitz et al. 2008). Studies that used positive looking to predict later mood change have found that positive looking appears to help older adults with good attentional abilities avoid negative moods (Isaacowitz et al. 2009; Noh et al. 2011). Positive looking has also been linked with improved mood regulation after upsetting videos among older adults (Isaacowitz and Choi 2012).

Positive Emotion Processing as Emotion Regulation

Cognitive processes factor into other models of aging and emotion. The selection, optimization, and compensation with emotion regulation (SOC-ER) model proposes that older adults compensate for cognitive, physical, and social losses by selecting and optimizing certain emotion regulatory processes, in order to maintain and even enhance positive emotional functioning (Urry and Gross 2010). In the SOC-ER model, in order to successfully regulate their emotions, older adults must select strategies that are likely to work the best for them in light of age-related changes in the availability of key underlying emotion regulation-relevant resources. Although SOC-ER focuses on the stages in the emotional process that an emotion may be regulated, it is relevant here in that it

suggests that strategies vary in effectiveness across the life span. If successful emotion regulation is to be maintained, the use of specific emotion regulation strategies must shift with age.

Empirical research suggests that certain emotion regulation strategies are more advantageous for older adults and that successful implementation of such strategies is likely an important mechanism for maintaining well-being later in life. One intriguing possibility, following SST, is that positive emotion processing in situations that call for emotion regulation allows older adults to maintain high levels of emotional well-being. For example, the positive gaze preferences demonstrated by older adults, described above, can be considered a form of attentional deployment and, specifically, positive attentional deployment (i.e., toward positive and away from negative, as opposed to, e.g., toward negative). As another example, research has shown that older adults are quite successful in implementing positive reappraisal, a cognitive change strategy in which people think about the positive aspects of the situation, whereas younger adults were more successful in implementing detached reappraisal, in which they were asked to remain objective (Shiota and Levenson 2009). A separate study found that older adults were especially effective in using positive reappraisal to regulate sadness (Lohani and Isaacowitz 2014). These findings are particularly interesting, given that reappraisal is considered a cognitively demanding strategy in general and is theorized to be less effective for older adults (Urry and Gross 2010). One possibility is that their advantage in using positive reappraisal reflects greater experience with positive emotion processing, though this has not been tested.

Another way that older adults can successfully regulate their emotions is by using situation selection: proactively selecting the situations to which they are exposed, based on how they predict those situations will make them feel (Urry and Gross 2010; Charles 2010). This process first involves predicting the emotional consequences of a situation. Life experience may provide older adults with knowledge that aids their ability to predict how a situation will influence their emotions (Charles 2010), especially with regard to the

hedonic implications of the situation. Situation selection also involves the explicit decision to enter or avoid a situation. Greater emphasis in older adulthood on pro-hedonic goals proposed by SST may lead older adults to use situation selection to a greater extent than younger adults. To examine this process empirically, an “affective environment” paradigm was created that allows participants to choose negative, positive, or nonemotional stimuli to interact with (“situations” that they could enter into or avoid). One study found that older adults with strong emotion regulation self-efficacy chose to interact with more positive, compared to negative, material (Rovenpor et al. 2013). A subsequent study found that the strategy was equally effective in eliciting more positive affect across all age groups (Isaacowitz et al. 2015). Thus, positive situation selection is consistent with research on attentional processes, in that older adults prefer to process positive elements of their environment over negative ones.

Positive Emotion Processing as a Result of Cognitive Decline

Though SST and emotion regulation theories have guided much research on potential positivity in older adults’ emotional processing, other theories also exist that predict or explain age-related shifts toward positive emotion processing. Dynamic integration theory (DIT) proposes that positive emotion processing reflects compensatory cognition, specifically a shift from more complex emotional processing to simpler, hedonically based emotional processing (Labouvie-Vief et al. 2007). This model describes two emotion regulatory processes: affect optimization, which maximizes positive affect and minimizes negative affect, and affect complexity, which involves emotion regulation for the development of personal and emotional growth, objectivity, and coordination with other emotional states, among other things. The latter mode of emotion regulation may involve delay of positive emotion and/or experience of negative emotions, for the sake of nonhedonic goals. According to DIT, these two

processes interact dynamically throughout the life span, though interaction varies by age. Adaptive emotion regulation consists of a dynamic integration of both processing systems, which, ideally, are flexibly coordinated over time, depending on the circumstances.

The ability to dynamically integrate these two processes changes over the life span, however. A longitudinal study over 6 years in a life span sample found that mean levels of affect optimization increased up to late middle age and leveled off; greatest increases occurred in early to middle adulthood and then showed minimal growth (Labouvie-Vief et al. 2007). In contrast, mean levels of affect complexity were highest in middle age, with declines as people aged. DIT proposes that these declines in affect complexity result from diminishing cognitive resources, resulting in an overreliance on affect optimization. Thus, in contrast to other models, for DIT, older adults’ emphasis on processing positive vs. negative aspects of the environment reflects simplified emotional processing, rather than a goal-driven process of active emotion regulation. One consequence of this is that it can also reflect a compensatory tool to protect against the effects of cognitive decline, used by older adults to maintain positive emotional states in the face of declining cognitive resources.

Positive Emotion Processing as a Result of an Aging Brain

Others have focused on age-related changes in the brain to account for shifts in emotion processing. For example, the aging brain model (Cacioppo et al. 2011) has been offered as another explanation for positive emotional responding (and perhaps also positive emotional states) in older adults. According to this model, age-related reductions in amygdala responses to negative stimuli make older adults less reactive to them, thereby also sparing them negative mood responses to the elicitors. While there is little direct support for this model to date, some indirect support comes from recent evidence that adults with frontotemporal dementia show greater

positive emotion reactivity compared to age-matched peers (Sturm et al. 2015). This indicates a potential role for brain-related changes in promoting positive emotion processing, though evidence from older adults with dementia cannot directly explain age-related patterns in older adults without dementia. While this model awaits future testing, it provides a neural-based explanation for potential age differences in positive emotion processing.

The role of the changing brain in age-related changes in positive emotion processing seems to be a matter of debate. Whereas the aging brain model (Cacioppo et al. 2011) suggests that greater positive emotion processing is a result of changes in the amygdala, others have argued that reduced amygdala activity in older adults during emotion-related tasks reflects unprompted emotion regulation rather than decline in functioning. This cognitive control model argues that rather than simple declines in the aging brain, there are shifts in which emotion regulation strategies are used and how they are deployed (Mather 2012). Specifically, older adults use the cognitive resources they have available to successfully regulate their emotions. For instance, the areas of the brain associated with cognitive control of emotion – specifically the ventromedial prefrontal cortex and the anterior cingulate cortex – show less decline with age than other areas. In addition, older adults show greater recruitment of areas of the prefrontal cortex indicating either heightened processing of positive stimuli or reduced processing of negative stimuli (Mather 2012).

Future Directions

As research on positive emotion processing continues, it will be important to establish the conditions under which these cognitive processes do or do not result in greater affective well-being. Social and financial circumstances and physical health likely provide boundary conditions on the influence of positive emotion processing on emotional well-being. Existing research suggests that individual differences in cognitive abilities seem to

play an important role in the effects of positive emotion processing in attention on experienced affect (Isaacowitz et al. 2009; Noh et al. 2011). Future research should incorporate important candidates for individual and situational factors that may influence the link between positive emotion processing and well-being. Some potential candidates include attentional functioning (Isaacowitz et al. 2009; Noh et al. 2011), executive control, and beliefs about emotion regulation (Rovenpor et al. 2013).

Many studies have investigated age differences in well-being and emotional experience, and the last few years have witnessed a large uptick in research on age differences in cognitive processing of emotional stimuli. There are still many open questions, however, about links between positive emotion processing on one hand and positive emotional experience on the other. Research on positive emotion processing suggests that it may be an important mechanism in helping older adults maintain high levels of well-being in the face of age-related declines in cognition and physical functioning. One important distinction that needs to be made is between use and effectiveness of positive emotion processing: Though older adults may demonstrate positive emotion processing, it is not always effective in eliciting positive emotions (Isaacowitz and Blanchard-Fields 2012). In particular, it seems most strongly linked to more positive affect in individuals with strong cognitive control (e.g., Isaacowitz et al. 2009; Noh et al. 2011) and in cases where individuals are allowed to engage with their environment naturally, rather than being restricted by experimental instructions or distracted by other tasks or information. Yet, many studies examine either use or effectiveness, rather than both. It will therefore be critical for all future studies of positive emotion processing (e.g., in attention and memory, in emotion regulation) to include measures of affective response to determine whether any observed age differences in cognition predict age differences in experience as well. In other words, studies of positive emotion processing preferences should also test effectiveness when possible.

Conclusion

Several theories have proposed cognitive mechanisms by which older adults report maintained or enhanced emotional well-being despite declines in cognitive and physical functioning. Research has demonstrated that older adults demonstrate a greater emphasis on processing positive over negative information, compared to younger adults. Motivation, emotion regulation, cognitive decline, and changes in the brain have been proposed as explanations for these age differences in cognitive processing of emotional stimuli. Future research will further clarify how and when these age differences lead to greater well-being, which in turn will improve our understanding of emotions across the life span.

Synonyms

Bridge employment; Career development over the life span; Late career development; Late career management; Late career planning; Older workers; Post-retirement employment

Definition

Post-retirement career planning refers to the planning process to actively engage in career-related activities after formal retirement entry.

Introduction

From a historical perspective, the nature of retirement has changed in many industrialized countries during the last century. Before 1900, retirement did hardly exist because people worked as long as they were able to work or the formal retirement age was well beyond life expectancy. In the first half of the twentieth century, retirement became a statutory opportunity due to the introduction of social security. Until 1980, male workers were striving toward earlier retirement, while female workers were delaying their retirement. From 1980 to 2000, the decline of men's retirement age continued due to social and economic conditions. From 2000 onward, the situation of retirement is on the move driven by population aging and economic uncertainty (Shultz and Wang 2011). Nowadays, the term retirement refers to a pension-receiving state that in many cases involves the dissociation from the main employment but generally allows further

work engagement. Although retirement has long been seen as a phase of complete disengagement from work, it has been recently reconceptualized as late career development stage based on (more or less) voluntary engagement in career-related activities (Kim and Hall 2013; Wang and Shi 2014; Voelpel et al. 2012). In many industrialized countries, demographic changes and economic conditions have caused a political shift from an agenda of early retirement toward an agenda of extending working lives that lay the foundations for individual post-retirement career planning in the contemporary society.

The entry provides an overview of post-retirement career planning from an individual perspective. After covering career development across the life span, post-retirement careers will be discussed in terms of its social cognitive foundations and in terms of its planning process. In addition, relevant antecedents of post-retirement career planning will be introduced with regard to their proximity to career-related behavior. This will be followed by a discussion of empirical support for post-retirement career planning and an outlook for future directions.

Career Development Across the Life Span

Career refers to the development of vocational interests, decisions, and behavior over the life span. The life-span, life-space theory of careers (in the literature also named as theory of vocational development, career development theory, and developmental self-concept theory; Super 1953, 1990; Super et al. 1996) combines the approach of having multiple roles in life (i.e., life space) with the approach of individual development of career paths (i.e., life span).

Life-Space Approach

The approach of life space of career development refers to the room that people take for their career while living their life. The life space is based on the constellation of different social positions that drive people to occupy multiple

roles in life. For example, a person takes the role of being a spouse, father, grandfather, brother, friend, golfer, and volunteer next to his occupational role. Although the work role is a significant role in contemporary society, it is only one among many others. Further, the multiple roles people occupy interact with each other with regard to the resources (e.g., energy, time, and money) that people have. Referring to the previous example, the person's choice whether to continue working in retirement is based on circumstances related to the constellation of his different social positions. For example, with the birth of his grandchild, he may have fewer resources available for his work role than before. In addition, the allocation of resources between the different roles depends on the meaning that each role provides to people's lives.

Life-Span Approach

Career development involves several transitions from one life stage into another. Figure 1 shows the ladder model of life career stages and development tasks referring to the approach of career development across the life span. Based on the sequence of life stages (i.e., growth, exploration, establishment, maintenance, and disengagement or reengagement), there are different task-related substages relevant in a prototypical pattern of career development.

Growth

The growth stage (approximately from ages 4 to 13) refers to the career development tasks involving curiosity, fantasies, interests, and capacities to answer the question "Who am I?" During this stage children learn to gain control over their own life, make decisions, and increase confidence in their own abilities. At the same time, children experience to get along with other children and adults guiding them to balance cooperative and competitive behavior in order to achieve their aims and keep up relationships to others. Further, time becomes a relevant factor that leads children to develop a future orientation. Overall, the growth stage helps a person to set the foundations for his or her vocational self-concept.

Exploration

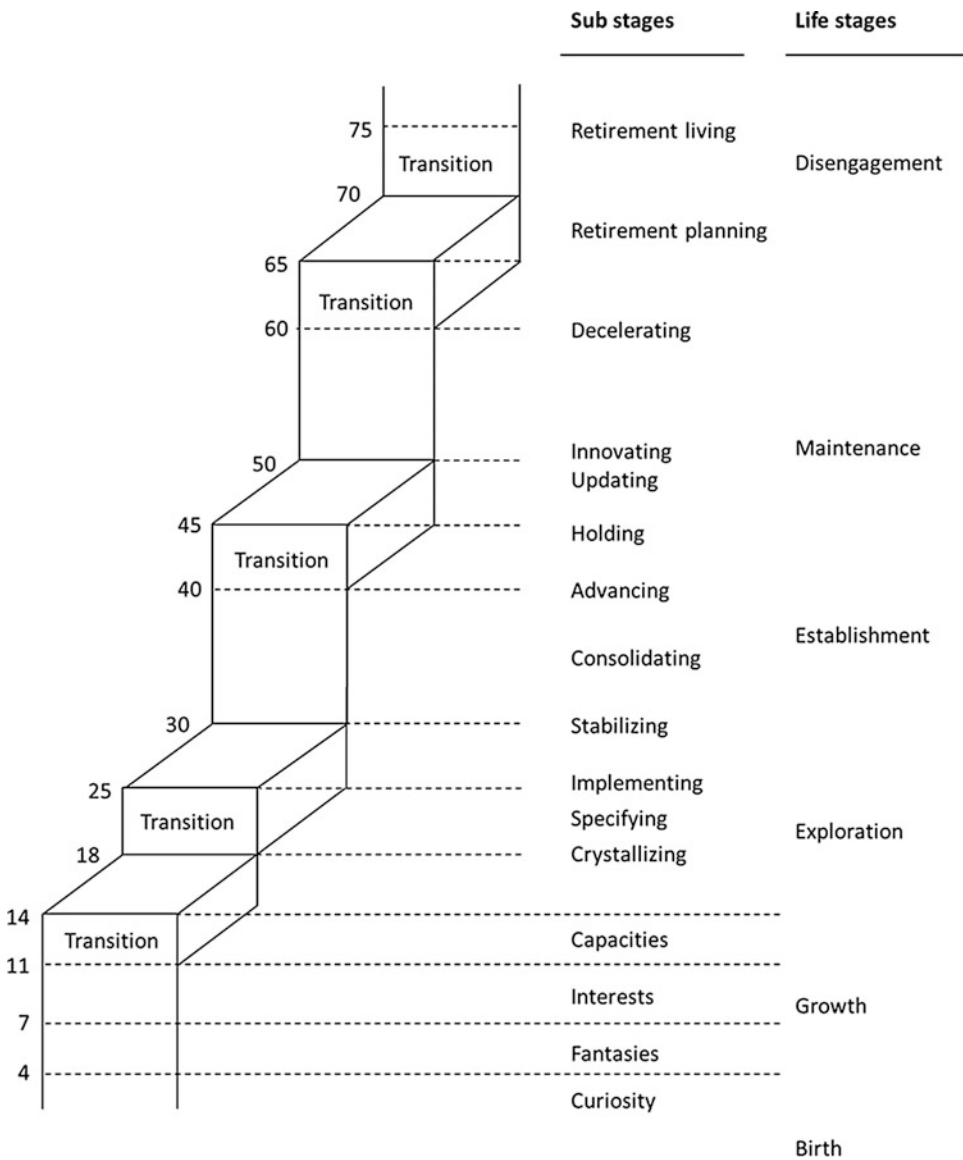

The exploration stage (approximately from ages 14 to 24) refers to the career development tasks crystallizing, specifying, and implementing a vocational choice and preparing work-role entry. In a first instance, exploration involves the imagination of possible selves in varying occupational contexts. This reflection of preferences is followed by the transfer of privately experienced vocational self-construct into educational and occupational choice. Finally, the exploration stage is completed by implementing choice through the means of selecting a training, preparing, and obtaining a specified occupational position.

Establishment

The establishment stage (approximately from ages 25 to 44) refers to the career development tasks stabilizing, consolidating, and advancing the vocational self-concept in order to build a secure work role. Stabilizing implies settling into the new position by assimilating to the work culture and fulfilling central job duties. This again facilitates consolidating the position by demonstrating sustained work, productive work attitudes, and positive coworker relations. At the final point of the establishment stage, people eventually pursue new levels of responsibility in order to move ahead to higher level positions inside or outside their work organization. Successful establishment yields to a consistent integration of the self-concept into the occupational role, which leads, besides earning a living, to higher levels of meaning in life.

Maintenance

The maintenance stage (approximately from ages 45 to 65) refers to the career development tasks holding, updating, and innovating the established position. For the majority of people, the transition from the establishment to the maintenance stage is characterized through the clarification of the satisfaction with the current work role and the critical examination of relevant work goals with regard to the future direction. At this point, people either decide to stay in the current position and therefore enter the maintenance stage or change their vocational orientation and therefore recycle earlier

Postretirement Career Planning, Fig. 1 The ladder model of life career stages and development tasks (Super 1990) (Source: Life stages and substages based on the typical developmental tasks, with focus on the maxicycle. From D.

E. Super (1990). A life-space, life-span approach to career development. In D. Brown (Ed.), *Career choice and development* (2nd ed.; p. 214). San Francisco: Jossey-Bass. Copyright by John Wiley & Sons, Inc. Reprinted with permission)

stages of career development (i.e., the exploration and/or establishment stage). With entering the maintenance stage, people hold on to their secured position and maintain job proficiency and work achievements. Further, this stage involves updating professional skills and knowledge in order to enhance job performance. At the same time, discovering new challenges and innovating

the way of doing tasks help preventing job dissatisfaction and hence decrease the likelihood of mid-career changes or career plateaus.

Disengagement or Reengagement

The disengagement stage (in Super’s model approximately from ages over 65) refers to the career development tasks of deceleration,

preparation, and transition to retirement. During this stage, a majority of people experience lower levels of energy and interest for the work role, which leads to slowing down on the job, reducing work hours, and passing over tasks, skills, and knowledge to the younger work generation (Hartung 2013). Eventually, this leads to a complete separation of self-concept and work, requiring new life structures for people entering retirement. However, the prototypical pattern of career development becomes less meaningful with higher ages because the variety of possible development paths increases. As a consequence, disengagement can become reengagement. As it has been already mentioned in the introduction, retirement can also be a late career development stage, which does not necessarily yield toward a separation of self-concept and work but rather to retaining the work-role identity. As people have often worked for their whole life, their self-concept may be closely tied to their work role, driving them to continue working after formally entering retirement (Feldman 1994; Jex and Grosch 2013).

Post-Retirement Career

Retirement is an enduring process that involves the planning to actively engage in career-related activities that often begins before entering retirement (Wang et al. 2013). There are a variety of factors that determine this planning process and influence retirees' decisions whether to engage in career-related activities or not. With formally entering retirement, people may continue working or volunteering as they have done before, or they create new opportunities for themselves and take up new responsibilities of societal participation and productive engagement. Career-related activities include post-retirement employment (also named bridge employment), which refers to paid work inside or outside the (pre-retirement) career field (Gobeski and Beehr 2009). There are different employment forms, including working for the same employer, for a new employer, or going into business for oneself (Shultz 2003). Also, post-retirement volunteering has been noted to be an important form of productive engagement after

retirement entry. Post-retirement volunteering includes formal activities that benefit civic organizations (e.g., managing a charity institution for cancer research) or informal activities that benefit family and friends (e.g., care of a disabled person). In real-life settings, often a combination of different career-related activity patterns including both post-retirement employment and volunteering can be found.

Social Cognitive Foundations of Post-Retirement Career Behavior

Interaction Between Person, Environment, and Behavior

Over 20 years ago, Lent, Brown, and Hackett (1994) have formulated the social cognitive career theory to explain the process of interest development, decision-making, and performance attainment of career behavior across the life span. The career process model builds on Bandura's (1986) general social cognitive theory that states a triadic reciprocity between person, environment, and behavior. Triadic reciprocity implies the bidirectional influence of three elements, which are the (a) personal factors that consist of internal capabilities, such as cognitive, emotional, and physical resources; (b) the environmental factors, such as external resources and surrounding conditions; and (c) the behavioral factors that consist of actions and decisions (rather than attributes and capabilities) of the person. This three-way mechanism goes beyond previous theoretical approaches that often described behavior as a result of the interaction between personal and environmental factors, $B = f(P \leftrightarrow E)$. However, it is important to note that the actions and decisions people take alter environmental factors and draw back on their affect and thoughts and influence subsequent behavior (Bandura 1986).

Based on the dynamic interplay of person, environment, and behavior, the social cognitive career theory that is crucial for post-retirement career planning emphasizes on self-efficacy, outcome expectations, and personal goals as cognitive person variables that enable the person to act as an agency of self-directed career behavior. These cognitive person determinants involve

different self-reflective and self-regulatory processes that are central for career development after formal retirement entry.

Self-Efficacy

Self-efficacy refers to a person's belief about one's own capabilities to deal with a situation and take action that are appropriate for the accomplishment of self-directed goals (Lent and Brown 2013). Beliefs about one's own self-efficacy determine a person as proactive agent within his or her own motivational orientation (Bandura 1986). The concept of self-efficacy is a dynamic set of beliefs linked to particular career and performance domains rather than being a global or unitary trait as self-esteem (i.e., the overall evaluation of self-worth), as can easily be confused. A person might, for instance, have strong self-efficacy beliefs about his or her ability to interact with different types of people (i.e., social task) but feel less competent at manual or technical tasks (Lent 2013). Further, there are different forms of self-efficacy, *task-specific efficacy* (i.e., the belief about one's capability to fulfill career-related requirements, such as having relevant work experience and knowledge), *coping efficacy* (i.e., the belief about one's ability to cope with career-related obstacles, such as age discrimination at work), and *process efficacy* (i.e., the belief about one's capability to guide the retirement transition, including post-retirement career preparation, retirement entry, role shift, and the adjustment to retirement), that are relevant to post-retirement career planning.

Outcome Expectations

Outcome expectations refer to a person's anticipation of the likely consequences of one's behavior. With regard to post-retirement career planning, these outcome expectations possibly involve the anticipation of *physical* (e.g., additional income), *social* (e.g., intergenerational contact, approval from others), and *self-evaluative* (e.g., self-satisfaction, work-role identity) outcomes that are likely to influence career-related decisions. Taken together, the two mechanisms of self-efficacy and outcome expectations can be transferred into the general questions "can I do this?" and "if I try, what will happen?"

Personal Goals

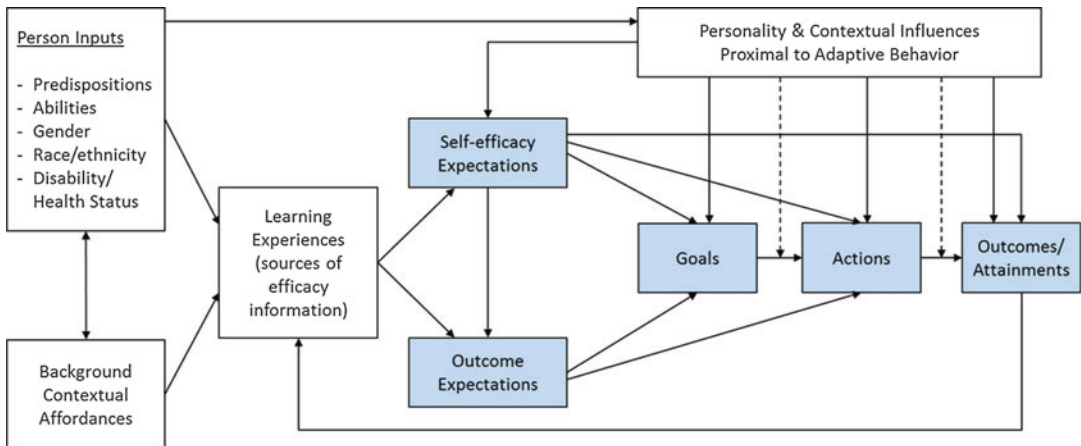

Another relevant instance of self-regulatory behavior that is central to post-retirement career planning is goal setting. People are more than mechanical performers following environmental forces but proactive agents that use personal goals as guiding principles to systematically take a course of action in order to achieve desired outcomes (Bandura 1986). Personal goals refer to one's intention to engage in particular behavior in order to produce a certain outcome (Lent 2013). Goals can be distinguished in *choice goals* (i.e., the type of behavior that one plans to pursue) and *performance goals* (i.e., the quality or level of performance that one wished to achieve related to the chosen type of behavior). Further, goals vary in specificity and proximity to the actual behavior (Lent and Brown 2013). In the context of post-retirement career planning, goals can be further divided into general career goals and specific intentions. While general career goals refer to occupational aspirations that exist independent of commitment or real considerations, specific intentions refer to the concrete willingness to take career-related actions.

Post-Retirement Career Planning Process (or Career Self-Management Process)

The core process of post-retirement career planning describes how self-efficacy, outcome expectations, and goals are related to action and outcome attainment. Figure 2 provides an overview of the entire process of career self-management including the core career planning process in shaded boxes and its proximal and distal antecedents in white boxes.

Note: Direct effects are indicated with solid lines; moderator effects (where a given variable strengthens or weakens the relationship between two other variables) are indicated in dashed lines.

In the core process of career planning, self-efficacy and outcome expectations are the initial antecedents of career-related behavior. As can be seen in the process model, the two factors promote actions directly and indirectly through goals. The way self-efficacy and outcome expectations influence career behavior depends on the certainty of outcome attainment. Under certain conditions

Postretirement Career Planning, Fig. 2 The process of career self-management (Lent and Brown 2013) (Source: Model of career self-management. From R. W. Lent & S. D. Brown (2013). Social cognitive model of career self-management: Toward a unifying view of adaptive career behavior across the life span. *Journal of*

Counseling Psychology, 60, p. 562. Adopted from: Toward a unifying social cognitive theory of career and academic interest, choice, and performance. From R.W. Lent, S. D. Brown, & G. Hackett, 1994, *Journal of Vocational Behavioral*, 45, p. 93. Copyright 1993 by R. W. Lent, S. D. Brown, & G. Hackett. Reprinted with permission)

(i.e., a high level of performance guarantees appointed career outcomes), self-efficacy is the predominant mechanism in determining career-related behavior, and outcome expectations are of lower importance. While under uncertain conditions (i.e., career outcomes are only loosely bound to the level of performance), outcome expectations are of crucial relevance for career behavior. For example, when an employee has worked for over 20 years for a company with a consistently high level of performance, he might be offered to continue working after retirement entry. However, due to company's skepticism regarding the work ability of the employee, the opportunity to continue working is uncertain. This means that the employee's self-efficacy and also his outcome expectations are highly relevant in order to set goals that help attaining outcomes. Therefore, when the employee believes that he or she can convince the company to hire him or her after retirement based on his or her capabilities and work experience (i.e., positive outcome expectations), the employee will (indirectly) be more likely to be hired. However, when the employee believes that the company will not be interested in him or her due to the company's negative views on older workers (i.e., negative

outcome expectations), the person will have lower chances to be actually hired independent from his or her believed capabilities to continue working in retirement.

That goals or intentions determine behavior has been proposed by various theories, such as the theory of planned behavior, social cognitive theory, or goal-setting theory. These theories also emphasize in particular qualities that are important for goals in order to be effective behavioral determinants. Referring to these qualities, goals should be explicit, specific, openly stated, in line with personal values, and proximal to actual behavior (Lent and Brown 2013). Taken together, self-efficacy, outcome expectations, and goals are relevant determinants of career-related actions. Further, goal-directed actions are more likely to promote desired career outcomes. For example, a person who is actively seeking for a job after formal retirement entry will be more likely to obtain a job compared to someone who is communicating his retirement situation neutrally without his career aspirations. In addition, self-efficacy is also directly linked to outcome attainment through its important role of facilitating, organizing, and persisting career-related behavior.

Antecedents of Post-Retirement Career Planning

Antecedents of post-retirement career planning can be distinguished in proximal antecedents that directly influence the core elements of post-retirement career planning (i.e., goals, actions, and outcome attainments), while distal antecedents are seen to indirectly influence post-retirement career planning by the means of learning experience that convey in self-efficacy and outcome expectations (as initial antecedents of post-retirement career planning).

Contextual Factors and Personality as Proximal Antecedents

Contextual factors can serve as proximal antecedents for career-related behavior as can be seen in Fig. 2. Among contextual factors, there are objective features and perceived features of the environment that are likely to facilitate, restrict, or override other factors (e.g., personality) involved in post-retirement career planning. In the eye of the beholder, support, opportunities, and barriers often vary in its importance to career-related behavior, which highlights the active and phenomenological function of people to interpret contextual factors around them (Lent et al. 1994). Environmental support (e.g., financial or social support), the absence of barriers (e.g., good working conditions such as low physical demand and low work stress), and other work-related factors (e.g., career attachment, intrinsic work motivation, or job satisfaction) support post-retirement career planning in a way that they directly influence outcome attainment and indirectly through self-efficacy, personal goals, and career-related actions that again convey in outcome attainment (Lent and Brown 2013).

Further, opportunity structures are seen to be highly relevant contextual factors shaping career-related behavior. Often sufficient socioeconomic and educational conditions allow people to convey their interests into personal career goals. However, interests and career choices are not necessarily linked to each other. As people working in a coal mine do not only work for simple pleasure but to fulfill their financial need, older people may decide for the same financial reason to continue

working in retirement. Some people are in the favorable position to choose their career option based on their special abilities, interests, and skills, while others are in the rather unfavorable position to have to take any job that is available for money. Opportunity structures (not only in terms of financial need) are, therefore, a major issue in determining post-retirement career planning (Lent et al. 1994).

In addition to contextual factors, certain personality dimensions are proximal antecedents for career-related behavior. Personality refers to a relatively stable set of dimensions (i.e., traits) that are seen to constitute people's endogenous basic tendencies of acting, feeling, and thinking (Brown and Hirschi 2013). In particular, conscientiousness (i.e., being responsible and self-disciplined) as one of the Big Five factors of personality may be relevant for career-related behavior, such as planning and persistence (e.g., while searching for a job after formal retirement entry). Also, other personality dimensions may facilitate career-related behavior with regard to networking or interviewing. Agreeableness (i.e., being cooperative and loyal) and extraversion (i.e., being action-oriented and enthusiastic) may facilitate engaging in social interactions, while emotional stability (i.e., being calm, stable, and relatively free from persistent negative feelings) may help coping with ambiguous situations. Further, openness to experience (i.e., being curious and imaginative) may facilitate career-related behavior that involves imagining or deliberating different (unconventional) career choice or problem-solving options (Lent and Brown 2013).

Learning Experience as Mediator of Distal Antecedents

Self-efficacy beliefs and outcome expectations do not operate in a social vacuum but rather function in interaction with other person inputs and their particular environments, such as genetic predispositions, specific abilities or disabilities and physical health, gender, ethnicity (or race), and socioeconomic conditions. At this point, it is important to highlight that these person inputs influence career-related behavior mainly indirectly through learning experience of cultural

socialization that again transfers to self-efficacy and outcome expectations. In this regard, learning experience refers to four types of information, which are personal achievements, observational learning and modeling, social encouragement and influence, and physiological and affective states.

To clarify the role of learning experience, gender, as one aspect of the person, may help to illustrate the psychological and social effects that arise with regard to career-related behavior. Gender affects career development at multiple stages, especially through the social-cultural reactions it evokes from the environment during the growth and exploration stage but also during later stages. For instance, gender can influence the context children acquire the foundations for their self-efficacy and outcome expectations due to role socialization processes. Early gender role socialization is likely to bias the access to certain experiences that are necessary in order to gain strong self-efficacy beliefs and positive outcome expectations in areas seen as rather typical for male (e.g., science) or typical for female (e.g., care). However, after the initial career choice is made, people are able to change or revise their career paths as they operate as proactive agents in a dynamic environment (Lent 2013).

With regard to post-retirement career planning, learning experiences that are made in earlier stages but also during the current stage of career development are crucial for the decision whether one continues to work after formally entering retirement. As can be seen in Fig. 2, previous outcome attainments are relevant to stabilize (or revise) the self-efficacy and outcome expectations by forming a feedback loop through the means of learning experience. In addition, the role of person inputs is persistent within the current stage of career development (i.e., disengagement or reengagement) as older people face certain age-related role socialization processes. From the environment, for instance, physical deprivation and declining work ability are perceived as a general law of aging that leaves no room for individual escape. This overall rather negative image of aging might lower opportunities to gain access to certain experiences that are necessary in

order to gain strong self-efficacy beliefs and positive outcome expectations in order to continue working in retirement.

To a large extent, person inputs like abilities or disabilities and physical health, gender, and socio-economic conditions affect the different aspects of career development (i.e., interest development, goal establishment, and activity planning) through processing a socially constructed reality that apparently operates in the background but yet powerfully influences self-efficacy and outcome expectations by the means of learning experience. At times, this leads to skewed conclusions about certain interests, goals, and career choices to be “right” for different types of people (Lent 2013).

Empirical Support

For over 60 years of research, the life-span, life-space theory has attracted much attention from researchers. As a result, there is a wealth of empirical support highlighting the two approaches of life span and life space for career development. However, although there is an impervious layer of research on career development among young adults and adolescents, it has been criticized that there is too little attention for mid- and late career development (Hartung 2013). Especially with regard to post-retirement career planning, a more thoughtful and fine-grained investigation of the disengagement or reengagement stage seems appropriate to further understand and compass the needs of a worldwide aging population.

Also, the social cognitive career theory has gained much attention in career literature related to various work domains (e.g., leadership, job search behavior) as well as to different career development stages from young professionals to mid- and late careers. A substantial body of research indicates the relevance of social cognitive variables (i.e., self-efficacy, outcome expectations, and personal goals) for career planning and development (Lent 2013). In particular, self-efficacy has been found to predict career-related interest, choice, and outcome attainment to a substantial extent (Lent 2013). Meta-analysis (i.e., a statistical technique that systematically

combines the research findings of published and unpublished primary studies) revealed that self-efficacy and outcome expectations are directly as well as indirectly (through interests, goals, and action) related to outcome attainment (Brown et al. 2011; Lent 2013; Sheu et al. 2010). Further, it has been found that contextual factors such as environmental support and barriers are relevant antecedents of career development. Although the direct effects of contextual factors on outcome attainment are relatively small, they persist to be central in strengthening or weakening the relationship between self-efficacy and outcome expectations with career outcomes (Lent 2013; Sheu et al. 2010). In addition, contemporary empirical approaches (e.g., Wöhrmann et al. 2014) have applied the social cognitive career theory firsthand to late career development, empathizing on the role of social cognitive variables for post-retirement career planning.

Future Directions

This entry provided an insight to the key elements of post-retirement career planning from an individual perspective. The role of career development over the life span has been addressed with particular focus on the stage of disengagement or reengagement. Further, the process of post-retirement career planning was presented including its core elements and relevant proximal as well as distal antecedents. Special attention was provided to the social cognitive variables (i.e., self-efficacy and outcome expectations) that promote people as proactive agents of post-retirement career planning along their own motivational orientation.

With regard to future directions of post-retirement career planning, two major issues should be addressed here. First, it is relevant to emphasize on the necessity for more research on the later stages of career development. As mentioned before, there has been too little research attention to mid- and late career development. Considering population aging, it is of high relevance to consider the special challenges of late career development. Also, it could be stated that

the ladder model of life career stages and development tasks (as presented in Fig. 1) needs to be adjusted with regard to the changing nature of work, aging, and retirement. A contemporary model for career development should allow back and forth jumping between different stages and also enable returning from later to earlier stages of career development. Taken together, a more fine-grained investigation of the later career development stages seems to be crucial for further understanding of post-retirement career planning.

Second, another major issue to be addressed here is the consideration of the diverse nature of work regarding the significant role of choice. The favorable position to choose a career option based on special abilities, interests, and skills may lead people to perceive work as gain, while an absence of choice due to economic pressure may lead people to perceive work as pain. Promoting active aging that encourages older people to be productive for the sake of themselves, their families and communities, and the society as a whole relies on a concept of work that is based on voluntary decisions to engage in post-retirement career activities. However, economic pressure may lead older workers to engage in precarious work that may help to prevent poverty but not necessarily guarantee further individual benefits such as health and well-being. Future research should, therefore, investigate different types of work, in particular, the role of manual labor in post-retirement career planning.

Definition

PPA is a clinical syndrome characterized by an isolated and progressive language deficit due to gradual neurodegeneration of the left and frontal lobes in critical points of the language network, causing disruption of syntactic, semantic and phonological processing. PPA can have different clinical presentations and in 2011, an international group of PPA investigators recognized the need for

establishing a common framework for PPA identification. This research group agreed on terminology and on clinical, imaging-supported and definite pathology criteria for the diagnosis of three distinct variants: non-fluent/agrammatic (PPAANF), semantic (PPAS) and logopenic (PPAL).

Introduction

Language disturbances may impact functionality, participation in leisure and social activities, and consequently, quality of life of elderly individuals. Some language changes are expected in the normal aging process but need to be distinguished from progressive aphasia syndromes that will require particular interventions.

Aphasia is a language disorder resultant from brain injury usually in the left hemisphere and that may have abrupt or insidious onset. The several aphasic syndromes are characterized by different degrees of impairment in comprehension or production of oral and written language due to disruption of one or more levels of language processing (i.e., phonological, syntactic, semantic). Aphasia in the elderly is often sequelae of cerebral vascular accidents. However, aphasic symptoms may also appear in isolation and insidiously as consequence of neurodegenerative diseases. The initial and very subtle language changes may go unnoticed or be confounded with those expected in normal aging.

In this entry, we are going to present the most common presentations of primary progressive aphasia (PPA), a clinical syndrome in which neurodegeneration of the frontal and temporal cortices gradually impairs language use and affects daily activities. First we are going to define PPA and present a brief historical background on the characterization and terminology used over the last decades. Then, we are going to introduce the most important clinical features of three common variants of PPA, according to current international consensus (Gorno-Tempini et al. 2011) along with their main neuroimaging and pathology correlates. Finally, we are going to address clinical management, focusing on behavioral interventions for those patients.

Primary Progressive Aphasia: Historical Background and General Characteristics

PPA is a clinical syndrome characterized by an isolated and progressive language deficit due to gradual neurodegeneration of the left and frontal lobes in critical points of the language network, causing disruption of syntactic, semantic, and phonological processing. Clinical and research interest for PPA has been growing fast, and three of its variants have been well specified in terms of clinical manifestations and neuroanatomical correlates. Advances have also been made in predicting the underlying pathology in those three subtypes and establishing associations between clinical phenotypes and genetic mutations, although findings in this area are still not entirely consistent (Harciarek and Kertesz 2011; Rascovsky and Grossman 2013).

Two of its most common variants, progressive nonfluent aphasia (PNFA) and semantic dementia (SD), have been included in the complex of brain neurodegenerative diseases referred to as frontotemporal dementia (FTD) or frontotemporal lobar degeneration (FTLD) (Harciarek and Kertesz 2011; Neary et al. 1998), the second most common form of young-onset dementia after Alzheimer's disease. The most frequent FTLD syndrome is the behavioral variant of FTD (FTDbv), characterized by marked personality and behavioral disturbances. But PPA is not uncommon in FTLD, accounting for about 40% of the cases. The third most common PPA variant, logopenic progressive aphasia, has been reported more recently (Gorno-Tempini et al. 2004) and is linked to Alzheimer's disease pathology.

There is great heterogeneity in clinical presentations, medium survival, and age of onset (Harciarek and Kertesz 2011), even when considering a particular PPA variant. In addition, recent studies have suggested that distinct forms of PPA are associated with different susceptibility factors (Miller et al. 2013).

Although PPA is usually an early-onset dementia, with symptoms starting before the age of 65, in some individuals, manifestations start in more advanced ages, reaching the late 70s (Hodges et al. 2010). Early identification of PPA

may be more challenging among those individuals since tip-of-the-tongue experiences increase significantly with aging and may obscure the perception of a more marked lexical deficit, usually the first sign of PPA.

A landmark in the study of PPA was the publication of Mesulam et al. in 1982, with the description of six patients presenting with slowly progressive deterioration of language without generalized dementia associated to atrophy in perisylvian regions of the left hemispheric cortex. In 1992, Mesulam and Weintraub (1992) proposed that a diagnosis of PPA should be made when language impairment due to neurodegenerative disease is the only factor to affect everyday activities at least in the first 2 years after symptom onset. Language deficits remain as single cognitive manifestations for variable periods over the course of the disease (in some cases as long as 14 years) (Mesulam 2001). This cognitive profile is different from other dementia syndromes that begin with prominent amnesic, behavioral, or visuospatial symptoms (i.e., AD, FTDBv, and posterior cortical atrophy, respectively).

In the 1980s and 1990s, another related syndrome received a great deal of research: semantic dementia. Snowden et al. (1989) suggested this name to refer to patients presenting with a progressive loss of conceptual knowledge (semantic memory) contrasting with relatively preservation of memory for events (episodic memory). Diagnostic criteria for SD were proposed by Hodges and colleagues (1992) that in the following years detailed clinical, neuroimaging, and neuropathological characteristics of those patients (Hodges and Patterson 2007).

First symptoms of SD include difficulties to process word meanings, object and people knowledge (a deficit affecting both verbal and nonverbal semantic memory), and surface dyslexia (difficulty in reading words with irregular or exception spelling).

In the 1990s, numerous PPA cases were reported, and a large variation of language profiles was evidenced. Although word-finding and naming deficits are common among patients in the early stages of PPA, in the longitudinal course of the disease phonological, semantic and syntactic

deficits in oral and written language differ considerably among patients. These observations motivated the use of fluency (rate of speech and number of words per minute in spontaneous conversation) to characterize PPA subtypes into fluent or nonfluent (Mesulam 2003). Fluent PPA patients encompassed some features of SD, and there were a lot of discussions as to whether those two clinical pictures should be considered the same or not (Hodges and Patterson 2007; Mesulam 2003).

In summary, at that point, PPA patients were either classified as SD versus PNFA in accordance with Neary et al. consensus (Neary et al. 1998) or as fluent or nonfluent as stated by Mesulam (2003). The term temporal variant of FTD has also been employed in the literature as a synonym for SD.

That binary classification was not suitable for a proportion of PPA patients (Harciarek and Kertesz 2011), and in 2004, a third variant was described, logopenic progressive aphasia (Gorno-Tempini et al. 2004).

In 2011, an international group of PPA investigators recognized the need for establishing a common framework for PPA identification and agreed on terminology and on clinical, imaging-supported and definite pathology criteria for the diagnosis of three distinct variants: nonfluent/agrammatic (PPAANF), semantic (PPAS), and logopenic (PPAL) (Gorno-Tempini et al. 2011). This step was necessary to make multicenter studies more feasible and to potentiate advances in the understanding of cognitive, neuroanatomic, and molecular bases of PPA.

The PPA criteria in current use have proven very helpful to reach those scientific and clinical goals despite the fact that a considerable amount of patients present language profiles that differ from those proposed for the three most common variants. In addition, as mentioned before, there is great heterogeneity among patients of each variant, and the criteria may be difficult to apply in a purely quantitative basis (Wicklund et al. 2004), requiring a certain degree of expertise in qualitative analyses of speech production. Another important factor is that criteria are more appropriate to characterize the relatively early stages of the diseases. On their longitudinal courses, clinical

pictures tend to mix due to spread of neurodegenerative processes to other points of the language network. Furthermore, other cognitive, behavioral, and/or motor deficits may also appear.

Before being classified into a specific variant, patients shall meet PPA criteria (Gorno-Tempini et al. 2011; Mesulam 2001, 2003), and for that, three conditions must be fulfilled: most prominent clinical feature should be difficulty with language, language difficulties are the main cause of impairment in everyday activities, and aphasia should be the most prominent deficit at symptom onset and for the initial phases of the disease. In addition, the pattern of deficits should not be better accounted for by other neurodegenerative nervous system or psychiatric disorder, and patients should not present initially with prominent behavioral disturbance or other cognitive impairments in episodic memory, visual memory, and visuo-perceptual skills.

Deficits in other cognitive functions may be evidenced in neuropsychological assessment, especially in cognitive functions that share neuro-anatomical correlates with the language network (i.e., verbal immediate memory, calculation and numeracy skills, ideomotor praxis), but those must be milder in comparison with the language deficit. Regarding this aspect, it is important to emphasize that many cognitive tests are language mediated and affected by aphasia. For instance, it is expected that lexical retrieval difficulties will impact performance in episodic memory tasks that demand immediate and delayed word recall, and for that reason, visual episodic memory tasks should be preferred to investigate this cognitive domain in this population.

The presence of limb apraxia and of problems with coordination of fine hand movements does not exclude a PPA diagnosis. On the other hand, tremor and rigidity found in parkinsonian syndromes should not be present in the initial phases of the disease.

PPA staging criteria that account for language use have been developed (Sapolsky et al. 2014), but the degree of impact in everyday activities will vary, depending on the premorbid occupational and social activities of each patient. Many of them maintain an independent status and continue

working and driving for long periods after onset of language symptoms. This is possible due to relative preservation of time and space orientation, episodic memory, and executive functions.

In the following sections, we will introduce the main clinical, neuroimaging, and pathology symptoms of each of the three most common PPA variants: nonfluent/agrammatic (PPAANF), semantic (PPAS), and logopenic (PPAL). PPAS is marked by a profound semantic deterioration; PPAANF is characterized by a progressive breakdown of syntactic processing and/or planning of motor speech (speech apraxia), and PPAL affects phonological processing and verbal auditory short-term memory. Controversies and open questions for each variant will also be addressed.

Characteristics of the Most Common PPA Variants

Nonfluent/Agrammatic Variant of PPA (PPAANF)

In PPAANF, there is a gradual deterioration of the syntactic level of language, which is usually but not always accompanied by speech motor deficits. Those patients are nonfluent, that is, present reduced verbal output and effortful, slow, and hesitant speech.

In order to fulfill clinical diagnostic criteria, at least one of the two core characteristics must be present in language production: agrammatism (impairment in the production of grammatically correct sentences) and apraxia of speech (a disturbance in articulatory planning). Also, two out of three of the following features must be found: impaired comprehension of syntactically complex sentences, spared single-word comprehension, and spared object knowledge.

Agrammatism is a disorder involving syntactic and morphological levels of language, evidenced by three main features: omission or substitution of morphology, reduced variety of grammatical forms in sentence production, and slow rate of speech, even in patients without articulatory problems (Kolk 1998).

In PPAANF, morphology changes are characterized by gradual omission of verbs, function

words (i.e., prepositions, pronouns, conjunctions), and grammatical inflections. Frank grammatical errors may also be present (Gorno-Tempini et al. 2011; Ash et al. 2010). Sentence production is characterized by reduced frequency of grammatically complex structures (Ash et al. 2010), and oral and written discourse analyses evidence a higher number of declarative sentences with canonical word order.

Regarding rate of speech, PPAANF patients present less than one third the rate of elderly healthy individuals. The nature of this deficit has been debated, but a strong view is that effortful and nonfluent speech in this syndrome is more likely to be linked to grammatical processing deficits than to speech difficulties attributable to apraxia of speech (Rascovsky and Grossman 2013).

For the purpose of early clinical diagnosis, it is important to call attention to the insidious nature of PPA. Unlike vascular aphasia, the full clinical picture in all PPA syndromes may take some time to evolve. In very mild PPAANF patients, detecting agrammatism in spontaneous conversation may require careful qualitative analyses of recorded samples of oral output. The initial few grammatical errors may be more evident in tests of written production (Gorno-Tempini et al. 2011). As disease progresses, sentences tend to become simpler and shorter, and patients present with telegraphic speech.

Apraxia of speech is characterized by inconsistent speech sound errors (omissions, distortions, transpositions, insertions) due to a deficit in articulatory planning. Patients and close relatives may notice those speech difficulties and may refer to them as “stuttering.” Patients try to correct themselves, and hesitations and reformulations are common. There have been reports of patients who present progressive speech apraxia without aphasia symptoms and debates to whether those cases should be classified in the PPA spectrum (Josephs et al. 2014). However, although predominant apraxia of speech may occur in the initial phase, most cases present aphasia in the evolution. In addition, detailed analyses of speech revealed that PPAANF speech errors consist mostly of substitutions typical of phonological disorders

(language related) rather than sound distortions typical of apraxia of speech (Rascovsky and Grossman 2013; Ash et al. 2009).

Prosodic features of speech (intonation, stress, and duration of speech sounds and rhythm) are impaired in PPAANF (Ash et al. 2009, 2010), and this feature may be useful for distinguishing this PPA variant from PPAL (Henry and Gorno-Tempini 2010).

Comprehension of words, concepts, and simple sentences is spared in PPAANF. However, patients may encounter difficulties to process syntactically more complex sentences such as reversible passive constructions (“The dog was chased by the cat”). Sentence comprehension is more affected by grammatical complexity than by utterance length, what lends support to the syntactic nature of the deficits.

There is a considerable overlap between PPAANF and atypical parkinsonian syndromes. After some years of isolated language deficits, many PPAANF patients evolve with motor symptoms compatible with a diagnosis of corticobasal syndrome (CBS) and progressive supranuclear palsy (PSP) (Gorno-Tempini et al. 2011; Harciarek and Kertesz 2011).

Regarding neuroimaging findings, PPAANF clinical profile is associated to predominant left posterior fronto-insular atrophy on MRI or predominant left posterior fronto-insular hypoperfusion or hypometabolism on SPECT or PET (Gorno-Tempini et al. 2011). Tauopathies are the most common underlying cause of PPAANF but around a third of the cases present with AD pathology, and another small proportion of patients were reported to have ubiquitin-positive inclusions (Harciarek and Kertesz 2011; Rascovsky and Grossman 2013).

The Semantic Variant of PPA

This variant has the most homogeneous clinical profile and is characterized by gradual deterioration of word and object meaning (semantic knowledge) with preservation of phonology and syntactic skills. This clinical picture contrasts with the early stages of probable Alzheimer’s disease characterized by a marked deficit in episodic memory and milder semantic deficits.

Impaired confrontation naming and single-word comprehension are the core features for clinical diagnosis along with three out of four of the following ones: impaired object knowledge, surface dyslexia or dysgraphia, spared repetition, and spared speech production (phonology, grammar, and motor speech) (Gorno-Tempini et al. 2011).

In spontaneous conversation, patients present fluent speech without phonological and morphosyntactic errors and anomia, evidenced by circumlocutory speech, semantic paraphasias, and use of generic or empty terms such as “everything” and “things.” Questioning the meaning of words (e.g., “what is giraffe?”) is a behavior not seen in the other PPA variants and that evidence the type of comprehension difficulty found in those patients (Kertesz et al. 2010). However, deficits may not always be clear in spontaneous conversation because patients benefit from contextual information to infer meanings.

PPAS patients are aware of symptoms in the early stages of the disease and mention difficulties in “remembering words” or sometimes “places” (actually in relating places’ names to their locations). In addition, some patients may have problems with face recognition (prosopagnosia) in early stages.

In naming tests, performance is dramatically impaired, and this contrasts with relatively good preservation of conversation skills. Different from other forms of PPA and from normal aging, PPAS patients refer they don’t know what is depicted on the pictures they are asked to name. Moreover, they rarely benefit from phonetic cues. When semantic knowledge is preserved (as in normal aging and in other PPA variants), giving the first syllable or phoneme of a word frequently helps individuals to retrieve a particular lexical item, whereas this is not significantly helpful to improve picture-naming performance of individuals with PPAS.

Retrieval of particular items in a given time (verbal fluency tests) is also markedly impaired. Some studies report patients find it harder to retrieve items from a semantic category (e.g., animals) compared to letters, but performance is

usually impaired in both tasks (Hodges and Patterson 2007; Carthery-Goulart et al. 2012).

In formal assessments of language comprehension, PPAS patients present worse performance for words than for sentences. This is an important feature to distinguish this variant from the other subtypes, but may not be evident in mild patients, unless sensitive neuropsychological tests are used. Verbal and nonverbal semantic association tests such as the Pyramids and Palm Trees test are frequently employed and show marked impairment. Auditory comprehension tests with several foils from the same semantic category are also recommended (e.g., asking patients to point “apple” in a set of eight fruits, as in the battery proposed by Hodges and colleagues) (Adlam et al. 2010).

On the other hand, PPAS performance is usually spared in sentence comprehension formal assessments. These tasks are designed to detect morphosyntactic problems and generally comprise simple and frequent lexical items. PPAS patients are able to use contextual cues and syntactic and problem-solving skills to choose the correct alternative.

PPAS patients generally present associative visual agnosia, that is, difficulties to recognize and assign meanings to objects, despite preservation of perceptual skills. In mild patients, difficulties are evidenced for low-frequency or low-familiarity items, becoming more severe as disease progresses.

Surface dyslexia and dysgraphia are common in PPAS. Oral reading and spelling are marked by regularization errors, that is, those patients tend to use rules for translating graphemes in phonemes and vice versa even in words with irregular or exception spelling.

Executive functioning and working memory are typically preserved, and these patients do not usually have problems to repeat verbatim long utterances and to solve nonverbal problems. Visuoperceptive skills and constructional praxis are also generally spared along with numerosity knowledge, calculations, and music knowledge (Rascovsky and Grossman 2013). The preservation of meaning in those categories, along with the reversal of the concreteness effect (abstract words

better understood than concrete ones) (Bonner et al. 2009), has been used to support the view that SD is not a universal semantic deficit but instead a problem of integrating visual features in the visual association cortex (Rascovsky and Grossman 2013).

However, the most accepted view is that the disease causes a breakdown in conceptual knowledge (Hodges and Patterson 2007), and the anterior temporal lobe is a “hub” for semantic processing. Supporting this view, patients have consistent errors across tasks using several input modalities. Thus, when a patient is not able to define “apple,” he will probably have difficulties with this same item in confrontation naming, in classification tasks, and in verbal and nonverbal semantic association tests.

The pattern of deficits in PPAS is not “all or nothing.” Semantic degradation is gradual and some semantic features may be initially retained. In the previous example, the patient may be able to define “apple” as “something we eat,” despite not being able to say it is a fruit and closest in meaning to “orange,” instead of “carrot.” In moderate to severe stages of the disease, conceptual information related to this item is gradually lost.

In the longitudinal course of the disease, PPAS patients develop behavioral and personality changes, predominantly eating disorders, aberrant motor behavior, and disinhibition (Rosen et al. 2006). Some of them evolve with motor neuron disease (Harciarek and Kertesz 2011; Hodges and Patterson 2007).

In MRI, PPAS patients present with bilateral anterior temporal lobe atrophy, usually greater in the left hemisphere. Prosopagnosia is usually associated to involvement of the right anterior temporal lobe (Snowden et al. 2004). SPECT or PET demonstrates predominant anterior temporal hypoperfusion or hypometabolism (Gorno-Tempini et al. 2011; Neary et al. 1998; Hodges et al. 1992). With regard to the underlying disease, 70% of the patients present tau-negative ubiquitin-positive pathology with TDP-43, 20% tau-positive Pick’s disease, and 10% AD pathology (Rascovsky and Grossman 2013; Hodges et al. 2010).

PPA Logopenic Variant

This variant is characterized by a progressive deterioration of phonological lexical entries and of auditory verbal short-term memory, specifically the phonological loop component of the working memory model proposed by Baddeley and Hitch (1974).

The phonological loop is the cognitive mechanism that allows the temporary storage of verbal material for repetition and language comprehension and that also plays a crucial role in vocabulary acquisition during early language development. In cognitively healthy individuals, the phonological loop is susceptible to two types of interference: word length and phonological similarity, what means that in tasks of immediate recall of verbal materials (usually words and letter strings), a lower number of items is retained the longer and the more similar in sound those items are. The absence of one or both of those effects suggests a dysfunction of the phonological loop, and this is exactly what has been recently demonstrated for PPAL patients (Gorno-Tempini et al. 2008).

The core features of clinical PPAL are impaired single-word retrieval in spontaneous speech and naming and impaired repetition of sentences and phrases. Also, at least three out of the following four features must be present: phonological errors in spontaneous speech and naming, spared single-word comprehension and object knowledge, spared motor speech, and absence of frank agrammatism.

Although controversies persist regarding to whether PPAL should be considered a discrete variant (Sajjadi et al. 2012), PPAL clinical picture has been proven consistent in terms of unique language features and neuroimaging patterns. It is a rather common profile in some research groups, found in almost one third of PPA patients (Henry and Gorno-Tempini 2010). But classifying patients into this PPA subtype can be challenging since in some domains those individuals present with intermediate deficits compared to the other two PPA variants.

The term “logopenic” from Greek, meaning “lack of words” was used to define the verbal output features of those patients (Gorno-Tempini

et al. 2004, 2008). In spontaneous conversation, after an initial stage of mild anomia and word-finding difficulties, fluency becomes gradually reduced. But differently from PPAANF patients, PPAL verbal output comprises grammatically accurate utterances and no effort or dysprosodic features. Phonological paraphasias, when present, are well articulated and no phoneme distortions are observed. Those errors reflect failures in linguistic mechanisms (retrieval of incomplete phonological word forms from the lexicon) and/or working memory-related deficits (failure to maintain the phonological word form, while articulation motor programs are being planned and executed).

Slow rate speech and frequent long pauses due to word-finding problems are typical. Differently from PPAS, concept knowledge and word meaning are preserved. As disease progresses, however, deficits in semantic memory may be also present, but they are much milder from those seen in PPAS (Etcheverry et al. 2012).

In formal tests, PPAL patients evidence naming difficulties, but they are not as severe as in PPAS patients and consist of lexical retrieval problems (patients are generally able to provide definitions for the items and benefit from phonetic cues). Phonological paraphasias usually occur. Word comprehension and word repetition are generally spared.

Sentence comprehension and verbatim sentence repetition are impaired, and those failures are more related to the length of the utterances rather than to their grammatical complexity. In fact, for many patients, sentence comprehension is improved when items are written instead of spoken to them. In sentence repetition, patients demonstrate they have understood what was said, providing semantically appropriate versions of the original sentences but failing to repeat them verbatim (Henry and Gorno-Tempini 2010).

Phonological dyslexia has been reported in PPAL. This reading deficit is characterized by phonological errors and difficulties to read pseudowords due to disruption of grapho-phonemic conversion mechanisms, contrasting with the pattern presented by PPAS patients (Brambati et al. 2009).

Magnetic resonance imaging in PPAL predominantly show atrophy in the left posterior temporoparietal regions, and SPECT or PET shows predominant left posterior perisylvian or parietal hypoperfusion or hypometabolism. AD is the most common underlying pathology (Gorno-Tempini et al. 2011; Henry and Gorno-Tempini 2010).

Some risk factors have been associated to PPAL. Whereas learning disability is a common finding among PPA patients and their first-degree relatives, a recent study has demonstrated that a history of developmental dyslexia is more common among PPAL (Miller et al. 2013). In this group of patients, PPA symptoms may start earlier, and atrophy occurs in more defined regions in the posterior temporal regions.

Treatment for PPA

The extensive progress in PPA diagnosis has led to a large number of patients in demand of treatment alternatives. In the absence of clearly effective pharmacological options, there has been an increasing interest in behavioral interventions, and literature on this topic has noticeably grown over the past 10 years (Croot et al. 2009; Carthery-Goulart et al. 2013).

Although highly controlled, randomized studies are still not available, a number of scientific reports of well-designed single-case investigations have revealed positive outcomes. Extensive generalization of the findings is not possible, but the consistent results of some types of interventions across studies increase their recommendation levels.

As PPA is a progressive disorder, not only therapies that achieve improvement of cognitive function but also those that demonstrate benefits at slowing the progression of deficits can be considered good treatment alternatives.

Interventions for speech and language deficits in PPA can be classified into two approaches: functional and impairment directed. Functional interventions focus on improvement of communicative skills and increasing/maintaining participation levels and are characterized by a more

ecological approach to deficits. Strategies include the implementation of environmental modifications and the use of several resources such as augmentative and alternative communication devices. The strong point of these proposals is that they focus on the patients' needs and try to establish a direct link between therapy practices and performance in daily routine tasks. Their weakness is the difficulty to achieve necessary experimental control to measure treatment effects.

Impairment-directed interventions, on the other hand, target specific speech and language deficits such as anomia, dysgraphia, or apraxia of speech and allow for a more controlled experimental setting. The need of detailed assessment to design personalized interventions directed to specific cognitive deficits is emphasized in many reports.

The majority of published interventions have been conducted with PPAS patients, were impairment directed, and targeted naming deficits. It has been shown consistently across a number of studies that PPAS patients are able to relearn target vocabulary during the active phase of treatment and to maintain gains above baseline levels for variable periods after ceasing intervention (Croot et al. 2009; Carthery-Goulart et al. 2013). However, generalization of learning to untrained stimuli and/or transference of therapy gains to different contexts have not often been achieved. This aspect should be a point of concern when selecting the set of stimuli to be trained and would also argue for the need of more context-based interventions. Recent studies have tried to fulfill this need by using personalized materials such as digital photos of individual household items (Savage et al. 2013) or training relevant activities for the patients, such as cooking (Bier et al. 2011).

It seems therapy benefits are maximized in PPAS if interventions start as early as possible in the presence of very mild semantic memory deficits and low levels of brain atrophy. Studies have shown that patients relearn significantly more items when they retain residual semantic knowledge about them (Jokel and Anderson 2012) and when they are able to link them to personal experience and context (Snowden and Neary 2002). A topic of debate is whether those learning

mechanisms rely on the relatively preserved episodic memory system involving the hippocampus and adjacent medial temporal lobe structures or if the anterior lobe neocortex also plays a role in those relearning mechanisms (Mayberry et al. 2011).

Other important issues have been investigated in PPAS patients. It has been shown that longer therapies are more effective in the maintenance of gains than shorter ones (Savage et al. 2013). Learning was achieved in PPAS patients after interventions of a single session, individual home practice, and computer-based therapies (a detailed description of the studies is available (Carthery-Goulart et al. 2013)). Individual home practice, especially aided by a computer (Bier et al. 2011), seems to be a very promising alternative both economically and also reducing caregivers' load. Nevertheless, all these issues need replication with a larger number of patients.

Fewer studies on behavioral treatments for PPAANF and PPAL have been published. In PPAANF, positive results in communication were shown with the use of augmentative and alternative communication devices, but some patients may show reluctance to use these tools (Croot et al. 2009; Carthery-Goulart et al. 2013). Impairment-directed interventions aimed at different aspects in PPAANF: agrammatism, phonological skills, apraxia of speech, and naming and lexical retrieval deficits. Differently from PPAS, most PPAANF patients are shown to present generalization of therapy gains to some extent, verified in untreated items (Schneider et al. 1996; Jokel et al. 2009), different tasks (Jokel et al. 2009), or functional communication.

PPAL is the variant with fewer intervention reports. Naming and lexical retrieval training resulted in significant improvement of these skills with generalization to untrained items (Newhart et al. 2009; Beeson et al. 2011) and also in conversation skills (Beeson et al. 2011). Active, errorful, and intensive treatment, involving problem-solving and generation of semantic information to facilitate lexical retrieval, has been suggested to help achieve those results, but more studies are necessary to confirm this hypothesis (Beeson et al. 2011).

Some case reports included functional MRI in order to understand the underlying brain plasticity mechanisms in PPA. These reports have suggested compensatory mechanisms through recruitment of cortical areas that are typically preserved for the specific PPA variant. Thus, behavioral treatment in PPAS has been shown to increase activation of the right superior and inferior temporal gyrus (Dressel et al. 2010). In PPAANF, Marcotte and Ansaldo (Marcotte and Ansaldo 2010) observed an expansion of networks involving semantic processing areas (i.e., left middle and superior temporal gyrus and inferior parietal lobe bilaterally). Finally, in PPAL, it has been suggested that behavioral improvements were supported by an increased reliance on the left prefrontal cortex during word retrieval, thus recruiting relatively unimpaired networks (Beeson et al. 2011).

In sum, cognitive rehabilitation is promising for PPA, but more research is needed to define the best types of interventions for each variant and stage of the disease, as well as their intensity, duration, and periodicity. Brain plasticity mechanisms also need further investigation in a larger number of patients. Controlled group studies comparing interventions to placebo treatments are a challenge in this field but may be achieved with research collaborations.

Conclusions and Future Directions

PPA classification system has proven useful but a proportion of patients remain unclassified (Wicklund et al. 2004; Sajjadi et al. 2012). Moreover, patients classified in each of the three most common syndromes may have great variability. To solve these problems, more research is needed on the characterization of the stages of each variant along with sensitive and specific neuropsychological tools to detect mild deficits.

That being said, it is undeniable that the recent consensus has been helpful to establish international research collaborations and to improve communication among researchers in this field. It was an important step to advance in the search for treatment alternatives for those patients.

Prison Populations

Rebecca S. Allen, Keisha D. Carden and Karen L. Salekin

The University of Alabama, Tuscaloosa, AL, USA

Synonyms

Incarcerated individuals; Prison inmates

Definition

Though there has been lengthy debate, the majority of researchers, criminologists, and correctional experts agree that an “aging prisoner” is an individual of 50 years of age and older (Chettiar et al. 2012; Kerbs et al. 2015).

Over the past few decades in the USA, both federal and state prison populations have increased exponentially. The number of older adult prisoners has quadrupled in the past 25–30 years as a result of international demographic changes and increased sentence length in the USA, which incarcerates more individuals per capita than any other nation (Wilper et al. 2009). According to the Federal Bureau of Prisons, aging prisoners over the age of 50 account for 17.2% of the entire prison population in the USA. This number is expected to increase rapidly over the next 5 years and is projected to reach 33% (Chettiar et al. 2012).

This proliferation of aging prisoners carries serious financial implications as well as health and safety concerns during a period of diminishing federal and state resources. Prisons pay approximately \$5,000 in health care annually to support the average prisoner; however, this number nearly doubles for prisoners of age 50 and above and increases eightfold for prisoners approaching age 80. The American Civil Liberties Union (Chettiar et al. 2012) estimated that the overall cost of incarcerating the average individual was \$34,135, while it is \$68,270 for prisoners age 50 and above. Older prisoners require

significantly more health-care services, as well as frequent assistance with activities of daily living (i.e., eating, bathing, dressing, etc.). Further, aging prisoners suffer higher incidences of both mental disorders and physical diseases including major depression, post-traumatic stress disorder, cardiovascular disease, arthritis, respiratory disease, endocrine disorders, hypertension, HIV, AIDS, and hepatitis C (Kim and Peterson 2014; Loeb and AbuDagga 2006). Moreover, aging prisoners experience an “accelerated aging” phenomenon. Prisoners are more likely to be of low socioeconomic status and engage in unhealthy lifestyles prior to conviction, which is subsequently compounded by the trauma of incarceration and limited access to medical care. As a result, aging prisoners suffer from a higher rate of age-related declines and chronic pain than same-aged community peers (Kim and Peterson 2014). Wilper and colleagues (2009) found that many prisoners with serious chronic health conditions failed to receive adequate care. These authors defined “adequate care” as having access to five clinically meaningful treatments: (a) medical examinations, (b) pharmacotherapy, (c) prescription medications, (d) laboratory tests, and (e) acute care for serious injuries.

The majority of prisoners are convicted for petty crimes including nonviolent drug crimes, property crimes, petty theft, fraud, and public order and traffic violations. Current arrest rates for individuals at age 50 are 2% and 0% for those 65 and older (Kim and Peterson 2014). Aging prisoners are also far less likely to recidivate. Trends suggest that the percent likelihood of recidivating drops significantly at age 40 then falls to nearly zero approaching age 80. This is known as the “aging out” phenomenon.

In this entry, current issues pertinent to the international aging prisoner population are reviewed with a focus on the USA. Both physical and mental health needs and interventions (or lack of programs) to meet those needs within the US prison system are addressed. Specifically regarding physical health, prisoners’ desires regarding end-of-life care and medical treatment preferences as well as issues surrounding compassionate release and medical furlough

programs are examined. With regard to prisoners' mental health, the focus will be on the relation of spirituality and mental health needs as a variety of faith-based programs are typically available to prisoners within US prisons. Next, two current intervention programs, one to address physical health needs and one to address mental health needs within the prison system, are reviewed. The final substantive section of this entry will consider ethical issues such as international approaches to the death penalty and whether older prisoners with compromised cognitive capacity may be put to death without considerations of whether this may constitute cruel and unusual punishment. Finally, several directions for future research and treatment programs within the prison system are suggested.

Advance Care Planning and End of Life in Prisons

With regard to the increasing population of aging prisoners, research has shown that the expectation of parole influences prisoners' end-of-life treatment preferences such that prisoners may prefer life-sustaining treatments if they believe they may live to be released from prison (Phillips et al. 2011). For example, Phillips and colleagues (2011) investigated life-sustaining treatment preferences and days of desired life within the context of varying chronic illnesses and physical disabilities among men in a medium security prison dedicated to the "aged and infirmed" in the Southeastern United States. In accordance with the demographics of the geographic area, most prisoners were non-Hispanic white (NHW) or African American (AA). These authors found that future days of desired life were related to prospective health condition, fear of death, negative affect, and trust in prison health care. Non-Hispanic white prisoners expressed a desire for more days of life out of prison, whereas minority prisoners did not differ in days of desired life either in or out of prison regardless of prospective health context. Minorities wanted more days of life than NHW prisoners regardless of prospective health context, but only if they believed that they would be paroled.

The findings of Phillips and colleagues can be used to understand the types of interventions that may be desired by older prisoners, with the ultimate goal of providing cost-effective quality care for older prisoners within the prison system. Specifically, negative affect and fear of dying may be ameliorated by greater accessibility within the prison system to prison-based hospice or palliative care programs that include prisoners serving as volunteers. The presence of prisoners acting as volunteers within chronic and palliative care clinics within the prison system may also partially ameliorate the lack of trust prisoners have in prison healthcare.

Given the aging demographic imperative and the enormity of the cost of caring for aging prisoners, creative solutions are warranted to provide quality of care that is in line with autonomous treatment preferences. In particular, alternatives to imprisonment for terminally ill prisoners, such as compassionate release and medical furlough programs, need to be further explored and more accessible (Loeb et al. 2007). Compassionate release, however, is rarely granted by state or federal courts within the USA. Medical furlough programs exist to provide terminally ill or disabled prisoners with an option for compassionate release. However, eligibility criteria for medical furlough are conservatively restrictive, excluding large groups of offenders (e.g., violent offenders). In Alabama, only three prisoners were released on medical furlough from 2001 to 2007 (Noonan 2010). Thus, it seems that very few ill prisoners may benefit from compassionate release and medical furlough programs within the USA, regardless of their age or health.

Mental Health

A disconnect currently exists between adult developmental and aging research regarding increased reliance on religious/spiritual coping and the availability of such interventions within the correctional system. This is unfortunate given that a variety of faith-based programs are provided within the US prison system at low or no cost, and these programs could serve as feasible,

acceptable, and economical adjuncts to mental health treatment programs. Researchers have documented significant mental health problems among older prisoners in US prisons (Loeb and AbuDagga 2006; Wilper et al. 2009) and among those of other nations (Fazel and Grann 2002, 2004). Aday (2003) reviewed several US studies of older prisoners and noted that depression, guilt, worry, and psychological stress are common.

In their meta-analysis of religious coping practices and psychological adjustment to stress among community-dwelling adults, Ano and Vasconcelles (2005) reported that positive forms of religious coping are associated with positive psychological adjustment, whereas negative religious coping (e.g., spiritual discontent, passive religious deferral, reappraisal of God's powers, and punishing God reappraisal) results in negative emotional adjustment. Fernander and colleagues (2005) underscore the multivariate nature and varying patterns of association between religiosity/spirituality and offense history among adult male prisoners.

Allen and colleagues (2008) examined the relation of religiousness and spirituality to self-reported symptoms of depression, anxiety, and desire for hastened death among male prisoners in a medium security prison in the Southeastern United States. These authors found an association between more years of incarceration and lower self-reported forgiveness (i.e., forgives self, forgive others, and know that God forgives). Moreover, they reported that older male prisoners who reported feeling abandoned by God also reported more symptoms of depression and greater desire for hastened death, whereas those describing greater daily spiritual experiences reported fewer symptoms of depression and less desire for hastened death.

Allen and colleagues (2012) conducted a second study at the same prison to further explore the relations of religiousness/spirituality and physical and mental health. Specifically, it was thought that religiousness/spirituality would moderate the relations between physical and mental health, where the experience of high levels of positive religiousness and spirituality would reduce the negative impact of poor health on mental health. In this

second study, NHW and minority prisoners reported relatively high levels of organizational (e.g., attendance at religious services) and nonorganizational (e.g., praying or meditating) religious engagement within the prison system. Both positive and negative religious copings were related to report of depressive symptoms in the expected directions; however, contrary to expectations, neither type of religious coping strategy interacted with health. As expected, depression was also significant in the model for desire for hastened death, as was the interaction between negative religious coping and functional status. Prisoners' report of desire for hastened death was enhanced when they reported both physical limitation and greater use of negative religious coping. Descriptive information regarding functional limitations in this sample provides useful information for the design of religious coping and mindfulness-based interventions for use within an older male prisoner population (see section "[Current Interventions](#)" below).

As suggested in prior research (Randall and Bishop 2012), it could be that religiousness/spirituality exerts the most powerful influence not through individual experience but rather by enhancing social support among prisoners and improving positive psychological states. The particular impact of forgiveness and forgiveness therapy (Randall and Bishop 2012) as well as meditation programs such as vipassana or mindfulness (Perelman et al. 2012) as they relate to physical health-care costs, behavioral infractions, and positive emotional experiences should be investigated in future research (see section "[Current Interventions](#)" below). Practitioners in the area of corrections should investigate these ongoing therapeutic programs as models for potential implementation within their own facilities.

Current Interventions

The rapidly increasing population of prisoners is heavily compounded by more frequent, longer, and more stringent sentences and institutions that are more restrictive on pardons, paroles, and compassionate release. Depleting federal and state

resources within the USA, growing proportion of aging individuals, and higher rates of poor mental and physical health outcomes highlight the need for comprehensive interventions that address these health, safety, and fiscal issues. Unfortunately, due to financial constraints, there are few comprehensive interventions being implemented currently in US prisons. There are, however, notable exceptions to this general trend.

Many aging prisoners are facing life sentences without the possibility for parole or have sentencing that will surpass their longevity. One case example of a comprehensive health intervention in the USA involves the Louisiana State Penitentiary (Angola). Angola is one of the largest maximum security prisons in the USA, housing over 5,000 prisoners with over 50% of them serving life sentences. Angola has implemented a program for its prisoners meeting the National Hospice and Palliative Care Organization criteria for community hospice programs. This hospice program is facilitated by trained prison staff and inmate volunteers. There is no independent or separate operating budget and no additional funded positions for this program. All training for staff and volunteers is provided by the local university hospice, and additional items (i.e., food/treats, toiletries, and religious items) are purchased through prisoner organizations and approved fundraisers or donated by community members. Prisoners' anxieties regarding imminent death are assuaged as they gain peace of mind knowing a hospice is available. Prisoners volunteering in prison hospice programs experience increases in self-esteem and knowledge. With the involvement of prisoners as volunteers in hospice programs, the overall trust in prison medical care is improved while the institution saves money. Programs such as Angola's address the multifaceted health issues within prison systems in the USA as the aging population in the correctional system increases.

With regard to low-cost programs that may have an impact on mental health, there is growing evidence that positive religious/spiritual coping practices or mindfulness-based religious practice helps prisoners cope with the prison experience (Chen et al. 2007; Perelman et al. 2012).

First, religious/spiritual coping and behaviors may reduce stress. Second, engagement in religious/spiritual behaviors may provide a social support network of like-minded persons, also contributing to the enhancement of psychological resources. The experience and expression of forgiveness may have particular salience in the prison setting (Randall and Bishop 2012).

In a maximum security prison in the Deep South, Perelman and colleagues (2012) examined the impact of 10-day vipassana silent meditation retreats in comparison with a mindfulness-based 10-week group intervention. They reported that, over the course of 1 year, prisoners in both groups reduced the number of behavioral infractions but only the vipassana group reported increased mindfulness and reduced mood disturbance. Neither group was found to have fewer health visits within the facility. Among male federal prisoners over the age of 50, 37% with a history of psychiatric treatment, approximately one-third claimed religion was their most important coping method and that lower levels of depression were associated with greater attendance at religious services and higher levels of intrinsic religiousness (Koenig 1995).

Prisoners are considered a vulnerable population internationally. Any intervention targeting physical or mental health must be approached with utmost care and attention to ethics in clinical health care and human subjects. Some ethical issues, however, have at their base policy issues or, potentially, political issues. Such is the case in consideration of death penalty cases, particularly within the context of diminished cognitive capacity or dementia.

Ethical Practice with Older Prisoners: Dementia and the Death Penalty

The US Supreme Court has established that individuals who lack the capacity to understand the nature of their crimes cannot be put to death because such action would constitute cruel and unusual punishment. This applies to two specific categories of offenders, the intellectually disabled (formerly mentally retarded) and youthful

offenders under the age of 18 years. To date, however, the US Supreme Court has declined to hear any case that addresses the constitutionality of the death penalty for aged prisoners (Wood et al. 2014), though such a case was brought to the court in 2006 (i.e., *Allen v. Ornoski*). This case involved the potential execution of a 76-year-old, blind, diabetic, and disabled man; yet the high court cited the fact that this petitioner for a stay of execution was, at the time of the crime, culpable and therefore exempt from protections facing the death penalty. Wood and colleagues (2014) reported that although 14 countries have excluded older adults from a sentence of death, the US Supreme Court has declined to consider this issue. It is highly likely that the international aging demographic imperative coupled with the high cost of incarcerating older prisoners who are unlikely to offend again will bring the US Supreme Court's attention to this issue once again in the next decade. Psychologists may be asked to help the court through the preparation of amicus briefs reviewing issues of diminished capacity.

Future Directions

This entry has presented information regarding current issues pertinent to the international aging prisoner population and addressed both physical and mental health needs and interventions (or lack of programs) to meet those needs. As per the authors' experience, the focus of the entry has been within the US prison system. It is noteworthy that, within such a cash-strapped system, interventions such as the Angola hospice program and the vipassana program have demonstrated positive results at low or no cost. Directions for future clinical and research efforts include translation of successful, low-cost interventions for greater implementation throughout the US-A. Volunteer efforts including hospice and palliative care or faith-based programs to meet mental health needs hold particular promise. Certainly, a focus on the aging prisoner population creates the need for certain modifications to accommodate changing physical, mental, and cognitive skills.

For example, the evidence-based religious/spiritual intervention, vipassana, reported by Perelman and colleagues (2012) assumes relative physical agility and stamina on the part of participants. Modifications would be necessary for older prisoners with arthritis or other functional limitations precluding the standard approach to meditation. Future research should focus on adaptations of evidence-based interventions such as vipassana for use by the burgeoning number of older prisoners. With regard to policy, the demographic imperative is likely to produce a resurgence of interest in compassionate release and medical furlough programs, particularly for prisoners of extreme age (80+) or with incapacitating chronic disease or functional limitations. Additionally, the US Supreme Court will likely consider the issue of death penalty sentences and cognitive incapacity in the coming decade. International attention to the issues faced by aging prisoners will facilitate a broad transformation that likely will create positive change for older inmates within prison systems.

Proactivity and Aging at Work

Marilena Bertolino¹, Hannes Zacher² and Dorien Kooij³

²Department of Psychology, University of Groningen, Groningen, The Netherlands

³Department of Human Resource Studies, Tilburg University, Tilburg, The Netherlands

Synonyms

Action regulation; Personal initiative; Proactive behavior; Proactive personality

Definition

Proactivity researchers distinguish between the concepts of proactive personality and proactive behavior (Crant 2000; Tornau and Frese 2013). Proactive personality was defined by Bateman and Crant (1993) as a relatively stable tendency to affect environmental changes. Individuals with high levels of proactive personality take action to influence their environments or “identify opportunities and act on them, show initiative, take action, and persevere until meaningful change occurs” (Crant 2000, p. 439). Behavioral expressions of proactivity constitute proactive behaviors, such as personal initiative, taking charge, expressing voice, and job crafting (Bindl and Parker 2011). Proactive personality has been linked to objective (salary and promotions) and

subjective (career satisfaction) indicators of career success (cf. Bertolino et al. 2011). Moreover, proactive personality has been shown to explain additional variance in career success even after accounting for other predictors such as demographics, motivation, type of organization, and type of industry (Bertolino et al. 2011). Proactive behavior has been shown to predict job performance above and beyond personality characteristics (Tornau and Frese 2013).

Age and Proactive Personality

Age has been studied in relation to a variety of work outcomes, such as performance, organizational citizenship behavior, turnover, motivation, and job attitudes (Hertel and Zacher 2015). Although researchers have suggested that proactivity may change with age (Warr and Fay 2001) and that proactivity may contribute to successful aging at work (Zacher 2015a, b; Kooij 2015), only few studies have so far investigated links between age and proactivity at work (see Zacher and Kooij *in press*, for a review). Motivational characteristics of young and older employees may differ due to changes across the lifespan in certain individual differences (e.g., cognitive abilities), organizational rewards, and career situations (Kanfer and Ackerman 2004). Accordingly, while young individuals' goal orientations are more focused on growth, older individuals are more focused on maintenance (Ebner et al. 2006). Similarly, young adults are more likely to persist in optimizing performance, while older adults persist in minimizing losses (Freund 2006). This research on differences in the motivation of young and older workers suggests that proactivity may manifest differently in organizational settings and that the meaning of being "proactive" may be different for young and older workers. In other words, young and older employees may not necessarily differ in their overall levels of proactivity but might differ in the specific type of proactive behavior they engage in.

Zacher and Kooij (*in press*) conducted a systematic review and identified twelve studies (including two meta-analyses) investigating

associations between employee age and proactivity. In line with the literature on age stereotypes that associates lower motivation and flexibility with older employees (Posthuma and Campion 2009), a study showed that older employees are perceived to be lower in proactive personality than young employees, independent of rater age (Truxillo et al. 2012). These stereotypes are generally not confirmed by empirical data. Meta-analytic evidence showed that age was very weakly and not significantly correlated with proactive personality and taking charge, but it was positively (although weakly) correlated with personal initiative and voice (Thomas et al. 2010). Similar results were found in a subsequent meta-analysis (Tornau and Frese 2013). As noted by Zacher and Kooij (*in press*), the samples included in these meta-analyses were composed of relatively young and mid-career employees, which may have attenuated the relationship between age and proactivity. Zacher and Kooij (*in press*) further described the results of a number of studies examining the moderating effect of age on associations between proactivity and work outcomes. For example, in a sample composed of 252 government employees, Bertolino et al. (2011) showed that age acted as a moderator of the relationships between proactive personality and training motivation, perceived career development from training, and training behavioral intentions. Specifically, there was generally a more positive relationship between proactive personality and the outcomes for young employees than for older employees. These results suggest that young and older employees prioritize different outcomes: proactive young employees may be more interested in investing effort into career advancement, while proactive older employees may find more satisfaction in social activities such as mentoring or organizational citizenship behaviors (Bertolino et al. 2011).

In a sample of 182 job seekers aged between 43 and 77 years, age was negatively related to job search intensity, but no relationship was found with proactive personality (Zacher 2013). More specifically, the relationship between proactive personality and job search intensity was stronger

for relatively older job seekers compared to the relative younger job seekers, and job seekers' future time perspective mediated this relationship. In a replication study with mature job seekers (aged between 40 and 64 years), no relationship was found between proactive personality and age, but job search self-efficacy mediated the interactive effect of age and proactive personality on job search intensity (Zacher and Bock 2014).

In summary, on the one hand, results of meta-analyses do not support that older employees are less proactive than young employees, which is in contrast with research on age stereotypes (cf. Truxillo et al. 2012). On the other hand, studies indicate that proactive personality may play a more important role for young employees with regard to career-related outcomes and for older job seekers with regard to job search intensity.

Age and Proactive Behavior

Studies on age-related differences in proactive behavior do not show differences between young and older employees in general, but there is some suggestion of differences between young and older women. Older women showed higher personal initiative (Warr and Fay 2001) and "on-the-job proactivity" (van Veldhoven and Dorenbosch 2008) in comparison with young women.

Proactive behavior has also been studied in the domain of organizational socialization and leadership. In samples of university faculty members and retail employees, a negative relationship was found between age and "indirect information seeking," a disadvantageous form of proactive newcomer behaviors (Finkelstein et al. 2003). In a study investigating proactive leadership behavior, older professors' behavior was perceived as less proactive compared to young professors' behavior but only when subordinates held negative age stereotypes (Zacher and Bal 2012). This result is consistent with research on negative older age stereotypes regarding proactive personality (Truxillo et al. 2012).

In summary, meta-analyses and single empirical studies agree on the fact that older employees do not show lower levels of proactive work and

"on-the-job behavior" than young employees. In contrast, there is some evidence that age stereotypes can have an influence on evaluations of proactive behavior of older employees.

Lifespan Theories Linking Age and Proactivity

The lifespan developmental perspective focuses on "constancy and change in behavior throughout the life course" (Baltes 1987, p. 611) and is considered a useful base to understand aging at work (Hertel and Zacher 2015). According to this perspective, age-related changes can take different forms, such as growth, maintenance, and decline. Indeed, generally, physical abilities and fluid cognitive abilities tend to decrease with age, whereas crystallized cognitive abilities, some personality traits, and socioemotional abilities tend to improve with age (Kanfer and Ackerman 2004). Moreover, extrinsic motives (e.g., challenging work, advancement) decrease, and intrinsic motives (e.g., autonomy, accomplishment, helping colleagues) increase with age (Kooij et al. 2011). The occurrence of age-related losses requires adaptation; the use of proactive strategies may contribute to successful aging by facilitating such adaptation. Since losses outweigh gains with increasing age, strategies to deal with losses are considered particularly fruitful for older individuals (Baltes 1987).

According to the lifespan developmental perspective, intraindividual variability is an aspect which is influenced by the interplay between individual and contextual factors (Baltes 1987). Individual agency (including proactive behavior), which refers to having control over the environment and the self, is considered a relevant variable accounting for this plasticity in development. Indeed, research showed that older individuals that proactively chose an active lifestyle (intellectually, physically, and socially) can decelerate cognitive decline (Hertzog et al. 2009; Lindenberger 2014).

As noted by Zacher and Kooij (in press), the lifespan developmental perspective is composed of several sub-theories that are useful to

understand the role of proactive behavior during the aging process. All of these theories posit that individual agency is a key variable for human development and that proactivity plays a role for successful aging. Specifically, successful aging in the work context refers to the achievement or maintenance of favorable work outcomes (subjective and objective); it is assumed that proactive older employees and/or older employees engaging in proactive behaviors achieve or maintain more positive work outcomes compared to less proactive employees (Zacher and Kooij [in press](#)).

Selection, Optimization, and Compensation Model

This model proposes that individuals engage in three types of proactive behavior that allow them to deal with age-related changes using their limited resources in beneficial way (Freund and Baltes 2000). The first strategy refers to selection and prioritization of goals that can be based on personal choices or due to the unavailability of goal-relevant resources. Optimization of goal-relevant resources is the second strategy and involves investing additional effort, participation in training and development, and seizing the right moment. The third strategy is compensation for losses and involves using other resources when previous resources are lost. These three strategies can be considered proactive behaviors because they are self-directed and future-oriented actions. Moreover, they have been found to be related to job performance and well-being, especially among older workers with high work demands (cf. Zacher and Kooij [in press](#)).

Socioemotional Selectivity Theory

The theory of socioemotional selectivity (Carstensen et al. 1999) posits that the perceptions people have about time play a critical role in goal setting. Specifically, when time is perceived as unlimited, people are more inclined to choose career-focused objectives. Translated into an

organizational setting, young employees who perceive having more time remaining in their careers would be more interested in training and development activities, while older employees would have greater motivation for activities oriented toward helping others and maintaining relationships with colleagues. Research pointed out a negative correlation between age and future time perspective which, in turn, is associated with development goals (such as training and career) for young employees and with generativity goals (such as helping and mentoring) for older employees (cf. Zacher and Kooij [in press](#)). These goals, in turn, direct proactive behavior.

Strength and Vulnerability Integration Model

This model developed by Charles (2010) is based on socioemotional selectivity theory and explains the role of age and perceptions of remaining time for emotion regulation. Emotion regulation strategies used for avoiding or limiting exposure to emotionally negative experiences, such as conflicts at work, are a form of proactive behavior. According to this model, the frequency and the use of attentional strategies, appraisals, and emotion regulation behaviors improve with age.

Motivational Theory of Lifespan Development

This theory posits that people can use two types of proactive behavior in order to maintain high levels of control (Heckhausen et al. 2010). First, they can use primary control strategies to shape their environment consistent with their needs. Second, they can use secondary control strategies that imply changing goals in order to fit environmental demands. Similar to the selection, optimization, and compensation model, the motivational theory of lifespan development posits that individuals use primary and secondary control strategies including selection, pursuit, and disengagement to respond to age-related changes. With aging

the use of primary strategies decreases, while the secondary strategies are used more frequently.

Model of Preventive and Corrective Proactivity for Successful Aging

According to this model, older adults develop resources and reduce stressors by engaging in preventive and corrective proactive behaviors (Kahana and Kahana 1996). Specifically, preventive behaviors refer to anticipating future stressors and minimizing them by engaging in health promotion activities or helping others or participating in social activities in order to enhance social resources. Corrective behaviors deal with extant stressors and may involve mobilizing social support and making environmental changes.

The Role of Job Crafting and I-Deals

Lifespan theories and models underline the relevant role of individual agency for reaching developmental goals by maximizing gains and minimizing losses. Individual agency would activate proactive behaviors that, in turn, may lead to successful aging (cf. Zacher and Kooij *in press*). Selecting fewer goals, deciding on priorities, or regulating emotions is consistent with the notion of plasticity, which suggests that development is not predetermined but flexible and modifiable by proactive strategies (Zacher and Kooij *in press*).

In recent theoretical contributions, job crafting has been proposed to be a variable that may help older employees “to fit the characteristics of their job to age-related changes in their abilities and needs” (Zacher and Kooij *in press*). Indeed, job crafting is defined as a form of proactive behavior that changes the characteristics of the job (Wrzesniewski and Dutton 2001), and it is founded in the concept of person-job fit. Kooij et al. (2015) developed three types of job crafting that they consider potentially useful for older employees. *Accommodative crafting* indicates that older employees may delegate certain activities to other in order to compensate some limitations that come with aging. *Developmental*

crafting refers to engaging in behaviors with the objective to develop personal and professional growth. Finally, *utilization crafting* supposes the use of knowledge and skills by focusing on tasks that require readily available resources.

Like job crafting, the concept of negotiating idiosyncratic employment deals (I-deals) is seen as a form of proactive behavior. It refers to the possibility of making individualized work arrangements with one’s employer, thereby increasing older employees’ motivation and performance. According to Bal et al. (2012), flexibility and development I-deals are relevant for older employees because their needs and preferences tend to be more heterogeneous compared to young employees.

Toward an Expanded Theoretical Framework of Aging and Proactivity at Work

Zacher and Kooij (*in press*) developed a theoretical framework of proactivity integrating age and age-related characteristics as predictors of cognitive-motivational and affective processes, and age-related characteristics as moderators of relationships between proactive behavior and work outcomes. The age-related person characteristics category is composed of a set of variables such as cognitive abilities, personality, emotional abilities, goal orientations, and health. Age-related changes in these characteristics influence cognitive-motivational processes in the sense that young employees strive for proactive development and career behaviors, and older employees prioritize on-the-job proactive behaviors such as personal initiative, voice, and generativity. Moreover, age may influence the contextual characteristics category composed of variables such as job characteristics, age stereotypes, organizational culture and climate, and work-family factors. Regarding job characteristics, the authors suppose that age-related increases in autonomy motivate older employees to show more proactive behaviors, including proactive compensatory and socioemotional behaviors, in comparison to young employees. Age-related

person and contextual characteristics are also proposed to moderate the positive associations between proactive behavior and worker outcomes, such as job performance and well-being. For example, age-related increases in negative age stereotypes may lower the positive influence of older employees' proactive behavior on other people's (e.g., supervisor, peers) evaluations of workers' outcomes. Moreover, due to age-related changes in emotional abilities, older employees are likely to react more negatively to proactive behaviors that elicit high-arousal emotions compared to young employees.

Future Directions and Methodological Recommendations

As suggested by proactivity scholars, research should continue to investigate the role of age and lifespan development (Zacher and Kooij *in press*). In their review, Zacher and Kooij (*in press*) noted that, in organizational proactivity research, there is a lack of research regarding proactive socioemotional and compensatory behaviors that may help to better understand proactivity during the lifespan. Indeed, on the one hand, proactive socioemotional behaviors may lead to helping others and increase social resources. On the other hand, proactive compensatory behaviors could refer to role change and modification of goals in order to be closer to personal needs. Future research should consider tactics of proactive work behaviors that may occur over the lifespan. Indeed, Finkelstein et al. (2003) found that older employees engage less in indirect forms of proactive information seeking during the socialization process.

In their theoretical framework, Zacher and Kooij (*in press*) illustrate some age-related variables as mediators and moderators between age and proactive work behavior and work outcomes. For example, the authors suggest that future research should incorporate emotional, cognitive, and physical abilities, as well as stereotypes in studies on proactive personality. Moreover, the authors suggest including other outcomes besides occupational well-being and job performance, for

example, motivation to continue to work after the legal retirement age.

Regarding methodological recommendations on research linking aging and proactivity, Zacher and Kooij (*in press*) propose to include age-related mediators and moderators and to use longitudinal and cohort-sequential research designs. This would help to allow conclusions about age-related changes. The choice of the sample is also an important issue; for instance, it should be representative of all age groups (younger, mid-career, and older employees). Moreover, age has to be operationalized as a continuous variable, as creating age groups leads to a loss of statistical power. As young, mid-career, and older employees may differ in terms of proactivity, curvilinear relationships between age and proactivity should be examined as well. Finally, attention should be paid to time-related constructs such as organizational tenure and job tenure, as potentially control and moderating variables in the relationship between age, proactivity, and work outcomes.

Practical Implications

Older employees are often victims of negative age stereotypes; indeed, they are perceived to be less proactive than young employees (e.g., Truxillo et al. 2012). Managers, decision-makers, and employees should be educated that older workers are not less proactive than young colleagues. They may be even more likely to engage in specific proactive behaviors, such as proactive socioemotional and strategic behaviors (Zacher and Kooij *in press*).

Special attention should be paid toward training design and career development activities in order to meet older employees' needs and preferences (Kooij and Zacher *in press*). Indeed, in most organizations, training and development activities are offered primarily to young people but very seldom to older employees. Managers should provide more opportunities for training and development to older employees, as this could be beneficial to them with regard to older employees' career-related proactive behaviors.

Studies have shown that older employees tend to engage more in proactive behaviors requiring socioemotional skills and social networks that help them compensate for potential age-related declines. In this line, organizations should support and encourage older workers to occupy roles having to do with mentoring, facilitating of knowledge transfer, and colleagues' supervision (cf. Zacher and Kooij *in press*). The adoption of these strategies would be beneficial for older employees and could improve their well-being and performance at work.

Problem Solving in Old Age

Christiane A. Hoppmann and Pavel Kozik
 Department of Psychology, University of British
 Columbia, Vancouver, BC, Canada

Keywords

Coping; Decision-making; Everyday problem solving; Problem solving; Collaborative cognition

Problem solving involves the recognition that there is a discrepancy between one's current state and a desired end state as well as the strategies aimed at reducing this discrepancy (Marsiske and Margrett 2006).

At a very general level, problem solving represents the process by which an individual appraises and approaches problem (Marsiske and Margrett 2006). Problem solving thus involves various subcomponents including identifying specific characteristics of the problem at hand, making concrete plans, deciding on appropriate strategies, and engaging in behaviors that are aimed at reducing the discrepancy between current status and desired outcome (Marsiske and Margrett 2006). Hence, problem solving is a complex process that unfolds over time and that may have meaningful real-world implications.

There is a very large spectrum of problems that have been addressed in the adult developmental and aging literature. To illustrate, two hypothetical problem-solving scenarios are presented that are both relevant to older adults. *Scenario A:* Susan has been diagnosed with strep throat, a bacterial infection that is usually treated with antibiotics. What sounds like a straightforward problem actually involves many different steps: Susan is asked to report all medications she is currently taking plus any allergic reactions to antibiotics she might have had in the past; she then needs to locate a pharmacy to purchase her medication, review the medication leaflet, and finally take the medication as prescribed by her doctor for a period of one week. Problems such as this one are often referred to as instrumental problems and are unique in that they typically have a right or wrong answer. Older adults often struggle with well-structured instrumental problems to the extent that solving them is tied to basic cognitive abilities like memory, inductive reasoning, or perceptual speed, which are known to decline with aging (Diehl et al. 2005).

Scenario B: Helen has spent several weeks setting up a family brunch that is tentatively scheduled to take place in her home during the holidays. This task has required a great deal of effort, planning, and organization. Two days prior to the event her youngest son calls saying that the weather is projected to be warm, sunny, and beautiful and asks if instead of a brunch, she might prepare dinner, allowing the family to take a hike earlier in the day and enjoy the marvelous sunshine. Feeling upset but wanting to hide her feelings, Helen briskly says that she will call him back, takes a deep breath, and turns to her husband for comfort and advice. She is very irritated given the energy she has put into the family brunch, but she does not want to start a conflict because she knows that her son may very well be thinking about the overall family experience. Scenario B differs in many respects from Scenario A. It does not have an obvious right or wrong answer, is emotionally charged, and involves several other people. Hence there may be multiple problem-solving strategies Helen could choose from to

solve her problem. Helen's problem would be considered an ill-structured emotionally salient interpersonal problem, and past research has shown that older adults appraise and approach such problems in systematically different ways from young adults (Blanchard-Fields 2007). For example, older adults are more likely to tailor their problem-solving strategies to the problem context than young adults, and older adults also more readily combine different problem-solving strategies including instrumental and emotion regulation strategies, which ultimately render them more successful problem solvers than young adults. With such problem solving mobility, older adults might succeed where their younger counterparts may stumble (Berg et al. 1998; Blanchard-Fields 2007; Hoppmann and Blanchard-Fields 2010).

Taken together, these two problem scenarios illustrate that older adults may struggle solving one type of problem while potentially excelling on another. Older adults tend to do poorly on well-structured problems like the instrumental problem that Susan is confronted with in part because they are tied to fluid cognitive abilities. In contrast, older adults perform just as well or even better than young adults on ill-structured social problems like Helen's as long as the problem allows them to capitalize on their life experience and crystallized cognitive abilities.

Given the key role of socio-emotional factors in shaping how older adults appraise and approach complex everyday problems like the one described in Scenario B, an important recent extension of research has been to explicitly take into account the perspectives of multiple individuals that are involved in problem solving (Berg and Strough 2011; Berg and Upchurch 2007; Dixon 1999; Hoppmann and Gerstorf 2009). As described in Scenario B, Helen engages in a mixture of individual and collaborative problem-solving strategies. For example, she ends the call with her son to keep him from seeing how she is feeling (individual emotion-focused problem-solving strategy), and turns to her husband to help her come to grips with her negative emotions (collaborative emotion-focused problem-solving strategy) and/or assist her in coming up with a

joint action plan of how to proceed given the new circumstances (collaborative instrumental problem-solving strategy). For the purpose of this entry, the sample case of married couples will be used to illustrate how a dyadic perspective may extend an understanding of problem solving in old age. Even though the initial focus is on married couples, there are additional meaningful units that should be targeted in problem-solving research such as dyads of friends, siblings, or parents and their children (Berg and Strough 2011; Strough et al. 2008).

What makes problem solving among spouses so interesting to aging research? Many individuals identify their marriage as their most central relationship (Lang 2004). Furthermore, spouses typically are very close to each other, share many life experiences, have an in-depth knowledge of each other's strength and weaknesses, and live in the same environment (Hoppmann and Gerstorff 2009; Lang 2004; Meegan and Berg 2002). As such, spouses have a particularly high potential to notice when their spouse is confronted with a problem, to be impacted by one another's problems, and to directly involve each other in the problem-solving process. Typically, research on problem solving in older couples draws on findings coming out of two distinct research traditions. First, research examining problem solving in spouses conducted under a collaborative cognition perspective, which often uses experimental paradigms to compare collaborations among young versus older romantic partners or collaborations among spousal versus opposite-gender stranger dyads (Dixon and Gould 1998; Margrett and Marsiske 2002; Peter-Wight and Martin 2011; Rauers et al. 2011). Research emanating from this tradition provides encouraging news because it shows, for example, that older spouses are able to compensate for their own cognitive deficits by virtue of collaborating with their respective spouse and that this collaborative benefit is specific to collaborating with the spouse and not present when collaborating with a same age, opposite-gender stranger (Rauers et al. 2011).

Second, problem solving in older couples is informed by findings from the dyadic coping

literature, which uses a broad spectrum of different methods including experimental paradigms, repeated daily life assessments, and long-term longitudinal methods (Berg et al. 2011; DeLongis et al. 2004; Hoppmann and Gerstorff 2013; Michalowski et al. 2014). Of note, findings from daily life assessments demonstrate that collaborations between spouses can take many different forms and that they may come at a cost. For example, spousal collaborations can involve both strain and support, and they may be associated with increased negative effect for everyone involved (Berg et al. 2011; DeLongis et al. 2004; Hoppmann and Gerstorff 2013; Michalowski et al. 2014). Taken together, both streams of research point to the potential that older adults collaborating with their spouse may achieve together what may not be possible alone.

In trying to better understand how spouses may promote problem solving in old age, two different forms of collaborating are considered. First, spouses may *optimize* individual problem solving through the following potentially overlapping mechanisms: (a) Spouses may support each other's problem solving by establishing a positive emotional climate and by providing self-affirmation allowing their spouse to perform at their best (Fredrickson 2000; Murray et al. 2001). (b) Spouses may help reduce tension, anxiety, and nervousness, which are known to undermine optimal cognitive performance (Charles 2010). For example, older adults bringing a companion such as their spouse to a high-stake medical consultation may perform better on cognitively demanding tasks related to their medical condition than older adults without a companion (Ellingson 2002; Jansen et al. 2010; Wolff and Roter 2011). (c) Positive experiences with close others such as spouses may also counteract the vicious effect of aging stereotypes that undermine older adults' performance on a variety of difficult tasks (Abrams et al. 2006; Chasteen et al. 2012; Martens et al. 2006).

Second, spouses may get actively involved in each other's problem solving, which is particularly important when emotional and motivational support is no longer sufficient to *compensate* for

age-related resource losses (Baltes and Carstensen 1999). One key factor that has been shown to facilitate spousal collaborations concerns effective dyadic communication, in part because it allows older spouses to capitalize on their joint experience, knowledge, and expertise (Dixon and Gould 1998; Margrett and Marsiske 2002). Hence, effective communication may represent a pathway through which older couples may be able to collaboratively compensate for age-related resource losses. Another factor that has been shown to improve collaborative outcomes in older married couples relative to nominal pairs is a clear division of responsibility (Johansson et al. 2005). Furthermore, positive affective exchanges facilitate collaborative problem solving. For example, it has been shown that older spouses with high-affiliation exchanges achieve better performance outcomes on collaborative decision-making and errand-running tasks than spouses with low-affiliation exchanges (Story et al. 2007). Hence there are a number of potential mechanisms through which spouses may either create a context that optimizes individual problem solving or, if this no longer suffices, get directly involved thereby boosting joint problem-solving outcomes.

Future Directions

Problem-solving research draws on a number of different approaches that make this literature rich, in hand with this go some challenges that ought to be addressed moving forward.

First, there is no established set of criteria to compare problem-solving effectiveness across studies, especially when it comes to ill-structured problems that have no right or wrong solution. This is concerning, because problem-solving effectiveness is central to almost all research on problem solving. So far, problem-solving effectiveness has been operationally defined using outcomes like the number of safe and effective solutions, self-reported problem-solving effectiveness, external judge ratings, or matches between goals and problem-solving strategies (Blanchard-Fields 2007; Thornton and Dumke 2005). It appears that

the field would greatly benefit if there were agreement on a coherent set of criteria that measure problem-solving effectiveness and that could be applied to different problem types and measures.

Second, experimental and daily life approaches to problem solving can be difficult to integrate because they target different pieces of the overall puzzle. On one hand, there is sophisticated *experimental* research focusing on different problem characteristics and how they are related to problem solving in young as compared to older adults (e.g., instrumental versus social; Blanchard-Fields 2007). On the other hand, there is *time-sampling* research showing that older adults tend to approach their problems in idiosyncratic ways based on their goals or certain personality characteristics (DeLongis and Holtzmann 2005; Hoppmann and Gerstorf 2013). Importantly, these person- and problem situation-focused perspectives are not mutually exclusive, but they are rarely investigated together (see Berg et al. 1998; Newth and DeLongis 2004 for an exception). To move the field forward, researchers might combine these different approaches. For example, one could ask older couples in the lab to work on well-structured instrumental and ill-structured social problems that could be solved individually or collaboratively. One might predict that collaborations are particularly beneficial for ill-structured social problems. A natural extension would then be to test if the respective lab findings have predictive validity for how the same couple approaches the problems they encounter as part of their everyday lives in their own environments.

Finally, problem solving does not take place in a social vacuum. As illustrated above, it may be fruitful to examine problem solving within the complexities of social relationships. Future research should advance knowledge by taking into account the perspectives of multiple individuals, by targeting the underlying mediating and moderating mechanisms as well as by examining the degree to which individuals of different ages benefit from collaborating with another person – be it one's romantic partner or someone else like a sibling or a friend.

Conclusion

Problem solving is a diverse field that is informed by cognitive aging research as well as clinical psychological evidence. Importantly, age-related differences in problem solving depend on the type of problem that is considered. Further research needs to establish a sound way to measure problem-solving effectiveness across different problem types and age groups, more readily combine experimental methods and daily life approaches, and take into consideration the social resources that are provided by close others such as spouses.

Definition

Problem-solving therapy (PST), developed by Nezu and colleagues, is a non-pharmacological, empirically supported cognitive-behavioral treatment (D'Zurilla and Nezu 2006; Nezu et al. 1989). The problem-solving framework draws from a stress-diathesis model, namely, that life stress interacts with an individual's predisposition toward developing a psychiatric disorder. The driving model behind PST posits that individuals who experience difficulty solving life's problems or coping with stressors of everyday living struggle with psychiatric symptoms more often than individuals considered as good problem solvers. This psychological treatment teaches a step-by-step approach to the process of identifying and implementing adaptive solutions for daily problems. By teaching individuals to solve their

problems more effectively and efficiently, this model assumes that their stress and related psychiatric symptoms will decrease. Older populations are suited to benefit from PST given support for its use for issues such as depression, stress associated with medical problems, or psychiatric issues in the context of cognitive impairment (Crabb and Areán 2015).

Overview

PST has been used as a primary treatment modality for older adults, but can also be used as adjunct or “add-on” to an existing treatment. Similar to other cognitive-behavioral therapies, PST has been adapted into different versions of administration including manuals tailored to older adult populations with major depressive disorder, homebound elders with depression, and older primary care populations (Kiosses and Alexopoulos 2014). These various manual versions of PST strive to maintain the core features of the problem-solving model, which consist of teaching the steps toward solving a problem. This treatment has been applied to a multitude of young and old populations with medical, developmental, or psychiatric issues. PST appeals to providers working with older patients because of the versatility of the treatment and its flexibility in terms of the ability to deliver it in a limited number of sessions or shorter sessions (Lynch and Smoski 2009; Shah et al. 2012). Sessions range from as few as 4–12 or more, and session lengths generally last 30–60 min depending on the patient and his/her needs (Shah et al. 2012). PST has success in treating patients with cancer and has been delivered to older populations classified as having depressive disorders or those coping with other major life stressors, e.g., dementia family caregiver or hospice patients (Kiosses and Alexopoulos 2014; Nezu et al. 1998). Through teaching problem-solving skills, there is decreased reliance on specific cognitive abilities, such as executive function, compared with traditional cognitive-behavioral therapy (Simon et al. 2015). The decreased cognitive burden in PST has made this an attractive option for treating older individuals, particularly due to age-related reductions in cognitive performance and

increased risk of cognitive impairment with advanced age.

PST for depression often includes additional cognitive-behavioral techniques known to help depressed patients, such as behavioral activation, used to increase participation in pleasant activities. PST incorporates strategies to promote an individual’s ability to take a positive approach to solving problems, that is, an increase in optimism and viewing problems as challenges rather than insurmountable issues that cannot be overcome. Techniques to promote a positive orientation to problems include recognition and acknowledgment of one’s feelings when there is a problem; using negative emotion to alert oneself to the fact there is a problem to solve; and using techniques to enhance motivation, understand the problem, and even to rehearse how one will respond in a problematic situation (D’Zurilla and Nezu 2006; Nezu et al. 2007).

Core Elements

The core elements of PST focus on identifying a problem and applying the steps of problem solving to a new problem during each session. This is typically delivered in an individual therapy context but can also be delivered in a group format. More recently, this treatment has been delivered by telephone and by live video chat technology (using the telephone or computer) with some preliminary success; however, in-person delivery constitutes the most common method of delivery with the most support (Kiosses and Alexopoulos 2014). PST teaches a methodical approach to solving everyday problems, which breaks the problem-solving process into distinct stages (D’Zurilla and Nezu 2006; Nezu et al. 2007). This allows the therapist to identify areas in which the patient might have difficulty problem solving and also ensures a measured, rather than a haphazard or avoidant, approach to the problem. Patients engage in the following steps during PST: (i) defining the problem and goals, (ii) brainstorming solutions, (iii) assessing the positives and negatives of each solution, (iv) deciding which solution to carry out and coming up with a plan to do it, (v) carrying out the solution, and (vi) assessing satisfaction with the outcome.

First, the patient defines the problem in specific terms. Therefore, a therapist would ask the patient to break down a broad problem into smaller problems. For example, the vague problem of “money trouble” distilled into several specific problems can include difficulty paying the rent, trouble affording holiday gifts for grandchildren, and challenges affording medication. Each of these issues would be treated as separate problems because each requires different solutions. After defining the problem, a specific goal would be stated. Obstacles to achieving this goal can also be documented and provide context to the problem. A goal that is specific and objective allows for an easy assessment of whether the goal was met. For instance, “pay the electricity bill” would be a specific and detailed goal and preferred over “increase income.” Older patients learn to simplify larger problems by asking themselves questions about the context and breaking the problem into smaller problems with manageable goals.

Next, the individual generates solutions to the problem. Given age-associated declines in executive functioning, this step can be challenging with some older adults, especially those who have issues with cognitive flexibility. Issues with executive functioning should not preclude use of this treatment approach given evidence that PST has been shown to work particularly well for older adults with executive dysfunction (refer to “[Cognitively Impaired Older Adults](#)”). Age-related or mild cognitive impairments including, but not limited to executive dysfunction, however, might require that the PST therapist spend more time reviewing some or all of the problem-solving steps. For improving a patient’s ability to generate solutions, experts recommend leading the patient through an exercise to demonstrate the brainstorming process with the most common exercise to generate as many uses as possible for a brick (D’Zurilla and Nezu 2006). Similarly, generating solutions requires that the older patient give as many goal-relevant solutions as possible and to hold off on weighing the positives and negatives until this step is completed. Therapists encourage the patient to give as many solutions as possible because the more solutions generated, the greater likelihood of finding an optimal solution or

solutions. Examples of possible solutions an older patient might give, relevant to the goal of paying the electricity bill, could include reducing electricity usage in order to lower the bill and make it feasible to pay, switching to energy saver bulbs, getting a part-time job to pay the bill, borrowing money from an adult child, and moving to a new place where the bill will be lower.

Next, in weighing the pros and cons of the solutions, the older adult might determine that while all solutions are possible, borrowing money is against their values and would put undue burden on someone else (i.e., their adult child). The anticipated effects of the solution on time, finances, friends, family, and other social contacts also factor into the consideration of these solutions. Keeping both the short-term and long-term goals in mind can be helpful in weighing these options. For example, getting a part-time job would help, but the older adult might have issues such as transportation or physical limitations that could make it hard to go back to work, making this a solution that will not work in the long term. The older adult might decide that a good short-term solution is to limit electrical use because they are only slightly short on their electricity payment each month.

After picking a solution based on the pros and cons, the patient next develops a plan of action to carry it out. For instance, the plan of action might include shutting off the lights when not in use, unplugging appliances not in use, and purchasing energy saver bulbs. Just as defining the problem is specific, so is the plan of action. In this example, the older patient’s plan of action might indicate how many and when new bulbs would be purchased as permitted by their budget, schedule checks of rooms to make sure all lights or unused appliances are off or unplugged, and leaving reminder notes in each room to shut off the lights.

The final step in this process involves evaluating how the plan went. If the patient expresses full satisfaction with the outcome, the patient takes stock in their success and rewards him or herself for a job well done. The therapist then guides the patient through a new problem. If the patient reports only partial satisfaction with the outcome,

he or she may wish to revisit the problem or a different aspect of the problem that week. Sometimes, patients discover new facts about the problem that will help to redefine the problem and goals, generate new solutions, and implement a plan that is now more likely to address the issue. In this example, the patient might discover that forgetting to shut off lights accounts for more energy usage than originally thought and remembering to shut off the lights, alone, would make up the difference in what they have been unable to pay in their monthly energy bill. An unanticipated obstacle could be the problem of forgetting to turn off the lights despite a desire to do so. This new information would guide the patient's process in working through the issue. The following case example describes how these steps might be applied in an older adult seeking treatment for depression.

Case Example

Mr. Z, an 82-year-old male, lives alone in an apartment at a senior living complex. He has no history of treatment for a psychological problem. His primary care physician, to whom the patient reported feeling sad and lonely and sometimes having difficulty with concentration and memory, referred him for outpatient treatment. During his visit with the geropsychologist, Mr. Z also describes having pain and sleep difficulties. Before his wife's death 2 years earlier, he often danced and attended social events at the local Senior Center. Since her death, however, he indicates he is no longer interested in these activities and spends most of his time in his apartment. He has three children with whom he has cordial, but not close, relationships.

At the onset of therapy, Mr. Z's therapist works with him to identify and define the problem for treatment. Mr. Z initially states that his problem is "loneliness." More specifically, he describes his problem as "my social network is too small." He states that his goals are to "meet more people in my apartment complex" and "improve my relationship with my children." He decides to focus on the former goal in order

to gain confidence before moving to the goal with higher stakes. Mr. Z initially has difficulty developing solutions to reach his goal, but lists the following: (1) say "hi" to people when passing them in the halls, (2) knock on neighbors' doors and introduce himself, (3) sit in the lobby of his complex (instead of in his room), (4) make dinner for his neighbors and invite them over, (5) attend programs offered at the complex, and (6) join a conversation with the ladies who sit near the complex's pool.

After developing solutions, Mr. Z and his therapist evaluate the extent to which the solution meets long- and short-term goals, impact, and feasibility for each of the solutions. For example, when Mr. Z examines the solution to make dinner for his neighbors, he notes that it is consistent with his short- and long-term goals and could be a positive way for Mr. Z and his neighbors to get to know each other. Nevertheless, he also recognizes that this requires buying food (expense), preparing the meal (time), and cleaning his apartment (energy and motivation). When comparing the alternative solutions, he considers all the pros and cons and decides that this solution is less feasible than some of the others. In discussing with his therapist, Mr. Z modifies this solution to make it more feasible. He decides to bake brownies and share them with people in his complex. He states that this is cheaper, requires less time and energy, and is enjoyable for him.

Mr. Z lists steps to implement this solution including (1) going to the grocery to buy ingredients, (2) baking the brownies, and (3) taking the brownies to his neighbors. He and his therapist then identify potential obstacles. He describes (1) lacking motivation to go to the store, (2) forgetting to go to the store, and (3) forgetting what ingredients he needs. He plans to make a list of the ingredients and go to the grocery store immediately after his session.

At the next session, the therapist reviews Mr. Z's satisfaction with the outcome and he reports that his neighbors enjoyed the brownies he baked. He observes that they greeted and started conversations with him

more frequently. He reflects that identifying obstacles increased the likelihood of him completing the task and confirmed improved mood. He continues to work on different problems, many of which focus on increasing his social engagement. After completing ten sessions with his therapist, Mr. Z reports minimal depressive symptoms, optimism for the future, and greater confidence in his ability to overcome future problems.

As illustrated in this example with Mr. Z, PST does not necessarily target depressive symptoms per se in an older adult with depression, but rather the patient works on an everyday problem that could maintain or could cause depression (i.e., isolation). This same principle would apply to other psychiatric symptoms or issues, such as anxiety, in which the patient's identified problems but not psychiatric symptoms per se constitute the primary target of treatment. An exception to this rule is when a problem-focused approach will not remediate an issue. In this case, switching to an emotion-focused approach (e.g., one in which the patient generates solutions to address the goal of coping with an unchangeable situation) is appropriate. Though these problem-solving steps are applicable to persons of all ages, the context of the older adults' problems typically differs from the context of these problems in younger individuals (Knight 2009). Specifically, older adults are more likely to have medical and psychiatric comorbidity, different life experiences, and different current life stressors than a younger person.

The Evolution of PST as a Clinical Approach

PST has a long history of support for use in both clinical and nonclinical populations and individuals of all ages (D'Zurilla and Nezu 2006). Creativity research findings first informed the development of a problem-solving model. A 1950 presidential address to the American Psychological Association called for more research in the area of creativity, proposing that that problem solving utilizes novel steps and creativity to identify solutions. Around that same time, an advertising executive developed one of the earliest PST programs called "Creative Problem-Solving

Program," which used brainstorming techniques to stimulate creative performance. Later, its focus expanded to social competence as a way to enhance patients' problem-solving abilities and their confidence in their ability to manage problems.

Amidst the backdrop of growing interest in creative problem-solving and social competence, the 1970s witnessed a paradigm shift among clinicians who questioned the prevailing medical model of psychiatric illness as a disease. These clinicians favored a positive approach targeting the underlying reasons for maladaptive behaviors. This new approach focused on the association between psychiatric disorders and low social competence. The hypothesis that low social competence reflects an inability to cope with problems effectively or appropriately, resulting in psychological problems, garnered empirical support. This new outlook in PST and other treatments that emerged at the time gave a positive outlook on an individual's ability to learn to function better in spite of preexisting psychiatric issues. Early interventions within the positive approach framework utilized behavioral methods (e.g., modeling, behavioral rehearsal) for specific problematic situations. Subsequent recognition of cognition as a mediator for self-control and utilization of cognitive approaches (e.g., cognitive appraisals) allowed for generalization beyond specific problematic situations to beliefs and attitudes within the context of PST. These cognitive approaches were particularly influenced by Lazarus's relational theory of stress (Lazarus and Folkman 1984).

Relational Problem-Solving Model

The primary model for PST is a relational problem-solving model of stress (D'Zurilla and Nezu 2006). This model is grounded in the relational model of stress (Lazarus and Folkman 1984) and social problem-solving model (D'Zurilla and Nezu 2006). In the relational model of stress, theorists posit that stress is a relationship between the individual and their environment. Stress arises when demands surpass an individual's coping resources and results in harm to the individual's well-being. In the relational

model of stress, problem-solving goals only apply when a person can change the environment; thus, problem solving will be ineffective when the environment or situation is unchangeable (D’Zurilla and Nezu 2006). For instance, in the previous case example, the older patient had control over the amount of time he spent socializing. If the problem in that example had been to walk better, but the older person had a medical issue causing a slow but inevitable decline in the function, focusing on ways to improve walking would be ineffective according to the relational problem-solving model. In contrast with this view that problem solving is ineffective for unchangeable problems, social problem-solving theorists believe that problem solving can in fact be used if the situation cannot be changed. In these cases, emotion-focused goals or a combination of emotion-focused and problem-focused goals is the target of problem solving. That is, if the situation cannot be changed, then the problem solving could focus on reducing distress (emotion-focused goal). Thus, a social problem-solving therapist might work with the older patient on problem-solving ways to address negative feelings and improve coping with losing physical functioning.

Three components of the relational problem-solving model, namely, stressful life events, problem-solving coping, and well-being, interact dynamically with one another. Stressful life events may be major negative events, such as notable occurrences like the death of loved one or daily problems that are time limited or ongoing situations. A major negative event may exacerbate the effects of daily problems on well-being, and compounding daily problems may precipitate a major negative event (e.g., illness, divorce). Research findings suggest that frequent daily problems lead to diminished psychological and physical well-being (D’Zurilla and Nezu 2006). The relational problem-solving model focuses on coping with daily problems, which in turn can be a problem-focused and emotion-focused goal.

Ineffective problem-solving coping also amplifies negative outcomes on well-being. Ineffective problem solving could be a function of difficulty with problem-solving skills or a

negative orientation to the problem, as discussed below. Additionally, extreme levels of stress may impede problem solving, thus adversely affecting well-being. The reciprocal relationships between the components of relational problem solving provide a strong foundation for PST with multiple targets in treatment (i.e., both emotion-focused and problem-focused goals).

Orientations/Styles, Use of Social Problem-Solving Scale in older Adults

The PST model presupposes two possible orientations to a problem and several problem-solving approaches that either increase or decrease the likelihood of successful outcomes. These orientations and approaches are relevant to adults of all ages. Orientations to a problem are simply positive or negative (D’Zurilla and Nezu 2006). Those with a positive orientation express optimism about their problems and feel their problems can be overcome. In contrast, individuals with a negative orientation expect the worst, feel hopeless, and feel that nothing they can do will fix their current predicament. Teaching patients with a negative orientation to problems to adopt a more positive orientation is essential for effective use of the problem-solving skills. In other words, patients who do not believe they can overcome a problem are not expected to succeed if they feel they are on the path to failure. For this reason, some versions of PST incorporate motivational exercises to increase receptivity and positive feelings toward the ability to address one’s problems. These exercises sometimes occur during discussion of the PST model, which can explicitly describe optimism toward the current predicament as a key ingredient for improvement in treatment. Some versions of PST built in exercises in order to motivate patients, such as visualizing the outcome if the problem were solved.

In addition to the two orientations, several problem-solving styles are also the focus, namely: impulsive, avoidant, and rational styles. The impulsive problem solver reacts rashly without careful planning of how to approach a problem. This style is often associated with a poor outcome in solving the problem. The avoidant style fits with classic procrastination, where an individual finds that

solving the problem is so overwhelming that they avoid trying to solve the problem at all. The outcome is also poor in that the problem often becomes worse. The ideal style would be the rational problem solver who systematically finds out the information needed to plan an effective solution to address their problem. The combined positive orientation, coupled with rational problem solving, is what patients aspire to achieve, with acknowledgment that these different styles and orientations can vary in the same individual in different situations. Situations that are stressful are more likely to be associated with more maladaptive orientations and styles than less stressful ones.

Therapists in clinical research settings, but sometimes those in clinical settings, assess a patient's problem-solving ability at the start of treatment in order to determine which specific abilities will need the most work. The most popular measure of problem-solving orientation and style is the Social Problem Solving Inventory-Revised (SPSI-R) (D'Zurilla et al. 2002). This scale has both a long form and a short form. The long form provides subscales that correspond with the different steps of problem solving taught in treatment and the positive and negative orientations. The short form has fewer subscales but still provides useful information about an individual's self-rating of their rational problem-solving skills. The SPSI has norms for individuals young (17–39 years old), middle aged (40–55 years old), and elderly (60–80 years old); thus, a benefit of this measure is that older adult norms exist. Comparing individuals' scores with SPSI norms indicate if problem-solving ability corresponds to below, at, or above the average responses for that age group.

Evidence in Older Adults

PST has gained additional popularity beyond its application to psychiatric populations to include medical patients, particularly patients with cancer who experience substantial psychosocial changes (Shah et al. 2012). Patients with cancer, who also tend to be older adults, face multiple challenges including adaptation to physical and biological changes during cancer treatment. Cancer can also affect outlook on life, strain social relationships, and lead to instrumental challenges to

functioning (e.g., difficulty with driving or bathing). A problem-solving approach with patients of this ilk bolsters coping efforts and can be offered in an individual or group format. The issues encountered by cancer patients share similarities with those issues encountered by other older medical populations. As such, it makes sense that PST has also been used to treat depression in frail older adults (Kiosses and Alexopoulos 2014), to prevent Generalized Anxiety Disorder in stroke patients (Mikami et al. 2014), general primary care populations (Kiosses and Alexopoulos 2014), older adults with diabetes (Crabb and Areán 2015), and family caregivers of loved ones with dementia (Zarit 1996). Successful outcomes of PST in these various older adult populations include reduced depressive symptoms and increased physical function (Kiosses and Alexopoulos 2014), decreased risk of developing GAD (Mikami et al. 2014), and reduced behavioral and psychological symptoms in persons with dementia or decreased negative feelings of dementia family caregivers (Zarit 1996). Other reported successful outcomes in populations of depressed older adults include improved quality of life and reduced disability-mediating reductions in depressive symptoms, but no supported improvements in various physical outcomes (e.g., weakness, weight loss, fatigue, and exhaustion) for frail elders (Kiosses and Alexopoulos 2014). The efficacy of PST has support when compared with active comparator interventions, including supportive or reminiscence therapies (Kiosses and Alexopoulos 2014). A large randomized control trial, problem-solving therapy versus cognitive restructuring of medically ill seniors with depression (PROMIS-D), will examine whether PST demonstrates an advantage beyond those obtained with cognitive-behavioral therapy in Australian older adults with multimorbidity (Sharpe et al. 2012). Data collection for PROMIS-D is underway (no data available at this time). Another randomized control trial, the Program to Encourage Active, Rewarding Lives for Seniors (PEARLS), targeted depression and health-associated quality of life using PST for older individuals receiving home-based primary care services (Ciechanowski et al. 2004).

PEARLS findings suggested superior effectiveness for PST compared with usual care for depressive symptoms and functional well-being.

In addition to the benefits of PST when delivered as the primary intervention for older patients or their caregivers, it has support for use as a step or adjunct to treatment. The large-scale study, Improving Mood—Promoting Access to Collaborative Treatment (IMPACT), demonstrated that brief PST delivered to older primary care patients with depression within 4 to 8 sessions in an integrative or collaborative care setting exceeded benefits of usual care in community settings in terms of depression-free days (Areán et al. 2008; Alexopoulos et al. 2005). An additional benefit of PST in the IMPACT study along with its effectiveness for treating depression was improved access to care (Simon et al. 2015). While most of the benefits of PST are focused on older individuals with depression or medical morbidity, the benefits also extend to persons with cognitive impairment.

Cognitively Impaired Older Adults

In the past decade, more attention has been placed on adapting PST and other psychotherapies to treat the contextually different circumstances which older adults may inhabit. For example, the likelihood of having comorbid cognitive impairment and psychiatric conditions such as depression and anxiety may increase with age. Although cognitive impairments are also seen in younger cohorts with depression or anxiety, there are additional factors that may have a larger impact on older adults with comorbid psychiatric conditions and cognitive impairment, which need to be considered and understood with respect to treatment. Older adults may experience greater disability due to these comorbid conditions than younger populations, which may further aggravate depression and anxiety symptoms. Cognitive impairments can also impact treatment receptivity and engagement in and response to treatments (both pharmacological and non-pharmacological) in all age groups.

PST can be particularly helpful in treating older adults with psychiatric conditions and cognitive impairment and more specifically executive dysfunction (Alexopoulos et al. 2005). As older adults age, there are concomitant

pathophysiological changes in the brain that can impact executive functions such as shifting attention, initiating and inhibiting responses, and processing abstract concepts (Areán and Huh 2006), which may contribute to reduced problem-solving ability. These cognitive functions may become further affected with depression and anxiety in the picture. There are many aspects of PST content that allow for less reliance on executive function abilities, which can make this therapy particularly helpful for older adults with executive dysfunction. PST has been shown to lead to better treatment response than supportive therapy due to the acquisition of problem-solving skills related to the executive function impairments of planning and initiation (Alexopoulos et al. 2005). If modifications are needed for cognitively impaired individuals, these modifications are not made on the content but instead on the process and manner in which PST steps are presented, in order to accommodate different cognitive patterns of impairment (e.g., greater repetition of PST concepts or skills in older adults with memory difficulties to facilitate learning). As previously discussed, there are different versions of PST that have been developed for administration in different settings, some of which may be appropriate versions to use to address varying cognitive abilities in older adults with depression or anxiety.

Several process modifications in the delivery of PST can accommodate specific cognitive impairments (Areán and Huh 2006). If an older individual has a noted problem in cognitive tasks that involve sequencing and this ability seems to be impacting his or her ability to benefit from PST, it may be more helpful to apply a version of PST in a step-wise and progressive manner, in which the older adult must master one problem-solving step before moving on to the next step. In addition, there are modifications to help older adults with executive dysfunction, particularly difficulty processing abstract concepts. Although D’Zurilla and Nezu (2006) underscored the importance of mastering problem orientation in younger cohorts in order for PST to be successful, a focus on problem orientation may impede implementation of PST in older adults who have difficulty processing abstract concepts. For example, the ability to understand

one's problem orientation entails understanding of abstract concepts such as self-worth, perceptions about oneself or others' views, and how these views may impact mood and the individual's skills for solving problems. For older adults who have difficulty with abstractions, it may be more helpful to provide education about problem orientations in the moment as the patient brings up negative thoughts about a problem rather than discussing problem orientation in the abstract. Finally, some aspects of PST patient forms have been simplified for older adults with difficulty organizing sections with more information and text than their cognitive capacity can allow.

Conclusions

The versatility of PST in terms of delivery and number of sessions makes it a useful treatment in the context of diverse challenges, psychiatric issues, and comorbidities that arise in many older patients. This approach has empirical support for its effectiveness and efficacy for use in older adults in the community, primary care settings, and home-based settings for use in-person or with technological delivery. It can be used as a primary treatment, adjunctive approach, or as a preventative intervention in group or individual settings. While most evidence has focused on depression, continued development of this approach to address anxiety or to treat mental health symptoms in patients with frank cognitive impairment, such as mild neurocognitive disorders or dementias, is a promising direction for expanding PST's application.

Definition

Memory is the explicit or implicit recall of information encoded in the recent or distant past. Depending on the type of information recalled, memory involves different memory systems. Memory can be divided into primary (short-term) and secondary (long-term) memory. Long-term memory in turn may refer to declarative or nondeclarative memory. Nondeclarative memory describes unconscious remembering, whereas declarative memory describes conscious remembering. Memory systems incorporate different

memory processes. These processes comprise, for instance, encoding, retention, and retrieval. With a grain of salt, memory systems can be described as the “hardware” of memory, whereas memory processes can be seen as the “software” of memory.

The expectation of an age-related decline in memory belongs to the most common beliefs about aging (Ryan 1992). Indeed, there are studies showing that, on average, memory declines in older age (see Kausler 1994 for a review). As will be discussed in this entry, such decline may refer to different memory systems differentially. Following this, in order to understand aging and memory from a process and systems view, it is necessary to describe memory and aging on a fine-grained level: What kind of memory system is the target memory system of the investigation? Moreover, due to different processes of different memory systems, it is necessary to be precise regarding age-related effects in a memory system and the corresponding memory process. Taking into account different memory processes is in particular relevant for discussing the issue on possible influences of age-related differences in memory systems.

Note that we will address these issues regarding normal aging and with a focus on episodic memory due to its relevance for research on memory and aging. Moreover, most of the research presented in the following has utilized, an average-based approach, meaning that “average” younger adults are compared “average” older adults regarding different memory systems. Limitations and possible extensions of this approach with respect to implications for cognitive aging research will be addressed in the concluding remarks of this chapter.

Memory Systems

Memory may refer to different memory systems. Broadly, primary memory (PM) is distinguished from secondary memory (SM). Whereas primary memory describes short-term remembering, secondary or long-term memory covers all aspects of long-term remembering. This systems view of memory is also known as the “modal view”

The order of authors is random; both have contributed equally.

Process and Systems Views of Aging and Memory,
Fig. 1 Memory systems

(Shiffrin and Atkinson 1969). In line with the modal view (Shiffrin and Atkinson 1969), information (regardless of what type of information) is first registered in the sensory register and subsequently, information enters short-term memory (PM). After successful registration and transformation of information, information is transferred to long-term memory (see Fig. 1). With respect to aging, each memory system shows differential age-related effects.

Short-Term Memory (PM)

Short-term memory is employed, for example, in tasks asking participants to recall the serial position of eight numbers that were presented in advance. Baddeley (1992) suggested that short-term memory may be more than a simple buffer, but rather consist of a complex memory system covering the holding and manipulation of information over a short-term interval. The model of working memory incorporates three distinct processes: phonological loop, visual sketchpad, and central executive. Briefly, the phonological loop describes the maintenance of phonetic information, whereas the visual sketchpad describes the maintenance of visual information. The central executive coordinates the phonological loop and the visual sketchpad and thus the active holding and maintenance of both types of inputs. Depending on whether information is maintained successfully in working memory, the information enters long-term memory.

Whereas age-related differences are small in short-term memory (cf. Grady and Craik 2000), there are findings suggesting that there are more pronounced age-related differences in working memory (see Hasher and Zacks 1988 for a review). While the term short-term memory refers to the capacity for holding a small amount of

information (7 ± 2 elements according to Miller's famous "magical number seven") active across a few seconds, working memory refers to the structures used for the processing of information in short-term memory, thus extending the idea of a relatively passive short-term memory store by the active processes of manipulating information in different but interacting subsystems of short-term memory. Overall, research shows that, on average, older persons show lower working memory abilities. Possible explanations for this age-related effect may be, for example, a deficit in cognitive inhibition in older adults (Hasher and Zacks 1988). Cognitive inhibition is relevant for working memory performance, because irrelevant in contrast to relevant information has to be suppressed—otherwise it would occupy valuable working memory space and processing resources.

Long-Term Memory (SM)

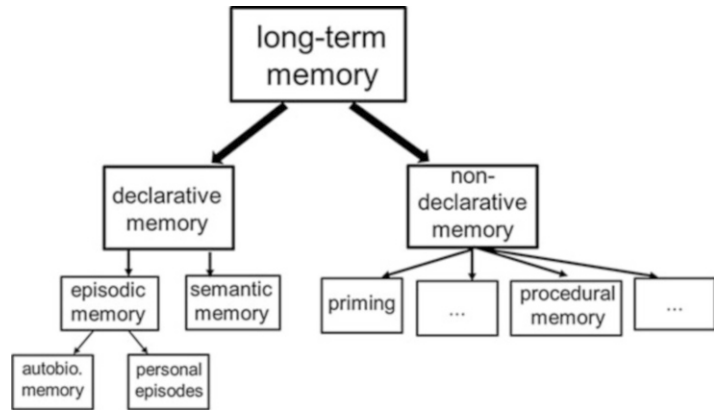

Long-term memory can be divided into declarative and nondeclarative memory (see Fig. 2). Typically, declarative memory is meant when the term "memory" is used; it refers to the capacity for conscious recollection about facts and events. Declarative memory is representational, and these representations can be either correct or incorrect. In contrast, nondeclarative memory is neither correct nor incorrect. It is dispositional and is expressed through performance rather than conscious recollection. Nondeclarative forms of memory comprise of specialized performance systems, e.g., priming and procedural memory.

Nondeclarative Memory

Procedural memory and priming are two examples of nondeclarative memory systems, which have been examined (at least to some part) with respect to aging. Procedural memory describes

Process and Systems Views of Aging and Memory,

Fig. 2 Memory systems of long-term memory

any acquisition and the successful performance of a specific skill over the long term. Examples of procedural memory are riding the bicycle, playing piano, or typing. Once a skill is learned, the skill is performed successfully consecutively without effort. Studies on aging and procedural memory suggest that there is, on average, an age-related decline in speed of performance but no or only little age-related decline in preserving the skill. For instance, in a study by Smith et al. (2005), persons in old age (65–95 years of age) were able to learn a novel visuomotor task, but they were, on average, slower than younger adults. During a follow-up after 2 years, it was shown that older adults preserved memory performance of that task as indicated by improved times of performing the original task across five trials.

There are mixed results regarding the issue of age-related differences in priming. Some studies show that there is an age-related decline in priming, while other studies suggest that there are no or only little age-related differences in priming (cf. Brickman and Stern 2009). Note that these mixed results may be due to comparatively low measurement reliability and/or the insufficient power to detect age differences. In turn, studies that show age-related differences in priming may have included older individuals with incipient dementia (cf. Brickman and Stern 2009).

Declarative Memory

As stated above, declarative memory reflects the capacity for conscious recollection. Depending on whether factual knowledge or personal events are

the target unit of remembering, declarative memory refers to semantic (knowledge) or episodic memory (personal events; Tulving 1972).

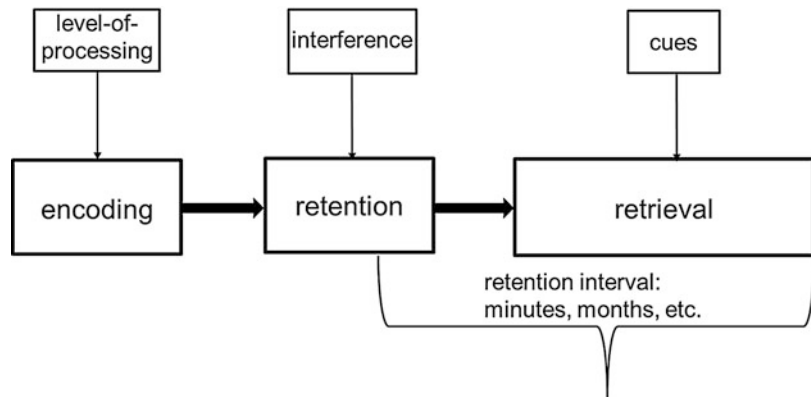

Semantic Memory

What is the capital of Poland? What is a synonym of “approval”? Asking such questions is one way of testing semantic memory. Semantic memory describes the successful retention of general and verbal knowledge. Due to a longer history of education, a longer history of using verbal material, etc., it is expected that semantic memory increases from being a child to a young adult until being a middle-aged person. Afterwards, semantic memory may still increase or remain relatively stable in old age. Thus, it is expected that there are no pronounced age-related effects in semantic memory toward older age – at least on average.

Note that these studies, which suggest that there are no deficits in semantic memory in older age, contradict subjective ratings of verbal abilities of older adults. For instance, many persons in older age report word finding difficulties and tip-of-the-tongue phenomena (cf. Brickman and Stern 2009). Light (Light 1991) argued that this discrepancy may be due to domain-specific retrieval processes of semantic memory. Accordingly, there might be domain-specific retrieval deficits. Apart from possible domain-specific retrieval deficits, language and underlying cognitive processes (e.g., understanding spoken language) may represent an influence of semantic memory of persons in older age (see Burke and Shafto 2004 for a review).

Process and Systems Views of Aging and Memory,

Fig. 3 Influences of long-term memory systems

Verbal fluency tasks represent another way to test semantic memory. Typical verbal fluency tasks require participants to retrieve as many candidates of a presented theme such as “animals with K as first letter” as possible. Verbal fluency tasks are often used in order to differentiate between healthy persons and persons with MCI or dementia. Regarding healthy or normal aging, there is empirical evidence that, on average, older persons show a deficit in verbal fluency as compared to younger adults (e.g., Kempler et al. 1998).

Episodic Memory

This chapter focuses on episodic memory because of its prominent role in cognitive aging research. This prominent role of episodic memory is expressed by the finding that here age differences are typically most pronounced (as compared to other forms of memory, e.g., semantic memory), which is why it has dominated the research on memory and aging. Episodic memory is defined as the conscious recollection about personal events. According to Tulving (1972), such personal events have to be related to each other in a spatial-temporal way. Autobiographical memory, thus, is one aspect of episodic memory. Besides autobiographical memory, any memory that refers to a personal event is episodic in nature.

Different Processes of Episodic Memory

Any long-term memory system – be it declarative or nondeclarative – incorporates different memory

processes, which are required to achieve the ultimate goal of any memory system: remembering. With respect to declarative memory, there are three processes, which are particularly relevant from an aging perspective: encoding (acquisition), retention (storage), and retrieval process (see Fig. 3). Encoding refers to the process of memory where incoming information is processed for the first time (see paragraph on “[Short-Term Memory](#)”). Information is transformed into a mental representation, which may consist of, for instance, a picture, or an association between objects (see the paragraph on “[Encoding](#)” below). This representation is stored. The retention phase “uses” the representation stored and keeps it without major transformations. Finally, the retrieval phase describes the process of retrieving the information after a defined retention interval (e.g., minutes, hours, days, months, etc.). Due to their relevance for possible age-related effects in episodic memory, we will describe these process and corresponding influences (general ones and specific age-related ones) regarding episodic memory. Note that these processes are also processes of semantic memory.

Influences of Age-Related Differences in Episodic Memory

As stated above, a large body of research focused on age-related differences in episodic and overall indicates that, on average, older adults have more difficulties to recall information in terms of episodic memory tasks than younger adults

Process and Systems Views of Aging and Memory,

Fig. 4 Example of individual differences of 80-year-old adults in verbal learning curves

(Kausler 1994). Because of their high controllability, verbal learning tasks are common in order to test episodic memory in the laboratory.

Verbal learning may refer to learn words, numbers, letters, etc. In a typical verbal learning experiment, a list of, for instance, known words is presented, and subsequently, participants are asked to recall as many words as possible in any order (i.e., free recall). In order to measure the trajectory of learning, thus, the dynamic part of episodic memory, usually multi-trial tasks are used. These tasks require participants to learn the given verbal material across several trials. Consequently, recall performance of these several trials can be plotted, and a typical learning curve emerges (see Fig. 4). Following this, parameters of a verbal learning curve can be investigated regarding aging and with respect to individual differences (see Zimprich et al. 2008).

According to Tulving (1972), verbal learning tasks can be seen as measures of episodic memory, because learning of verbal material in a new spatial-temporal context represents a personal event. A large body of research suggests that age-related differences are highly pronounced in these verbal learning tasks of episodic memory (Kausler 1994). In contrast to the majority of studies on verbal learning and age-related differences, which were realized in the laboratory, there is also a line of research that implements verbal learning tasks in a naturalistic environment. This line of research has been mainly influenced by Neisser (Neisser and Hyman 2000) and his

approach of “remembering in naturalistic contexts.”

There are several influences on episodic memory, which were suggested to explain age-related differences in different memory processes of episodic memory (see Roediger 2008 for a review). In general (and regardless of age-related effects), quantitative influences of episodic memory processes can be distinguished from more qualitative influences. An example of quantitative influences is time (respectively, practice). Ebbinghaus (1885/1964 as cited in Roediger 2008) showed that an increasing number of trials enhances recall performance. Miller (1956) argued that, on average, 7 ± 2 items (or “chunks”) can be remembered. Of course, the use of effective mnemonics may lead to an increase of this number. Besides such quantitative variables, more qualitative influences were also suggested. For example, depending on the quality of the to-be-learned material, e.g., whether this is more or less meaningful, memory performance may differ (Craik and Lockhart 1972). Overall, age-related differences are more evident if, for example, material is less meaningful – highlighting the qualitative, content-dependent aspects of different episodic memory processes. In the following, possible influences on age-related differences in episodic memory will be discussed separately for the three different processes of episodic memory: encoding, retention, and retrieval (although some influences tap different processes simultaneously).

Encoding (Acquisition)

A large body of research examined influences on encoding. Beginning with Bower (1970), the idea of an effect of imagery during encoding was formulated. Basically, the assumption is that due to imagery of the to-be-learned material, such material is “richer” (higher associations) and in turn more easily transformed into a broader mental representation, which is transferred into long-term memory. For instance, in a study by Bower (1970), it was shown that the instruction to create imagery during encoding of the to-be-learned material leads to higher recall performance than without such instruction.

Apart from the imagery approach, (more or less in same decade) the generation effect has been the focus of many researchers (e.g., Slamecka and Graf 1978). Briefly, these researchers argued that due to the conscious action of actively generating to-be-remembered material, recall performance is enhanced in contrast to simply reading the material. Examples of generating material are finding synonyms or the completion of words or sentences.

A further approach addressing influences on encoding is the level-of-processing approach by Craik and Lockhart (1972). Craik and Lockhart (1972) state that in dependence on the level of elaboration, which refers to a deep or more shallow elaboration, encoding, and, thus, acquisition, is facilitated. In line with this hypothesis, Craik and Tulving (1975) showed that persons who were instructed to process material in a semantical way leads to higher recall performance compared to the recall performance of persons who were instructed to process the material based on phonemic or orthographic characteristics.

Craik and Byrd (1982) suggested that an age-related decline in conscious processes such as episodic memory may be due to age-related differences in attentional resources and its effect on encoding *and* retrieval. Attentional resources, or as Craik and Byrd (1982) have termed them metaphorically, mental energy, are essential for successful encoding and retrieval. In line with the level-of-processing approach (Craik and Byrd 1982), Craik and Byrd (1982) also assumed that deeper (more elaborative) encoding is related

to higher recall performance. Moreover, due to the (functional) relation between higher attentional resources and deeper encoding, Craik and Byrd (1982) argued that due to a deficit in attentional resources, encoding and retrieval may be hampered. Based on studies which tested these hypotheses by using divided attention tasks (in order to measure age-related differences in attentional resources), Craik and Byrd (1982) concluded that encoding is diminished due to decreased specificity and less spontaneously initiated processing; additionally, retrieval is diminished due to less resources available that are for successful retrieval.

Salthouse (1996) suggested that processing speed is a major explanatory variable of age-related differences in episodic memory. The main premise is that processing speed, that is, the ability to process information rapidly and correctly, decreases on average with older age and that due to this age-related decrease in processing speed, episodic memory performance decreases. Processing speed represents a basic cognitive ability, which may act as a (limiting) resource for the successful performance of effortful tasks (e.g., episodic memory tasks). According to Salthouse (1996), the relation between age, processing speed, and episodic memory is based on two mechanisms: the simultaneity and the limited time mechanism. Briefly, the simultaneity mechanism asserts that processing speed enables people to keep information activated, which then, can be used for further processing. The limited time mechanism posits that processing speed is also needed to execute elementary cognitive operations more rapidly. In conclusion, lower processing speed is associated with an internal lack of time, which leads to canceling ongoing elementary operations (limited time mechanism) and with insufficient information required simultaneously (simultaneity mechanism). These consequences of (relatively) low processing speed come into play during encoding and retrieval when both time and information of prior processes are required.

The associative binding approach by Naveh-Benjamin (2000) argues that older adults have more difficulties than younger adults in

associating to-be-learned material. Building cues during encoding, that is, creating associations between objects, may be helpful to make material more meaningful. One reason that old age is accompanied by a deficit in building such associations may be that older adults do not have good or even the necessary strategies (which may be trained, e.g., during memory trainings) of how to build such associations.

Similarly, it was shown that older adults may have a deficit in organizing to-be-learned material to each other in a meaningful way as compared to younger adults (Witte et al. 1990).

Retention (Storage)

Of course, the number of potential influences of age-related difference in episodic memory “via” encoding must be bigger than the one via retention, because encoding describes the process of memory in which material is transformed. During retention, such action is not present – at least it would be difficult to measure. Instead, as stated above, in this process the transformation is kept into memory without major transformations or actions. Nevertheless, one major potential influence on episodic memory via retention is interference (Underwood 1957). Interference describes recall difficulties due to interfering material, that is, material which, for instance, is similar. An example would be that a person who learned both the Spanish word “sueño” and the Italian word “sogno” (both mean “dream” and are pronounced similarly) may have problems differentiating between them. Interfering material may collide with the to-be-learned material during retention (and retrieval; see below), which may result in less stable memory traces and, as a consequence, more forgetting. Interfering material is material that was acquired before the encoding of the target material (retroactive interference) or afterward (proactive interference). Due to such overlap of material encoded, retention of the “target” material (in the sense of having a stable representation in memory) might be hampered, and following this, retrieval may be wrong or unsuccessful.

An approach on age-related differences in episodic memory is the inhibition account by Hasher

and Zacks (1988). The inhibition account by Hasher and Zacks (1988) states that inhibition is an influence variable of age-related differences in episodic memory. Inhibition, that is, impeding incorrect responses, is relevant during retrieval if there are interferences during retention. In other words, because “sueño” and “sogno” are so similar, their representation in memory may be less stable and, at the same time, share more overlap than if only one of both words would have been learned. If the task is to recall one of both, the other has to be successfully inhibited during retrieval – which becomes more difficult the larger the overlap or the less stable retention is. Hasher and Zacks (1988) argued that old age is characterized by a deficit in inhibition, which may explain age-related differences in episodic memory.

Retrieval

In contrast to retention and similar to encoding, during retrieval, there are several influences, which had been the focus of a large body of research. Note that general influences that are relevant for encoding are also relevant for retrieval. If to-be-learned material was encoded successfully by creating associations, organization, etc., the resulting cues may be used during retrieval. For instance, Tulving and Osler (1968) stated that retrieval is successful if there are adequate retrieval cues. In general, retrieval cues facilitate any retrieval because they are associated with the to-be-learned material. Thus, if there is an adequate cue, the corresponding association is activated, and in turn the material associated is available and accessible. Cues may refer to internal or external cues. Example candidates for external cues are music, seeing a friend, etc. Example candidates for internal cues are thoughts, emotions, and so-called internal subjective cues. Tulving (1962) assumed that during a multi-trial learning task, with free recall as the output modality, any person creates his or her own internal cues across the to-be-learned material even if this is semantically unrelated. For example, a person may have been asked to learn a word list containing the words “pencil” and “water.” Due to individual prior association with “pencil” and “water,” that person may have the

association of “holidays” in order to use “pencil” as cue for “water,” respectively, and vice versa. As stated above, it was shown that older adults may have a deficit in this type of organization (Witte et al. 1990). Such a deficit in organization during encoding may thus affect the quantity and quality of internal cues, which are required for successful retrieval.

More recently, retrieval itself has been suggested to represent an influence variable of episodic memory (see Roediger and Karpicke 2006 for a review). In terms of this approach, retrieval may function as a “memory booster.” Put differently, due to successive retrievals (retrieval practice), the to-be-learned material is strengthened with regard to its availability. This retrieval practice effect is also named the testing effect. Bjork (1975) argued that retrieval can be considered as a memory modifier, meaning that more retrieval leads to higher recall performance even if there is no new encoding occasion. The benefit of retrieval practice is in particular evident after longer retention intervals such as a week.

With respect to aging, there are studies showing that retrieval practice is a potential influence of age-related differences in episodic memory (Meyer and Logan 2013; Tse et al. 2010). For instance, Meyer and Logan (2013) showed that older adults benefitted from additional testing to a similar degree as younger persons. However, there are other studies demonstrating that older adults cannot take advantage of retrieval if there is no feedback for their performance (Tse et al. 2010). Note that the testing effect requires relatively high recall performance during the initial test. Due to relatively low recall performance in initial trials of older adults, feedback may influence retrieval practice of older adults.

Further possible variables influencing retrieval processes of episodic memory in old age are, as stated above, attentional resources (Craik and Byrd 1982) and processing speed (Salthouse 1996) due to their suggested mechanisms on both encoding and retrieval. With regard to retrieval and in line with the approach by Tulving and Osler (1968), lower benefit of retrieval practice, lower attentional resources, and processing

speed may be related with more inadequate retrieval cues leading to hampered retrieval, that is, worse remembering of episodic events.

Concluding Remarks

Knowing possible influences of age-related differences in different memory systems and corresponding memory processes, one approach might consist of providing older adults the relevant support during the corresponding memory process. For example, there are studies showing that older persons increased their recall performance if there was support during encoding as realized by instructions to organize the to-be-learned material (compared to a standard instruction) (Bäckman and Larsson 1992). This result suggests that the relation between a suggested predictor limiting a memory process (such as the encoding quality) and memory performance is stronger for an older person than for a younger person. Put differently, there is a reliable interaction between retrieval support and age. Future research could follow this line of research and thus extend existing research on influences of age-related differences in memory systems. If it were known that relations between possible influences of memory processes, such as encoding or retrieval, and memory performance are stronger for persons in older age than for persons in younger age, hints regarding optimizing memory systems could be formulated. This issue is particularly interesting from a cognitive aging perspective, because some researchers suggested that in older age the so-called dedifferentiation is a possible pattern of relations between different cognitive domains (Baltes and Lindenberger 1997). Dedifferentiation means that cognitive domains become more associated in older age in contrast to childhood or adulthood, when cognitive abilities are more differentiated from each other.

Similarly, approaches that focus on individual differences in aging than on mean differences in memory systems (as realized by the large body of research discussed above) may extend research on

aging in a similar vein. These approaches derive from a lifespan development approach (Baltes et al. 1999), respectively, from approaches of individual aging (Hofer and Sliwinski 2001). Hence, we would expect that there are individual differences in a variety of abilities between persons (1) of different ages but also (2) between persons of similar age. Due to individual initial abilities, their interaction with the environment, and an individual history of these influences, we would expect that there are individual differences in memory systems in persons of older age, too. Future approaches which investigate individual differences in different memory systems in age-homogenous groups could provide ideas of processes underlying aging. More precisely, analyzing predictors of individual differences in memory systems among persons of similar old age may help to gain insights into mechanisms of aging: *why* do persons in similar old age show different performances in different memory systems?

Longitudinal studies, for instance, allow for investigating individual differences in aging and memory by analyzing changes of a variable of interest and individual differences therein (e.g., Zimprich 2002). Furthermore, longitudinal studies on correlated changes may provide hints on the coupled development of memory systems and influences of corresponding memory processes on the individual level. If it were known how individuals change their episodic memory and, in particular, regarding how a particular episodic memory process changes, changes therein could be related to individual changes in the suggested influences (e.g., processing speed, attentional resources) (e.g., Zimprich and Martin 2002). Moreover, examining age-related and individual differences in the converse of remembering, that is, forgetting, may also further our understanding of memory aging (e.g., Zimprich and Kurtz 2013).

Summing up research on processes and systems views of aging and memory, the issue of aging and memory is complex and requires a fine-graded analysis insofar as it incorporates (1) different memory systems, (2) different

memory processes of different memory systems, and (3) age-related differences, which depend regarding their relevance on the corresponding memory system and process. With regard to aging, the episodic memory and corresponding processes have been the focus in research due to the most prominent age-related differences therein. Other memory systems seem to be relatively unaffected by aging. Thus, in society the common belief about aging as reflected in an age-related decline in memory (Ryan 1992) needs to be adjusted: Aging is, on average, associated with declines in episodic memory. With respect to research, study aims could involve focusing on different memory processes explicitly, precise analyses of interactions between possible influences of memory processes and age, and individual aging – at least if the aim is to understand aging and memory from a process and systems view.

Definition

Prospective memory (PM) designates the ensemble of processes recruited to remember to perform an intentionally planned action after a certain delay (e.g., Ellis and Kvavilashvili 2000). Typical everyday-life examples are to remember to call a friend after the weekend, to take medication according to schedule, or to take a meal out of the oven after 30 min. Notably, several studies have revealed that 50–80% of everyday forgetting is attributable to PM failures, which underlines its core role for everyday-life functioning (Crovitz and Daniel 1984). Given its importance for the maintenance of an individual's independence and autonomy and considering its implication in social functioning and health behavior, PM has more and more often been considered to be a key topic for studying real-life outcomes of cognitive aging (e.g., Aberle et al. 2010; Ihle et al. 2012; Schnitzspahn et al. 2011a; Woods et al. 2012). Thus, the two key questions for a geropsychology of PM that will be discussed in the present

chapter are: (1) What are the developmental trajectories of PM across old age and (2) what are the mechanisms that underlie stability and change in PM?

What Do We Know About Adult Age Effects in PM?

To address the first issue, 30 years ago, systematic research on PM and aging started with the question of whether PM shows similar declines as other types of memory. In his seminal chapter on memory and aging, Craik (1986) suggested that typical PM tasks are characterized by high demands on self-initiated processes and low environmental support. Since the ability to recruit self-initiated processes declines with advancing age, Craik argued that PM performance should be particularly sensitive to the effects of aging (see also Maylor 1995; McDaniel and Einstein 2000). Consistent with this prediction, some 20 years later, in the first meta-analytic review on age effects in PM, Henry et al. (2004) concluded that, on average, older adults perform substantially worse than young adults in laboratory-based PM tasks. However, closer inspection of the literature reveals that age-related differences across individual studies vary substantially. While some studies found pronounced age-related declines in PM performance (e.g., Maylor 1996; Park et al. 1997), other reports revealed that older adults perform as well as their young counterparts in some event-based PM tasks (e.g., Einstein and McDaniel 1990). Consequently, solving the “puzzle of inconsistent age-related declines in prospective memory” (McDaniel et al. 2008, p. 141) constitutes a pressing issue in research on PM and aging.

Current Theoretical Accounts for Age Effects in PM in the Laboratory

Why is there sometimes a PM impairment and sometimes not? Before answering this question, one needs to consider a little more how PM is measured. Crudely speaking, research can be divided into laboratory tasks, or more

naturalistic tasks. In laboratory tasks, which are discussed first, participants take part in “ongoing tasks” which simulate the ongoing mental operations and current concerns of daily life. Participants are given a prospective task to carry out on top of or as part of this ongoing task, either in response to a given cue, such as “press this button when the word is written in red”; or at a given time point. As will be highlighted below, the relationship between the ongoing task and the type of cues given greatly influence PM performance and yield insights into the aging profile of PM.

Several conceptual models have been used to describe and explain varying age effects in PM. The multiprocess theory (McDaniel and Einstein 2000) suggests that – in contrast to Craik’s (1986) proposal that all PM tasks are highly demanding – specific characteristics of a PM cue and/or the accompanying ongoing task, in which the PM cue is embedded, determine the amount of resource-demanding attentional processes involved in the successful performance of a PM task. As controlled resources decline with age, the general prediction of this model is that age deficits will emerge when a task requires high amounts of controlled attention while age stability may be found when the task may rely on more spontaneous processing. Conceptually, the multiprocess theory has suggested several specific factors that are key in determining the amount of controlled attention involved in PM performance. The most prominent of these factors is cue focality. This refers to the overlap between the processing required for the ongoing task (OT) and the PM cue (Einstein and McDaniel 2005): The greater the overlap (i.e., the more focal the cue, e.g., when being engaged in an ongoing lexical decision task and having to detect a specific word such as “tornado” as PM cue), the more the information that is required for the PM task is already treated in the course of the OT, enabling spontaneous retrieval of the intention. By contrast, in the case of nonfocal cues, there is no or only a small overlap (e.g., having to detect a specific syllable such as “tor” in a lexical decision task). Here, controlled attention is required for the extra cue monitoring which is assumed to be especially difficult for older adults. In line with

the general prediction of the multiprocess theory, Kliegel et al.’s (2008) meta-analysis confirmed larger age differences for nonfocal versus focal cues; yet, they also revealed reliable age deficits for focal tasks, suggesting that other variables besides cue focality need to be identified as additional moderators.

One of those additional moderators was recently revealed by a third meta-analysis conducted by Ihle et al. (2013) who extended the focus from the cognitive processes involved in cue-detection such as cue monitoring to the analysis of post-cue-retrieval processes. Specifically, to answer the question of whether age effects in PM are further moderated by post-retrieval response management processes, we compared PM and aging studies as to whether they used PM paradigms that required a fixed order of responses after detecting a PM cue (e.g., immediately interrupting the OT and switching to the PM task) or whether participants had to freely coordinate the two parallel task goals in their responses. Again, in all analyses, estimated population PM age effects were reliably greater than zero suggesting clear age deficits in the PM tasks analyzed. When comparing task types, however, a main effect of task order specificity with larger PM age effects in specified than in unspecified PM tasks and, confirming prior results, a main effect of cue focality with larger PM age effects in nonfocal compared with focal PM tasks. Of conceptual importance, there was no interaction between task order specificity and cue focality suggesting that both cue monitoring and response coordination exert independent effects on age-related PM performance.

These abovementioned findings are in general in line with the multiprocess theory, but they also call for an extension as well as a specification of these models with respect to possible interactions and interdependences of the single factors proposed. One of the possibilities for extending the model will be discussed later in the chapter. For the sake of completeness, it is underlined that these findings are generally in line with another important theoretical account on event-based PM, the preparatory attention and memory processes theory (PAM; Smith 2003, 2008; Smith and

Bayen 2004) which suggests that PM performance relies on the amount of cognitive capacity devoted to preparatory attentional processes in order to monitor for the target cue. The amount of these resources can be influenced by certain task characteristics. Thus, both theoretical frameworks suggest that less strategic resources are needed in PM tasks requiring low amounts of monitoring which should enhance PM performance and reduce age effects. On the contrary, those PM tasks which require resource-demanding processes should result in (larger) age-related performance differences, as the ability to recruit strategic attention-demanding processes declines with advancing age. Note that the two models differ with respect to the question of whether controlled resources are always involved in PM (PAM) or whether some PM tasks may fully rely on spontaneous processes – multiprocess theory – yet, for the prediction of age differences, this conceptual difference is of minor importance, as in both cases, age stability may be predicted if the task is low/non-dependent on controlled attention.

While these models derived from laboratory PM research have been powerful in explaining heterogenous results of lab-based studies, they cannot account for a (in cognitive aging research relatively unique) pattern that has been revealed with respect to age effects in PM when performance in the laboratory is compared with performance in participants' everyday lives and that goes even beyond the dissociation of finding decline versus stability.

The Age PM Paradox: A Unique Challenge for Cognitive Aging

Considering the broader literature that has studied PM in the lab but also used more naturalistic tasks in older adults' everyday life (e.g., asking them to send a text message twice a day), results have revealed a unique pattern introduced as the age-PM paradox (Rendell and Craik 2000). This phenomenon is reflected in an age advantage (i.e., older adults outperform younger adults) across tasks carried out in everyday environments (e.g.,

remembering to call the experimenter once a day) and the reverse pattern (age deficit, as reviewed above) in tasks carried out in the laboratory (e.g., remembering to press a prospective response button upon encountering a specific word in a test session). In fact, Henry et al.'s (2004) meta-analysis demonstrated that both effects were almost of identical effect size, with the age-related deficits in laboratory PM tasks showing an effect size $r = -.34$ and age benefits in naturalistic tasks showing an effect size $r = +.35$. Importantly, more recently, the pattern obtained mostly in comparing age effects across studies has been cross-validated in single samples using matched lab-based and naturalistic tasks and revealing a clear and strong cross over interaction between age and task setting on PM performance (see, e.g., Schnitzspahn et al. 2011a). Thus, while most laboratory studies would suggest the answer to the question of whether PM declines with age to be yes, several other studies might suggest this to be not the case. In their meta-analysis, Henry et al. conclude that this may indicate that PM performance in real-life tasks (i.e., PM "tasks" that naturally occur in everyday life such as the examples given above) may actually be spared, even if aging was associated with a decline in the basic cognitive processes involved in PM (such as working memory, see Zeintl et al. 2007; or inhibition or switching; see Schnitzspahn et al. 2013). In consequence, the descriptive pattern of age effects on PM shows in fact three possible outcomes that need to be explained: decline, stability, and possible improvements.

In consequence, considering the age-PM paradox, this pattern strongly calls for research on both (a) the precise pattern of PM performance that young and older adults show in their everyday life and (b) the mechanisms and processes involved in both age-related lab and real-life PM performance underlying all three possible trajectories. In consequence, the second part of this chapter aims to advocate for two extensions to the current state of the art in research on PM and aging. The first considers an extension of the search focus on the descriptive level from lab to life and the second concerns a conceptual extension of factors discussed as possible

mechanisms for explaining different age trajectories in PM in and outside the lab.

Need for Extensions in a Geropsychology of PM – Part 1 (Descriptive Focus): From Lab to Life

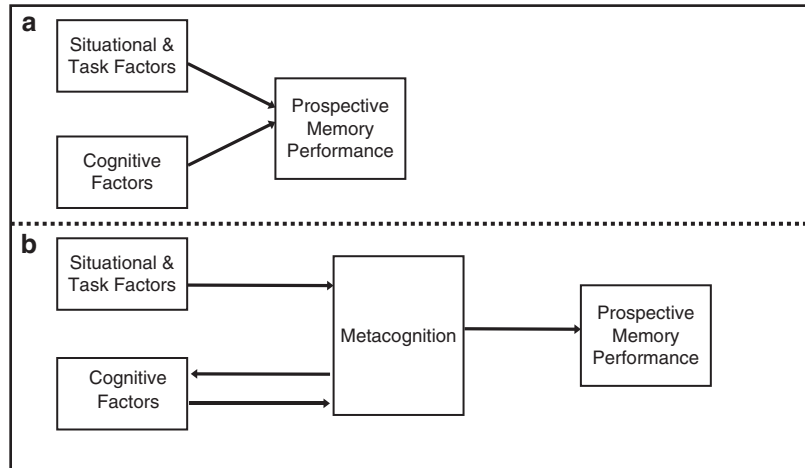

Although, considering the findings on the age-PM paradox, one may actually predict that PM performance in real life may be spared or even improved in older adults, surprisingly, virtually nothing is known about everyday-life PM performance. So far, naturalistic studies have always provided participants with to-be-remembered tasks by the experimenter (e.g., Kvavilashvili and Fisher 2007) but not yet directly investigated naturally occurring intentions.

As one of the rare examples, following up on earlier diary studies on young adults (see, e.g., Ellis 1988; Ellis and Nimmo-Smith 1993), Ihle and colleagues (2012) measured PM performance in everyday situations on five consecutive days in young and older adults. Specifically, participants were called every evening to ask them about their intentions for the following day and to verify if they successfully remembered and performed the planned intentions for that very day. In addition, all intentions were rated regarding their importance. Results showed an age benefit in everyday PM performance. However, this only held true for intentions with low to medium importance, whereas performance in both age groups was comparable for intentions rated as highly important. While both age groups seemed to profit equally from the use of reminders and were impaired by everyday stress, older adults' superiority was associated with the strategy to consciously reprioritize initially planned intentions. In sum, this study suggests that the age-related benefit observed in naturalistic, experimenter-given tasks transfers to everyday PM. More recently, Schnitzspahn et al. (2016) followed up on this finding asking 20 younger and 21 older adults to keep a diary of their naturally occurring intentions over the course of 30 days. Results confirmed a general age benefit for real-life PM tasks. Importantly, this finding was qualified by

revealing that the benefit only held true for specific types of intentions such as health and social intentions. Further, moderation analyses showed that the relationships between cognitive functioning and everyday PM were different for young and older adults. While better inhibition and short-term and long-term memory were related with successful PM performance in the young, this was not the case in the older adults. These findings again corroborate the notion that the age benefit found in naturalistic experimenter-given tasks may in fact extend to real-life PM performance, but they also underline that it may differ depending on the type of intention. Furthermore, these results suggest that individual differences in cognitive functioning may be important predictors for performance in the young, but not so much in the older adults, calling for research on possible compensatory processes.

While these findings shed some initial light on the vastly unknown pattern of age-related changes in real-world PM performance, several key issues remain open. First, and most important, even though Ihle et al. and Schnitzspahn et al. targeted real-world naturally occurring PM tasks, they still relied on self-report data. Thus, to properly test whether PM is compromised in old age (as suggested by the majority of laboratory studies) or whether PM functioning may be well preserved (as suggested by studies using diaries or naturalistic experimenter-given tasks) it would be necessary to – unobtrusively – measure inter- and intraindividual differences in real-world functioning of individuals' PM (without giving people a task that without the study they probably would never had the intention to do). Only such an approach would constitute an objective test of whether there actually is an age-PM-paradox that transfers to observable real-world behavior. Second, cognitive decline, and especially changes in PM, is not a linear function of (negative) changes in basic information-processing resources; clear associations exist between the rate of severity of decline in core outcome variables and a variety of notably modifiable factors, like high levels of stress, lifestyle, and social engagement (Ihle et al. 2015). Thus, an important consequence of these research lines is that while cognitive decline

Prospective Memory, New Perspectives for Geropsychological Research, Fig. 1 (a) The state of the art: explaining PM performance (b) Explaining PM performance: the “missing link” of metacognition

is a major threat to individuals and the aging society, it is not inevitable and it is therefore necessary to study the predictors of everyday cognitive performance in general and of everyday PM performance in particular. This is especially important because – as demonstrated – these mechanisms have to explain not only more or less decline in PM but also possible age benefits in the realization of delayed intentions. One possibly core variable for explaining the diversity of PM age effects that has just recently received some attention and that is suggested in the final part of this chapter as promising target for future research is metacognition.

Need for Extensions in a Geropsychology of PM – Part 2 (Explanatory Focus): Metacognition in PM

From existing research it seems clear that the differential aging effects on PM tasks do not simply reflect higher complexity of laboratory tasks: age deficits are found even on very simple laboratory tasks, while age benefits are retained in complex naturalistic tasks (see; Henry et al. 2004; Phillips et al. 2008). Further, the PM paradox holds even where naturalistic PM tasks are contrived (e.g., the time logging task used in Rendell and Thomson 1999) and laboratory tasks are plausible and contextualized (e.g., the Virtual Week

task used in Rendell and Craik 2000). Further, although the majority of naturalistic tasks require a PM response at a specific time, while most laboratory-based tasks require a PM response to a specific event, this time/event distinction cannot explain the pattern of age effects identified (Henry et al. 2004; Phillips et al. 2008; Rendell and Craik 2000). It is also not simply the case that increasing the ecological validity of any cognitive task inevitably reverses the direction of age effects (Aberle et al. 2010). Finally, it has recently also been tested whether the laboratory test situation itself represents a greater stressor for older adults which in consequence may then cause or enlarge age deficits, but this hypothesis could also be rejected (Ihle et al. 2014).

Thus, while so far a number of possible explanations could be ruled out, only a few positive results have been reported which carve out a potential pattern of processes involved in explaining the paradox (captured as situational or task factors; Fig. 1a). These are (i) the influence of a busy or unpredictable lifestyle in the everyday life of younger adults (Ihle et al. 2012), (ii) the emotional salience of the PM task (Altgassen et al. 2010), as well as (iii) the extent to which participants use reminders (see Phillips et al. 2008).

From a conceptual perspective, one critical element missing in the current literature is the link between situational and task related factors such as busyness of lifestyle or task importance

and the (meta-)cognitive processes employed by the (aging) individual in response to these context variables which actually may mediate the age and context effects in PM behavior (e.g., using more or less reminders) (see Fig. 1b for a conceptual overview). This idea was initially put forward in an exploratory study by Schnitzspahn et al. (2011b)). In short, the general conceptual hypothesis is that participants with a better awareness of their actual performance are able to better invest in the appropriate strategies (see similar findings in the domain of learning, e.g., Thiede et al. 2003; Vrugt and Oort 2008; Dunlosky and Connor 1997). As older adults have more experience in naturalistic PM tasks, they might evaluate their performance in those settings more precisely and might then initiate proper strategies to achieve an optimal level of performance. In reverse, the same might hold for younger adults in laboratory settings as they will be more familiar for the younger age group. In short, we are proposing that overconfidence may lead to faulty PM performance in the laboratory in older adults, and overconfidence in the field leads to low naturalistic task performance in younger adults.

How and Where is Metamemory Involved in PM Performance and is Metamemory Affected by Aging?

In PM, effective ongoing performance monitoring is paramount as one needs to be able to be aware of our ongoing mental operations, while keeping active the planned intention. In the real world, one can readily compensate for any perceived PM difficulties, because our activities fit into a schema of expectations and habits, and environmental factors, or external aids, can help our PM. However, one can only invoke such measures if one detects the possibility of forgetfulness and are aware of our mental operations. Older adults show deficits in some aspects of metacognition, which is related with their deficits in executive function (e.g., Souchay et al. 2000 but see Eakin and Hertzog 2012; Hertzog et al. 2010). In particular, they show an overconfidence on most

assessments: thinking that they will perform better than they do on a wide range of tests (e.g., Crawford and Stankov 1996). This deficit is particularly clear on memory for cue-target word pairs. That is, when presented with a cue, older adults fail to accurately judge whether or not they can accurately recognize later the word that they learned was associated with the cue (e.g., Morson et al. 2015). Healthy older adults also fail to show the standard relationship between control and monitoring: when they judge items as more difficult to remember, they fail to allocate their cognitive resources accordingly (Dunlosky and Connor 1997). Finally, they show a deficit in using their memory to access specific information on which to base their monitoring (Souchay et al. 2007).

However, most importantly, there is not a uniform deficit in metamemory in older adults – their ability to accurately gauge performance on existing knowledge is unimpaired (e.g., Allen-Burge and Storandt 2000; Souchay et al. 2007), and there is evidence that monitoring of face-name pairs is unimpaired (Eakin et al. 2014), which means that where task-specific deficits exist, it may point to the ability to use intact processes to better control and monitor deficient processes. Of particular interest here is the idea developed in the memory literature according to which, if encoding fails, participants will not access sufficient information to monitor accurately and make accurate judgments (*Memory Constraint Hypothesis*, Hertzog et al. 2010). This could explain for example why metamemory is more impaired in older adults in episodic memory tasks than in semantic memory tasks. Considering these findings, the current chapter proposes that in natural contexts, older adults are more aware of the function of their PM and that this may be the key mechanism they can use to compensate for their loss in general processing resources (which would be in line with Schnitzspahn et al.'s (2016) recent findings that neurocognitive test performance only predicted PM performance in real-life intentions in younger but not in older adults). Thus, metacognition may be a core but so far mostly ignored factor in age-related PM performance and could be underlying the age advantage in PM in everyday life; this remains a priority for future research.

Conclusions

Taken together, PM is an important function for maintaining autonomy and independence in old age. In terms of descriptive age effects on PM functioning, the current literature reveals potential for decline, stability, and sometimes even improvement. Yet, while most of the literature has studied PM performance in controlled laboratory tasks or providing participants with tasks to be performed in their everyday life, little is known about age effects in naturally occurring everyday PM tasks (which, by the way, holds probably true for a lot of cognitive domains). Future research will have to uncover whether the age-PM paradox extends beyond self-report data on real-life performance. In terms of developmental mechanisms associated with the variety of age effects, in this chapter, it has been argued that metacognitive awareness and subsequent control processes may be key in explaining the puzzle of inconsistent age-related effects in PM. Again, future research testing this proposal will have to reveal the validity of this hypothesis.

Acknowledgements Preparation of the chapter was supported by a joint grant from the Swiss National Science Foundation (SNSF) and the Agence Nationale de la Recherche (ANR) to MK, KS, CS, and CM.

Introduction

With the growth of the older adult segment of the population, there has been increasing attention given to the health and mental health needs of this cohort. In the arena of mental health care, it has become common knowledge, based on an expanding foundation of research, that older adults can and do benefit from psychotherapy for a variety of mental health needs. In general, they can make good use of the same therapeutic procedures employed with adults of all ages. Accordingly, in this article basic issues and processes in contemporary psychodynamic psychotherapy with older adults will be discussed. In so doing, psychodynamic aspects of some other therapies often used with older adults will be noted. Even if a therapist is not doing focused psychodynamic therapy with an older adult, there are issues common in aging that lend themselves to psychodynamic perspectives as part of overall case conceptualization and intervention.

History and Ageism

Readers may recall that in 1905, Sigmund Freud expressed his view that adults over the age of 50 did not make good candidates for psychoanalysis (Knight 2004). However, in the decades to follow more encouraging contributions to psychodynamic work with older adults began to appear.

Likely the first of these was by Karl Abraham, who in 1919 reported, “to my surprise a considerable number of them [older adults] reacted very favorably to the treatment. I might add that I count some of these cures among my most successful cases.” In following years, more and more efforts were made to expand psychodynamic thinking to encompass older adults. These included works by individuals such as Carl Jung (Knight 2004), as well as declarations made by leading organizations in the profession. For example, in 1980 the Committee on Psychoanalytic Practice of the American Psychoanalytic Association observed that older adults were underserved by psychoanalysts and advised increased efforts to include them. In a 1986 summary, the American Psychoanalytic Association (Cath and Miller) declared further that, “evidence is accumulating from all over the world suggesting that chronological age, contrary to Freud’s impression, is not a valid predictor of analyzability; that throughout evanescence and senescence, new assimilation, leading to modifications in psychic structure, and new enthusiasm and vitality . . . remain possible” (Plotkin 2014).

In spite of these more hopeful perspectives, other authors have identified persistent ageist assumptions in the field that still discourage taking a psychodynamic approach to older adults. These include beliefs that older adults develop psychic rigidity, lose their sense of investment in the future, develop an excessive attachment to the past, and undergo a weakening of life-fulfilling drive. Such assumptions, based as they are in linear, stage models of lifespan development, become quietly reified into unquestioned truths. Also, there are unique, and sometimes daunting, transference and countertransference issues that can arise in working with older adults. The opportunity for these to emerge is especially ample when engaging psychodynamic perspectives, with their emphasis on fundamental human needs, fears, and longings (Wagner 2005).

Definitions and Context

It is important at the outset to operationally define what is meant here by the term “psychodynamic”

care, and to emphasize that these characteristics apply as much to older adult care as to younger adult care. As described by Roseborough et al. (2013), contemporary psychodynamic approaches to therapy have seven core features: (1) emphasis on affect, (2) exploration of attempts to avoid distressing thoughts and feelings (attention to resistance and defenses), (3) identifying and working with recurring interpersonal “themes and patterns,” or what dynamic clinicians might call enactment, (4) attention to the past and a developmental focus, (5) attention to interpersonal relations (i.e., object relations and attachment), (6) attention to the therapy relationship as something potentially therapeutic and as a driver of change in itself, and (7) an invitation to explore one’s fantasy life (i.e., free association) (Roseborough et al. 2013).

Garner (2002) described psychodynamic work similarly, emphasizing its foundational beliefs as applicable to working with patients of any age. These include that symptoms and personality issues have meaning, that people have complex inner worlds, that people may be unaware of some aspects of their inner world, but that there is close interaction between this and conscious experience. Further, it is held that life is a developmental process, unfolding in stages across the lifespan, that at each stage there is an interaction between past history and current circumstances, and that the therapy relationship is both a diagnostic and therapeutic tool (Garner 2002).

Likewise, a brief review of the predominant models of aging can be useful in understanding psychodynamic work with older adults as well. An older approach is that termed the “loss-deficit model,” in which aging is viewed as a series of inevitable losses (loved ones, life roles, physical health, etc.) that erode the older adult’s selfhood and sense of value. The results are depression, emptiness, loneliness, and nihilism. The therapist who ascribes to this model would approach emotional symptoms as manifestations of losses, and likely take a “grief work” approach to mourning and adapting to these. Importantly, while the “loss-deficit model” is often endorsed by both

professionals and popular culture, the data available do not support its universal validity (Dalzell 2001).

In contrast there is the “developmental lifespan” approach to aging. From this perspective, older adulthood is viewed as but one of several stages encountered during the human lifespan. It holds its own challenges, offers its own rewards, and requires its own transitions. Because loss is indeed a common experience as we age, it is seen as one of the unique challenges an older adult patient might bring to therapy. However, it is not assumed to be the only reason an older adult might seek mental health treatment (Dalzell 2001). It is epitomized by the work of Jung (1929), who described a “psychology of life’s morning and psychology of its afternoon.” He viewed the second half of life as revolving around culture and spirituality, as opposed to the childhood experiences and relationships with parents examined in a younger patient. With an older adult, self-illumination was the ultimate goal. To use the phrase, Jung literally endorsed “growing old” (Garner 2002).
