Electrocatalysis Beyond the Computational Hydrogen Electrode

61

Harald Oberhofer

Contents

Abstract

The computational hydrogen electrode approach allows the alignment of theoretical electrochemical potentials calculated with ab initio methods to those measured in experiment. It contributed greatly to opening up the fields of electrochemistry and photo-electrochemistry to theoretical treatment. Yet, virtually all practical implementations of the computational hydrogen electrode relied on a number of simplifications and approximations, which are not necessarily always justified. This chapter highlights three of these approximations as well as the challenges prompting them and gives a brief review of the computational methods available to overcome each. Specifically, it addresses the effects of the

electrolyte, the important choice of the model reactive site – including surface defects and co-catalysts – and the evaluation of kinetic barriers.

1   Introduction

The field of modeling electrochemical and photo-electrochemical processes made a tremendous leap forward with the introduction of the computational hydrogen electrode (CHE) approach in 2004 (Nørskov et al. 2004), with the name CHE coined later by Peterson et al. (2010). Thanks to its conceptual simplicity and computational efficiency, the CHE approach enabled both in-depth studies of reaction pathways and large-scale computational screening studies, dedicated to identifying optimal catalyst materials and facets. Thanks to its popularity, the CHE approach has received a number of updates and additions to account for effects not originally considered. This chapter is dedicated to illustrating the available computational approaches beyond the original implementations of the CHE. Thereby, many of the examples give focus on the water splitting reaction, one of the most ubiquitous and well-studied processes in electrocatalysis, yet all methods can equally be applied to other (photo-)electrochemical processes.

In essence, one needs to model the removal of two protons and electrons from a H_2O molecule which go on to form a hydrogen molecule. It is generally thought of in the form of two half-reactions, the water oxidation

$$H_2O \rightarrow \frac{1}{2}O_2 + 2H^+ + 2e^- \tag{1}$$
and the hydrogen evolution

$$2H^+ + 2e^- \rightarrow H_2, \tag{2}$$

which occur on anode and cathode, respectively.

Any simulation of complex, multistep reactions such as water splitting necessarily rest on an understanding of the involved reaction pathways. Although it is conceivable to explore the space of all possible reaction steps leading from an initial state (such as water) to a number of final products (molecular oxygen and hydrogen), such an approach is rarely feasible for more complex reactions and catalysts. Thus, studies more commonly rely on the assumption of certain predetermined reaction pathways going through one or more reaction intermediates. For the process of water oxidation, such intermediates could, for example, be OH^*, O^*, and OOH^*, where the asterisk denotes a species adsorbed on the catalyst surface. The task of the modeling scientist is then to determine how a reaction can proceed between those, given the associated energetic cost.

The CHE method, described in more detail in Sect. 1.1, is a way to assess the free energy profile of a (photo-)electrochemical reaction at a given catalyst surface. Yet, most of its practical realizations rely on a number of approximations and

simplifications which, as outlined in Sect. 1.2, are not necessarily justified in all cases. The first of these is the omission of any direct solvent effects on the binding free energies of reaction intermediates. Considering that these intermediates might be highly polar – in photo-electrochemical setups even charged – solvation could significantly alter the free energy profiles. In Sect. 2, we outline both explicit and implicit approaches to including solvation effects in (photo-)electrocatalysis and highlight their strengths and weaknesses.

Another hurdle in many simulations at the solid-liquid interface is the determination of the nature of the reactive site. As discussed in Sect. 3, realistic catalysts in reaction conditions are rarely pristine surfaces found, e.g., in vacuum conditions. Instead, they show all manners of non-periodicities such as defects, terraces, or edges, and computational methods to treat these are outlined in Sect. 3.1. In this context, we also examine co-catalysts, i.e., small molecules or metal or oxide clusters, usually employed in photo-electrocatalytic setups. Therefore, an overview over theoretical efforts to treat co-catalysts is given in Sect. 3.2.

Finally, most free energy profiles calculated with the CHE are composed of the relative free energy differences between the initial state, the intermediates, and the final state of a given reaction, respectively. While this gauges the ability of a reaction to proceed at given reaction conditions or get stuck along the way, it assumes that kinetic barriers between these states are negligible. In Sect. 4, we review the techniques and results of first calculations based on explicitly dynamical simulations, showing this to not always be the case. The chapter is finally rounded off by a summary and synopsis in Sect. 5.

1.1 The Computational Hydrogen Electrode

In analogy to earlier work on heterogeneous catalysis (Reuter and Scheffler 2001; Reuter 2016), the revolutionary CHE method of Nørskov and Rossmeisl renders a thermodynamic picture for (photo-)electrocatalysis (Nørskov et al. 2004; Valdes et al. 2008; Peterson et al. 2010). Given a reaction pathway proceeding through a number of intermediates, one can determine the free energy difference between them in order to gauge if a reaction can continue to the desired final state, deviate to another product, or get stuck along the way. The approach taken by Nørskov and Rossmeisl was to formulate each of these steps as the removal (or indeed addition) of a proton and an electron. In the case of the water oxidation half-reaction, the pathway commonly employed reads (Nørskov et al. 2004; Valdes et al. 2008):

$$A: H_2O + {}^* \rightarrow OH^* + H^+ + e^- \tag{3a}$$

$$B: OH^* \rightarrow O^* + H^+ + e^- \tag{3b}$$

$$C: H_2O + O^* \rightarrow OOH^* + H^+ + e^- \tag{3c}$$

$$D: OOH^* \rightarrow O_2 + {}^* + H^+ + e^-. \tag{3d}$$
Here, and in the following, a single asterisk * denotes an empty reactive site on the catalyst. The nature of this site will be discussed in more detail in Sect. 3. At each step, a proton H^+ and an electron e^- are abstracted from the adsorbates, in principle to partake in the other half-reaction. As this half-reaction is omitted from the calculation for practical reasons – i.e., to keep system sizes computationally tractable – protons and electrons can be thought of being put into a reservoir. The free energy cost or gain ΔG_X for each step X in the oxidation reaction can then be expressed as

$$\Delta G_A = G_{OH*} - G_{H_2O} - G_* + \mu_{H^+} + \mu_{e^-} \tag{4a}$$

$$\Delta G_B = G_{O*} - G_{OH*} + \mu_{H^+} + \mu_{e^-} \tag{4b}$$

$$\Delta G_C = G_{OOH*} - G_{OOH*} - G_{H_2O} + \mu_{H^+} + \mu_{e^-} \tag{4c}$$

$$\Delta G_D = G_{O_2} + G_* - G_{OOH*} + \mu_{H^+} + \mu_{e^-}. \tag{4d}$$

The chemical potentials of the removed protons and electrons in their reservoirs are given as μ_{H^+} and μ_{e^-}, respectively. The Gibbs free energies of the involved species are written as G_X.

From a modeling point of view, the calculation of the free energies of surface adsorbed species is relatively straightforward with, for example, density functional theory (DFT) (Stampfl et al. 2002; Hu et al. 2007), while for the gas phase, they can often be found in chemical tables (Kandoi et al. 2004; Haynes 2014; Aktins and de Paula 2014). Each of its three main contributions, the energy E, the entropy S, and a zero point energy correction ZPE, has been studied in standard surface science calculations, with E taken as the total DFT energy of the system and S and ZPE determined from the system's phonon spectrum. The chemical potentials of proton and electron reservoirs are, on the other hand, much less straightforward to determine in ab initio calculations. Yet, especially for a comparison to experiment, calculated energies need to be aligned with respect to known quantities via the reservoir potentials. As a remedy to this dilemma, Rossmeisl and Nørskov put forward the transformative idea of following a route analogous to experiments. There, to allow a comparison of measurements between different experimental setups and electrodes, potentials are aligned with respect to a well-defined standard reaction, very often the formation of hydrogen

$$H^+ + e^- \leftrightarrows \frac{1}{2}H_2. \tag{5}$$

Depending on the reaction conditions, this is called the standard or the normal hydrogen electrode and provides a known potential to align measurements against. In computer simulations, the explicit inclusion of a further electrode into the simulation box is obviously not practical. Yet, observing that each step is formulated as simultaneous proton and electron transfers, an analogous alignment of free

energies can be achieved by identifying the chemical potentials of protons and electrons with the free energy G_{H_2} of a hydrogen molecule

$$\mu_{H^+} + \mu_{e^-} = \frac{1}{2} G_{H_2}. \tag{6}$$

This identity can directly be inserted into Eq. 4 for free energy differences comparable with experiment.

While this *computational* hydrogen electrode allows an alignment of potentials with experiment, there are still a number of contributions missing. First, the electron reservoir is the respective electrode the reaction is occurring on. As such, its chemical potential depends strongly on any external potentials U that could be applied to the electrode. This manifests as a term $-eU$ added to the free energy of each step which essentially provides the driving force for the reaction. Similar corrections apply in the case of photo-electrochemistry on semiconductors, where the electron reservoir is a photo-generated electron hole at the surface (Valdes et al. 2008).

The last component missing so far is the effect of pH on the reaction free energy due to changes in the concentration of unbound protons in solution. This contribution is generally taken as $k_B T pH \ln 10$ and simply added to the total free energy for each reaction step. This simple dependence is not necessarily always justified. Koper, for example, showed (Koper 2013a, b; Göttle and Koper 2017) that an uncoupling of proton and electron steps could lead to more complex dependence of the free energy on pH. Note that this is not a failure of the CHE approach per se, as the reservoir potentials could simply be defined with respect to the experimental *reversible* hydrogen electrode as demonstrated by Peterson et al. (2010). In this case, pH dependence trivially vanishes.

In any case, the restriction to simultaneous proton and electron abstraction steps seems like a severe one at a first glance. After all, both processes can occur on wildly different timescales and are influenced by different factors. Yet, for a purely thermodynamic viewpoint, the ordering of these processes is not important because of the properties of the free energy as a thermodynamic state function. This means that the exact path taken between two states is irrelevant for the free energy difference between them. In the (photo-)electrochemical case, this means that the free energies calculated with Eq. 4 hold, independent of the formulation of the step as a combined proton-coupled electron transfer or sequential process. As long as the true reaction pathway proceeds at some point through the same intermediates (cf. Fig. 1), ΔG_{A-D} can be a valuable estimates.

The sequence of free energy differences can, for example, be used to estimate the minimum potential U_{min} required to drive the reaction. Generally, the effect of the potential is thereby to lower ΔG_X by eU for each step X. At the minimum potential $U = U_{min}$, the free energy cost ΔG_X is either zero or negative such that the overall reaction can occur unhindered without additional thermodynamic barriers. For water oxidation to O_2, the overall energetic cost is known from experiments to be 4.92eV.
Fig. 1 Schematic diagram of the four steps of water oxidation including coupled (black and colored dashed lines) and uncoupled proton and electron pathways. Orange pathways proceed by first removing a proton and then an electron, while for pathways in blue first an electron is removed before the proton follows. Colored dashed lines depict coupled pathways that proceed solely through charged intermediates. The free energy being a state function, ΔG of each intermediate (boxes) is independent of the path taken to arrive there. In principle the reaction could proceed through any combination of the depicted pathways

An ideal catalyst would thereby distribute this cost over all four steps such that each of them only needs 1.23 eV to proceed, yielding an ideal catalyst potential of $U_{\text{ideal}} = 1.23\text{V}$. Realistic catalysts on the other hand differ from ideal behavior, leading to some steps needing considerable more energy than 1.23eV and others much less. The minimum necessary potential, though, needs to lower all ΔG_X to zero or less, resulting in a U_{min} significantly larger than U_{ideal}. The difference between U_{min} and U_{ideal} is known as the overpotential which essentially measures the energy lost due to less than ideal catalysts. Consequently, a lot of research to date, both experimental (Halter et al. 2018; Qian et al. 2017; Maayan et al. 2018; Thiyagarajan et al. 2018) and theoretical (Reda et al. 2018; Seh et al. 2017; Seitz et al. 2016; Zhang et al. 2016), has focused on designing catalysts with minimal overpotential.

Finally, the CHE approach can also serve as the basis of computational screening of novel catalyst materials. Utilizing the observation that binding energies of OH and OOH adsorbates are correlated at least in metallic systems – the so-called scaling relations (Abild-Pedersen et al. 2007) – allows the use of just one binding energy as a screening descriptor. A more detailed discussion of this approach can be found in ▶ Chap. 54, "Energy Trends in Adsorption at Surfaces" of this book.

1.2   Approximations Commonly Made in CHE-Based Calculations

While the CHE approach so far has undeniably led to great advances in our understanding of electrochemistry, most of its implementations so far are not without room for improvement. Foremost, standard applications of the CHE, being a posteriori corrections, where the effects of the applied potential and the pH are added to the energetics of potential-free calculations, cannot address their influence on the catalyst surface. This can lead to an erroneous representation of (photo-)electrochemistry in alkaline environments (Rossmeisl et al. 2013).

The problem of simulating pH in electrochemical environments has been tackled in recent work by Rossmeisl and co-workers (Nielsen et al. 2015; Hansen and Rossmeisl 2016; Hansen et al. 2017), where they presented a generalization of the computational hydrogen electrode (GCHE) which treats the overall electrochemical potential as a function of the applied electrostatic potential and the chemical potential of protons and electrons. As an input, this approach still only takes energetics but for different numbers of hydrogen atoms (protons and electrons) in the system. A more detailed account of the GCHE is given in ▶ Chap. 57, "Microkinetic Modeling of Surface Catalysis" of this book.

Furthermore, the assumed pathways do not necessarily represent the lowest energy ones, potentially leading to an overestimation of the overpotential (Koper 2013a, b). Also, especially in photo-electrochemistry on semiconducting electrodes, other pathways might proceed via charged intermediates (Göttle and Koper 2017) which to a large part are stabilized through the solvent response, often neglected in CHE-based calculations. The reason for this is twofold. First, the computational cost associated with the then necessary sampling of solvent degrees of freedom can easily render simulations of realistically sized systems infeasible. Second, the actual structure of the solid-liquid interface is not only strongly dependent on the choice of the catalyst material and facet but also on the applied potential which is not always readily controllable in computer simulations. To avoid both of these complications, a lot of recent effort was devoted to the development of sufficiently accurate effective simulation methods, so-called implicit solvation models.

On top of that, as with most computational studies, CHE-based calculations can depend strongly on the chosen model for the reactive site (Rao et al. 2017). On ideal flat surfaces, this is less of a problem as the sites there tend to be equal. Famous counterexamples to this do exist with e.g., the CO-adsorption "puzzle" at transition metal surfaces (Hu et al. 2007). Yet, under realistic conditions, no catalyst truly is an ideal single crystal surface. Rather, in order to maximize surface area, catalysts are present as nano-particles leading to a high number of defects, edges, and steps which can significantly alter the material's reactivity (Gambu et al. 2017). Additionally, experimental catalysts often employ small metallic nano-clusters as so-called co-catalysts to facilitate the reaction. Furthermore, oxide materials, which are commonly employed as photo-electrocatalysts, are prone to surface defect formation under reaction conditions (Berger et al. 2015), which can also influence predicted reaction free energies. Neglecting any of these properties of the catalyst can again lead to an erroneous estimate of the energy necessary to drive the reaction.

Recent studies therefore have begun to shed some light on the precise nature of the reactive site (Reuter et al. 2017).

Finally, CHE-based studies of (photo-)electrochemical reactions only consider overpotentials due to the thermodynamic free energy differences between intermediates, neglecting any kinetic barriers between them. These might in turn influence the respective minimum free energy pathway and thus lead to a completely different picture of the reaction. The main reason these have rarely been considered is again the computational cost associated with the dynamical calculations necessary to determine free energy profiles and thus barriers from first principles. With the advent of more elaborate simulation methodology and increased computing power, recently a number of studies of kinetic barriers in (photo-)electrochemistry have been put forward.

These three improvements over standard CHE calculations – i.e., solvation effects, nontrivial reactive sites, and free energy barriers – as well as the methodologies necessary to effectively study them, will be discussed in the following sections.

2 Solvation Effects

As already alluded to above, a simplification made in most early CHE calculations was to omit solvents and solvation effects from the DFT calculations of the energies of reaction intermediates (Nørskov et al. 2004; Valdes et al. 2008). The justification behind this omission is that due to the calculation of only potential-free neutral systems in a CHE-based calculation, solvent effects can be expected to play a minor role in the energetics of surface reactions. Also, up until recently even the basic structure of the solid-liquid interface was still under heavy debate (Feibelman 2002; Michaelides et al. 2004; Meng et al. 2004; Schnur and Groß 2009; Groß et al. 2014) and thus could not easily be tackled in computer simulations. An in-depth discussion of the solid-liquid interface can be found in ▸ Chap. 59, "Structure of Electrode-Electrolyte Interfaces, Modeling of Double Layer and Electrode Potential" of this book. Nowadays, though, the importance of an accurate description of the interface, also with a view on the structure of the reactive site discussed in Sect. 3, is undisputed (Filhol and Neurock 2006; Janik et al. 2007; Filhol and Doublet 2013; Siahrostami and Vojvodic 2015; Hansen and Rossmeisl 2016), and a number of methods have been put forward to tackle solvation, both explicitly and based on more approximate models. An account of both kinds of approaches, insofar as they are relevant for (photo-)electrochemical simulations, is given below.

2.1 Explicit Approaches

At a first glance, explicit simulation of solvents on a catalyst surface seems relatively straightforward. Considering, for example, metal catalysts, it has long been known that water layers closest to the metal surface tend to exhibit relatively ordered,

icelike structures due to strong surface-solvent interactions (Ogasawara et al. 2002; Schnur and Groß 2009; Groß et al. 2014). As a first improvement over vacuum calculations, many studies therefore employ a few layers of highly ordered icelike water (Skúlason et al. 2007, 2010; Chan and Nørskov 2015). This is achieved by a local geometry optimization of the water layer(s) for a given distribution of first-layer water molecules with hydrogen atoms either pointing toward or away from the surface. The exact distribution of "up" to "down" waters and thus the structure of the ice layer are thereby governed by the applied potential (Filhol and Doublet 2013). Potential-free calculations as performed in "standard" CHE calculations thus would not reproduce the correct behavior of the surface water layer. As a remedy, a number of approaches to simulate potentials in electrochemical calculations have been put forward in recent years. They fall, broadly, into two categories, one which directly includes an electrostatic potential dragging electrons from one side of the catalyst slab to the other (Otani et al. 2008; Otani and Sugino 2006) and one where the catalyst surface is charged by explicitly adding electrons to the simulation box. In this case, in order to keep the simulation box overall charge neutral, counter-charges have to be applied either directly in the solvent layer (Skúlason et al. 2007) or in the form of a homogeneous charge background (Filhol and Neurock 2006). In both cases, the applied potential can then be calculated from the work function of the solvated catalyst surface in relation to the vacuum level, which is generally taken as the potential in the vacuum far above the thin, icelike solvent (Chan and Nørskov 2015).

Such more or less ordered layers of water with low molecular mobility not only exist on simple metal surfaces but have also been observed in other materials such as photo- and electrochemically highly relevant phosphides (Wood et al. 2013) and oxides (Sumita et al. 2010; Zhao et al. 2012). Yet, where on metals long range ordered, hexagonal structures dominate, the more complex structure of oxides gives rise to only a local ordering, with, on average, higher lateral molecular mobility (Tilocca and Selloni 2004). This, nevertheless, still suggests that a first description of solvation effects on oxides can be achieved by adding a number of icelike solvent layers to the catalyst surface (Siahrostami and Vojvodic 2015). Indeed, recent CHE-based calculations of, e.g., the water oxidation reaction on IrO_2 (Gauthier et al. 2017) showed a pronounced influence of solvation on the stabilities of the reaction intermediates OH^* and OOH^* (cf. Sect. 1.1), which are both polar and capable of donating hydrogen bonds. Of these two properties, the latter was found to be of greater importance for the relative binding energies, as they showed very little dependence on solvent layer thickness beyond one bilayer, which suggests that electrostatic effects play only a limited role here.

While the ice-layer approach has been shown to yield very good results at only insignificantly increased cost compared to vacuum simulations, there definitely are systems where such an approach is not applicable. For example, electrodes with only weak or intermediate water-binding strengths – which could become relevant in ongoing efforts to break scaling relations or increase product selectivity – showed a preference of more liquid than icelike behavior (Groß et al. 2014). In such cases, due to the disordered nature of the solvent "layers" near the surface, static total energy

calculations are not applicable, and a full sampling of solvent degrees of freedom cannot be avoided. Indeed, a great number of studies employed DFT-MD to model the solid-liquid interface also for electrode materials attracting more ordered water structures.

Sprik and co-workers, for example, employ dynamical sampling to investigate the alignment of electronic and protonic energy levels with respect to water (Cheng and Sprik 2010b; Cheng et al. 2014a) as well as acidity constants of oxides (Cheng and Sprik 2010a), based on a dynamical formulation of the computational hydrogen electrode calculated from the proton work function in a large water box (Cheng et al. 2014b). Similarly, a number of groups Chen et al. (2013), and Stecher et al. (2016) used DFT-MD sampling with explicit solvent degrees of freedom to investigate kinetic barriers in electrochemical processes on cluster models (Mattioli et al. 2013) or extended surfaces (Chen et al. 2013; Stecher et al. 2016). A detailed description of the thereby applied methods will be given in Sect. 4. Along similar lines, Otani et al. employed explicit solvation sampling in a semi-infinite simulation box, giving rise to well-defined electrode potentials (Otani and Sugino 2006), to investigate the dynamics of the hydrogen evolution reaction on platinum (Otani et al. 2008). They find non-negligible influence of both electrode potential and solvent dynamics on the reaction pathway, further underlining the importance of solvation effects. Finally, explicit solvent dynamics was applied by Hansen and Rossmeisl (Hansen et al. 2017) to investigate pH dependence of the electrode solvent interface in a grand canonical approach.

2.1.1   Ion Effects

Up to this point, the discussion of solvation effects was restricted to pure water, neglecting solvated ions present in electrolytes. In electrochemical solid-liquid interfaces, these play the role of mobile counter-charges which are attracted by the buildup of charge in the electrode due to the applied potential, forming the so-called electric double layer (EDL). Due to the presence of charge carriers of opposite signs in solid and liquid phase, respectively, the EDL is characterized by strong electric fields, which themselves can have non-negligible influences on reactions within the interface. Unfortunately, the simulation of the EDL is hampered by two finite size effects. On the solid side of the interface, experimentally realistic field strengths would lead to surface charges of only fractions of an electron per surface unit cell (Rossmeisl et al. 2008). Thus, reactions involving the transport of charges to or from the electrode would lead to large jumps in the potential. Similarly, in the liquid phase, realistic ionic strengths would necessitate very large water boxes. Due to the condition of charge neutrality of the EDL, arising from the fact that electrolyte is conductive (Cheng and Sprik 2014), both these problems are related to the applied electrode potential and can be tackled with the methods discussed in the introduction to this section.

In the literature, explicit simulations of solid-liquid interfaces containing ions have been carried out both in the icelike interface approximation (Chan and Nørskov 2015) and fully dynamical simulations (Cheng and Sprik 2014). Both approaches compare favorably with regard to the respective experiments but are

computationally more expensive than plain CHE calculations in vacuum due to added solvent and ionic degrees of freedom. Even in an icelike approximation, the position of the solvated ions needs to be sampled to yield an authentic representation of the EDL (Rossmeisl et al. 2008). The added computational cost all but precludes high-throughput screening of catalyst materials. The next section will therefore focus on more approximate, but potentially much cheaper continuum approaches to solvents and ions.

2.2   Implicit Approaches

Historically, the idea to treat the electrostatic response of a pure solvent implicitly as a polarizable continuum goes back to works of Kirkwood (1934) and Onsager (1936) and therefore precedes most modern computational methods by far. Based on the assumptions of isotropy and homogeneity of the solvent and linearity of its response to electrostatic perturbations, it is possible to determine the total electrostatic potential $\Phi(\mathbf{r})$ of a solute with charge distribution $\rho_{\text{sol}}(\mathbf{r})$ embedded in a dielectric continuum from a generalized Poisson equation (Tomasi et al. 2005):

$$\nabla \varepsilon(\mathbf{r}) \nabla \Phi(\mathbf{r}) = \rho_{\text{sol}}(\mathbf{r}). \tag{7}$$

The function $\varepsilon(\mathbf{r})$ thereby denotes the dielectric permittivity of the system, which far away from the solute takes on the solvent's macroscopic bulk value (e.g., $\varepsilon(\mathbf{r} \to \infty) \approx 80$ for water) but is equal to one in the vicinity of the solute. This reflects the fact that solvent molecules carrying the response can only approach the solute to within a finite distance, thus forming a so-called solvation cavity (cf. Fig. 2).

Though seemingly quite simple, Eq. (7) gives rise to a multitude of different models and methods. The dielectric function, for example, not only mediates
Fig. 2 Sketch of a solvation cavity based on an electron iso-density surface for biphenyl. Discrete, equidistant points on the cavity surface (green dots) were generated for the MPE model with a pseudo-dynamic simulation (Sinstein et al. 2017) in the FHI-aims code (Blum et al. 2009)

between solute and solvent but in principle also has to include entropic effects due to the loss of degrees of freedom solvent molecules undergo near the solute, e.g., forming solvation shells. As such $\varepsilon(\mathbf{r})$ is always an effective parameter of the solvation model and can be chosen in a number of ways, the two most prominent being a hard step function or a soft transition, both of which can again be defined in a number of ways, such as iso-surfaces of the density (Fig. 2) (Andreussi et al. 2012; Sinstein et al. 2017), soft spheres (Fisicaro et al. 2017), or spheres with van der Waals radii (Klamt and Schüürmann 1993). Furthermore, there are also numerous ways to define the basis used to represent the electrostatic response, ranging from two-dimensional charge distributions on the solvation cavity surface (Klamt and Schüürmann 1993), to multipole moments (Sinstein et al. 2017) and real-space grids (Mathew et al. 2014). Given this great wealth of methodological options, we direct the interested reader to the excellent review by Tomasi et al. (2005) for a more detailed discussion of solvation methods.

As an illustration of the inner workings of an implicit solvent model, we here give a short description of the recently reformulated multipole moment expansion (MPE) model (Sinstein et al. 2017). Based on the linearity of the Poisson equation and a stepwise transition in $\varepsilon(\mathbf{r})$, the problem is split into an inner part with $\varepsilon_{\text{in}} = 1$ and an outer part where the permittivity takes on the solvent's macroscopic bulk value (ε_{b}).

$$\Phi(\mathbf{r}) = \begin{cases} \Phi_{\text{int}}(\mathbf{r}) = \Phi_H(\mathbf{r}) + \Phi_R(\mathbf{r}), & \text{inside,} \\ \Phi_{\text{ext}}(\mathbf{r}) = \varepsilon_{\text{b}}^{-1}\Phi_H(\mathbf{r}) + \Phi_Q(\mathbf{r}), & \text{outside.} \end{cases} \tag{8}$$

Here, $\Phi_R(\mathbf{r})$ and $\Phi_Q(\mathbf{r})$ denote the potential inside and outside of the solvation cavity due to the polarization of the solvent. Both the internal and the external potential are regularized with $\Phi_H(\mathbf{r})$, which is the electrostatic potential of the solute in the absence of the solvent. The latter is, due to the necessity to solve the Schrödinger equation, generally known in any quantum chemistry code anyway. The solution of Eq. (7) then reduces to determining only the polarization potentials $\Phi_{R,Q}$ which are generally smoother and, most importantly, free of Coulomb singularities from the solute's nuclei. Additionally, the specific regularization given here was shown to completely eliminate errors stemming from charges outside of the solvation cavity common to other approaches (Sinstein et al. 2017). In the MPE, the three potentials $\Phi_{H,R,Q}(\mathbf{r})$ are first expanded in multicentered multipole moments up to a certain order. The unknown coefficients of $\Phi_R(\mathbf{r})$ and $\Phi_Q(\mathbf{r})$ are then determined via boundary conditions on the full potential and its derivative at a number of points on the cavity surface. This procedure yields an approximation to the electrostatic contribution to the solvation free energy with only the shape of the cavity – or in the case of a density iso-surface the iso-value – as a parameter. Additional parameters can be introduced with corrections for non-electrostatic contributions, such as van der Waals interactions or entropic contributions of the cavity (Scherlis et al. 2006; Andreussi et al. 2012).

This means that this model contains a number of free parameters (two or three at a minimum (Sinstein et al. 2017)) which need to be determined, e.g., by fitting (Andreussi et al. 2012; Ringe et al. 2016; Sinstein et al. 2017) to a sufficiently large database of experimental solvation free energies (Shivakumar et al. 2010; Marenich et al. 2012). While such a procedure works very well for molecules in solution, it leads to a problem for the use of implicit solvation methods in (photo-)electrochemistry due to the lack of appropriate reference data. Transferability of solvation parameters gained from molecular solvation free energies to extended surfaces is still a topic of ongoing research. Furthermore, it was shown for the example of the MPE model (Sinstein et al. 2017) that also for small molecules, the choice of functional (e.g., generalized gradient or hybrid functional) exerts some influence over the optimal choice of solvation parameters. This was found to be partially due to the different extents of the electron density given by different functionals but also due to the implicit solvent model canceling some DFT errors. Examining cross-correlations between parameter sets and functionals, a most general set was found for the HSE06 functional yielding mean absolute errors (MAE) smaller than 50 meV for neutral solutes. The same set of parameters still gives a reasonable MAE of $\approx$85 meV for cationic solutes but fails completely for anions ($\approx$500 meV). This behavior is in fact not restricted to the MPE model alone but common among implicit solvation models and especially pronounced in those relying on a density-based solvation cavity (Dupont et al. 2013). Recent work showed that this failure can be ameliorated by employing fixed soft spheres around the solute's atoms (Fisicaro et al. 2017). Nevertheless, also with the added charge-independent degrees of freedom awarded to the cavity generation by using soft spheres, the authors found that no single parameter set can satisfactorily describe both neutrals and cations on one hand and anions on the other.

The reason for this ultimately lies in the simplicity of both the employed electrostatic and non-electrostatic model. Virtually all continuum models show for identical cavities a symmetry of the electrostatic response with respect to positive or negative charges. Additionally, in the simple non-electrostatic model employed here, the response is completely independent of solute charge, as it only depends on the properties of the cavity. Especially for water, such a behavior does not reflect the physical realities (Latimer et al. 1993; Mobley et al. 2008) as sketched in Fig. 3 and thus has to be compensated for in implicit solvation models either through separate sets of parameters for cations, neutrals, and anions or through explicit treatment of such asymmetries (Bardhan and Knepley 2014).

We will return to the problem of parametrization again at the end of this section. First, though, it is important to note here that, while potentially yielding a good description of solvation effects in pure polar media, Eq. (7) cannot, by construction, describe electrolytes. In the form given in Eq. (7), the only charge carriers accounted for are those of the solute, while the solvent is assumed to be free of charges. An obvious fix for this is to simply augment the right-hand side with an additional charge density term $\rho_{\text{ion}}(\mathbf{r}; \Phi(\mathbf{r}))$ representing ions in solution.

$$\nabla \varepsilon(\mathbf{r}) \nabla \Phi(\mathbf{r}) = \rho_{\text{sol}}(\mathbf{r}) + \rho_{\text{ion}}(\mathbf{r}; \Phi(\mathbf{r})). \qquad (9)$$
Fig. 3 Sketch of the first solvation shell of cations (left) and anions (right). Differently charged solutes lead to very different solvent responses, which are usually not captured by implicit solvation models. In the two solvation motifs shown, each water molecule has very different freedoms to move, which would be reflected in the local dielectric permittivity

Yet, as ions are mobile in solution, they will arrange themselves according to the electrostatic potential. Assuming that they are in equilibrium with both the solvent and the solute, the ion densities can be represented through their Boltzmann distribution function

$$\rho_{\text{ion}}(\mathbf{r}; \Phi(\mathbf{r})) = c_+ e^{-\beta z_+ \Phi(\mathbf{r})} - c_- e^{\beta z_- \Phi(\mathbf{r})}, \tag{10}$$

where $c_{\pm}$ and $z_{\pm}$ denote concentration and charge of cations and anions, respectively, and $\beta = 1/k_B T$ is the inverse temperature. This modification of the Poisson equation is then known as Poisson-Boltzmann theory (Chapman 1913; Gouy 1917) and has found many applications in literature (Honig and Nicholls 1995; Fang and Liu 2010; Boda et al. 2002; Bohinc et al. 2012).

Yet, it is important to note that even within the above-discussed assumptions (homogeneity, isotropy, linear response, and equilibrium), Eq. (10) constitutes an approximation to the actual equilibrium ion density, as it neglects non-electrostatic interactions between solutes and ions. For example, ions described by Eq. (10) could get arbitrarily close to the solute and each other, which is clearly unphysical. Modern implementations of Poisson-Boltzmann theory (Andreussi et al. 2012; Fang et al. 2013; Mathew et al. 2014; Ringe et al. 2016) thus introduce additional constraints on the ionic densities to correct for finite sizes of the ions (Borukhov et al. 1997) – including their own solvation shells – and the fact that due to their solvation shells ions can only approach solutes up to a finite distance forming a so-called Stern layer (Stern 1924). While these modifications restore the correct physical behavior of the ion densities, they come at the price of introducing additional free parameters, which again need to be determined beforehand.

For example, in the case of the Stern layer and size-modified Poisson-Boltzmann equation (Ringe et al. 2016), there are in total four parameters defining the solute-solvent interactions (cf. also the MPE model described above) and three ionic parameters. While these could, given a large enough training set, be determined by

fitting them all together at the same time, such an approach would bear the dangers of over-fitting, i.e., a severe lack of transferability between solvents and salts. The common approach thus is to first fit non-ionic parameters for calculations in ion-free solvents (Andreussi et al. 2012; Ringe et al. 2016; Sinstein et al. 2017) and then keep these fixed while determining ionic parameters. While for ion-free solvents there are a number of databases collecting experimental solvation free energies (Shivakumar et al. 2010; Marenich et al. 2012), reference data is decidedly more sparse for the ionic case, especially considering that there needs to be data available at different ionic concentrations as well. A solvent model should reproduce properties not just at a single ion concentration but over a certain range to be useful for electrochemical simulations. Recent approaches to determining ionic parameters have thus focused on Setchenow coefficients (Setchenow 1892), which describe the linear decrease or increase of the solvation free energy with salt concentration. This relationship tends to hold for salt concentrations up to 2–5M with corresponding coefficients being available for a wide range of molecular solutes (Long and McDevit 1952; Pérez-Tejeda et al. 1987; Keeley et al. 1988; Waxman et al. 2015). Studies based on the SMPB model showed (Ringe et al. 2017) not only that implicit models can reproduce Setchenow coefficients and thus relative solvation free energies very well but also that ionic parameters correlate with the properties of the salt. Specifically, they demonstrated that the SMPB ionic parameters can be scaled from well-characterized systems such as NaCl electrolytes with the respective experimentally accessible hydration number of the salt (Marcus 1985). The reason for this is that the hydration numbers reflect the size of the ion with its solvation shell and thus yield a measure of the sizes of the respective Stern layers (Kiriukhin and Collins 2002).

Finally, the local solvation environment around molecules, to which all these parametrizations have been fitted, does not necessarily reflect the properties of the EDL on a surface. The extent to which existing parameter sets can be transferred to (photo-)electrochemical systems is thus not entirely clear. Future work in this direction is clearly needed.

In summary, with explicit and implicit solvation methods, there are two distinct approaches to including solvent effects in (photo-)electrochemical simulations. While explicit methods have potentially greater accuracy due to their trivial inclusion of non-mean-field effects such as hydrogen bonding, they are, for sufficiently realistic system sizes and density functionals, rather expensive. Implicit approaches are, on the other hand, relatively cheap and not limited to certain (high) ion concentrations but need to be carefully parametrized to the specific system. Thus, the optimal choice here likely depends on the question to be answered.

3   Reactive Sites

In Eq. 4 and the following, reactive sites and molecules adsorbed at them were simply denoted by an asterisk (*). All structural information of the reaction is included in this one character. This notation, while undeniably convenient and

useful (Reuter et al. 2017), somewhat obfuscates the complexity of the underlying situation. It is well known, that the exact choice of model for the reactive site critically influences (Neurock 2003) the binding energies of reaction intermediates and thus any assessment of the reactivity of a catalyst material. Even pure metallic single crystal surfaces already present more than one possible binding site, including different facets. In more complex but chemically also more promising systems such as alloys, oxides, phosphides, or carbides, the situation is generally even less clear-cut. Under reaction conditions, these tend to diverge from the clean, idealized surfaces often employed in CHE studies. In part, this was already recognized in the early days of photo- and electrochemical surface simulations where, as a first step, surface oxygenation and hydrogenation was determined using the CHE (Valdes et al. 2008). For example, the most stable surface termination for a rutile TiO_2 (110) facet was shown to be potential-dependent. Each of the distinct terminations in turn shows a different reactivity in terms of free energy profiles calculated with the CHE.

While the effect of the potential on the specific surface termination can thus already be included in CHE-based simulations, they still rely on idealized periodic surface models, which do not necessarily reflect reality in a catalytic device. The most common setup for TiO_2-based catalysis, for example, is in the form of nano-particles, decorated with smaller co-catalyst particles (cf. Sect. 3.2) or molecules (Graetzel 2012). The catalyst nano-particles thereby are rife with non-periodicities, such as defects, kinks, terraces, and edges, all of which could significantly influence the catalyst reactivity (Diebold 2003). The importance of these deviations from the pristine periodic structure thereby stems from the occurrence of under-coordinated metal atoms which can exhibit exceptionally strong binding to certain adsorbates (Diebold et al. 1998; Gong et al. 2006) and can also attract localized charge carriers in the form of polarons (cf. Fig. 4) (Setvin et al. 2014). These can, if localized near a suitable reactive site, drive reduction and oxidation reactions (Deskins et al. 2010; Zawadzki et al. 2012). In the following, we discuss some of the complexities of incorporating surface non-periodicities into simulations of photo-electrochemical systems.

3.1 Defects

Computer simulations of extended systems, both quantum mechanical and classical in nature, rely heavily on the method of periodic boundary conditions (PBCs). There, a given simulation supercell, or in the case of surfaces a slab geometry, is essentially repeated infinitely. Short-range interactions are treated directly, while long-range ones, such as the Coulomb interaction, are summed up in reciprocal space. This approach, together with an appropriate sampling of the Brillouin zone in reciprocal space, has proven to yield highly accurate results in the different fields of computational materials science. PBCs have been extensively applied in DFT calculations to straightforwardly simulate the electronic band structure and density of states of metals, semiconductors, and insulators.
Fig. 4 Illustration of polaron localization near a neutral oxygen vacancy in TiO$_2$, with titanium atoms shown in silver and oxygen depicted in red. Removal of one oxygen from the surface leaves behind two electrons, which localize near the overall positive defect. Polarons, here represented as blue iso-surfaces (iso-value = 0.02e) of the absolute value of the spin density, are shown in their most stable configuration (Deskins et al. 2011; Shibuya et al. 2012; Kick et al. 2019)

Unfortunately, defects, terraces, kinks, and edges present a problem for the PBC approach as they are by nature non-periodic. In order to avoid unrealistic defect densities and defect interactions, one has to increase the size of the simulated supercell or slab, greatly increasing the computational cost as well. This increase in cost, as well as the problem of sampling every likely defect geometry, is at the heart of why early simulations of photo-electrochemical reactions concentrated almost exclusively on idealized model surfaces.

The problems of simulating non-periodicities are exacerbated even further in nonmetallic catalysts such as carbides (Choyke et al. 2013), phosphides (Demers and van de Walle 2012), and oxides (Janotti et al. 2010; Janotti and Van de Walle 2011; Berger et al. 2015), due to the appearance of charged defects. In order to avoid divergence of the reciprocal space sum over infinitely repeated simulation cells, only overall charge neutral systems can be considered with PBCs. As explicit counter-charges, e.g., in the form of oppositely charged defects, cannot easily be incorporated in the small systems accessible to electronic structure calculations, the standard approach is to introduce a space charge in the form of a uniform charge background. While this can yield excellent results for similar systems of equal charge, it introduces an a priori unknown offset of the potential and thus the total energy, complicating the comparison of simulation supercells.

There are essentially two distinct approaches to correcting for both defect-defect interactions and offsets of the potential. One is to carefully extrapolate to the dilute limit from supercells of increasing sizes (Lany and Zunger 2009; Komsa and

Pasquarello 2013; Freysoldt et al. 2014). In the case of neutral defects, this is a straightforward process, yet Makov and Payne (1995) showed that in the case of charged simulation supercells, such a procedure would converge infeasibly slowly – roughly with $1/\varepsilon L$, where ε is the dielectric permittivity of the medium and L the linear dimension of the supercell. In order to compensate for the long-range interaction of charges, they put forward a correction scheme based on a model point charge embedded in a dielectric continuum. This highly simplified approach, though, can lead to a significant overcompensation due to a neglect of screening through short-range reorganization (Van de Walle and Neugebauer 2004). This led to the emergence of a number of other corrections which yield significantly improved energetics for the comparison of charged supercells (Lany and Zunger 2009; Janotti et al. 2010; Komsa and Pasquarello 2013; Freysoldt et al. 2014).

The other approach to simulating charged defects in solids is to forego the use of PBCs altogether and use a non-periodic cluster model instead. In analogy to the explicit and implicit solvation approaches discussed in Sect. 2, only a small cluster is treated fully quantum mechanically, while the influence of the environment is simulated on a lower, classical, level of theory (Sherwood et al. 2003). In this quantum mechanical/molecular mechanical (QM/MM) approach, also the environment is described by a cluster, albeit vastly larger compared to the QM region. Thus, arbitrary charge states of the active QM region can be calculated without spurious offsets, yet at the cost of additional approximations regarding the interaction of QM and MM zones. In the case of ionic materials, the MM environment also needs to account for the long-range contributions to the overall potential of the simulation cell to yield the correct level alignment with respect to the fully periodic system (Berger et al. 2014), which can be achieved by fitting to periodic reference calculations (Sokol et al. 2004). On top of that, through the close contact of QM and MM atoms in a solid, spurious delocalization of charges from the QM into the MM region needs to be counteracted, e.g., by applying suitable nonlocal effective core potentials to MM atoms within range of the QM basis functions. A schematic of a solid-state QM/MM setup for TiO_2 is depicted in Fig. 5.

In addition to a more straightforward treatment of charged systems, QM/MM embedding can lead to much more favorable computational costs compared to fully periodic calculations, allowing, for example, the treatment of catalytically relevant surfaces on the level of hybrid or double hybrid functionals (Berger et al. 2014), or even with coupled cluster theory (Kubas et al. 2016), the current "gold standard" of computational chemistry. In addition to yielding accurate binding energies of various catalytically relevant adsorbates (Berger et al. 2014; Kubas et al. 2016), embedded calculations have demonstrated realistic descriptions of defect levels and formation energies in TiO_2 at different charge states (Berger et al. 2015). In the dilute limit, surface oxygen vacancies were shown to be stable across a wide range of conditions with regard to doping (i.e., Fermi level position) and oxygen chemical potential. For photo-electrochemical applications, most interesting was the finding that, analogously to the bulk (Janotti et al. 2010), positively charged defects are most stable for a diverse set of conditions.
Fig. 5 Schematic of a QM/MM setup for TiO_2. The QM region contains 17 titanium (brown) and 34 oxygen atoms (red). The QM region is embedded into a roughly 3000 atom strong TiO_2 cluster (silver) represented by a polarizable force field. Seventy-seven positively charged MM Ti-centers near the QM region are replaced by effective core potentials (blue spheres). The long-range electrostatic Madelung potential of a periodic calculation is simulated with the help of fitted charges (pink spheres) far away from the QM region. For illustration purposes only the back half ($y > 0$) of the MM setup is shown here

Finally, the embedding approach is not constrained to only point-defects but can also be applied to the study of terraces, corners, and edges. By definition, these present a large number of under-coordinated sites and are thus prime candidates in the search for the reactive site. Indeed, a recent study by Bhattacharya and co-workers (Bhattacharya et al. 2017) showed that corner sites can also act as charge carrier traps. Moreover, employing ab initio thermodynamics (Reuter 2016), the authors showed that changes to the coordination of edge atoms drastically alter the relative stability of surface sites in terms of oxidation or reduction.

In summary, material non-periodicities such as point-defects, terraces, corners, and edges have been shown to exhibit properties that could significantly influence both photo- and electrocatalytic properties of materials. Through the increased availability of computational methods in recent years, defects have wandered more and more into the spotlight of theoretical research. With that they could open the door to controlled, purposeful nano-engineering of defects for more targeted and efficient catalysts.

3.2 Co-catalysts

Ever since the early days of photo-catalysis, semiconducting photocatalysts have been decorated with co-catalyst particles, which have been found to aid in the overall photoreaction (Graetzel 2012). The co-catalyst particle is thereby assumed to fulfill one of three possible functions (Yang et al. 2013; Ran et al. 2014):

- *Exciton dissociation*: Co-catalysts can aid in the separation of charge carriers, created through a photoexcitation. One of the carriers can then get trapped in the co-catalyst and partake in a reduction or oxidation reaction (cf. Sect. 3.1).
- *Lowering barriers*: Providing additional reaction sites, co-catalysts can contribute to the lowering of activation free energies or overpotentials, e.g., through different binding energies compared to the catalyst surface.
- *Catalyst stabilization*: Many semiconductors with bandgaps in the visible range –which are the best candidates for photocatalyst materials – are susceptible to oxidation through photo-generated electron holes. By trapping these holes and applying them in oxidation reactions, co-catalysts can help to protect the semiconductor surface from self-decomposing.

For all of these functions, the electronic energy levels in the co-catalyst have to be more or less closely aligned to either valence or conduction band of the semiconductor, in order to allow the exchange of charge carriers between them. A typically found sketch of the mechanisms involved is given in Fig. 6. In the last decade, a great variety of co-catalysts have been put forward (Yang et al. 2013; Ran et al. 2014), from metal clusters of varying degree of earth abundance (Ikeda et al. 2001; Tsuji et al. 2004; Wang and Hammer 2006; Zong et al. 2008; Rayalu et al. 2013; Li et al. 2014a; Ran et al. 2017), to bioinspired molecules (Hou et al. 2011; Bi et al. 2015). Thereby, co-catalysts offer a great deal of flexibility in their design, as, for example, shown by Su et al. (2014), who engineered and calculated bimetallic co-catalyst particles which facilitate the photocatalytic hydrogen evolution while suppressing the back reaction.

Computational treatment of co-catalysts on surfaces faces, to a certain degree, similar problems as other deviations from pristine surfaces. Most co-catalyst particles are sized at least a few tens of nano-meters, making them impossible to simulate in full with ab initio methods. Even small clusters in the non-scalable size regime can easily demand very large surface unit cells to avoid spurious interaction between the co-catalysts (Hou et al. 2011). Additionally, combined theoretical and experimental studies have found metal particles on oxides to aggregate near vacancies (Wahlström et al. 2003; Matthey et al. 2007), which facilitate the growth of nano-clusters. Furthermore, Gong et al. (2008) found Au clusters to predominantly aggregate near terraces, while Pt clusters form near steps of the support material. Indeed, non-periodicities in the substrate material were found to be essential for pinning clusters, thus preventing the otherwise highly mobile particles simply forming larger and possible less reactive clusters through sintering.

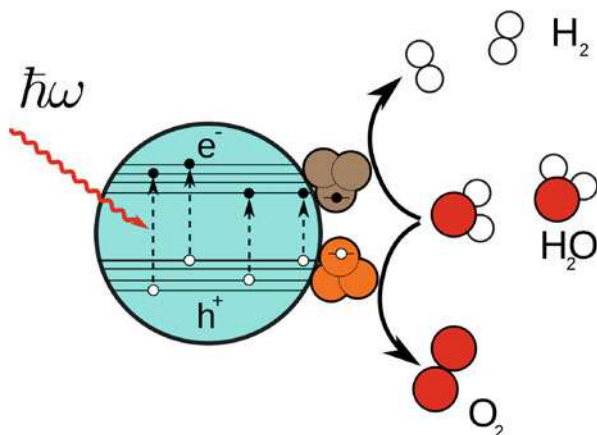
After determining the geometries, the next step in a computational study of the reactivity of co-catalysts is the analysis of their electronic structure, such as level alignment (Hou et al. 2011; Su et al. 2014) and local charge depletion or aggregation (Wang and Hammer 2006). This is necessary to test if charge carriers can localize in the co-catalyst without any additional barriers (cf. Fig. 6) and thus if they can contribute to the system's reactivity. Then, the effect of the co-catalyst, e.g., on the overall overpotential of a photochemical can be estimated via the CHE approach, with the same limitations discussed in Sect. 1.2. The necessary


Fig. 6 Schematic of photocatalytic water splitting depicting both oxygen and hydrogen evolution co-catalysts. Holes and electrons are depicted as empty and full circles, respectively, with energy levels drawn as horizontal lines. Note the alignment of energy levels of the co-catalysts with respect to the photo-absorbing particle. Transitions from support to co-catalyst should be downhill in energy to allow charge migration, yet not too much to avoid losing energy necessary for the photocatalytic reaction

potential to drive a reaction on the co-catalyst can then be compared to the energy available in the photo-generated charge carrier localized at a respective facet of the substrate. Oberhofer and Reuter (2013) employed a modified version of the CHE which explicitly accounts for the hole localization energy, to screen gold clusters in the non-scalable size regime up to Au_{55} for their suitability as a co-catalyst with different facets. Due to the high computational costs involved in calculating large Au clusters on a hybrid level of theory, this study neglected support effects beyond that of the localized electron hole. Nevertheless, a number of promising candidates were found to yield clear improvements over pristine TiO_2 surfaces.

In summary, due to the large system sizes necessary to accurately describe supported co-catalyst particles, few studies have attempted to do so to date. Yet, with both increases in computing power and improvements to methodology, considering, e.g., solid-state embedding, theory can further contribute to the important field of co-catalyzed photocatalysis in the future.

4   Kinetic Barriers

Finally, the overall energetic cost of a catalytic reaction is not solely due to the thermodynamic cost of formation of the reaction intermediates but also may include free energy barriers between the intermediates. While these do not influence the equilibrium constant of the reaction, i.e., the ratio of reactants to products in equilibrium, they do determine the dynamical properties of the reaction such as the turnover

frequency. High turnover frequencies are of paramount importance for the viability of a catalyst in industrial applications. Therefore, for a complete assessment of the suitability of a given material as a catalyst, kinetic free energy barriers should be considered as well. Indeed, in theoretical studies of, e.g., heterogeneous catalysis, it has been a long-standing practice to calculate barriers which can then be employed in the study of even very complex reaction networks to predict turnover frequencies (Reuter 2016).

Photo-electrochemical simulations have unfortunately lagged behind here for a number of reasons, all more or less related to problems of time- and length-scales. The defining property of electrochemical reaction steps is the transfer of protons and electrons, charged species which incur significant response from the dielectric environment (cf. Sect. 2). In determining a barrier between reaction intermediates, one thus – in principle – has to sample all environment degrees of freedom for each value of the reaction coordinate. This means that, in contrast to heterogeneous catalysis, entropic contributions to the free energy barrier cannot necessarily be approximated as a simple harmonic contribution.

Nevertheless, a lot of insight can already be gained from the potential energy surfaces (PES) of elementary reaction steps. Mattioli et al. (2013), for example, employed the nudged elastic band method (NEB) to determine energy barriers between intermediates of the water oxidation reaction on small cobalt-oxide clusters to elucidate likely reaction sites and mechanisms. A similar approach was followed by Li et al. (2014b) to elucidate the reaction mechanism of $NaBH_4$ hydrolysis. Both approaches draw their intermediate configurations from equilibrium ab initio molecular dynamics (AIMD) simulations, yet the actual reactions are described on a static level with NEB to determine the minimum energy pathways, disregarding entropic contributions. They are therefore well suited to give a first mechanistic insight into the respective reactions and could serve as a starting point for more general free energy calculations, for example, using collective coordinates constructed from the minimum PES data (Li et al. 2014b).

Fully dynamical simulations of (photo-)electrochemical reactions, on the other hand, suffer from a number of problems on their own. Next, to the high computational costs associated with AIMD simulations of realistically sized systems, accounting for the electrochemical driving force on metal electrodes is far from straightforward. Real electrochemical reactions, though, occur at a constant potential with an infinite reservoir of electrons, with respect to the catalyst surface. Yet, due to the limited size of the simulation supercells, the reservoir of electrons in the simulation is limited as well. This means that all simulations are naturally performed at a constant total charge which corresponds to a change of interfacial charge density and thus potential across the reaction pathway (Skúlason et al. 2007; Wasileski and Janik 2008). Earlier studies by Rossmeisl and co-workers tried to estimate this finite size error by simply simulating the system in differently sized simulation cells and extrapolating to the infinitely extended surface (Rossmeisl et al. 2008; Skúlason et al. 2010). This approach is, however, fairly impractical, especially for more complex reactions. Recently, Chan and Nørskov (2015) therefore presented a much simpler approach, which requires only a single barrier calculation which is

later augmented by a simple correction factor due to the change in work function Φ and surface charge q between initial (I) and transition state (TS).

$$\Delta E_{corr} = \frac{1}{2}(q_{TS} - q_I)(\Phi_{TS} - \Phi_I) \qquad (11)$$

Charges $q_{I,TS}$ can thereby be determined with any sufficiently accurate estimation scheme, such as Bader or Hirshfeld charges, directly from the DFT calculation of the respective states. Note that this simple correction does not only apply to barriers but is equally valid for free energy differences between reaction intermediates. Initially demonstrated for static calculations of only energy barriers (Chan and Nørskov 2016; Shi et al. 2016), this approach can straightforwardly be applied to dynamical simulations as well, as demonstrated by Cheng et al. (2015, 2017). They employed ab initio meta-dynamics to determine reaction barriers for the CO reduction on a Cu(100) surface to shed light on possible reaction pathways at different applied potentials. Only by including the calculation of free energy barriers into the picture, they were able to fully explain experimental observations. They accurately predicted the competition between electrochemical reactions and surface sites and the selectivity toward different products at different potentials (Cheng et al. 2017).

The situation is somewhat different in photo-electrocatalysis on semiconductors, where localized polaronic charge carriers (electrons or holes) are known to drive the reaction (Cowan and Durrant 2013). There, rather than a good description of constant potentials, it is important to accurately model polarons and their interaction with the reactants. In again a mixed dynamical/statistical approach, Selloni and co-workers (Chen et al. 2013) determined the PES of the first – and most likely rate determining – step of water oxidation on TiO_2 anatase (101) driven by an explicit electron hole. Specifically, they determined the energy profiles of the proton transfer step in two different electronic configurations with the hole on the surface (initial state) and in the water (final state), respectively. As a reaction coordinate, they thereby employed a geometric criterion of the proton being attached to the surface adsorbed water or the water molecule in the first solvation shell. Their results highlight a problem with this kind of approach, as a neglect of the solvent reorganization leads to the electron hole staying at the surface adsorbed water even if the proton is moved all the way toward the designated final step.

Finally, a fully dynamic scheme was presented by Stecher et al. (2016) who utilized a solid-state embedding scheme (cf. Sect. 3.1) to allow for an explicit and finite size effect free treatment of the electron hole. They also employed a Marcus theory-inspired reaction coordinate based on the energy gap between initial and final state (Mones et al. 2009; Mones and Csányi 2012), which explicitly includes solvent reorganization effects and thus minimizes hysteresis. Using umbrella sampling, they determined the free energy barrier for the first reaction step of water oxidation TiO_2 rutile (110) to be roughly 0.2eV, comparable to estimates by Selloni and co-workers.

All of the above studies share a common theme in that they show non-negligible barriers much larger than the thermal energy k_BT at room temperature. Thus, without additional driving forces, the respective (photo-)electrochemical

reactions are predicted to show very small turnover frequencies. For the modeling scientist, this means that although first estimates based solely on thermodynamic considerations and the CHE can be very useful in identifying rate limiting steps and reaction intermediates, only a full picture including free energy barriers can accurately determine the suitability of a given catalyst.

5   Summary

Since its inception, the computational hydrogen electrode method has undeniably led to great insights in electrochemistry and photo-electrochemistry. Together with the scaling relations, which at least for metals allow extrapolation of a material's suitability as a catalyst from just a few binding energies, the CHE enabled the large-scale screening of likely catalyst materials. On the other hand, in terms of practical implementation, most studies utilizing the CHE employed a number of simplifications for reasons of computational efficiency. Yet, with the development of more complex catalysts, especially those with the ability to go beyond the performance limits dictated by the scaling relations, the need for augmentations to the classical CHE approach became more apparent. In this chapter, we discussed three possible improvements over standard CHE calculations.

In the original applications of the CHE, solvation effects were assumed to play a minor role for the energetics of neutral reaction intermediates and thus omitted. Additionally, leaving out sampling of all solvent degrees of freedom led to huge boosts in efficiency. Yet, considering, e.g., photo-electrochemical reactions on semiconductors going through charged or even just differently polar intermediates, omission of solvation effects can lead to erroneous results. In Sect. 2, we discuss methodological approaches to including solvation effects on the level of the electronic structure calculations, both with their own sets of advantages and disadvantages. Explicit solvation in the form of ab initio molecular dynamics is generally very expensive and, regarding, e.g., electrolyte concentrations, limited with respect to system size. Matters can be improved by employing the approximation of immobile, icelike water on the catalyst surface, which, though, is not applicable to all systems. The upshot here is the correct description of non-mean-field effects, such as potential-dependent solvent reorientations and hydrogen bonding. Implicit solvation models, on the other hand, offer much improved computational efficiency, with, using appropriate models, less constraints on system sizes and ion concentrations. This comes at the cost of non-mean-field interactions being described only as effective corrections. On top of that, most implicit solvent models to date are parametrized to fit test sets of small- to medium-sized molecules and therefore do not necessarily reproduce the solid-liquid interface. Finally, depending on the specific reaction of interest, the solvation environment is not always in equilibrium with the reaction center due to differing timescales of reaction and solvent reorganization. In this case, effective solvent models, which essentially assume an equilibrium response of the solvent to the solute, cannot be straightforwardly applied. Given the wealth of available methods, there is no single

optimal choice as each has its own set of drawbacks and advantages, and each specific approach needs to be tailored to the specific problem at hand.

Another fundamental question, treated in Sect. 3, is that of the exact nature of the reactive site. On simple monometallic catalysts, one can often expect reasonably pristine surfaces, where the exact choice of reactive site is less influential on, e.g., the adsorption energetics. This picture is radically altered on more complex materials such as oxides or nitrides, where terraces, steps, and – under reaction conditions – defects are abound. These can have tremendous influences on (photo-)electrochemical reactions by trapping charge carriers or pinning co-catalyst particles. Being deviations from perfect pristine periodic structures, they are hard to tackle in computer simulations, as they necessitate very large simulation cells to avoid spurious interactions between periodic images. In the case of charged defects, this situation is exacerbated through the interaction between the charge carrier and the neutralizing background charge, which has to be accounted for through extrapolation from increasing system sizes. Another approach shown to effectively tackle the problem of charged defects is the solid-state embedding or QM/MM technique. There, only a finite region of interest is treated quantum mechanically, while the environment is represented as an equally finite cluster of polarizable MM atoms. Adding a correction for the long-range Madelung potential, this approach effectively yields a description of non-periodicities in the QM region in the infinitely dilute limit. Thereby, it can also be used with higher-level methods such as (double-)hybrid DFT or even highly accurate coupled cluster methods. These advantages come at the cost of possibly increased inaccuracies due to an imperfect description of the electronic structure at the QM/MM interface, which means that convergence with cluster size and shape needs to be carefully tested.

A further fundamental aspect in the search for the reactive site, generally overlooked in most applications of the CHE method so far, is the role of co-catalysts. These can range from bioinspired molecules to metal or metal-oxide clusters and, as laid out in Sect. 3.2, can have a number of effects in a photocatalyst. Depending on the exact role, they need to be energetically aligned with conduction or valence band edges of the photo-absorbing support material. Most computational studies so far therefore concentrated on structures and electronic alignment of co-catalyst and support. Using a reformulation of the CHE methodology, a first study of Au clusters in the non-scalable size regime showed several promising co-catalysts for water oxidation on varying TiO_2 facets. Nevertheless, theoretical research into the nature and effects of co-catalysts in photocatalysis is still in its early stages and much needs to be done in the future.

The third and final kind of improvement over standard CHE-based (photo-) electrochemical studies discussed in Sect. 4 is the study of kinetic barriers. CHE calculations in the past focused on the optimization of catalysts with respect to the thermodynamic overpotential and free energy barriers along the reaction pathway were generally neglected. On metal catalysts this was mainly due to the problems associated with simulating reactions at constant potential – instead of constant charge – during proton transfer steps. Several correction schemes have been proposed, and in the last few years a number of studies estimating potential energy

barriers have been published. On semiconductors, on the other hand, photocatalytic reactions are known to be driven by surface localized charge carriers, which again leads to the aforementioned problems due to the neutralizing charge background. As in the case of surface defects, these problems can be tackled by charge correction or QM/MM embedding schemes.

The other drawback in simulating barriers at the solid-liquid interface is again the question of sampling the solvent response. Recent simulations on both metals and semiconductor catalysts showed that the reorganization of the solvent exerts a great influence on the reaction barriers. Given this fact, even the choice of reaction coordinate is not entirely straightforward, as simple geometric coordinates fail to account for solvent response and thus can lead to very large hysteresis effects. More complex reaction coordinates, based on a Marcus theory model of charge transport, demonstrably yielded a much improved description of the reaction free energy profile.

In summary, the last few years have seen tremendous methodological advances for the simulation of electro- or photo-electrochemical surface reactions. First insights into their microscopic details were made possible by the theoretical framework of the CHE, together with a number of additional approximations used in its practical implementation. Yet, like pieces of a jigsaw puzzle, more and more details have been included into the picture, such that a fully quantitative simulation of (photo-)electrochemistry from first principles is now within reach. Depending on the system and the questions to be answered, some of these simulations will be based on the framework of the CHE, one of its generalizations, or completely different, fully dynamical ways to align computations to experiments. This chapter focused on a number of methodological improvements to the way the CHE has been applied in the past. These allowed us, as a community, to graduate from model simulations on idealized surfaces in vacuum to defected catalysts in realistic environments, bringing us closer and closer to experimental realities.

Hierarchical Materials Modeling: Mechanical Performance

Multiscale Modeling of Structural Materials: Chemistry and Mechanical Performance

62

Francisco J. Martin-Martinez and Markus J. Buehler

Contents

Abstract

Through an overview of selected chapters in this section we navigate the state of the art of different materials with crucial structural features at different length scales. It includes a discussion on hierarchical biomaterials like silk, new aerogels with enhanced thermal and mechanical properties, and infrastructure materials like wood, concrete, and asphalt, whose complex composition leads to specific modeling challenges. The wide range of materials discussed cover different length scales from nano- to macro-, and different macroscopic properties, e.g., from soft to stiff. All of them together represent a selection of case studies that exemplifies the importance of multiscale modeling and simulation in combination with experimental techniques to design and develop more sustainable materials for structural applications in the future.

1   Introduction

Developing more resilient, lighter and stronger structural materials to support our current technologies and infrastructure, while coping with sustainable principles and supporting a circular economy requires a deep fundamental understanding of materials chemistry and hierarchical structure that can be only be achieved by a synergistic combination of theory and experiment. The approaches to model and simulate the key structural features of any material strongly depend on the scale at which the key underlying mechanisms take place, as well as on the desired performance needed for the intended application. Thus, a proper description of materials structure and properties through the implementation of this multiscale modeling paradigm provides a predictive framework to design and develop new materials under sustainable principles. It also allows a deeper understanding of the fundamental mechanisms that enable the performance of the materials, to provide the foundations for developing novel materials, recycling them, or identifying new applications. In this section, as we navigate from silk, to aerogels, asphalt, wood, and concrete case studies, we describe key structural features of these materials along different length scales, and how their complex composition (e.g., asphalt, concrete), their hierarchical structure (silk, lignocellulosic biomass, bamboo), or their specific nanoscale molecular arrangement (e.g., aerogels) is important to generate those unique properties that define the applications of these materials.

2   Methods

Different modeling and simulation methods are applied to describe the properties of the materials at different time and length scales. Starting from quantum mechanics methods based on density functional theory (DFT) to molecular dynamics (MD) simulations, coarse grained (CG) modeling, and finite elements methods (FEM), we review how to connect the study of chemical reactivity and mechanical properties from the nanoscale to the mesoscale and up to the continuum scale. DFT is applied to study small molecular systems like lignin fragments, and periodic systems varying from polymers to cement crystals, and how these can be tackled by these fundamental calculations. In some cases, conceptual DFT descriptors are also employed to explain qualitatively and quantitatively the reactivity of any molecular system. Polarizability, dipolar momentum, and also molecular electrostatic potential (MEP) are discussed specially in chapters related to wood. At a larger scale, MD simulations with reactive force fields, as well as nonreactive, are discussed in most of the systems in the section, i.e., silk, aerogels, concrete, asphalt, wood. For example, in the particular case of silica aerogels, MD modeling and simulations are shown to play a crucial role in advancing the fundamental understanding of structure-property-function relationships. Both fully atomistic and CG MD modeling methods are discussed to characterize aerogels' structural, mechanical, and thermal properties. In the case of silk, dissipative particle dynamics (DPD) are

presented as a remarkable approach to develop a mesoscale framework to study the self-assembly of silk proteins into polymer networks and to model the effect of shear flow and terminals on the processed silk fiber. In bulk materials, observations from MD, discrete element method (DEM), and FEM modeling at multiple length scales are used to further understand the role of cohesive-frictional interactions in the strength development of cementitious materials. This is also closely connected to the methods used for studying bamboo, and asphalt, as presented in the related chapters of the section. All these methods together provide a sample of the diversity, applicability, and impact of multiscale modeling when describing the properties of any structural material.

3   Case Studies

Starting from materials whose properties and structural applications are closer to the nanoscale (e.g., silk) to those bulk-like materials whose applications are more closely related to their use in a massive quantity (e.g., asphalt, wood, or concrete), a sequence of case studies helps us to extract common methodologies related to design, modeling, and simulation, in connection with experimental production and characterization.

Silk is a unique natural material whose mechanical properties have intrigued scientist and engineers for decades (Tarakanova and Buehler 2012). Its unique hierarchical structure underlies an outstanding performance in many different applications related to medicine, materials science, and engineering. In Nature, silkworms and spiders have developed glands to produce different types of silk for prey capture or as protective shells. Nowadays, there are available recombinant synthesis techniques and microscale processing approaches to produce silk with tailored properties. As discussed in ▸ Chap. 63, "Silk-Based Hierarchical Materials for High Mechanical Performance at the Interface of Modeling, Synthesis, and Characterization," by Tarakanova et al. a wide range of applications has been achieved by combining modeling, synthesis, and characterization.

Reaching larger scale applications, porous, lightweight, robust, and cost-effective silica aerogels (Sangha et al. 2011) have been developed from supercritical drying of wet gels. As described in ▸ Chap. 64, "Silica Aerogels: A Review of Molecular Dynamics Modelling and Characterization of the Structural, Thermal, and Mechanical Properties," by Yeo et al. this is made by introducing extreme porosity while, at the same time, maximizing their strength and toughness. Experimental and simulation studies on silica aerogels have led to commercialization in numerous engineering applications, like aerospace and civil engineering. In this direction, multiscale modeling techniques have helped the application of aerogels in Cherenkov radiators, integrated circuits, solar energy collection devices, and thermal insulation, as discussed in the chapter dedicated to aerogels.

At an intermediate scale between the applications of silk biomaterials and the large-scale applications of asphalt or concrete, wood is an intriguing material that displays also a hierarchical structure starting from the nanoscale to

achieve an outstanding mechanical performance at the macroscale. As a case study, the increasing interest in the use of bamboo is remarkable, as described in ▶ Chap. 65, "Toughening and Strengthening Mechanisms in Bamboo from Atoms to Fibers," by Askarinejad et al. Bamboo is a fast-growing, naturally occurring bio-composite material, whose use as an eco-friendly structural material has increased dramatically during the last decade. To get further understanding of bamboo structure and performance, numerical methods such as FEM have been applied. This has supported many experimental studies on bamboo, including measuring strength, Young's modulus of matrix and fiber, and analysis of microstructures and fiber distribution.

Despite the intrinsic mechanical performance of bamboo, wood's composition of cellulose, hemicellulose, and lignin makes it useful not only from the structural point of view but also as a source of new materials to be extracted from wood waste. In fact, lignocellulosic biomass is a key feedstock for the development of future sustainable technologies to produce carbon-based materials fuels and chemical, also known as biorefineries. Martin-Martinez et al. (▶ Chap. 66, "Multiscale Modeling of Lignocellulosic Biomass") provide an insight to the current state of the art in multiscale modeling of lignocellulosic biomass (especially lignin) (Sangha et al. 2011), as well as an overview of molecular simulations that have helped understanding lignocellulosic biomass structure.

The development of biorefineries does not diminish the importance to innovate for increasing the sustainability of some petroleum-based technologies. Asphalt is of special growing interest. Being the leftover of petroleum distillation, asphalt is a complex mixture of organic molecules that are difficult to characterize and hard to model. These challenges, together with the fact that asphalt have worked decently well for its intended application with a considerably low cost of production, have hampered the development of technologies devoted to nanoscale control of asphalt properties, as well as modeling and simulations platforms for asphalt. This has changed the last decade, and extensive modeling and characterization are being devoted to understand asphalt composition and structure-property relationships. As discussed by Mullins et al. (▶ Chap. 67, "Simple Asphaltene Thermodynamics, Oilfield Reservoir Evaluation, and Reservoir Fluid Geodynamics"), this research expands to oilfield reservoir evaluation, and reservoir fluid geodynamics. Reservoir crude oils are a complex mixture consisting of dissolved gases, liquids, and dissolved (or colloidally suspended) solids, the asphaltenes. It is essential to know the properties of the crude oil in order to know whether to produce the reservoir fluid. Several oilfield case studies are presented by Mullins et al. (▶ Chap. 67, "Simple Asphaltene Thermodynamics, Oilfield Reservoir Evaluation, and Reservoir Fluid Geodynamics") to elucidate major production concerns, showing that "*when new technology is combined with new science, great accomplishments come into view.*"

Closely connected to infrastructure applications, Palkovic and Büyüköztürk (▶ Chap. 68, "Multiscale Modeling of Cohesive-Frictional Strength Properties in Cementitious Materials") show how computational modeling has been a valuable tool for studying the role of molecular structure and chemical composition in

cementitious materials. Their chapter described the linking of molecular details to macroscale properties that define the durability of the material. This is done through a holistic multiscale approach that translates the essential physics across atomistic, mesoscale and microstructural length scales. Observations from MD, discrete element method (DEM), and FEM modeling at multiple length scales are combined to further understand the role of cohesive-frictional interactions in the strength development of cementitious materials (Palkovic et al. 2016).

All these case studies exemplify the potential of multiscale modeling to elucidate fundamental mechanisms and to enable the rational design and manufacture of structural materials, whose properties can be tailored along different scale for an uncountable number of applications.

4   Conclusions and Perspectives

Moving forward, many challenges are still ahead for the development of more sustainable structural materials. One of the challenges is related to computational modeling, both in terms of new algorithms and more advanced computers. The implementation of Machine Learning (ML) and Artificial Intelligence (AI) into the already established computational methodologies has the potential to contribute to significant speed up of simulations. In a similar manner, the use of cloud computing and the entrance of big corporations into cloud computing applied to materials science will dramatically increase the computational resources available for modeling and simulations. The other big challenge is related to the production of the materials. New advances in additive manufacturing, microfluidics, and synthetic biology will enable an unprecedented level of control over the structure of any materials.

In the case of silk-based materials, multiscale modeling methods are expected to overcome still-existing bottlenecks to accurately describe the mesoscale. This limitation also applies to most of the materials discussed in this section for which the gap between nanoscale mechanisms and macroscale behavior imposes a significant challenge. In the case of silica aerogels, the next big leap is expected in the manipulation of their molecular structures in a bottom-up production approach, leading to aerogels that are stronger, tougher, and more optically transparent, while retaining their low weight and thermal conductivity. In a different field, understanding lignin structure and composition, as well as its integration with cellulose and hemicellulose into the hierarchical structure of lignocellulosic biomass, is crucial for deciphering biosynthetic pathways, producing plants with more easily degradable cell walls, and developing better technologies for biomass depolymerization. At the molecular level, the structure of bamboo microfibrils composed by crystalline and amorphous cellulose in the matrix of lignin-carbohydrate complex (LCC) required also mesoscale modeling to fully decipher the connection between LCC structure and strength and stiffness. In the case of cementitious materials, improved parameterization of cohesive-frictional force fields with molecular models of C-S-H that implement different chemical compositions provides new possibilities

for future exploration. This is especially important for understanding the role of additives. Also, microstructure models to consider mortar and concrete are still a challenge. The development of more advanced computational methods will also likely contribute to a much broader understanding of many oil reservoir concerns over space and time.

great progress in characterizing and exploiting silk as a functional material for a myriad of applications. Silk can be characterized first as a sustainable material, as it is easily and controllably degradable. Moreover, it is biocompatible and biodegradable, finding many applications in medicine. Silk's properties stem from the unique hierarchy in its structure and the specific cooperativity of these different layers of hierarchy. In this chapter, we will give an overview of silk's unique hierarchical structure and resultant properties and provide case studies where a combination of modeling and experimental synthesis and characterization approaches have been used to study various features of silk-like materials. In particular, we will discuss three case studies: (1) responsive chimera silk-elastin-like materials, (2) silk scaffolds for silk-mineralization, and (3) functional applications of regenerated silk for inkjet printing, and filtration membrane synthesis.

1 Overview

Silk is an exceptional emerging material for diverse applications in medicine, materials science, and engineering. In the natural world, many organisms, including silkworms and spiders, have developed glands to produce different types of silk for applications ranging from prey capture to protective shells. In the lab, synthetic silks have emerged with the development of recombinant synthesis techniques and microscale processing approaches. In recent years, the combination of experimental work and computational investigation has made great progress in characterizing and exploiting silk as a functional material for a myriad of applications. Silk can be characterized first as a sustainable material, as it is easily and controllably degradable. Moreover, it is biocompatible and biodegradable, finding many applications in medicine. Silk's properties stem from the unique hierarchy in its structure and the specific cooperativity of these different layers of hierarchy. In this chapter, we will give an overview of silk's unique hierarchical structure and resultant properties and provide case studies where a combination of modeling and experimental synthesis and characterization approaches have been used to study various features of silk-like materials. In particular, we will discuss three case studies: (1) responsive chimera silk-elastin-like materials, (2) silk scaffolds for silk-mineralization, and (3) functional applications of regenerated silk for inkjet printing, and filtration membrane synthesis.

2 Silk Properties in Nature

In nature, silks are produced by a diverse family of organisms, including silkworms, spiders, honeybees, beetles, ants, and even mussels and certain crustaceans (Sutherland et al. 2010). The properties of silks produced by these different organisms vary based on primary protein sequence and the specific processing environment within the anatomy of the insect. There is tremendous variety even within a single family. Spiders, for example, may spin up to seven mechanically different silk

fibers, and this diversity stems from the unique biology of the spider's body that contains multiple glands that modulate chemical and mechanical processing of the silk (Guerette et al. 1996). The range of properties associated with silk results in a broad spectrum of functions.

Silk is chiefly known for its superb mechanical properties. It surpasses high energy-absorbing materials such as Kevlar and carbon fiber and provides an extremely lightweight alternative (Gosline et al. 1999; Agnarsson et al. 2010; Swanson et al. 2009; Vollrath 2010). A combination of high tensile strength on par with high-grade alloy steel (at 1–2 GPa (Swanson et al. 2009)) and extensibility (up to 60% strain at failure (Swanson et al. 2009)) results in superior toughness and exceeding performance when normalized by its density.

Tensile properties are dependent on humidity conditions as water plays the role of a plasticizer in silk (Plaza et al. 2006). In fact, when humidity is increased and water is absorbed through the silk fiber, the fiber undergoes significant shrinkage and reversibly converts the materials into a rubber (Liu et al. 2005; Shao and Vollrath 1999; Gosline et al. 1984). This process is termed supercontraction (Liu et al. 2005) and renders silk a great candidate material for lightweight actuators in micromachines, sensors, biomimetic muscles, and green energy applications.

Similar to other materials with a high content of amorphous structure, silk undergoes a glass transition, from a glassy to a rubbery state upon increasing temperature (Plaza et al. 2006). Tensile properties of silk fibers transition from stiff to compliant as temperature are increased. Unlike synthetic fibers, silk has higher toughness at lower temperature (Yang et al. 2005). In fact, its retention of exceptional material properties across a wide temperature range ($-66\,°C$ to $100\,°C$) suggests applications as a super-fiber in harsh environments (Yang et al. 2005). Silk's mechanical properties paired with its unique responsive features provide a unique platform for developing biomimetic fibers that are strong, lightweight, and elastic and undergo reversible phase change or supercontraction.

3 Structure of Spider Silk

Spider silk is a highly hierarchical system (Table 1, Fig. 1a) with evolutionarily "optimized" structure at many length scales (Tarakanova and Buehler 2012). We survey these optimization schemes to give a flavor of the many levels of control that are theoretically available to design multiscale morphology for nanoengineering applications.

Silk protein is composed of beta-sheet nanocrystals interspersed within less orderly amorphous domains, where the underlying molecular structure is dominated by weak hydrogen bonding. Beta sheet crystals contain a dense network of hydrogen bonds, while dispersed hydrogen bonds join together amorphous domains, composed of unordered structure, extendable helices, and beta turns (Tarakanova and Buehler 2012).

In fact, nanocrystal size, moderated by the reeling speed of the silk, is the primary factor controlling the strength and toughness of silk (Keten et al. 2010). Smaller crystals exhibit superior properties up to a critical size of 2–4 nm, as a result of the

Table 1 Summary of structural hierarchy of spider silk spanning length scales from angstroms to centimeters, along with key mechanisms that define its mechanical function. (Table modified from Tarakanova and Buehler 2012)

Structure	Hierarchical level	Description	Key mechanism and experimental validation
Amino acid sequence	Primary protein structure (Å)	The primary protein structure is composed of a sequence of amino acid residues which define the folding of the protein. In silk, poly-alanine regions are responsible for stiff beta-sheet rich domains while glycine rich regions define structures within amorphous domains	Basic building block that dictates secondary protein structure. Experimental techniques such as NMR and X-ray diffraction are limited in their atomic resolution for certain complex materials, so molecular dynamics permits a discrete qualification of primary structure through folding mechanisms. Recent work has been successful in sequencing silk genes and using this information to generate recombinant engineered versions of the natural protein (Ayoub et al. 2007). Such changes of amino acid sequence can be experimentally realized through genetic engineering or peptide synthesis (Rising et al. 2010)
Beta-sheet nanocrystals	Secondary protein structure (nm)	The secondary protein structure defines local conformations, such as alpha helices and beta turns. Beta sheet crystals in silk have a critical size of 2–4 nm, exhibiting exceptional strength due to cooperative hydrogen bonding between the sheets. This invokes a highly dissipative stick-slip mechanism that provides the basis for larger-scale toughness and strength	Nanoconfinement of crystal optimizes cooperative hydrogen bond activity, resulting in shear deformation shown to result in most regulated and least catastrophic failure, through the self-healing capacity of hydrogen bond formation. Critical crystal sizes were validated against experiment, based on AFM images (Du et al. 2006) and using diffraction techniques (Du et al. 2006)
Protein composite (beta-sheet crystals, beta turns, 3_1 helices)	Tertiary protein structure ($\sim$10–20 nm)	Tertiary protein structure is the three-dimensional arrangement of interacting secondary structures. The interplay between beta sheet crystals and amorphous domains ensures strength and extensibility of the composite structure	The cooperative interplay and load-balance of protein composite domains achieves a unique hyperelastic material behavior in silk. Molecular dynamics allows the tracking of nanoscale protein-unfolding regimes which are difficult to discern experimentally

<div align="right">(continued)</div>

Table 1 (continued)

Structure	Hierarchical level	Description	Key mechanism and experimental validation
Fibrils	(∼100 nm)	Fibrils exhibit dimensions of 50 ± 30 nm in diameter, where cohesive interaction of protein domains composing the fibril is responsible for homogeneous load distribution upon loading, ensuring optimal strength	Nanoconfinement of fibril size results in homogeneous deformation of all protein domains within the fibril, thereby achieving greatest strength and toughness through contributions of many protein components acting together. Optimal fibril size is validated, e.g., through SEM images (Du et al. 2006)
Fibers	(∼1–2 μm)	Bundles of fibrils into fibers enhance mechanical properties of silk threads	Bundling of several geometrically confined fibrils into a fiber enhances material properties through reaching homogeneous deformation state (flaw tolerance). Structure and geometry of fibers are visible through SEM imaging (Du et al. 2006)
Spider web	(>cm)	Spider web geometry and material composition determine the deformation mechanisms of the web, responsible for optimized prey capture mechanisms	Localization of failure due to a combined yielding-stiffening behavior at deformation. In situ experiments conducted on garden webs show a very similar result (Cranford et al. 2011; Swanson et al. 2007)

difference in deformation mechanism on the molecular scale (Keten et al. 2010). In small crystals, a stick-slip motion is observed as hydrogen bonds brake and reform. The self-healing ability of smaller crystals owing to the continuous reformation of hydrogen bonds protects the crystals from catastrophic failure as hydrogen bonds are shielded from exposure to water, which facilitates rupture. In contrast to soft and brittle larger crystals, which fail catastrophically by crack-flaw formation and consequent bending, smaller crystals exhibited shear deformation. The effective capacity of hydrogen bonds to resist failure by self-healing in conjunction with nanoconfinement at the crystal scale results in strong, stiff crystals of characteristic size, as verified experimentally (Du et al. 2006).

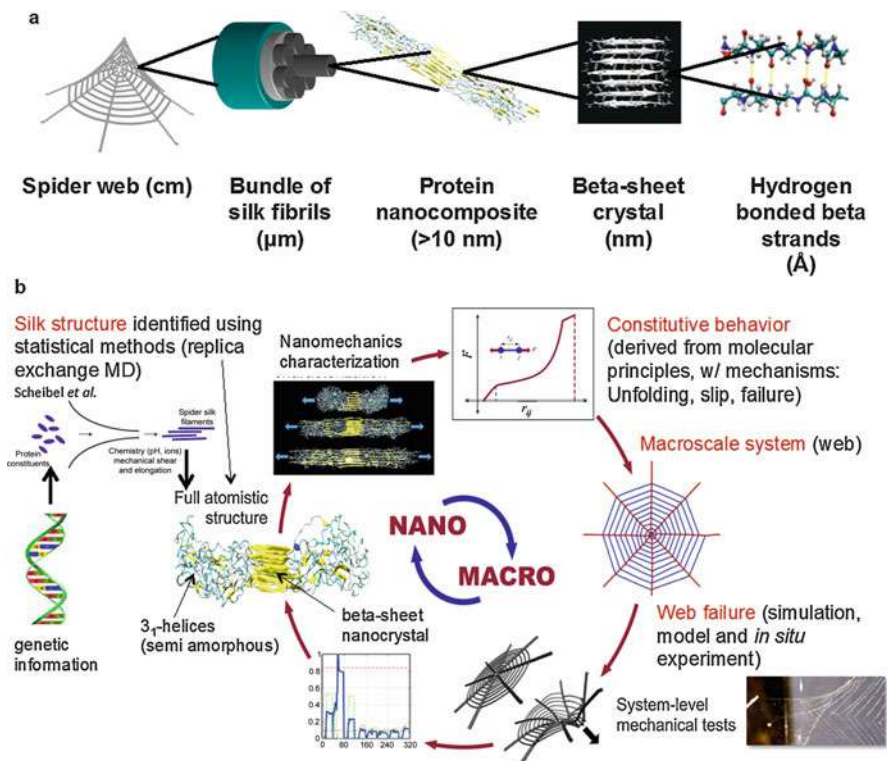
At the next scale, beta sheet crystals are embedded in the amorphous meshwork of less ordered domains. These molecular nanocomposites – crystals embedded in an amorphous matrix – create a network of fibrils that bundle into fibers, forming mature threads. At the fibril scale as well there exists a critical length at which the molecular properties of the protein network are most effectively scaled up to the micrometer scale (Giesa et al. 2011). The underlying mechanism responsible


Fig. 1 (**a**) Hierarchical structure of spider silk, from amino acids to an orb web architecture. (**b**) A summary of the multiscale approach used to link the molecular to the macroscale. Silk protein structure, based on the information about its genetic makeup, is identified and characterized to define a constitutive behavior. The molecularly derived behavior is incorporated into a macroscale web system. Web scale deformation experiments link macroscale deformation to molecular mechanisms (Rising et al. 2010). (Figure adapted with permission of Springer)

for this remarkable behavior is a homogeneity of stress distributions as fibril sizes approach the critical length scale. There is a delocalization of stress at the crack tip as fibrils reach the critical fibril size, resulting in completely homogeneous deformation where the entire sample reaches uniform stress concentrations before failure, improving performance (Giesa et al. 2011).

At the macroscale, for instance, in the orb web of a spider, mechanical robustness stems not from spider silk's high ultimate stress and strain, but rather from the nonlinear response of silk threads and their geometrical arrangement within the web (Cranford et al. 2012). When a silk fiber deforms, there is a softening at a yield point and substantial stiffening at large strain until failure. This is critical for localizing load-induced deformation in comparison to standard engineering materials having linear elastic or elastic-plastic deformation behavior. Under distributed loads, such as wind, the stiff behavior of silk threads under small deformation is essential in

maintaining the web's structural integrity (Cranford et al. 2012). This nano-to-macroparadigm, depicted in Fig. 1b, underlines the interplay between hierarchical structure and function through mechanical response.

The structure of silk suggests new design paradigms in applications ranging from high performance fibers and multifunctional materials produced from artificially spun silk or derived materials (Omenetto and Kaplan 2010; Rammensee et al. 2008) to novel material platforms for tissue engineering or even structural applications in the defense or aerospace industry (Buehler and Yung 2009; Vepari and Kaplan 2007).

4 Silk Processing

In addition to silk's unique hierarchical structure, the processing of silk within the duct of the insect is particularly important for the properties of the resultant material. Using dissipative particle dynamics (DPD) coarse-grained models, a mesoscale framework was developed to study the self-assembly of silk proteins into polymer networks and to model the effect of shear flow and terminals on the processed silk fiber (Fig. 2). Models captured the presence of several different "blocks": "A" (poly(alanine) containing, hydrophobic domains), "B" (GGX (X = R, L, Y, or Q) rich, hydrophilic domain), and "H" (hexahistidine fusion tag, introduced for facile purification). It was shown that intermediate ratios of hydrophobic to hydrophilic blocks (domains) of the amino acids in recombinant spider silk result in well-connected networks (Fig. 2a). Moreover, shear flow increased the connectivity of the network of polymers, which translated to outstanding silk fiber formation. Stronger polymer networks were formed when longer polymer chains were present (Fig. 2b). The addition of a charged N-terminal domain (NtSp) improved alignment of the polymer network with the shear flow (Fig. 2c). Moreover, the H(AB)12-NtSp showed greater tendency to aggregate compared with the H(AB)12 (Fig. 2d). Molecular dynamics studies also identified that the shear stress on aqueous silk in the spinning duct of an insect results in helix to beta sheet transitions, key to the strength and function of mature, spun silk fibers (Giesa et al. 2016).

5 Chimera Silk-Elastin-Like Materials

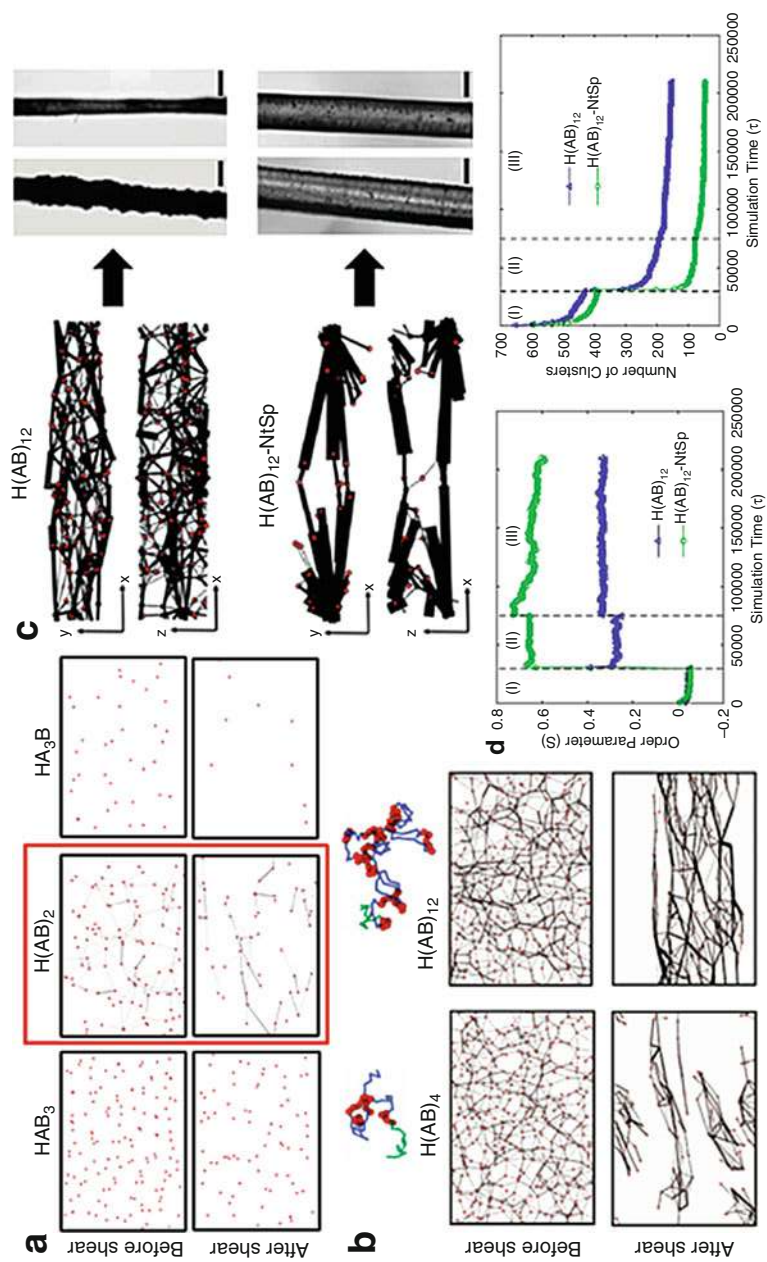
Silk is a good material candidate for developing responsive, tunable, nature-inspired biomaterials. In particular, silk-elastin-like protein polymers (SELPs) have gained attention as bio-inspired composites for their biocompatibility, degradability, and stimuli-responsive tunability (Huang et al. 2015, 2016; Wang et al. 2014; Xia et al. 2011, 2014). In the past two decades, genetically engineered SELPs were shown to be quite versatile. SELPs can be processed in a variety of ways: as nanoparticles, films, nanofibers, thin coatings, hydrogels, and scaffolds, providing a diverse set of structures for material applications (Xia et al. 2011, 2014; Hwang et al. 2009a; Ner et al. 2009; Qiu et al. 2009, 2010; Zhu et al. 2016). These applications include


Fig. 2 (continued)

biosensors, tissue engineering, targeted drug delivery release systems, gene therapy, and nanocarriers (Gustafson et al. 2009; Haider et al. 2005; Hwang et al. 2009b; Megeed et al. 2004; Anumolu et al. 2011), among others.

SELPs are composed of alternating silk-like and elastin-like domains, combining the properties of the component parts. Silk-like domains (GAGAGS) mimic the *Bombyx mori* silkworm silk sequence. They assemble into tightly packed structures and provide stability and mechanical resilience. Elastin-like pentapeptide domains (GXGVP) are representative of the elastin protein sequence and exhibit an inverse temperature transition, modulated by changing the second X residue of the pentapeptide. SELPs combine the mechanical strength, resilience, and self-assembling properties inherent to silk together with tunable mechanics derived from the elastin domains, which in physiological conditions exhibit reversible sensitivity to stimuli, including temperature, pH, ionic strength, electric fields, and enzymes (Huang et al. 2016). By combining silk-like and elastin-like domains, SELPs achieve useful mechanical properties and discrete tunability.

Molecular modeling is instructive for studying these materials to obtain a molecular perspective of their unique features. Together, molecular modeling and experiments based on recombinantly synthesized SELP sequences can be combined to probe the molecular scale temperature transition effects and single-molecule mechanical responses to thermal stimulation. In particular, a recent SELP model has identified thermally stimulated structural transitions at the single molecule scale and extracted temperature effects on molecular unfolding pathways and mechanical signatures.

Silk-elastin-like protein polymers, based on the amino acid sequence $[(GVGVP)_4(GYGVP)(GVGVP)_3(GAGAGS)]_{14}$, a 14-mer built from units composed of eight alternating silk-like and elastin-like blocks (Fig. 3a), can be synthesized using recombinant DNA technology. The turbidity profiles for 1 mg/ml of the SELP aqueous solution structures display a temperature transition range between 28 °C and 45 °C, henceforth referred to as T_t (Fig. 3b). To distinguish structures below and above transition range, two systems are considered: at 7 °C and 57 °C, well below and above T_t. Below the transition, at 7 °C, the SELP

Fig. 2 Modeling, production, and processing of silk block co-polymer systems. (**a**) Modeling at the mesoscale coarse grain shows that alternating hydrophobic/hydrophilic domains at a 1:1 ratio promote network formation over other block distributions. (**b**) As length is scaled, mature networks form through shear flow, which can be correlated to potential targets for physical processing and spinning. (**c**) Additional structures can be modeled using this framework, including the addition of the N-terminal domain (NtSp), which is predicted to promote better molecular alignment. Accompanying production and processing, model inputs lead to effective predictors for spinning, which was demonstrated from the core H(AB)12 system to the N-terminal variant. (**d**) Larger order parameter means better alignment of the polymer networks with the shear flow. In all cases shear results in greater alignment in the direction of shear, with H(AB)12-NtSp aligning the most. Moreover, the N-terminus caused clusters to consolidate, leading to unique behavior of continuous aggregation, even after shear. (Figures adapted from Lin et al. (2015), Rim et al. (2017), Jacobsen et al. (2017) with permission)

solution appears transparent. As the temperature is raised above the transition for the polymer, to 57 °C, the SELP solution becomes cloudy, indicative of the phase transition taking place (Fig. 3c).

To capture this behavior at the nanoscale, SELP molecular structures can be predicted using Replica Exchange Molecular Dynamics simulations (Fig. 3d). At the single-molecule scale, the transition occurs as a gradual structural change, manifested by a decreasing radius of gyration with temperature. Both the molecular models and the synthesized polypeptides exhibit up to 90% of unordered secondary structure with minimal beta sheet and helical content, consistent with the high content of elastin-like sequence within the polymer. A comparison between representative structures at 7–57 °C shows a structural collapse at high temperature as the structure bends across the principal axis and assumes a more compact conformation (Fig. 3d). Measurement of the end-to-end distance confirms a reduced molecular size (Fig. 3e).

A similar trend to a compacted structure with increasing temperature is observed in the synthesized polymer by measuring the hydrodynamic radius (R_h) of the SELP free chain. R_h at temperatures below and above T_t is determined by dynamic light scattering (DLS). DLS measurement at 7 °C and 57 °C displays a reduction in the R_h of the free chain from 3.8 ± 0.6 nm to 1.4 ± 0.2 nm (Fig. 3f). Such drastic reduction in molecular size suggests that the free chains of the SELP folds at high temperature above T_t, leading to a decrease of the overall size of the SELP free chains.

At the macroscale, a corresponding behavior is observed in silk-elastin hydrogels that are fabricated and tested at different temperatures. A shrinkage of 57% in the hydrogel radius is measured between 7 °C and 57 °C (Fig. 3g). The structural collapse observed at the single molecule scale is propagated up to the macroscale. It is proposed that the packing geometry of SELP molecules in the hydrogel ultimately propels the shrinking phenomenon, causing structural reorganization at the molecular scale.

Modeling at the molecular scale permits characterization of temperature-dependent mechanics at a fundamental scale. Unfolding pathways for representative SELP structures below and above T_t, at 7 °C and 57 °C, respectively, can be studied using steered molecular dynamics simulations. Drastically different deformation behavior can be observed at low and high temperatures (Fig. 4a–c). At 7 °C, the mechanical response includes a steep linear regime followed by a plateau, compared with a gentle linear slope at 57 °C. The unraveling of the high temperature structure reveals a smooth unfolding mechanism (Fig. 4d). The molecule unraveled from a single cluster, uniformly like a ball of yarn, corresponding to a linear deformation regime. By contrast, as the low temperature structure unfolds, a plateau in the force-displacement appears at a displacement of about 150 nm (Fig. 4e). A series of smaller clusters detaches from the main densely folded region as the molecule is pulled. These clusters act to dissipate the force, resisting the pulling, and produce the plateau that differentiates the low and high temperature deformation curves.

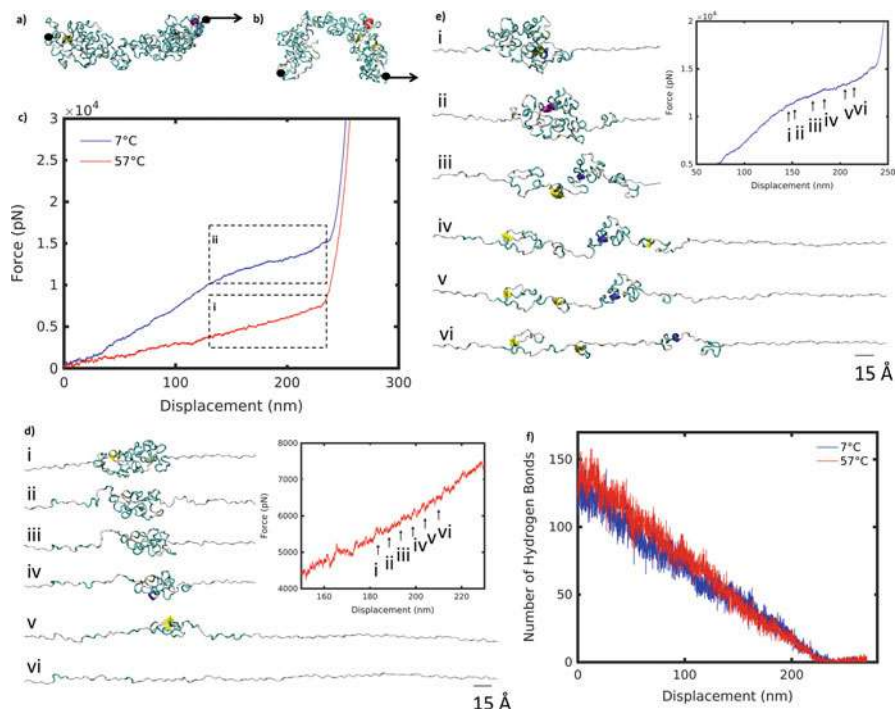
To understand the internal molecular landscape through the unfolding process, the intramolecular hydrogen bond evolution at high and low temperature is considered (7–57 °C, respectively). Notably, the number of hydrogen bonds that exists


Fig. 4 Steered molecular dynamics set-up for SELP at (**a**) 7 °C and (**b**) 57 °C. Molecule is fixed at the C-terminal end and pulled at the N-terminal end. (**c**) Force-displacement curves at 7 °C and 57 °C for pulling speed 50 m/s. Unfolding snapshots for region (i) (**d**) and (ii) (**e**), in plot of (**c**), respectively. Structures correspond to displacements indicated by numbered arrows on the force-displacement plot. Scale bar: 15 Å. (**f**) Hydrogen bond evolution at 7 °C and 57 °C during SMD pulling. (Reprinted with permission from Tarakanova et al. (2017a). Copyright 2017 American Chemical Society)

within the SELP molecule is higher by 15% at high temperature, and this difference persists through two thirds of the unfolding stages (Fig. 4f). This observation is counterintuitive, as higher temperature is expected to more easily disrupt weak intramolecular hydrogen bonds, and is attributed to the presence of elastin-like segments, which are known to assume a folded, hydrogen-bond-rich conformation above T_t. The enhanced hydrogen bonding at high temperature may help to maintain a large, uniform region in the unfolding pathway. Fewer hydrogen bonds at low temperature create a less compact structure that permits the separation of small, independent clusters as the molecule experiences a pulling force. In fact, it is predicted theoretically that the energy barrier to unfold the structure at 57 °C is greater than the energy barrier at 7 °C due to the presence of a dense network of hydrogen bonds at high temperature (Tarakanova et al. 2017b).

The inverse temperature transition observed in SELPs is a reversible, controllable process that motivates applications in drug delivery, shape changing materials,

and biomimetic devices. Using a combination of experimental, modeling, and theoretical methods, the structure and nanomechanics of SELPs can be identified at different temperatures. These findings offer a foundational perspective on the molecular scale mechanisms of temperature-induced phase transition in SELPs and suggest a novel approach to combine simulation and experiment to study materials for multifunctional biomimetic applications.

6   Silk as a Scaffold for Silk-Mineralization

Biomineralization is the process of producing minerals (inorganic material) by proteins (organic material) in living organisms. Through complex hierarchical assembly of composite organic-inorganic material, mineralized tissue becomes stiffer and harder (Launey et al. 2010). Understanding the organic-inorganic interface to fine-tune mineralization is the key to control biomaterial function in repair and regeneration of tissues, preventing the process in dynamic tissues as in the case of calcific aortic valve disease where calcium deposition prevents its function, or promoting mineralization in disease like osteoporosis where one loses bone density.

Recently, silk protein-based biomineralized composites have been studied as tissue scaffolds. An efficient scaffold material for tissue regeneration should be biocompatible with suitable stiffness, strength, and degradability (Chan and Leong 2008). Silk is a biocompatible protein approved by the US Food and Drug Administration to be used in some biomedical applications (Altman et al. 2003). Strength, stiffness, and degradability of the silk protein could be tuned by controlling its crystalline beta sheet content (Nova et al. 2010; Dinjaski et al. 2018). A suitable scaffold should mimic the structure and properties of natural extra cellular matrix (ECM) (Polo-Corrales et al. 2014). Moreover, ECM-cell bidirectional signaling interactions should be understood and controlled. It is known that ECM properties such as biochemistry, structure, and mechanics could change the interplay between genotype and phenotype (Benoit et al. 2008; Teixeira et al. 2004; Engler et al. 2006). Silk-hydroxyapatite (HA) (Bhumiratana et al. 2011) and silk-silica (Mieszawska et al. 2010a) scaffolds have been studied for bone tissue repair with human mesenchymal stem cells (hMSCs) to regenerate bone tissue. HA or silica promoting peptides are tethered onto silk protein and provide biochemical and signaling properties to enhance hMSCs differentiation in addition to adsorption of ions to form minerals (Marolt et al. 2006; Rockwood et al. 2011; Meinel et al. 2004).

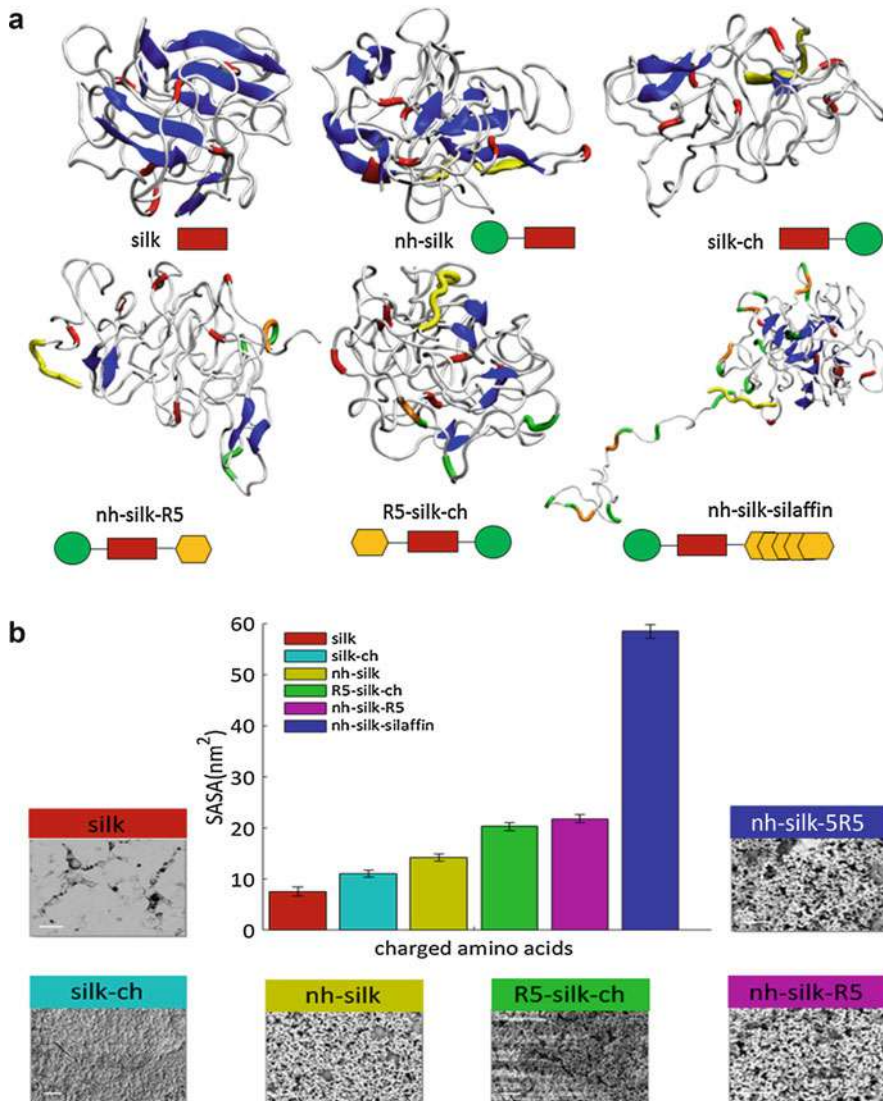
In modular protein engineered biomaterials, different peptide building blocks could be combined to generate different scaffolds with diverse properties (Sengupta and Heilshorn 2010). For instance, Fig. 5 shows an integrated modeling and experimental approach for design of silk-based biomaterials and control of silicification (Dinjaski et al. 2016). The study provides valuable insight into key factors to control mineralization such as protein folding, and exposure and alignment of charged units. Genetically engineered constructs were designed with three basic building blocks (Fig. 5a): Histidine tag (green box) is added to facilitate purification, the artificial


Fig. 5 (**a**) Folded protein structures: His tag (green box) is added to facilitate purification, the artificial silk polymer (red box) is added to form β-sheet structures, and R5 (orange box) is added to facilitate silicification. (**b**) Solvent accessible surface area for positively charged amino acids correlates with the amount of silicification in experiment. (Figures adapted from Dinjaski et al. (2016) with permission)

silk polymer (red box), derived from the consensus repeat of *N. clavipes* dragline silk protein, is added to form β-sheet structures, and R5 (yellow box) domain derived from *C. fusiformis silaffin* gene is added to facilitate silicification. "nh" and "ch" stand for N- and C-terminal fused histidine tags. Figure 5a shows sample snapshots of different protein structures in explicit water. β-sheets and random

coils are colored in blue and white, respectively. Histidine, arginine (in silk block), arginine (in R5 bonding peptide), and lysine are charged residues of the proteins which are color coded in yellow, red, orange, and green, respectively. Results (Fig. 5b) show that the presence of positively charged amino acids is essential for catalyzing biomineralization; however, the process is not amino acid specific. Moreover, the location of the charged biomineralization domain in the fusion protein could affect protein folding and consequently surface exposure of charged amino acids. In summary, solvent accessible surface area for positively charged amino acids correlates with the amount of silicification in experiment. Silk and silk-ch have the least accessibility of charged amino acids, resulting in no silicification and low silicification in experiments, respectively. On the other hand, nh-silk-R5 and nh-silk-silaffin (5R5) show the highest amount of mineralization. The study furthers the understanding of intracellular pathways involved in bone regeneration triggered by recombinant silk–silica chimeras (Martín-Moldes et al. 2018).

The same three building blocks were used to construct silk-silica interfaces. Then the intracellular pathways involved in the process of mineralization were assessed, when stem cells were grown on those silica substrates. Integrins are a family of cell adhesion receptors consisting of heterodimeric transmembrane proteins called α and β subunits. They interact with ECM proteins, triggering activation of intracellular pathways, such as mitogen-activated protein kinase (MAPK). Figure 6a–c shows modeling of the headpiece from integrin αVβ3 in solution, in contact with the silica surface and the silk-chimera protein surface. Similar models were prepared for α5β1 integrin. Figure 6d shows gene expression analyses of hMSCs seeded on 15mer-ch and R5-15mer-ch films with or without silicification and on tissue culture plastic (TCP) for one day. When compared to TCP, cells seeded on nonsilicified films showed no difference in expression of integrin subunits. Meanwhile, the cells seeded on the silicified films showed increased gene expression of α5, αV, and β3 integrin subunits, but not the β1 integrin subunit. The detected expressions suggest αVβ3 and α5β1 as two candidates for triggering the hMSCs. Based on the results of the MD simulations (Fig. 6e), only αVβ3 integrin is activated in contact with the silicified surfaces, since the head piece opens up with respect to the integrin in solution, while there is a decrease in head piece distance in contact with silk-chimera protein surface (nonsilicified surface) and for α5β1 integrin in contact with silica surface. The use of a blocking antibody against integrin αVβ3 in experiment validated results of the simulation, and the induction of the osteoblast differentiation genes was abolished. In summary, in the absence of the silica surface (nonsilicified) or in the presence of a neutralizing antibody against αVβ3 integrin, there was no activation of the MAPK cascades, thus no induction of bone extracellular matrix genes and therefore no differentiation.

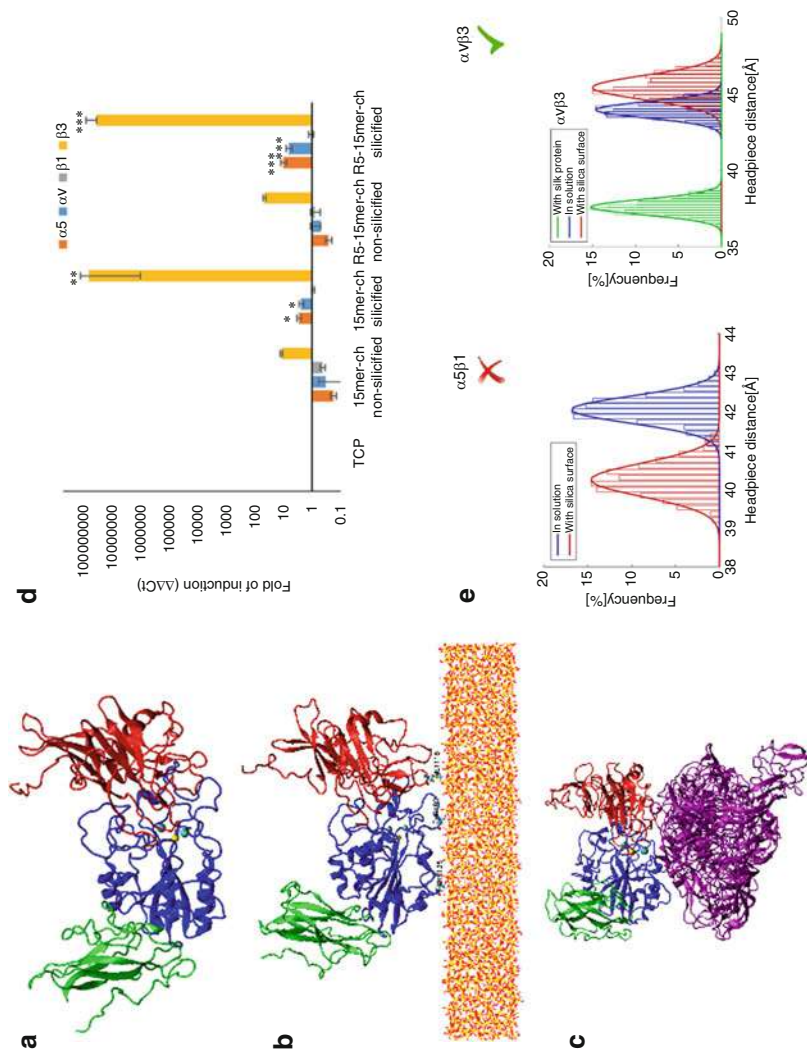
The main components of bones are apatite crystals, the inorganic mineral phase, collagen fibrils, and the organic protein phase, which control nucleation and growth of the minerals (Nudelman et al. 2010). By combing silk with different amount of minerals such as hydroxyapatite or silica, compressibility of the composite scaffold could be improved which is required to match properties of natural bone tissue at the site of implementation (Bhumiratana et al. 2011). Two types of silk proteins could be used to generate tissue scaffold: natural silkworm silk (Mieszawska


Fig. 6 (continued)

et al. 2010b; Sofia et al. 2001; Liu et al. 2008) and recombinant spider silk (Moisenovich et al. 2012). The integrated modeling/experimental approach could be used to develop modeling guided platform for rational design of recombinant silk proteins for biomaterials and material design needs. This strategy could forecast the influence of the addition of biomineralization domains to silk sequence on the fusion protein structure and folding, and identify the optimal processing parameters by understanding the mechanisms and identifying the key factors involved in the process.

7   Design and Synthesis of Silk-Based Filtration Membranes

Membranes for water treatment have progressively been developed to address global challenges of water pollution in recent years, because they are energy- and waste-efficient to remove molecular-level contaminants (Shannon et al. 2008; Vandezande et al. 2008; Werber et al. 2016). A variety of new materials and novel fabrication methods (e.g., block copolymer self-assembly (Wang et al. 2011; Krieg et al. 2011; Deng et al. 2013), template synthesis (Liang et al. 2010; Peng et al. 2007), track-etching technique (Eguizabal et al. 2014; Striemer et al. 2007), chemical vapor deposition (Mourhatch et al. 2010; Karan et al. 2012), and layer-by-layer assembly (Joseph et al. 2014) have been developed to improve the purification efficiency of these membranes. However, it remains challenging to prepare low-cost water purification membranes while retaining the mechanical strength and high purification performance.

Recently, a de novo strategy was used for making multilayer nanoporous membranes via integration of computational simulation and experiments. The core methodology is to use soft and hard nano-building blocks for constructing multilayer nanoporous structures (Ling et al. 2017). Here, the soft layer with a smaller pore size (several nanometers in diameter) serves as a size-selectivity layer to effectively filter out molecular level contaminants. The hard layer with a large pore size and high porosity allows water to pass through quickly and provides structural supports to the soft layer. In addition, the alternating arrangement of these two layers can further improve permeability of these membranes. Many natural systems, such as nacre, enamel, and bone, use proteins and calcium-based minerals to build their sophisticated multilayer architectures with enhanced physical

---

Fig. 6 (**a**, **b**, and **c**) Simulated head piece domain of the integrin in molecular dynamics (MD) modeling, in solution (water molecules are not shown), in contact with silica surface, and in contact with silk-chimera protein surface. (**d**) Gene expression of α5 (orange bars), αV (blue bars), β1 (gray bars), and β3 (yellow bars) subunits of human mesenchymal stem cells (hMSCs) seeded on tissue culture plastic (TPC). There are two candidates for triggering the differentiation of hMSCs to osteoblasts in contact with silicified surfaces: αVβ3 and α5β1. (**e**) Activation of integrins measured as opening of their head pieces in MD simulations shows αVβ3 integrin and not α5β1 integrin is activated in the presence of silica surface. (Figures adapted from Martín-Moldes et al. (2018) with permission)

properties (Chen et al. 2012). Moreover, both proteins and calcium-based minerals have showed promising application in water purification; thus, we selected these two components as starting building blocks.

In order to disclose the condition in which these two components can form the porous multilayer structures, simple coarse-grained models of the protein nanofibers (NFs) and calcium-based minerals nanoplates (NPs) were developed. Each NF and NP was modelled by an elastic network with carefully chosen elastic constants to reflect the materials' elastic properties and mass concentrated at the junction beads to reflect the material densities. Using the collection of these models, molecular dynamics (MD) simulations are performed to simulate their assembly during the deposition process in the water flow.

As examples, Fig. 7 shows the comparison of the assembly process of NFs and NPs. It is found that by tuning the material stiffness, density, and interfacial interactions between the subunits, the NFs and NPs can either assemble to form a multilayer structure with a clear boundary between two material phases or a
Fig. 7 Coarse-grained computational MD simulations for SNF/HAP assembly and deposition. Elastic network models are built on mechanics and geometry feature of the unit building blocks. HAP-SNF surface energy γ (J/m^2) is not certain as it depends on the molecular structure and the hierarchy structure of the interface in contact. This is important for forming the layered structure. For the SNF/HAP model, HAP and SNF particles were randomly distributed initially and then subjected to a gravity field that accounts for the drag force from the water flow. a, b, and c are the snapshots of the HAP/SNF assembly process during deposition with γ set as 0 (**a**), 0.217 (**b**), and 0.53 J/m^2 (**c**), respectively. (Figures adapted from Ling et al. (2017) with permission)

homogenous mixture of the two materials. It was discovered that for a wide range of mineral density (as the material density of protein is almost fixed) and stiffness of NFs and NPs, the interfacial energy (γ) between NF and NP plays the dominating role to govern the way of their assembly. It is revealed by computational simulations that for weak NF/NP interaction, NFs are assembled into a continuous network during the deposition process and their deposition rates are smaller than that of NP flakes that lack such self-assembly process. Turning to strong NF/NP interactions, NF and NP flakes are well mixed by self-assembly before being deposited on the substrate. Accordingly, a NF/NP interaction weaker than both NF/NF interaction and NP/NP interaction ($\gamma < 0.217$ J/m^2, which is the average surface energy measured for protein filament assembly) is necessary to form the layered structure (Fig. 7). This discovery is critical for selecting the suitable combination of materials to form the multilayer structure, because many protein/mineral combinations have strong interfacial interactions and are not suitable to be used as raw materials for forming the multilayer structure.

On the basis of simulation findings, different material combinations were scanned and silk nanofibril (SNF) and HAP were chosen to conduct experiments. It is noted that silks in nature do not have the propensity to form mineralized bulk materials as collagen and experimental evidence shows that SNF can easily exfoliate from the HAP surface to validate its weak interaction with HAP. Moreover, different from a liquid exfoliation (top-down) route, here, a new and more energetically efficient approach was developed to produce SNFs, that is, to control the self-assembly of silk protein. First, aqueous silk solution (0.1 wt%) was assembled into elongated SNFs with a height of ∼3 nm and a contour length up to 5 µm. Then, the SNFs were used as templates to grow HAP nanosheets through in situ biomineralization. These HAP nanocrystals, with a length of 100–300 nm and a width of 20–30 nm, showed a uniform needle-like morphology and were stabilized by the connected SNF networks. Thus, such HAP nanocrystals were finely dispersed and highly stable in the SNF solution, in contrast to the flower-like HAP aggregates in silk solution from control experiments. Finally, the SNF/HAP dispersion was assembled into water insoluble macroscopic membranes via vacuum filtration. Indeed, these SNF/HAP membranes show highly ordered multilayer structures with ∼200 nm thick alternated HAP and SNF layers (a 4-µm-thick membrane as an example, Fig. 8). The number of layers is tunable by changing the consumption of dispersion (Fig. 8). Typically, 1 mL of ∼0.2 wt% dispersion generates a double-layer membrane, with HAP settling in the bottom layer and the SNFs remaining on the top (Fig. 8a, b). Each layer has a similar thickness of approximately 500 nm. Both layers have uniform dispersions of SNFs and HAPs, respectively, but they show distinct pore sizes (Fig. 8c, d). The SNF layer has a narrow pore size distribution with a diameter of 8 ± 2 nm (could serve as size-selectivity layer). In contrast, the HAP layer has a larger pore size distribution with a diameter of 28 ± 5 nm (can enhance the water permeation). By progressively adding the volume of the SNF/HAP dispersion, the number of layers is increased and reaches tens of layers (Fig. 8f–g). The alternating arrangement of SNFs and HAPs layers can be observed in all cases.
Fig. 8 The well-organized multilayer structures of SNF/HAP membranes. (**a–d**) The double-layer structure of the SNF/HAP membranes was formed through vacuum filtration of 1 mL of dispersion. The picture (**a**) gives the schematic of double layer structures. The top layer is the SNF-rich layer with small pore sizes. The bottom layer is the HAP layer with larger pore sizes. False color is used in SEM images. (Figures adapted from Ling et al. (2017) with permission)

The core methodology used soft silk nanofibrils and hard mineral-building blocks for constructing multilayer nanoporous structures. Here, the soft layer (protein nanofibrils) with a smaller pore size (several nanometers in diameter) gives size-selectivity to effectively filter out molecular level contaminants. The hard layer (mineral nanoplates) with a large pore size and high porosity allows water to pass through quickly and provides structural support to the soft layer. In addition, the alternating arrangement of these two layers can further improve permeability of these membranes. Comparative computational simulations based on coarse-grained models of protein nanofibrils and mineral plates reveal that the multilayer structure can only form with weak interactions between nanofibrils and mineral plates. On the basis of this finding, a series of protein/mineral systems were scanned and silk nanofibrils (SNFs), and a hydroxyapatite (HAP) system was used to conduct the

experimental fabrication. In the manufacture process, a new biomimetic route was developed by using protein self-assembly and in situ biomineralization. The resultant SNF/HAP membranes indeed present the highly ordered nano-sized multilayer structures. Profiting from these well-organized hierarchical multilayer nanoporous structures, the resultant membranes not only show ultrafast water penetration (over five times greater than other reported ultrathin membranes with similar thickness), but also exhibit universal and high efficiency to remove and even reuse (in some cases) heavy metal ions, dyes, proteins, and nanoparticles. A multilayer membrane, on the basis of the simulation findings, may be formed by using different materials. Natural protein-based (e.g., amyloid, collagen fibril) and engineered peptides and protein-based (e.g., silk-, silk-elastin-, silaffin-, apatite-binding) fibrils and their corresponding biomineral plates (e.g., calcification, silicification) are also suitable for building multilayer nanoporous structures. Therefore, a biomimetic process for membrane synthesis could lead to large-scale production of multilayer membrane materials with a broad-spectrum (and possibility to design for a specific spectrum) and efficiency for water purification, useful in waste-water treatment, biomedicine, food industry, and life science applications.

8 Inkjet Printing of Regenerated Silk

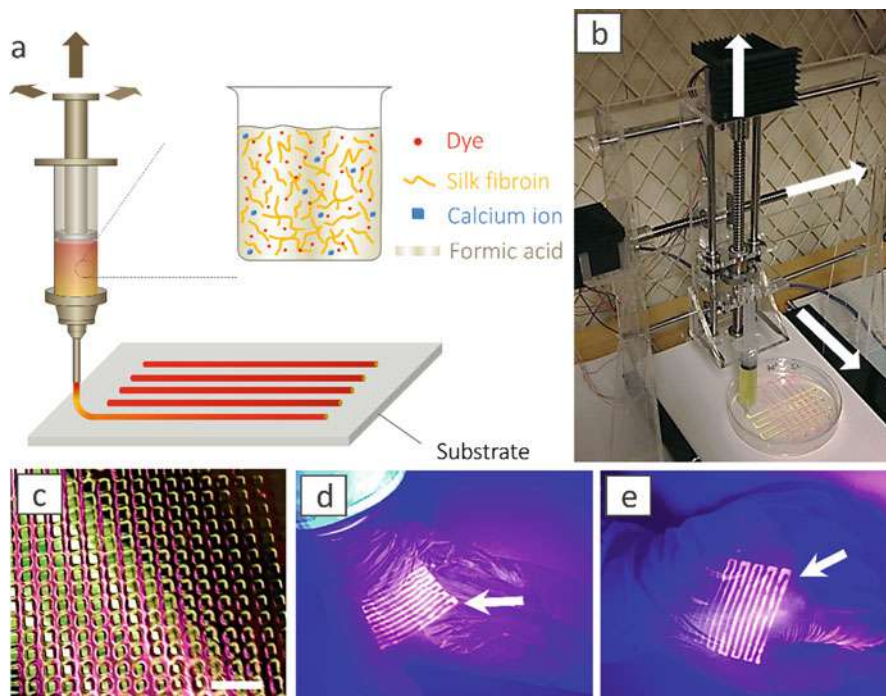
Recently, pure silk fibroin (SF) derived from *Bombyx mori* cocoons has been used as ink for direct printing (Ling et al. 2016). Figure 9 illustrates the general process of the inkjet 3D-printing of the silk membrane as an optical strain gauge. The florescent silk solution was prepared and contained the materials in a syringe right before printing. The concentrations of silk and ions were tested to make sure the viscoelastic property of the material is appropriate so it can be printed without clogging at the front tip of the syringe needle and also keeps a relatively stable form on the substrate surface after printing. Specifically, the degummed silk fiber was dissolved in $CaCl_2$/formic acid (FA) solvent (Zhang et al. 2015) with the concentration of SF ink reaching 30 wt% without any aggregation or gelling (Fig. 9a). The syringe is mounted to an in-home-build 3D printer that can move in all the directions and works by controlling the squeezing speed of the syringe during printing (Fig. 9b). All movements of the printer are digitally controlled by stepper motors and a computer numerical control board. Using such printing facility, different florescent patterns can be printed that are made of silk materials, such as a rectangular network with different florescent colors in two different orthogonal directions and parallel bands (Fig. 9c). Patterns were printed on different kinds of deformable substrates including polypropylene film, rubber, and PDMS because of the high viscoelasticity of silk solution. After rapid curing owing to quick evaporation of FA (about 10 min), the printed silk pattern can get deformed together with the substrate, even for a common rubber glove after wearing (Fig. 9d) and getting stressed in full tension (Fig. 9e).


Fig. 9 3D printing of silk. (**a**) Schematic illustration of the 3D printing process. A fluorescent silk/Ca2+/FA ink is printed onto a substrate. (**b**) Photograph of home-made 3D printing device. (**c**) Photograph of printed silk pattern on polypropylene film. The scale bar is 1 cm. (**d**, **e**) The photograph of printed silk pattern on gloves with palm open (**d**) and clenched fist (**e**). The florescent silk pattern can get deformed with the deformation of gloves. (Figures adapted from Ling et al. (2016) with permission)

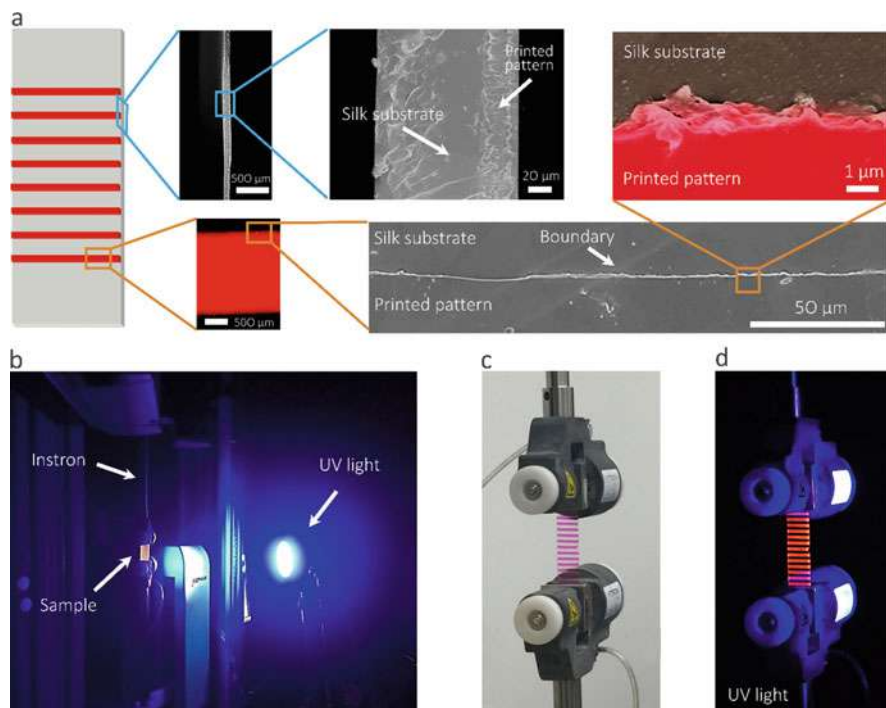
By using this printing technique, a new method was developed and a set of membrane materials based on silk could be used as accurate optical strain gauges. It is noted that the pure silk fibroin (SF) derived from *Bombyx mori* cocoons is biocompatible and biodegradable due to the absence of toxicity and immunogenicity (Omenetto and Kaplan 2010), making them ideal candidates for in situ and implantable strain measurements (Qin et al. 2015). By using inkjet 3D-printing, silk membrane materials could be accurately printed with a structure according to a specific design. This study shows that the materials are extremely flexible, allowing them to conform to the irregular curved surfaces and bond well to them. Figure 10a presents the schematics and microscopic structure of a prototype of the printed silk strain gauge. The silk membrane and the printed fluorescent silk pattern are bonded very well with each other as both fluorescence microscope and scanning electron microscope (SEM) images confirm a sharp boundary without any significant gap between the two materials in the scale spun from millimeter to micrometer. The


Fig. 10 Morphologic characterization and strain measurement setup of 3D-printing silk membrane. (**a**) The observation of the fluorescence microscope image (the second on bottom left) and SEM images (others except schematic diagram on the left) of 3D-printing silk membrane from cross-section and surface direction. The false color was used in top right SEM image to distinguish printed pattern and substrate. (**b**) The strain measurement setup. printed silk pattern has a uniform thickness of 30 μm. A camera was used to record the deformation of the silk strain gauges under a UV-light irradiation environment (Fig. 10b). The printed silk lines emit strong red light due to the UV excitation of rhodamine B dyes; however, the silk substrate stays transparent because of weak UV excitation of silk (Fig. 10c, d). Such a difference in the florescent features between the substrate and the printed silk pattern causes the great contrast between the two materials which significantly improves the image resolution for strain analysis as shown in Fig. 10d. Furthermore, two-dimensional discrete Fast Fourier Transform (2D-FFT) can be used to easily obtain the strain of the membrane in deformation. It is demonstrated that the material is more stretchable than most biological tissues and can accommodate strains of at least 250% in deformations that is more than two orders of magnitude larger than almost any commercially available strain gauges (Hammock et al. 2013).

9 Conclusions and Prospective

In this chapter, we have summarized the various unique properties that silk-based and silk-inspired materials embody and addressed the various structural features, dependent on hierarchical material organization and specific processing conditions, required to achieve these properties. Several case studies describe the wide range of applications of a combined modeling, synthesis, and characterization approach at different material scales. Starting from the single-molecule scale, silks can form a basis for developing chimera tunable materials (e.g., silk-elastin-like protein polymers) with phase transition capabilities for multifunctional biomimetic applications. Silks can be used in silk-silica composites to create biodegradable and biocompatible scaffolds as a modular protein engineered biomaterial for tissue repair and regeneration applications. Energy- and waste-efficient silk filtration membranes can be engineered to remove molecular-level contaminants. As an example, we describe multilayer tunable designs made of silk nanofibrils with hydroxyapatite domains. The final example provided here is a 3D-printed silk membrane for use as an optical strain gage. Through these examples, we hope to convey the broad applicability of silk-like systems and the relevance of combining modeling approaches together with experimental synthesis and characterization to design new systems and applications drawing from and building on fundamental properties of this unique material.

Moving forward, interesting challenges abound. The development of tunable silk-based materials has been realized for molecular systems and macroscale systems, as the case studies reviewed here attest. Recent work has made significant progress incorporating modelling and experiment for predictive material design and characterization. In the future, it will be important to consider advanced and hybrid multiscale modeling methods to overcome still-existing bottlenecks to accurate predictive modeling of silk-based systems at the mesoscale. A predictive computational model for dense, high-molecular weight tunable silk-based materials is still needed that can integrate molecularly driven responsive features into a larger system (e.g., a hydrogel). Further work on understanding the specific mechanisms of interfacial behavior is needed to design mineral-protein composites, expanding on the silk-silica materials described in this chapter. From the experimental point-of-view, recombinant protein design and synthesis is expensive and inefficient. Advancements in recombinant synthesis, and alternative biogenetics methods, including genetic engineering of silk worms to produce spider silk as one example, can greatly accelerate the rate of material production. 3D printing also has been a useful alternative biomanufacturing method; however, low resolution and optimization of processing methodology (e.g., solution viscosity, evaporation rate) can still be improved. Because 3D printing is a time-consuming process, development of novel self-assembly methods would help with manufacturing ease. Finally, we believe that novel optimization algorithms applied to silk-based systems can greatly expand the material design space, leading to new applications of silk-based systems.

imental and simulation studies, eventually led to the commercialization of silica aerogels in numerous engineering applications, especially for thermal insulation in aerospace and civil engineering applications. Rapid progress in the synthesis of silica aerogels provided great impetus for characterizing and optimizing their molecular structures. This created significant numerical challenges in understanding their structure-property-function relationship at several hierarchies of length scales. Both fully atomistic and coarse-grained molecular dynamics modeling and simulations have been extensively developed to tackle these challenges. We reviewed the development of new empirical molecular dynamics forcefields, novel methods of generating aerogels' percolated backbones, and compelling algorithms for characterizing their structural, mechanical, and thermal properties that have resulted in unprecedented insights into silica aerogels. These developments will drive the eventual creation of a comprehensive set of multiscale modeling platforms, which can minimize the trials and errors during experimental synthesis and even bring silica aerogels into the fold of the materials-by-design paradigm.

1   Introduction

Over the past few decades, the unending pursuit of lightweight, robust, and cost-effective engineering materials have driven the development of diverse classes of ultralight materials. Aerogels are one such class of materials that is developed by introducing extreme porosity to drastically minimize their overall weight while, at the same time, maximizing their strength and toughness. S. S. Kistler and his colleagues successfully synthesized the initial form of such gels through supercritical drying of wet gels of silica, alumina, nickel tartarate, stannic oxide, tungstic oxide, gelatin, agar, nitrocellulose, cellulose, and egg albumin (Kistler 1931, 1932; Aegerter et al. 2011), thus demonstrating the incredible flexibility in the choice of the materials that can be made into aerogels. Furthermore, supercritical drying at high temperatures and pressures prevents the development of strong interfacial tensions between the phase boundary of liquid and gas. High surface tensions, generated by processes such as liquid evaporation in air, would cause the gel to collapse and shrink, thus forming much denser gels known as xerogels which have only 50% porosities (Fricke and Emmerling 1992).

For silica aerogels in particular, multistep processes involving polymerization, gelation, hydrolysis, and condensation are used to form the tortuous porous backbone of the aerogels. To synthesize silica aerogels, hydrolysis and condensation of water or alcohols drive the polymerization of linear oligomers of particulate colloidal silica through crosslinking, with subsequent continuous sol-gel transition. Initially, chemical precursors of the silica gels were sodium metasilicate (Na_2SiO_3) (Kistler 1932), but these are now largely replaced by silicon alkoxides ($Si(OR)_4$, where R and OR denote alkyl and alkoxide groups, respectively. Some examples are tetramethyl orthosilicate (TMOS) and tetraethyl orthosilicate (TEOS), where the R groups are CH_3 and C_2H_5, respectively. Polycondensation of these monomers

results in the formation of coherent porous gels which are then dried supercritically to obtain the final aerogel structures. Numerous alkoxide-related precursors are used nowadays, including 3-(2-aminoethylamino) propyltrimethoxysilane (EDAS), polyethoxysilane (PEDS), and perfluoroalkysilane (PFAS) (Aegerter et al. 2011). Such chemical diversity is required to produce different desired structural, mechanical, chemical, electrical, and optical properties in the resulting gel, in combination with variations in solvents, catalysts, and ratios of water to precursors (Aegerter et al. 2011). Aerogels with an even wider range of properties have been developed by using materials other than silica, such as carbon, sodium silicate, zirconium dioxide, as well as many other organic and inorganic compounds. An exhaustive overview of all these variations in aerogels is beyond the scope of this review, but further details can be obtained from the Aerogel Handbook (Aegerter et al. 2011).

Silica aerogels are highly suitable for an exceptionally wide range of engineering applications due to their unique properties. One of the most notable applications of aerogels is in Cherenkov radiators as Cherenkov counters (Cantin et al. 1974; Kharzheev 2008) for identification of particles. They are also used in dielectrics for integrated circuits (ICs), passive solar energy collection devices (Hrubesh 1998), and for the trapping, storing, and releasing of an extensive range of nanoparticles and molecules (Burchell et al. 2006; Tabata et al. 2014). Another prominent area of application is in thermal insulation. Commercial production of modern porous aerogel on a large, cost effective manner is driving the proliferation in the usage of silica aerogels as thermal insulators (Herrmann et al. 1995; Jelle et al. 2011; Cotana et al. 2014). For greater flexibility in tailoring the optical and thermal properties for the required application when used as thermal fillers, silica aerogels are produced as granular beads (Ackerman et al. 2001; Neugebauer et al. 2014). Some of these applications include passive solar windows (Wittwer 1989), cryogenic thermal insulation systems on space launch vehicles (Fesmire 2006; Jones 2006), and thermal insulation of windows (Rubin and Lampert 1983; Duer and Svendsen 1998). The theoretical reduction in thermal conductance of a window using just 5 mm thick aerogel as insulation is found to be more than half (Rubin and Lampert 1983), which is significantly more insulating than even double-glass windows. Experimentally, aerogel glazing units outperformed conventional double glazing as they reduce heat loss by 58% (Gao et al. 2014). Furthermore, other than capturing space dust in NASA's Stardust mission, silica aerogels have also kept two recent Mars Rovers, Spirit and Opportunity, at relatively steady temperatures even though the temperature variation on the surface of Mars can be above 100 °C (Jones 2006).

2   Properties of Silica Aerogels

Due to the extremely porous nature of silica aerogels, their densities can approach values as low as 0.003 g/cm^3 (Tillotson and Hrubesh 1992). This remarkably low density is only three times higher than the density of air which is approximately 0.0012 g/cm^3. The nanoscale architecture of silica aerogels is usually characterized

as having fractal geometries due to self-similar patterns that appear geometrically similar even when viewed at different hierarchical length scales. The degree of fractality of a structure is usually represented by its fractal dimension which is a ratio that relates the change in detail to a given change in scale. Small-angle neutron scattering (SANS) and small-angle x-ray scattering (SAXS) spectroscopy and adsorption of molecules with different cross-sectional areas are some experimental methods for determining the fractal dimension of silica aerogels (Woignier et al. 1990). Silica aerogel's fractal dimensions vary with processing conditions, where it is approximately 1.8 under basic processing conditions (Vacher et al. 1988b) and about 2.2–2.4 in both acidic and neutral conditions (Vacher et al. 1988a).

Pure silica aerogels tend to be mechanically weak due to their low density and high porosity, but there is still a broad range of mechanical properties that can be obtained by varying their processing conditions and thereby controlling crucial factors like the porosity, density, defects, and network connectivity. The mechanical properties of silica aerogels are measured through a variety of methods. By measuring the velocity of sound through the gel, a density power-law scaling exponent of 3.17 ± 0.11 and 3.25 ± 0.15 is found for the elastic and shear modulus, respectively, in aerogels with densities between 0.05 and 2 g/cm^3 (Cross et al. 1989). A higher value of 3.7 is determined by Gronauer et al. (1986) using the same experimental method. The difference in the Young's moduli obtained using either the propagation of sound or uniaxial compression tests is also compared (Gross et al. 1988), and there is good agreement only at a medium density of 0.158 g/cm^3. Further uniaxial compression tests at ambient conditions found that the elastic moduli scaled with density differently depending on the processing conditions, with scaling constants of 3.37 ± 0.13 for acid catalyzed silica aerogels, 3.77 ± 0.21 for prehydrolyzed aerogels, and 2.85 ± 0.17 for base catalyzed aerogels (Lemay et al. 1990). This is for a density range between 0.1 and 0.6 g/cm^3. Three-point beam-bending and hydrostatic compression tests are also compared and it is found that reasonable agreement can be obtained with these two methods in the elastic regime (Scherer et al. 1995). Beam-bending tests are also performed to determine the variation of elastic moduli with density in the range of 0.1–0.4 g/cm^3 and a scaling exponent of 3.8 is determined (Woignier et al. 1987). Further bending tests revealed a scaling exponent of 3.7 ± 0.2 for the density range of 0.05–0.4 g/cm^3 (Woignier and Phalippou 1989). Flexural and uniaxial compressions tests are also compared and the results differed strongly as different precautions have to be taken to ensure each method's accuracy (Alaoui et al. 2008). Both the elastic and brittle mechanical behaviors of silica aerogels are attributable to the same kinds of gel characteristics of pore volume, silanol content, and pore size (Woignier et al. 2015).

The highly porous nature of pure silica aerogels is deleterious for their mechanical properties, but this porosity is remarkably beneficial for conferring unusually low thermal conductivity, especially for purposes of thermal insulation. Figure 1 shows the incredible insulating properties of a slab of silica aerogel preventing intense heat from affecting a delicate flower. Silica aerogels' thermal transport mechanisms have been characterized experimentally (Lu et al. 1995; Heinemann et al. 1996; Zeng et al. 1996; Wei et al. 2011), and it is found that separate

Fig. 1 To demonstrate the extremely low thermal conductivity of silica aerogel, a burner is lit under the translucent blue aerogel and the flower shows no detrimental signs of excessive heat, by J. Cormac 2009, https://commons.wikimedia.org/wiki/File:Aerogelflower_filtered.jpg

components of gaseous, solid, and radiative thermal conductivity constitute the total thermal conductivity of monolithic silica aerogels. Numerous factors decrease each component of the thermal conductivity, including negligible coupling between the different modes of heat transfer, absence of gaseous convection (and therefore diminished heat transfer) within the pores, and effective restriction of local excitations within the aerogel backbone due to the high number of pores (Ebert 2011; Koebel et al. 2011). In particular, a power-law variation of the solid thermal conductivity with density is found, similar to the variation of the elastic modulus with density, such that

$$\lambda_S = C\rho^{\alpha} \tag{1}$$

where the factor C varies with the particle connectivity within the aerogel, and α is approximately 1.6, for densities, ρ, in the range of 0.3–1 g/cm^3 (Fricke 1988), and 1.5, for ρ between 0.07 and 0.3 g/cm^3 (Fricke et al. 1992).

3   Characterization of Silica Aerogels with Molecular Dynamics

Due to the intricate link between silica aerogel's molecular structure and its properties, molecular dynamics (MD) modelling and simulations have played crucial roles in advancing the fundamental understanding of silica aerogel's structure-property-function relationship. This is reliant on significant improvements in two

basic factors: the accuracy of the MD forcefields and the algorithms for constructing representative aerogel structures. These advances have driven the ability of MD models to comprehensively capture aerogel's structural, mechanical, and thermal properties. Extensive details on the theory, methods, and implementations of MD models and simulations can be found in many textbooks (Allen and Tildesley 1989; Haile et al. 1993; Frenkel and Smit 2002; Rapaport 2004); hence, these aspects will not be covered here.

3.1   Molecular Dynamics Forcefields

MD simulations are underpinned by the quality of the mathematical formulations (the equations of motion, otherwise known as forcefields) that can meticulously reproduce a subset of properties needed for examining a certain phenomenon. Several forcefields have been proposed for modeling silica, however, only a small number of these have been implemented and validated for modeling various aspects of silica aerogels. One of the primary interaction potential used to model both amorphous bulk silica (Horbach and Kob 1999; Horbach et al. 1999; Jund and Jullien 1999; Shell et al. 2002; McGaughey and Kaviany 2004; Mahajan et al. 2007; Coquil et al. 2011) and silica aerogels (Ng et al. 2012, 2016; Yeo et al. 2013; Yeo 2014) is introduced by van Beest, Kramer, and van Santen (BKS) (van Beest et al. 1990; Kramer et al. 1991). The BKS potential's mathematical formulation is

$$U\left(r_{ij}\right) = A_{ij} \exp\left(-B_{ij} r_{ij}\right) - \frac{c_{ij}}{r_{ij}^6} + \frac{q_i q_j}{r_{ij}} \tag{2}$$

The first and second terms in Eq. 2 are the short-range attraction and repulsion of atoms, respectively; the final term is the long-range Coulombic interaction. r_{ij} is the separation between atoms of indices i and j; q_i and q_j their atomic charges; and A_{ij}, B_{ij}, and C_{ij} the different constants for different pairs of atoms i and j. These parameters are fitted simultaneously to both experimental macroscopic data and results from microscopic ab initio, including data for α-quartz (van Beest et al. 1990). Surprisingly, the comparatively simpler mathematical formulation of the BKS potential is capable of predicting the properties of various silica polymorphs more accurately than other pair potentials such as the Tsuneyuki, Tsukada, Aoki, and Matsui (TTAM) potential (Tsuneyuki et al. 1988). The BKS potential is able to accurately depict the structural and mechanical properties of various silica polymorphs, such as the unit-cell dimensions and elastic moduli, respectively. A downside of the BKS potential for simulating aerogels is that at high quenching temperatures, atoms can approach each other too closely and lead to dynamics that are unmanageable. However, this can be overcome by steeply increasing the repulsive capabilities of the BKS potential at small atomic distances through the addition of a "24–6" Lennard-Jones potential (Guissani and Guillot 1996) to obtain

$$U\left(r_{ij}\right) = A_{ij}\exp\left(-B_{ij}r_{ij}\right) - \frac{c_{ij}}{r_{ij}^{6}} + \frac{q_{i}q_{j}}{r_{ij}} + 4\varepsilon_{ij}\left[\left(\frac{\sigma_{ij}}{r_{ij}}\right)^{24} - \left(\frac{\sigma_{ij}}{r_{ij}}\right)^{6}\right] \quad (3)$$

Several studies have also implemented the Vashishta potential (Vashishta et al. 1990) to model silica aerogels (Nakano et al. 1993, 1994; Murillo et al. 2010; Patil et al. 2017). This potential introduces more sophistication by having terms that account for both two- and three-body interactions

$$U = U_{2}\left(r_{ij}\right) + U_{3}\left(r_{ij}, r_{jk}, r_{ik}\right) \quad (4)$$

where the two-body interaction term is

$$U_{2}\left(r_{ij}\right) = \frac{H_{ij}}{r_{ij}^{\eta_{ij}}} + \frac{Z_{i}Z_{j}}{r_{ij}} - \frac{\frac{1}{2}\left(\alpha_{i}Z_{j}^{2} + \alpha_{j}Z_{i}^{2}\right)}{r_{ij}^{4}}e^{-\frac{r_{ij}}{r_{4s}}} \quad (5)$$

and H_{ij} and η_{ij} are the strengths and exponents of the steric repulsion; Z_{i} and α_{i} the effective charge and electronic polarizability; r_{4s} is the decay length of the dipole interactions. The three-body interaction term is expressed as

$$U_{3}\left(r_{ij}, r_{jk}, r_{ik}\right) = B_{ijk}f\left(r_{ij}, r_{ik}\right)p\left(\theta_{jik}, \overline{\theta}_{jik}\right) \quad (6)$$

Here, B_{ijk} is the strength of the interactions. The effects of bond-stretching are represented by the function

$$f\left(r_{ij}, r_{ik}\right) = \begin{cases} \exp\left[\frac{l}{r_{ij}-r_0} + \frac{l}{r_{ik}-r_0}\right] & for\ r_{ij}, r_{ik} < r_0 \\ 0 & for\ r_{ij}, r_{ik} > r_0 \end{cases} \quad (7)$$

where r_0 is the interaction cutoff distance. The effects of bond-bending are given by the function

$$p\left(\theta_{jik}, \overline{\theta}_{jik}\right) = \left(\cos\theta_{jik} - \cos\overline{\theta}_{jik}\right)^{2} \quad (8)$$

where θ_{jik} is the angle subtended by atoms i, j, and k with atom i as the vertex.

Increasing complexity of inter-atomic interactions is needed for more rigorous simulations of the chemical environment that each atom encounters, thus requiring terms that account for multibody interactions. While pair approaches are relatively inexpensive computationally, they have a limited ability to model structurally and chemically complex materials, especially where elements like silicon and carbon have multiple possible polymorphs. These issues are addressed by varying the strength of each bond such that it is dependent on the conditions within the local environment through a bond-order function. The Tersoff potential (Tersoff 1988) is an example of a MD potential developed for this purpose and it has also been parameterized for silica (Munetoh et al. 2007), showing excellent utility in

predicting the thermal and mechanical properties of silica aerogels (Lei et al. 2013; Yeo et al. 2013; Ng et al. 2016). This potential has the general mathematical form of

$$U = f^c\left(r_{ij}\right)\left[V^R\left(r_{ij}\right) + b_{ij}\,V^A\left(r_{ij}\right)\right] \tag{9}$$

where V^R and V^A refer to the repulsive and attractive terms; f^c is a function that smoothly limits short-range interactions; b_{ij} is the bond-order that is monotonically decreasing according to the coordination of atoms i and j. Separately, the repulsive and attractive terms are

$$V^R\left(r_{ij}\right) = A_{ij}\exp\left(-\gamma_{ij}r_{ij}\right) \tag{10}$$

$$V^A\left(r_{ij}\right) = B_{ij}\exp\left(-\mu_{ij}r_{ij}\right) \tag{11}$$

$$A_{ij} = \left(A_i + A_j\right)^{\frac{1}{2}},\; B_{ij} = \left(B_i + B_j\right)^{\frac{1}{2}},\; \gamma_{ij} = \frac{\gamma_i + \gamma_j}{2},\; \mu_{ij} = \frac{\mu_i + \mu_j}{2} \tag{12}$$

The cutoff function is given as

$$f^c\left(r_{ij}\right) = \begin{cases} 1, & r_{ij} < R_{ij} \\ \frac{1}{2} + \frac{1}{2}\cos\left(\pi\,\frac{r_{ij}-R_{ij}}{S_{ij}-R_{ij}}\right) & R_{ij} < r_{ij} < S_{ij} \\ 0, & r_{ij} > S_{ij} \end{cases} \tag{13}$$

$$R_{ij} = \left(R_i R_j\right)^{\frac{1}{2}},\; S_{ij} = \left(S_i S_j\right)^{\frac{1}{2}} \tag{14}$$

where R and S denote the interaction limits. Finally, the bond-order term is

$$b_{ij} = \chi_{ij}\left(1 + \beta_i^{n_i}\,\zeta_{ij}^{n_i}\right)^{-\frac{1}{2n_i}} \tag{15}$$

$$\zeta_{ij} = \sum_{k \neq i,j} f^c\left(r_{ik}\right)\omega_{ik}g\left(\theta_{ijk}\right) \tag{16}$$

$$g\left(\theta_{ijk}\right) = 1 + \frac{c_i^2}{d_i^2} - \frac{c_i^2}{d_i^2 + \left(h_i - \cos\theta_{ijk}\right)^2} \tag{17}$$

Here, χ_{ij} dictates the strengthening or weakening of the heteropolar bonds and the remaining terms are parameters that can be fitted to experimental or ab initio data corresponding to the system under investigation.

3.2   Structural Properties

Using the MD interaction potentials in the previous section, the structural properties of silica aerogels can be represented using multiple schemes for very varied purposes such as investigating the atomic coordination, mechanical and thermal properties, chemical and gelation kinetics, and structural evolution and relaxation of aerogels. Generally, there are two broad categories of methods to obtain porous silica. The first category is "mimetic" simulations where experimental preparation of the aerogel is mimicked through dynamic representations. The second category is the construction of statistically accurate models to represent as much detail from available experimental data as computationally possible. For both of these categories, the aerogel models are usually characterized by structural and geometrical properties such as the pore size distributions, fractal dimensions, surface areas, and bond length and bond angle distributions (Gelb 2011).

Kieffer and Angell developed one of the earliest and most elementary atomistic methods to model the percolated structures of silica aerogels through MD (Kieffer and Angell 1988). In the scheme termed "negative pressure rupturing," an equilibrated sample of amorphous silica is instantaneously expanded in a stepwise manner until the percolation threshold is reached, as illustrated in Fig. 2a. All existing bonds are stretched simultaneously at each expansion step to lengths that are 10–35% beyond their equilibrium, and subsequently the structures are relaxed to remove excessive accumulated stresses. A similar method is used to simulate much larger systems of more than 40,000 atoms (Nakano et al. 1993, 1994) together with the Vashishta potential (see Sect. 3.1), as shown in Fig. 2b, c. This combination of factors generated porous structures with fractal dimensions that varied with density and good agreement with experimental data is obtained for the neutron-scattering static structure factor, bond statistics, and pore size distribution. Another study (Ng et al. 2012) also employed negative pressure rupturing but with the BKS potential instead (see Sect. 3.1), and this scheme generated silica aerogels whose fractal dimensions scaled with density in a manner similar to previous MD studies (Kieffer and Angell 1988).

By correlating with experimental data, three separate and distinct methods of modelling silica aerogels are compared for in-depth understanding of aerogel synthesis and the underlying pore structure (Pohl et al. 1995). The first method involves packing spherical silica particles of varying diameters into a cell to determine their surface areas. The second method proceeded in similar manner to negative pressure rupturing. Cluster-cluster aggregation of silica clusters is the final method and it produces the structure of aerogels upon gelation. The first method agrees reasonably well with theoretical curves as the porosity increases. For the second method, it is found that differing pore size distributions is obtained if the expansion rates are varied. In terms of the composition and the characteristic size, the final method is the most representative of experimental aerogels.

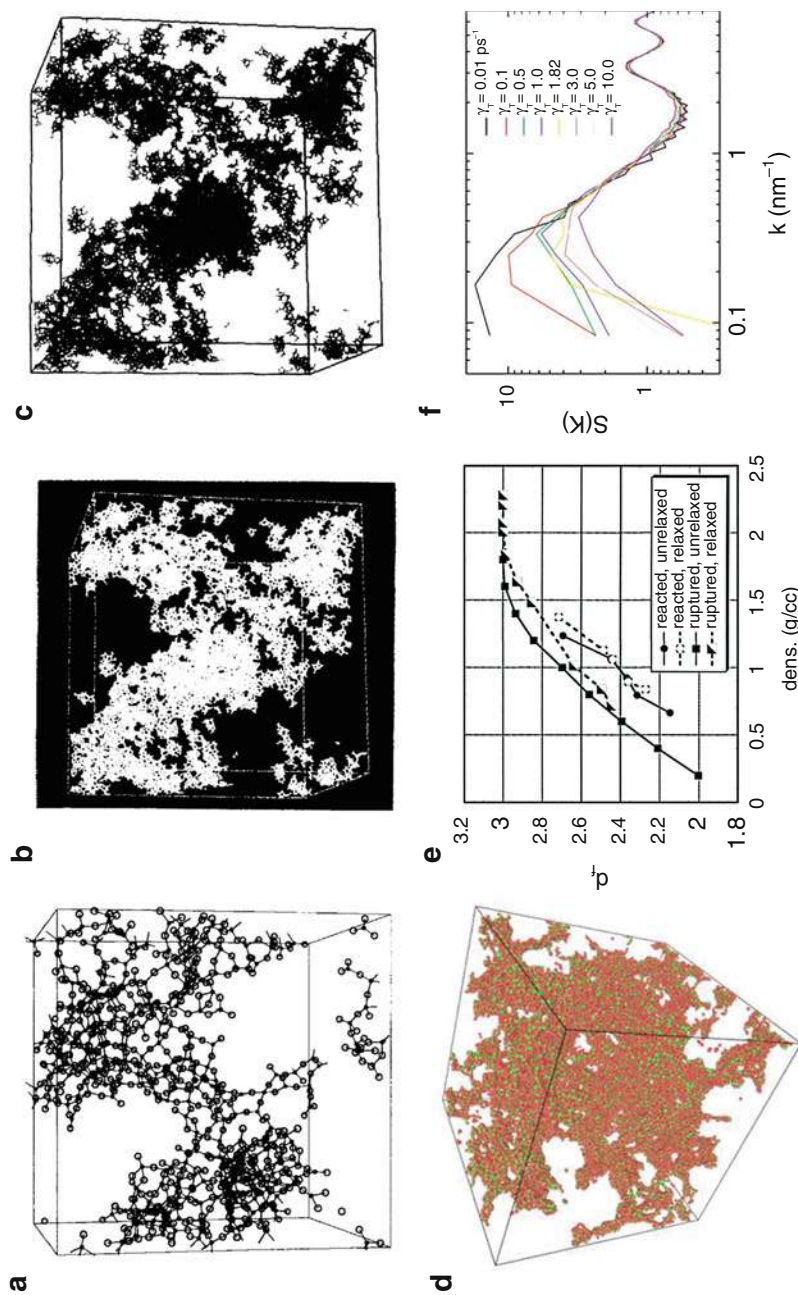
A recent MD scheme that modifies the approach of negative pressure rupturing is used to reconstruct the silica aerogel's percolated backbone together with the


Fig. 2 Various porous backbone of silica aerogels generated through (**a–c**) negative pressure rupturing. (Reproduced from Kieffer and Angell 1988; Nakano et al. 1993, 1994 with permission from Elsevier and the American Physical Society) and (**d**) the expanding, heating, and quenching scheme. (Reproduced from Yeo et al. 2013 with permission from IOP Publishing Ltd). Numerous structural information of percolated silica aerogels has also been investigated, such as (**e**) the variation of fractal dimensions with density. (Reproduced from Bhattacharya and Kieffer 2005 with permission from AIP Publishing) and (**f**) the structure factors. (Reproduced from Gelb 2007 with permission from the American Chemical Society)

Vashishta potential (Murillo et al. 2010). In this scheme, which we dubbed as the expanding, heating, and quenching scheme (Yeo et al. 2013; Yeo 2014), a crystalline lattice of β-cristobalite with 24,000 atoms is expanded to the density required. Thereafter, the entire system is allowed to diffuse and aggregate by increasing the temperature up to 3000 K with subsequent relaxation by cooling down to temperatures that are between 2500 K and 0 K. Good agreement with experimental data is found for the *structural* features, such as the fractal dimensions, characterized using pair distribution functions and simulated scattering experiments. The expanding, heating, and quenching scheme is also used in combination with the Tersoff potential (see Sect. 3.1) (Lei et al. 2013; Yeo et al. 2013), as depicted in Fig. 2d, and the scaling of the fractal dimensions with density agreed very well with previous MD studies (Nakano et al. 1994; Murillo et al. 2010).

Through reactive MD simulations, the process of oligomerization and gelation during the production of silica aerogels can also be modelled in greater detail. A series of studies (Garofalini and Melman 1986; Feuston and Garofalini 1990; Garofalini and Martin 1994) simulated solutions of water, silicic acid monomers, and silicic acid dimers with the MD potentials derived from the Born-Mayer-Huggins (Garofalini 1983) and Rahman-Stillinger-Lemberg (Stillinger and Rahman 1978) potentials. The initial study validated the forcefields used through comparisons with data from molecular orbital calculations and experimental studies of bulk silicates. Pentacoordinated silicon is found during the reaction of two silicic acid monomers in vacuo (Garofalini and Melman 1986). Further revision of the models (Feuston and Garofalini 1990) led to the discovery of more intermediates during polymerization, including ionized monomers and pentacoordinated silicon. The simulated structures also compared favorably with X-ray and neutron diffraction data as well as quantum chemical calculations. The next study then simulated significantly larger systems with 216 silicic acid monomers at densities between 1.4 and 1.6 g/cm^3 (Garofalini and Martin 1994). The simulation data are consistent with experimental sol-gel systems in terms of chain formation, the activation energy for branching, and the relative time evolution.

Further advances in observing the gelation processes are made by incorporating the transfer of charges in a more realistic all-atom reactive approach (Bhattacharya and Kieffer 2005, Kieffer and Bhattacharya 2008). Comparison of the fractal dimensions, d_f, to those obtained from negative pressure rupturing revealed that the d_f is process-dependent rather than being associated with the density and porosity of the gel structure (Bhattacharya and Kieffer 2005), as shown in Fig. 2e. It is also determined that this fractal nature is not significantly affected by the supercritical drying process. Furthermore, three different growth regimes are observed in a subsequent study of silica aerogels' polycondensation process in both dry and aqueous environments (Kieffer and Bhattacharya 2008). The regimes of compact particles, percolated network structures, or branched clusters depend on the ratio between silicon and water as well as the density of the system. The growth kinetics and mechanical stability of the individual regimes are also studied.

There are inherent limitations in spatial sizes of MD simulations due to the computational intensity of fully atomistic simulations that extends to more than

millions of atoms, although there have been attempts to achieve this recently (Gonçalves et al. 2016). Several studies aim to circumvent this limitation by developing coarse-grained (CG) models of silica aerogels. These models aggregate numerous atoms into a single particle to reduce the number of computations needed while creating the ability to probe phenomena that exist at higher spatiotemporal scales that are out of the reach of fully atomistic MD simulations. This ability comes at the expense of losing atomistic detail; therefore, a good balance must be achieved to ensure that the observed phenomenon is not a computational artifact. One such CG model is developed using data from simulations of silica sol particles that are 2 nm in size to examine the gelation and relaxation mechanisms at much larger spatiotemporal scales (Gelb 2007), such as the structure factors in Fig. 2f. This is known as the flexible reactive aerogel model. A range of gelation behavior is observed by tuning the model's effective forward rate constant for bond creation. For highly relaxed clusters in low-reactivity conditions, reactions correspondingly became infrequent. The properties of the resulting gel are invariant even if reactivity is decreased further. In contrast, higher reactivity will result in increased amounts of structures that are far from equilibrium, leading to significant shrinkage at low pressures due to the presence of high stresses. We anticipate that future developments in CG models of silica aerogels will eventually lead to accurate multiscale models that link molecular structures to macroscale phenomena such as heat transfer and fracture of silica aerogel beads.

3.3   Mechanical Properties

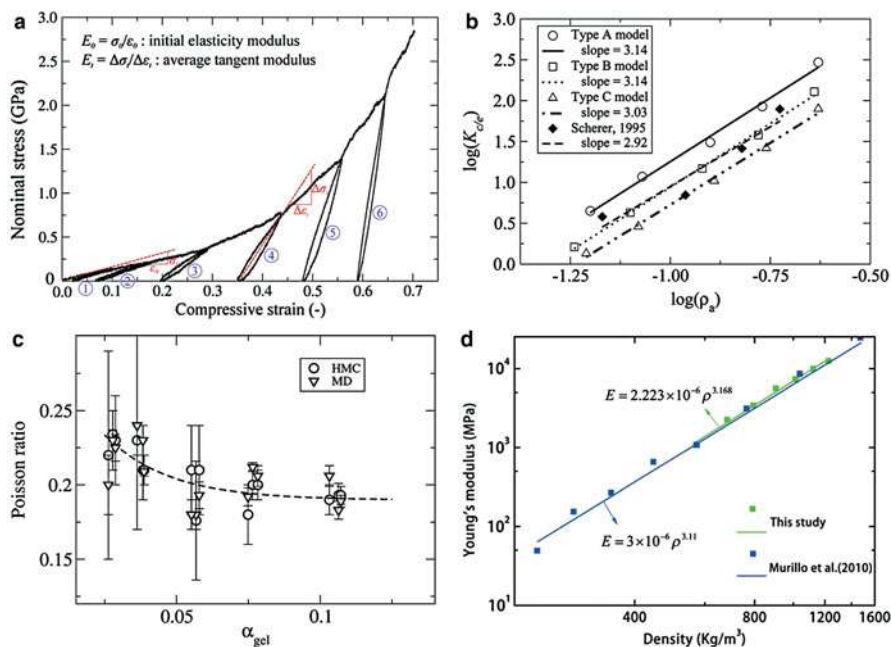
Studies that utilized MD simulations to characterize the nanomechanical properties of silica aerogels have been a fairly recent development compared to the characterization of silica aerogel's structural properties. After the extensive validation of various MD methods of reproducing the fractal nature of silica aerogels, the Vashishta potential (see Sect. 3.1) and an algorithm to mimic diffusion-limited aggregation (DLCA) are used to generate porous silica with densities between 1.67 and 2.2 g/cm^3 (Campbell et al. 1999). This density range resembles xerogels more closely rather than extremely percolated aerogels. The variation of the bulk, shear, and Young's moduli with increasing density is examined. The Young's moduli are found to scale with density via a power-law with an exponent of 3.5 ± 0.2. Another manner of DLCA is adopted in another study (Murillo et al. 2010), which is the expanding, heating, and quenching scheme detailed in Sect. 3.2, together with the Vashishta potential. Percolated structures with densities between 0.23 and 2.2 g/cm^3 are studied, where the density range corresponds to that of aerogels and xerogels. Power-law variations are found for the Young's moduli and strength, where the exponents are 3.11 ± 0.21 and 2.53 ± 0.15, respectively, in good agreement with experimental data (Woignier et al. 1998). This same scheme is applied in another study (Patil et al. 2017) but on a much larger scale, having more than 192,000 atoms and system sizes that are larger than 17^3 nm^3. A density range of 0.28–2.2 g/cm^3 is investigated. The power-law exponent of the Young's moduli is estimated to be


Fig. 3 Mechanical properties of silica aerogels that can be obtained from numerical simulations, such as (**a**) the relationship between stress and strain during cyclic loading. (Reproduced from Patil et al. 2017 with permission from the American Chemical Society), (**b**) the bulk moduli. (Reproduced from Ferreiro-Rangel and Gelb 2013 with permission from the American Chemical Society), (**c**) the Poisson ratio. (Reproduced from Ferreiro-Rangel and Gelb 2015 with permission from American Chemical Society), and (**d**) the elastic moduli. (Reproduced from Lei et al. 2013 with permission from The Royal Society of Chemistry)

3.25 ± 0.1 and brittle fracture is observed in tensile tests while early densification occurred for compression tests. Poisson ratios are between 0.18 and 0.21. Cyclic compressive loading at three densities of 0.28, 0.42, and 0.62 g/cm^3 caused permanent deformations under large strains due to inelastic phenomena related to residual deformation, hysteresis, and the Mullins effect (Fig. 3a). Mathematical relations are also determined between the compressive strain and the residual strain, the dissipated energy, and the average tangent modulus.

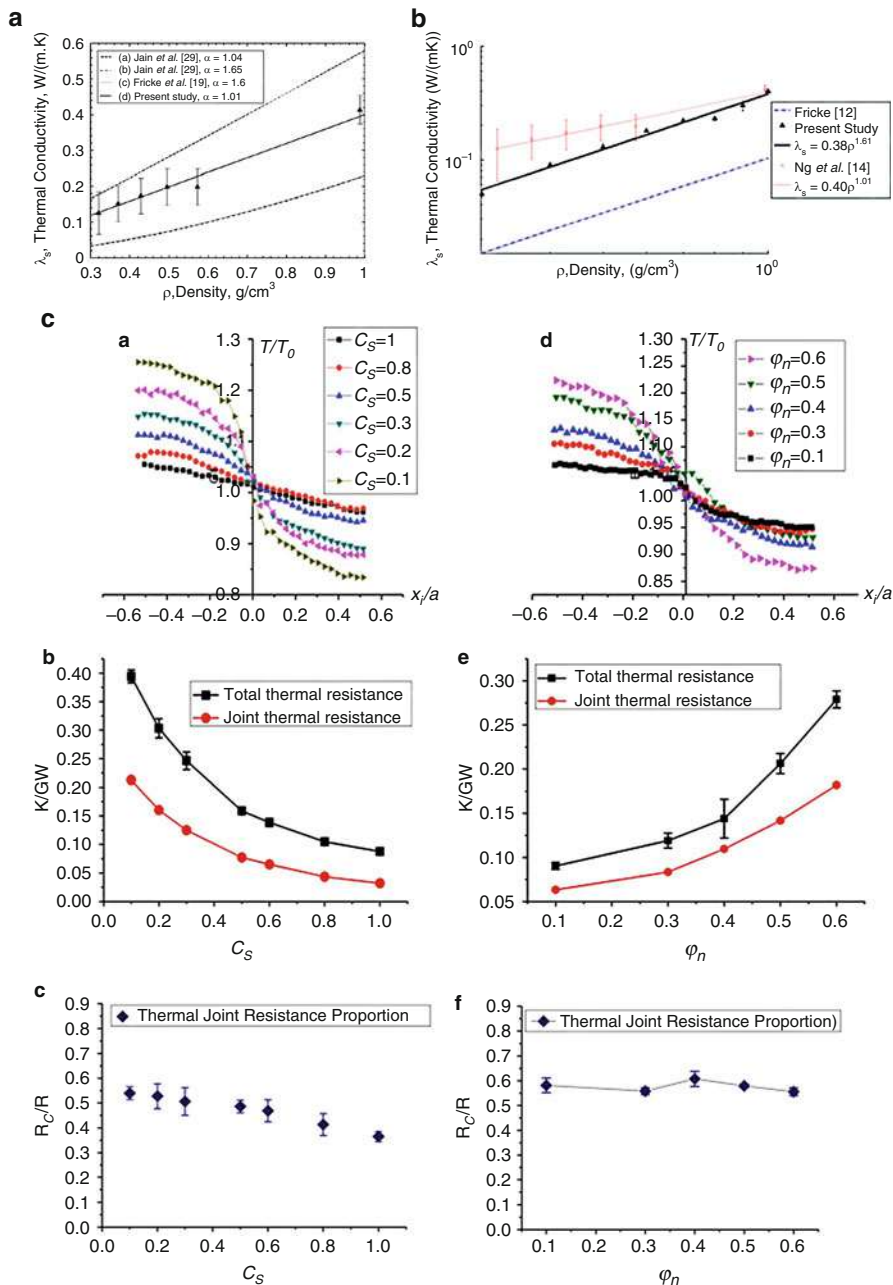
CG modelling (see Sect. 3.2) of silica aerogels has also been used to characterize the mechanical properties of silica aerogels at higher hierarchical length scales. In a series of studies using the flexible reactive aerogel model, it is found initially that the bulk modulus is significantly lower (1.0–2.3 bar) than experimental data (~7.0 bar) at similar densities (Gelb 2007). A subsequent study (Ferreiro-Rangel and Gelb 2013) looked at this issue in more detail by considering variations in particle sizes, densities, and size dispersity, along with two separate methods for obtaining the bulk modulus: fluctuation analysis or direct compression and expansion simulations. The bulk moduli derived from direct compression and expansion simulations appear


Fig. 4 (continued)

to be more reliable than those from fluctuation analysis which requires careful parameterization of the barostat mass. The power-law scaling of the bulk moduli with density has an exponent of approximately 3.1 as shown in Fig. 3b, but polydisperse particle sizes cause the bulk modulus to decrease due to the reduced density of bonds. In the most recent study (Ferreiro-Rangel and Gelb 2015), MD and hybrid Monte Carlo methods are used to investigate the uniaxial deformation and mechanical properties of silica aerogels as depicted in Fig. 3c. The power-law dependence of the Young's moduli has an exponent of approximately 3.0. Poisson ratios lie between 0.17 and 0.23. The Young's modulus and Poisson ratio are found to be largely isotropic, but anisotropy became more prominent as density decreased. Large deformation uniaxial tensile and compressive tests are also performed, where high density aerogels exhibited brittle failure, whereas low density aerogels are generally more elastic.

Extrapolation of MD simulations to bulk elastic properties has also been investigated. For instance, analytical-numerical models can be constructed with molecular details obtained from MD simulations (Lei et al. 2013). MD simulations with the Tersoff potential (see Sect. 3.1) and the expanding, heating, and quenching scheme are used to derive the Young's modulus at the molecular scale, as illustrated in Fig. 3d. These data are used to parameterize an analytical model of a much larger nanoparticle, leading to a fast and convenient analytical method of depicting the silica aerogel's Young's modulus.

3.4   Thermal Properties

MD simulations have also been used for the extensive characterization of nanoscale thermal transport in the solid backbone of silica aerogels. The vibrational density of states (vDOS) are determined for CG percolated silica structures generated by placing individual fully atomistic samples of vitreous silica in an infinite 3D percolated cluster (Rahmani et al. 1994). Through the development of a linear-frequency moments method, the vDOS of systems that are 50 nm × 35 nm × 35 nm in size and have densities between 0.10 and 0.26 g/cm^3 can be rapidly determined, especially in the low-frequency region, and the data are in good agreement with experimental results. A follow-up study (Benoit et al. 2001) generated a CG model that can reproduce small-angle neutron scattering (SANS) experimental data for the

Fig. 4 The thermal properties of silica aerogels investigated with various numerical models. (**a**), (**b**) The thermal conductivities are compared with experimental studies, where the power-law variation with density, determined through the Tersoff potential with the expanding, heating, and quenching scheme, showed excellent agreement. (Reproduced from Ng et al. 2012 and Yeo et al. 2013 with permission from Elsevier and IOP Publishing Ltd). (**c**) Other properties that are characterized include the variations in thermal resistance. (Reproduced from Liu et al. 2014 with the permission of AIP Publishing)

vDOS and inelastic scattering intensity of silica aerogels. This model is derived from a DLCA algorithm that incorporates primary particles of fully atomistic samples of vitreous silica modelled using the BKS potential (see Sect. 3.1).

The thermal conductivity of silica aerogels has also been studied in a series of MD simulations that are primarily performed using a class of MD methods known as nonequilibrium MD (NEMD) (Rapaport 2004). In each study, the MD forcefields used are validated extensively due to the paucity of simulation and experimental data available for thermal transport on such a small length scale. In the initial study (Ng et al. 2012), the thermal conductivity of dense vitreous silica is validated using the BKS potential. Vitreous silica is generated by quenching with the BKS potential while the thermal conductivity is determined through the method of reverse NEMD (Muller-Plathe and Bordat 2004). In a system with 648 atoms, the thermal conductivity is 1.20 ± 0.07 W/(m·K), in good agreement with MD results published previously (Jund and Jullien 1999; Coquil et al. 2011), while a thermal conductivity of a larger system with 3000 atoms is determined to be 1.39 W/(m·K) at 300 K, close to the experimental value of 1.40 W/(m·K). This variation in thermal conductivity is a phenomenon that is well known in MD simulations due to finite size effects (Yeo et al. 2013). Negative pressure rupturing is then applied on the larger system, producing percolated aerogels with densities between 0.32 and 0.99 g/cm^3. The thermal conductivity is determined subsequently using RNEMD and the power-law dependence with density has an exponent of 1.01, in contrast with experimental values of 1.6 (Fricke 1988). Moreover, the thermal conductivity at the density of 0.3 g/cm^3 is higher than experimental values by almost an order of magnitude, as shown in Fig. 4a. This is partly explained by the influence of processing conditions as well as the lack of defects, impurities, and sufficiently broad pore size distributions. It is verified that the largest pore diameter at a density of 0.3 g/cm^3 is significantly smaller than the pores found in experimental aerogels.

In order to minimize the effects of finite sizes and to investigate the role of the MD forcefields in determining the thermal conductivity, a subsequent study developed an enhanced model (Yeo et al. 2013) that is a combination of the expanding, heating, and quenching scheme (see Sect. 3.2) with larger system sizes of more than 52,000 atoms and the re-parameterized Tersoff potential (see Sect. 3.1). For vitreous silica, it is shown that the Tersoff potential predicts bulk thermal conductivity values and vDOS that are significantly closer to experimental data. This scheme dramatically improved the power-law scaling of thermal conductivity with density in the aerogel models, where the exponent is now 1.61, while having a much lower thermal conductivity of 0.05 ± 0.003 W/(m·K) at the lowest density of 0.3 g/cm^3 (Fig. 4b). This model is extended further to investigate the thermal resistance between secondary spherical particles of silica aerogels (Liu et al. 2014), with the exception that the percolated primary structure in each secondary particle is generated by deleting atoms prior to heating and quenching. The thermal resistance between two particles that are in close contact is in the range of 0.1–0.4 K/GW, depending on the complex interplay between contact length and defect concentration, as illustrated in Fig. 4c. Analysis of the vDOS shows that contact length fractions that are lower than 50% significantly suppress the longitudinal

acoustic (LA) modes of vibration. A similar phenomenon is found for defect concentrations higher than 50%.

4 Conclusions

The intention of this review is to provide a sufficiently broad yet in-depth understanding of historical developments in the fully atomistic and coarse-grained molecular dynamics modelling and simulations to characterize silica aerogels. The development of new empirical forcefields, including the modified BKS potential, the Vashishta potential, and the re-parameterized Tersoff potential, accurately captured numerous properties of amorphous silica. By coupling these forcefields with novel methods of generating percolated architectures, researchers can now perform multiscale optimization and characterization of silica aerogels' structure-property-function relationship. Both fully atomistic and coarse-grained molecular dynamics modelling methods have been discussed, including negative pressure rupturing, the expanding, heating, and quenching scheme and DLCA algorithms. These compelling algorithms have characterized silica aerogels' structural, mechanical, and thermal properties, delivering unprecedented insights into silica aerogels. We anticipate that the next big leap of development in silica aerogels is the manipulation of their molecular structures in a bottom-up production approach, leading to aerogels that are stronger, tougher, and more optically transparent, while retaining their incredibly low weight and thermal conductivity. This may be achieved through advances in 3D printing of ceramics in combination with rigorous characterization and optimization through a comprehensive set of multiscale modeling platforms, which ultimately minimize the trials and errors of traditional experimental synthesis and can even bring silica aerogels into the fold of the materials-by-design paradigm.

Toughening and Strengthening Mechanisms in Bamboo from Atoms to Fibers

65

Sina Askarinejad, Sina Youssefian, and Nima Rahbar

Contents

Abstract

Bamboo, a grass, with stiffness-to-weight and strength-to-weight ratios higher than steel and concrete is a wonder of nature. In this chapter we present a comprehensive review of the mechanical properties of bamboo from nano- to macroscale. After presenting the main toughening mechanisms in bamboo, we present a summary of the atomistic simulations of bamboo microfibril which is the main sources of stiffness and strength in bamboo fibers. The role of humidity in bamboo microfibril is also presented at small scale. It is shown experimentally and numerically that the addition of 1% moisture content to the system does not change density and increases the elastic modulus in the longitudinal direction. This is probably due to the relatively larger fractional free volume in the

e-mail: nrahbar@wpi.edu

structure of lignin, and subsequently LCC, at low moisture contents. This interesting phenomenon is important in understanding the mechanics of bamboo microfibrils.

1   Introduction and Background

Bamboos (Graminaceae) include numerous species that grow in all continents, except for Europe and Antarctica, in tropical, subtropical, and temperate regions of the world. They are one of the swiftest growing plants on Earth in terms of rate of mass accrued during their growth phase (Zachariah et al. 2016). Bamboo's attractive combinations of high strength-to-weight ratio, high stiffness-to-weight ratio, and shape factor (Ghavami 2005; Wegst 2011; Xiao et al. 2010; Gibson 2012; Huang and Netravali 2009) have led to an increasing interest in the use of bamboo as an eco-friendly highly efficient structural material (Wegst and Ashby 2004). Such unique properties have resulted in many applications of bamboo such as in bicycles, housing in rural and urban environments (Janssen 1981), and microscopes (Basu 2007). In countries such as China, bamboo has been widely used as structural material for centuries (Yu et al. 2011a). Bamboo has also been used to fabricate structural elements and as alternative to steel in reinforced concrete (Geymayer and Cox 1970). Recent economic data also show significant growth in innovative materials from bamboo that are helping a new industry to sprout (Watching Grass Grow 2018).

Excluding the outer layer (epidermal layer) of bamboo stalk, its structure consists of fibers and vascular bundles that are surrounded by parenchyma cells. Researchers attribute the outstanding mechanical properties of bamboo to the presence of the fibers which are nonuniformly distributed in the cross section of bamboo (Tan et al. 2011; Lo et al. 2008). The nonuniform distribution and the orientation of these fibers make bamboo an orthotropic material with high strength along the fibers and low strength transversal to the fibers (Ghavami 1995; Lakkad and Patel 1980; Lo et al. 2004). This evolutionary designed structure establishes bamboo as a great representative of a naturally occurring functionally graded material (FGM) (Nogata and Takahashi 1995; Habibi et al. 2015; Ray et al. 2004; Ghavami et al. 2003). FGMs Suresh and Mortensen (1988) are generally characterized by their variation in composition and structure over volume. As the most dominant loading on a bamboo plant is bending along the main axis of the plant due to wind, the profile of bending stress along the cross section of the bamboo varies from the highest at the outer layer to the lowest at the inner later. Evolutionary, this stress profile has resulted in the corresponding variation in the material properties in a continuous manner that reduces the stress concentration and increases bending overall strength (Shao et al. 2009; Janssen 1991).

The structure of bamboo is a typical example of plants with highly developed architectures in which bamboo culm is divided by the nodes (Fig. 1). Taylor et al. studied the role of bamboo nodes and found out that beyond being a point of strength, the node may be a point of weakness when loaded in tension. However,
Fig. 1 Hierarchical microstructure of bamboo (Mannan et al. 2017)

the spacing of nodes is too large to affect the stiffness and strength of the tube as a whole and also greater than the critical crack length for brittle fracture. Thus, the diaphragm and ridge structure of the node are possibly evolved to reinforce a biologically essential feature which would otherwise be a point of weakness (Taylor et al. 2015). It has a hierarchical structure that makes a typical natural functionally graded bio-composite (Amada and Untao 2001). In this structure, there are no tree rings in the culm's cross section. Instead, bamboo comprises three fundamental tissues named epidermis, parenchyma, and vascular bundles (Tan et al. 2011).

The epidermis is the outermost layers of bamboo which protects the internal components from invaders. The attractive green color of bamboo culm is due to the chlorophyll of epidermis. Smooth surface of the bamboo, also, exists because of silica, a wax layer, and other substances of epidermis. The silica also facilitates CO_2 uptake of plants and strengthens the outer epidermis for prevention of external attacks (Chang et al. 1998; Chung et al. 2014).

Parenchyma tissue is the non-woody structure of bamboo. The ground parenchyma tissues of crop species such as rice and maize have only one type. Bamboo, however, has two types of parenchyma cells named short and long parenchyma cells that have differences in lignification and the hemicellulose distribution. These differences reflect the differences in function of the two types of parenchyma cells (He et al. 2002). Parenchyma ground tissue forms a matrix in which vascular bundles are placed.

The vascular bundles mainly consist of xylem, phloem, and fiber caps which are playing a decisive role in bamboo physiological growth and biomechanical function. The vascular bundle inhomogeneous distribution is dense in the outer region and sparse in the inner region (Amada et al. 1997). This special dissemination is a perfect structural adaptation toward a high bending stiffness and strength of the bamboo culm. The conducting elements (vessels and phloem) provide a channel for the transport of water and nutrients. The fibers, which are accounting for approximately 40% of a culm by volume, primarily carry out the function of mechanical support.

The fibers around the phloem do not have the same thickness. The immature fibers close to the vessels and the phloem complete their wall thickening first, whereas those at the periphery of the fiber caps are in a transition state. Therefore, a distinct density gradient can be observed from the fibers adjacent to the vessels

toward the fibers connected to the surrounding parenchymatic tissue (Wang et al. 2012a). The six different fiber wall types could be distinguished in the bundle fibers close to phloem that all have mainly hemicellulose-lignin matrix surrounding the cellulose microfibrils, in their secondary walls. The degree of lignification varies remarkably across the fiber wall, with a higher lignin content present in the narrow layers (Wang et al. 2012a, b).

There are numerous studies on material properties of bamboo, including measuring strength, Young's modulus of matrix and fiber, and detailed analysis of microstructures and fiber distribution (Nogata and Takahashi 1995; Amada et al. 1997; Tan et al. 2011; Bai et al. 1999; Lee et al. 1997). Dixon et al. measured the flexural properties of moso bamboo in the axial direction, along with the compressive strengths in the axial and transverse directions. Based on the microstructural variations and solid cell wall properties, analytical models of mechanical properties of bamboo which describe the experimental results were developed (Dixon et al. 2014).

Considering that bamboo is an inhomogeneous orthotropic material, numerous methods have been used to model its macroscale properties numerically (Askarinejad et al. 2015). Moreover, in order to estimate how the microstructure influences the effective properties of these materials, multiscale methods such as homogenization have been previously used (Silva et al. 2006).

The fracture toughness of bamboo culms was studied by many such as Amada et al. (2001). The average value obtained was 56.8 MPa.m$^{1/2}$. This value is higher than Al alloys. The fracture property of bamboo as a natural composite material depends on where the crack initiates. Using multiscale mechanical characterizations coupled with advanced environmental electron microscopy (ESEM), Habibi and Lu showed that fiber interfacial areas along with parenchyma cell boundaries were preferred routes for crack growth in both radial and longitudinal directions (Habibi and Lu 2015). The occurrence of interfacial fractures within the cellular parenchyma matrix along with honeycomb structure of fibers in both radial and longitudinal directions is mainly responsible for the remarkable fracture toughness of bamboo by reducing the overall effective stress intensity factor. Keogh et al. performed fatigue tests on bamboo culm (Keogh et al. 2015). Bamboo culm samples display fatigue failure when loaded in compression across their diameters, simulating a type of deformation which commonly occurs as a result of culm bending. However, they observed no fatigue behavior when samples are loaded in axial compression.

2   Toughening Mechanisms in Bamboo

The main toughening mechanisms in bamboo are observed to be fiber bridging (Tan et al. 2011; Habibi and Lu 2015). Habibi and Lu investigated the asymmetric flexural responses of natural bamboo strips under different loading configurations, during elastic bending and fracture failure stages, with their respective deformation mechanisms at microstructural level (Habibi and Lu 2015). They found fiber

bridging and crack deflection are also partly responsible for the gradient and remarkable flexural strength and toughness of bamboo strips. Hence, as the overall volume fraction of fiber decreased (thickness of the strips approached the entire thickness of bamboo culm), the contribution of triggered toughening mechanisms, due to the presence of fibers, also diminished which resulted in minimizing the flexural strength and toughness of bamboo strips. They performed the flexural tests in modes A and B. In the mode A, the load was exerted on the higher fiber density side and the mode B on the lower fiber density side of bending configurations. For mode A fracture, the crack bridging, due to the fiber bridging, alongside its resultant fiber debonding is the most significant toughening mechanism. Accordingly, the layers with very large volume fraction of fibers result in very low extent of crack bridging and fiber debonding in mode B, because delamination occurred more often. This considerably reduces the flexural strength.

Constant moment crack growth resistance tests were previously performed on single-edge-notched bend (SENB) specimens (Tan et al. 2011; Askarinejad et al. 2015). The specimens were characterized into two categories, according to the placement of the notch. Specimens notched in the outer side of longitudinal(L)/tangential (θ) orientation are hereby referred to as outside cracked, while those notched on inside part of the L/θ orientation are referred to as inside cracked.

Three-dimensional finite element simulations were performed to extract the exact values of crack-driving forces. Fiber volume fractions as a function of thickness were extracted from the optical microscopy measurements. Later, classical rule of mixture was applied to estimate the actual graded elastic properties of bamboo microstructure as a function of distance from the outer layer. The estimate of bamboo Young's modulus as a function of the distance from the outer layers was applied to bamboo cross section in the finite element simulation, Askarinejad et al. (2015).

The cracks in both inside- and outside-notched samples grow parallel to the longitudinal direction of fibers. In all the specimens tested, the crack does not grow straight. All cracks kink 90° with respect to fiber orientation and advance parallel to the fiber direction. It was observed that the bamboo toughness appears to depend on the placement of the notch, with higher value for inside-notched specimen than the outside-notched specimens. After pre-cracking further stable crack growth occurs at a higher load.

The fracture toughness of a composite structure, toughened by the mechanism of crack bridging, was first modeled by Budiansky et al. using elastic-ideally plastic springs (Budiansky et al. 1988). This model analytically estimates the toughening due to small-scale bridging (SSB). In this case the bridge length is relatively small compared to crack length, specimen dimensions, and distances from the crack to the specimen boundaries. The toughening due to SSB, $\triangle K_{SSB}$, is given by,

$$\triangle K_{SSB} = \sqrt{\frac{2}{\pi}} V_f \int_0^L \frac{\alpha \sigma_y}{\sqrt{x}} dx \qquad (1)$$

where α is a constraint/triaxiality factor, V_f is the volume fraction of ductile phase, σ_y represents the uniaxial yield stress, x is the distance from the crack tip, and L is the bridging length, which is equal to the distance from the crack tip to the last uncracked reinforcement.

A large-scale bridging model developed by Bloyer et al. (1998, 1999) was used to estimate the toughening due to large-scale bridging (LSB) effects. This model that depends on the traction distribution, crack length, and specimen geometry employs a weight function $h(a, x)$ to calculate the stress intensity diminution caused by the shielding zone. For LSB the toughening due to ligament bridging $\triangle K_{LSB}$ is given by,

$$\triangle K_{LSB} = V_f \int_0^L \alpha \sigma_y h(a, x) dx \qquad (2)$$

The weight function for the bridging tractions is given by Fett and Munz (1994). Hence, the fracture toughness of the composite bamboo structure is the summation of crack initiation toughness K_m and the added toughness, $\triangle K$, due to SSB or LSB. K_m is referring to mixed mode matrix toughness before fiber bridging happens and is found through experiments.

$$K_c = K_m + \triangle K \qquad (3)$$

Once K_c is obtained, the energy release rate can be calculated.

For the case of bamboo, α can be taken to be 1.0 (Budiansky et al. 1988), and the volume fractions of fibers for outside and inside cracks are 0.45 and 0.2, respectively. The uniaxial yield stress for outside crack with denser fibers is around 620 MPa, whereas for inside crack is around 220 MPa. The Young's moduli are around 16 and 7.5 GPa for outside and inside cracks, respectively.

The resistance curve for the bamboo structure as a function of crack (kinked) length is presented in Fig. 2. It is noted that the R-curve of bamboo does not exhibit saturation behavior. However, the curve rises gradually up to point of instability. This instability point can be considered as a point of failure for any given notch position. In general, it can be said that this corresponds to a crack size of ~12 mm. The differences in the fracture resistance of the bamboo in different notch orientations can be explained as a result of the graded structure of bamboo. In general, bamboo derives its strength from the vascular fibers that can sustain higher stresses during deformation. In the presence of notches or cracks, however, the high energy involved with the deformation and bending of regions with higher density of fibers causes high stress concentrations at the notch/crack tips, which leads to high crack-driving forces at crack tips for a unit load. Meanwhile, the regions with the least fiber density do not result in high stress concentrations at crack tips, but rather tend to dissipate the energy by some inelastic deformation. It could be said that the much higher loads observed for the inside-notched sample can be explained by two following reasons: (a) the higher level of strain energy of the uncracked outer layer
Fig. 2 Fiber bridging toughening mechanism model and R-curve behavior of bamboo for two possible crack configurations

to applied bending loads and (b) the energy-dissipating capability of lesser fiber-density notched region. The combination of these two conditions results in higher crack initiation/propagation loads for a sample with an inside crack. For the case of outside-notched sample, the opposite occurs. That is, the part in contact with the applied load (the bottom part of the bamboo) is weak and bends easily under lower applied loads. The resulting bending stress is tensile in the region that contains the notch. As a result of the high fiber density, which causes high stress concentrations at the crack tip, much lower stresses are magnified to levels equivalent to crack-driving force. Hence, lower loads for crack initiation/propagation are observed for the outside-notched samples.

The main effect of mixed mode on toughness of a bamboo is postulated to be on the matrix toughness, K_m. Afterward, the large-scale mode-I fiber bridging formulations can precisely predict the toughening behavior of bamboo. Hence, as the formulation clearly shows, the contribution of mode-II toughening mechanism to intrinsic toughness of bamboo is negligible.

It is quite clear from Fig. 2 that the bamboo exhibits R-Curve behavior in both inside and outside cracked directions. However, this behavior is more pronounced for samples with an outside crack than samples with an inside crack. The results show that the crack starts from two corners of the notch due to the relatively high stress concentrations at these points. However, the load at which crack growth starts depends on the side of the bamboo that contains the notch, being highest for the inside-notched specimen and least for the outside-notched specimen. The important observation from these experiments was that the direction of crack growth or the crack growth path deviates from that of the original notch, which is perpendicular to fiber longitudinal direction.

Another observation from crack/microstructure interaction is that the length and width of the crack increases with applied loads, with bridging across the faces of the cracks. Such bridges absorb energy and, thus, reduce the effective stress intensities at the crack tip. Hence, higher applied loads are required for crack growth, leading to rising observed crack-resistance curves (R-curves) of Fig. 2. A comparison of crack/microstructure interaction reveals that the effects of crack bridging on toughness in the inside-notched specimen are larger and more pronounced, due to the lower fiber density. This shows that the inner side of the bamboo culm is tougher than the outer side, which in turn is stronger than the inner part.

3 Multiscale Mechanical Properties of Bamboo Fibers

Fibers are a fundamental structural component of the bamboo culm as they provide mechanical support. The structure of the fibers in which cellulose fibrils are surrounded by a matrix of mainly lignin and hemicellulose has been widely investigated (Youssefian and Rahbar 2015; Rao et al. 2007). Between 20% and 30% of the cross-sectional area of the stalk is made of longitudinal fibers which are heavily concentrated near the exterior layer (Silva et al. 2006). To gain better understanding of the principles of mechanical optimization in bamboo fibers, a single-fiber tensile test at four different span lengths for fibers of the bamboo species was performed by Osorio et al. (2011). The average strength values of 800 MPa and Young's modulus of 43 GPa were obtained. The strength and elastic modulus of bamboo fibers was reported to be around 610 MPa and 46 GPa, respectively (Amada et al. 1997; Amada and Untao 2001). Nogata and Takahashi compared the strength and elastic modulus of bamboo fibers with different steel alloys, aluminum alloys, and ceramics. They showed that the bamboo fiber has a specific elastic modulus and strength which are much higher than that of steel, Al alloys, and ceramics (Nogata and Takahashi 1995).

Microstructures of bamboo fiber have been previously investigated using scanning electron microscope (Phong et al. 2011). The results showed the fibers were longitudinally aligned in the flat-wise direction. They were together bonded by hemicelluloses and lignin with different bonding levels. Mechanical properties of fiber bundle and their interfacial shear strength (IFSS) with typical resins such as unsaturated polyester and polypropylene are related to lignin and hemicelluloses content in chemical composition. The experimental results also proved that the IFSS of alkaline-treated fibers were better than that of steam-exploded and untreated fibers. Moisture absorptions of bamboo fibers at 50%, 60%, 70%, 80%, and 90% relative humidity at 200 °C were also determined. The results showed that the difference of moisture content of the alkaline-treated and the steam-exploded fibers was much lower than that of the untreated fibers at all relative humidity levels.

The chemical composition of bamboo fiber consists mainly of cellulose, hemicelluloses, and lignin. These components are actually the same high-glycans and make up about 90% of total weight of bamboo fiber. The other constituents are protein, fat, pectin, tannins, pigments, and ash. These constituents play important

role in physiological activity of bamboo, and they are found in cell cavity or special organelles (Khalil et al. 2012). The lignin is considered to provide stiffness and yellow color to bamboo fibers. Different treatments cannot remove all the lignin content of the bamboo fibers, as lignin has been found quite resistant to various alkalis. Noncellulosic components have enough contribution to fiber properties such as strength, flexibility, moisture, and even density (Li et al. 2010). The unidirectional arrangement of bamboo fibers in tissues and cell wall structure of bamboo is one of unique properties of bamboo.

Bamboo fiber is different from the other cellulose fibers in morphology, crystalline structure, and molecular structure. In SEM images, the cross section of the bamboo fiber is round with a small lumen, and there is no node in the longitudinal surface (Yueping et al. 2009). Most of the bamboo fibers have multilamellar cell walls with various layers. By means of viscometry, Yueping et al. showed that the bamboo fiber has a small molecular mass and degree of polymerization (Yueping et al. 2009). Wegst et al. reported that bamboo cellulose microfibrils imbedded in a lignin-hemicellulose matrix shaped into hollow prismatic cells of varying wall thickness (Wegst et al. 2014). Natural fibers themselves are cellulose fiber-reinforced materials, and the microfibril angle and cellulose content determine the mechanical behavior of the fiber (Jain et al. 1992).

3.1   Nanostructure of Bamboo Microfibrils

The bulk properties of materials are dictated not only by their elemental composition and molecular connectivity but also by their macromolecular architecture. A principal example of this is observed in plant cell walls, which are composite materials comprising biopolymers designed to serve multiple functions including structural support, microbial defense, and transport of water and nutrients throughout the organism.

Ciesielski et al. introduced a computational methodology to extract nanoscale geometry of cellulose microfibrils within thermochemically treated biomass directly from electron tomographic data sets. Computational analysis of the tomographic data is used to extract mathematical descriptions for longitudinal axes of cellulose microfibrils from which we calculate their nanoscale curvature (Ciesielski et al. 2013). They have extracted mathematical representations for the nanoscale geometry of cellulose microfibrils in pretreated biomass from tomographic data sets. The resulting parametric equations were used to calculate the curvature of plant cellulose microfibrils for the first time. They also found that orienting microfibril models to bend about the 100 crystal planes reduced the formation of kink defects after energy minimization (Ciesielski et al. 2013). The structure of the cellulose microfibrils of spruce wood was investigated by Fernandes et al., using a range of spectroscopic methods coupled to small-angle neutron and wide-angle X-ray scattering (Fernandes et al. 2011). Disorder in chain packing and hydrogen bonding was shown to increase outward from the microfibril center. The extent of disorder blurred the distinction between the Iα and Iβ allomorphs. Chains at the surface were

distinct in conformation, with high levels of conformational disorder at C-6, less intramolecular hydrogen bonding, and more outward-directed hydrogen bonding.

Fernandes et al. suggest that cellulose microfibrils with about 24 chains possibly twisted and with considerable disorder increasing toward the surfaces. Less extensive disordered regions probably exist within the core of each microfibril. Tight lateral binding is facilitated by the hydrogen-bonding pattern of the surface chains, at only a small cost in tensile stiffness due to the loss of intramolecular hydrogen bonding between $O-_2$ and $O-_6$. The surface location of these disordered chains means that a parallel mechanical model with tight lateral bonding to the ordered core is more appropriate than a series model, consistent with Fourier-transform infrared spectroscopy (FTIR) observations. The twisting of adjacent cellulose microfibrils may explain why they do not come into crystallographic register with one another over enough of their length to merge (Fernandes et al. 2011). A rectangular model is favored for spruce microfibrils, differing from more crystalline celluloses in having one hydrophobic and one hydrophilic face exposed. It is not clear how other polymers restrict access of celluloses to the hydrophobic surfaces, but impacts of the structure and aggregation of microfibrils on the recalcitrance of woody biomass are to be expected.

Kulasinski et al. investigate the influence of adsorbed water on amorphous cellulose structure and properties, within the full range of moisture content from the dry state to saturation, by molecular dynamics simulation (Kulasinski et al. 2014a). They found out that the properties of amorphous cellulose undergo a significant change about 10% of moisture content.

3.2   Molecular Origin of Strength and Stiffness in Bamboo Microfibrils: Molecular Dynamics Simulations

COMPASS (Sun et al. 1998) (cff91 ver. 2.644) was chosen as a proper force field for accurate atomistic simulations. COMPASS has been used successfully by many researchers for modeling the structural and mechanical properties of cellulose (Miyamoto et al. 2009; Moon et al. 2011; Sturcov et al. 2005; Eichhorn and Davies 2006; Eichhorn et al. 2005). Its accuracy for modeling cellulose molecular structure is proven.

In COMPASS, the nonbonded energies include van der Waals and electrostatic energies, with hydrogen bonds being a natural consequence of electrostatic energies. To study the hydrogen bond energies between particles, the following criteria have been used:

1. The maximum distance between the hydrogen and the acceptor atom for which hydrogen bonding is possible is 2.5 Å.
2. The minimum angle between the donor, hydrogen, and acceptor atoms in degrees for which hydrogen bonding is possible was chosen as 120°.

We have used a CHARMM-like MacKerell et al. (1998) hydrogen-bonding potential such as Eq. 4 to calculate the hydrogen bond energies between particles,

$$E_{hb} = D_{hb}\left[5\left(\frac{r_{hb}}{r_{DA}}\right)^{12} - 6\left(\frac{r_{hb}}{r_{DA}}\right)^{10}\right]\cos^4(\theta_{DHA}) \tag{4}$$

where θ_{DHA} is the bond angle between hydrogen donor (D) and the hydrogen (H) and the hydrogen acceptor (A). r_{DA} is the distance between the donor and acceptor. The values of D_{hb} and r_{hb} were adopted from the literature (Mayo et al. 1990).

To study the nanostructures of the models, radial distribution function (RDF) was used. RDF gives a measure of the probability of finding an atom, within a spherical shell of infinitesimal thickness at a distance, r, from the reference atom. To calculate elastic modulus, the periodic structures were expanded along each direction to the maximum strain amplitude of 0.01 in ten steps. In each step the stresses were obtained from virial stress expression which is commonly used to relate the computed stress in molecular dynamics to continuum stresses.

The unique mechanical properties of bamboo fibers come from their composite structure, in which cellulose fibrils are surrounded by a matrix of mainly lignin and hemicellulose (Zou et al. 2009; Wegst et al. 2014; Fernandes et al. 2011). Prior researchers have investigated the mechanical properties of cellulose fibers, lignin, and hemicellulose and their interactions (Chung et al. 2002; Moon et al. 2011; Sathitsuksanoh et al. 2010; Lahiji et al. 2010; Iwamoto et al. 2009; Sinko et al. 2013; Kulasinski et al. 2014b; Cousins 1976, 1978; Bergander and Salmen 2002; Salmen 2004; Dri et al. 2013). Among those previous efforts, Besombes and Mazeau (2005a, b) performed molecular dynamics simulations on the assembly of a threo guaiacyl β-O-4 dimer of lignin and different surfaces of cellulose. They showed that the adsorption of lignin onto cellulose is surface-dependent. They also found a major contribution of van der Waals interactions onto (100) face and a major influence of hydrogen bond interactions in the adsorption of lignin onto (110) and ($\bar{1}$10) faces. Linder et al. (2013) performed non-equilibrium molecular dynamics simulations of lignin and cellulose. They found that lignin strongly associates with the cellulose nanofibril. Nevertheless, few attempts have been made to use the cross-linked structure of lignin-hemicellulose to study the mechanical behavior of bamboo microfibrils and the interfaces of its matrix with cellulose nanofibrils.

Youssefian and Rahbar presented the role of each component in the mechanical properties of bamboo microfibrils as well as the underlying mechanisms of interactions between the matrix and cellulose nanofibrils (Youssefian and Rahbar 2015). With this aim, molecular models of lignin, bamboo hemicellulose, and a cross-linked structure of these two materials as representative matrix materials were developed. Molecular dynamics techniques described above were used to elucidate the structures, mechanical properties of the lignin, hemicellulose, and the matrix. It is important to note that the properties of the systems under study are known to be sensitive to the percentage of water molecules (Chung et al. 2002). Therefore, initially, no water molecule was added to the simulations to remove this effect from the results.

The most abundant carbohydrate in bamboo is cellulose with the volumetric percentage ranging from 40% to 45%. Figure 3 presents the structure of cellulose
Fig. 3 Hierarchal structure of bamboo fiber Youssefian and Rahbar (2015)

at different scales down to its building unit cell. Cellulose nanofibrils are formed by assembling linear chains of aldehyde sugars often referred to as glucose molecules, to make either rectangular or hexagonal cross sections with diameters of 3 to 5 nm (Lahiji et al. 2010; Ding and Himmel 2006). If the hydrogen bonds between the hydroxyl groups form in an order, highly ordered (crystalline) regions are formed. However, if random hydrogen bonds form, disordered (amorphous) regions develop (Lahiji et al. 2010; Pakzad and Yassar 2013). The positions of the hydroxyl groups determine the crystal system. These can be either triclinic or monoclinic unit cells (α or β type, respectively) with latter being the building block of plants such as bamboo. In a bamboo fiber, cellulose nanofibrils are surrounded by lignin-carbohydrate complex (LCC) matrices that mainly contain lignin and hemicellulose with volumetric percentages that ranging from 20% to 30% and 15% to 25% of the bamboo structure, respectively.

Lignin is a natural phenolic macromolecule that mainly presents in the plant secondary cell wall. It is made up of three main phenylpropanoid subunits, namely, p-hydroxyphenyl (H-type), guaiacyl (G-type), and syringyl (S- type) units (Malherbe and Cloete 2002). The biosynthesis of lignin occurs from different polymerizations of these three subunits. Hence, there are many possible bonding patterns between the individual units. Advancements in spectroscopic methods, however, have enabled scientists to elucidate the leading structural features of lignin (Pu et al. 2008). They have also enabled scientists to propose different models for the molecular structure of lignin (Adler 1977; Brauns 1962; Forss et al. 1966; Nimz 1974; Glasser and Glasser 1974). In this study, a structural model with 28 subunits of lignin proposed by Sakakibara (1980) has been used (Sakakibara 1980). In this model, the value of the structural units and the number of protons per C9 structural units are close to that of spruce milled wood lignin reported by other researchers.

In order to be able to provide a rigid support and shape for plants, lignin polyphenols are linked together in a three-dimensional cross-linked structures by covalently bonding to hemicellulose (Vanholme et al. 2008; Xiao et al. 2001; Sun et al. 2000). Hemicelluloses are a heterogeneous group of polysaccharides that, unlike the cellulose, frequently have side chain groups. They are essentially amorphous with little strength (Scheller et al. 2010). The two major categories

of hemicelluloses are glucomannans and xylans. Bamboo hemicellulose has been shown to be a xylan and further characterized as a β-(1→4)-linked-xylopyranosyl backbone, with the presence of L-arabinofuranose and 4-O-methyl-D-glucuronic acid as single side chains (4-O-methy1-D-glucurono- arabino-xylan (Maekawa 1976)) that are arranged in an irregular manner. Therefore, the positions of the side chains are not fully determined. With the ratio of uronic acid/arabinose/xylose of 1:3:32 reported (Shi et al. 2013), we consider hemicellulose structure as hybrid chains of two extreme positions of the side chains, one is a hemicellulose structure in which two functional groups are attached to the adjacent xylans and are in the closest possible distance (CPD). The other structure has the functional groups in the furthest possible distance (FPD). A preliminary study of the energy of different configurations revealed that the total energies were of the same order of magnitude. Hence, from the energy point of view, they are both acceptable. Hemicellulose molecules bond to lignin by a variety of different chemical bonds; however, most of the evidence refers to ether and ester bonds. Jeffries proposed structures for ester and ether linkages for lignin/uronic acid and lignin/arabinoxylan groups, respectively (Jeffries 1990). These linkage models have been used to create the bonds between lignin and hemicellulose in the cross-linked LCC network. Based on the structures discussed here, molecular models of the typical lignin, hemicellulose, LCC, and cellulose nanofibrils were created. Atomistic simulation techniques were used to study the structure, thermodynamic and mechanical properties, and interactions of the bamboo microfibril materials.

Thermodynamic properties such as density and glass transition temperature are good physical properties for evaluating the realism of the conformations of atomistic models and the reliability of the COMPASS force field in simulating mechanical behavior of lignin and hemicellulose. The computed glass transition temperature for LCC, presented in Table 1, falls between the obtained values for hemicellulose and lignin which are in good agreements with the experimental data. The final relaxed conformations of lignin and hemicellulose have average densities of 1.26 $\pm$ 0.02 and 1.45 $\pm$ 0.03 g/cc, respectively. These are comparable with experimental results, in Table 1. Hence the lignin and hemicellulose models estimate the real densities within 5.2% and 4.6%, respectively. These differences are partly attributed to the vacuum condition assumed in the simulation that does not occur in the experiments. The density of LCC relaxed conformation was determined to be 1.34 g/cc. Implementing the simple rule of mixture density, in which two materials are mixed physically without any changes in mass or volume, the LCC density, ρ_{LCC}, was estimated to be about 1.35 g/cc, using densities obtained from the lignin and hemicellulose simulations. This value is close to the density of the relaxed LCC model. Therefore, the molecular dynamics calculations showed the volume fractions of hemicellulose and lignin do not significantly change in the process of LCC creation. Hence, by using the same equation and the available experimental values for lignin and hemicellulose densities, the true value of LCC density can be estimated at 1.41 g/cc (Table 1).

The Young's moduli of the hemicellulose, lignin, and LCC are presented in Table 1. The average Young's moduli of lignin and hemicellulose were estimated to

Table 1 Density (g/cc), glass transition temperature, T_g, (°C), and elastic modulus of lignin, hemicellulose, and LCC obtained from the molecular dynamics simulations (Youssefian and Rahbar 2015) and experiments (Gibson 2012)

Density			Glass trans. temp.		Elastic modulus	
Material	Simul.	Exp.	Simul.	Exp.	Simul.	Exp.
Lignin	1.26	1.33	140.26	97–171	5.90	2–6.7
Hemicell.	1.45	1.52	186.06	140–180	8.40	3.5–8.0
LCC	1.34	N/A	166.11	N/A	6.93	N/A

be 5.90 ± 0.37 and 8.40 ± 0.15 GPa, respectively. These are in good agreement with the respective experimental measurements of 6.7 and 8.0 GPa for nearly dry Pinus radiata lignin and hemicellulose (consisting of arabino-4-O-methylglucuronoxylan which have a close structure to bamboo hemicellulose) (Cousins 1976, 1978). Other studies suggest respective values in the range of 1 to 2 and 3.5 to 7 GPa for different types of lignin and hemicellulose (Bergander and Salmen 2002; Salmen 2004). Hence, the results from the simulations and experiments show that hemicellulose has better mechanical properties than lignin. Performing the same procedure on the LCC model resulted in an average Young's modulus of 6.93 ± 0.31 GPa, which is between the Young's modulus of hemicellulose and lignin.

The elastic modulus of a material is defined by its resistance to the tension or compression of bonds. It is affected by factors such as interatomic and intermolecular energies per unit volume. For the amorphous materials, such as LCC, lignin, and hemicellulose, applied stresses are mostly used to overcome the nonbonded energies between the molecules. They are also used to unwind the chains rather than directly struggle with the potential energies between atoms or the crosslinking between chains. Therefore, at small strains, nonbonded energies play more important roles in determining the elastic moduli of amorphous materials. However, the effects of nonbonded energies are not equal. According to the Lennard-Jones function, nonbonded energies with lower equilibrium energies or shorter equilibrium distances exhibit greater resistance to stretching or compressing. Thus, they result in higher Young's moduli. The lower minimum potential energy creates a greater curvature (second derivative) of its energy-distance curve at the point of equilibrium and thus leads to a greater force-distance slope. The same situation holds true for the case where the minimum energies are the same, but equilibrium distances are different. In this case, the shorter equilibrium distance results in a greater curvature, which increases the slope of the force-distance curves. Therefore, the strong short-range hydrogen bonds play more important roles in determining the Young's modulus than the other weak long-range nonbonded interactions.

3.2.1 Adhesive Interactions and Mechanisms of Microfibril Strengthening

In the composite structure of a bamboo microfibril, knowledge of adhesive interactions between the different layers determines its strength. Applied stresses on a microfibril are carried either by cellulose nanofibrils, the LCC matrix, or the

interfaces of these two regions. To investigate the adhesion energies at these interfaces, 24 different assemblies of lignin, hemicellulose, and LCC on top of cellulose substrates were created, each of which simulates the interaction between one of the materials and one face of the eight possible faces of cellulose nanofibrils. The adhesion energies were computed from final trajectories of the simulations and presented in Fig. 4a. Although these results indicate that the overall adhesion energies for these materials are different, their tendencies to adhere to nanofibril faces exhibit almost the same pattern. For each material, the interaction energies of (100) and ($\bar{1}$00) faces are the lowest, whereas the energies of other faces vary around an average value. The average adhesion energy between lignin and nanofibril faces was about 152 mJ/m^2. This is higher than adhesion energy between LCC and nanofibril faces which is about 133 mJ/m^2. Hemicellulose with average adhesion energy of around 83 mJ/m^2 shows the lowest adherence to nanofibril among the three materials. This adhesion trend, also, has been shown by Hosoya et al. in the pyrolysis of hemicellulose and lignin with cellulose where lignin-cellulose interactions were significant compared to low hemicellulose-cellulose interactions (Hosoya et al. 2007). Therefore, lignin with greater overall adhesion energy to cellulose is responsible for providing strong interaction between LCC matrix and cellulose nanofibrils to create strong bamboo microfibrils.

To understand the mechanism of interactions between these materials and cellulose, we computed the electrostatic and van der Waals energies, accountable for the adhesion, as shown in Fig. 4b, 4c. These results suggest that the van der Waals energies do not change significantly over the nanofibril faces, whereas the electrostatic energies of (100) and ($\bar{1}$00) faces are less than that of other faces. Hence, the electrostatic energy is responsible for reduction of adhesion energy between cellulose (100) or ($\bar{1}$00) faces and hemicellulose, LCC, and lignin.

One of the major components of electrostatic energies at the interface of cellulose nanofibril and hemicellulose, LCC, and lignin is hydrogen bonding which are illustrated in Fig. 4d. Regardless of the slightly higher average hydrogen bond energy between lignin and cellulose, all three materials have almost the same hydrogen bond interaction energies with cellulose nanofibrils. The hydrogen bond energies show a similar pattern to the electrostatic energies presented in Fig. 4c. In other words, (100) and ($\bar{1}$00) faces have the lowest hydrogen bond energies which are similar to that of the electrostatic interactions. This suggests that different levels of hydrogen bond energies at the interface of nanofibril and hemicellulose, LCC, and lignin are the main reason for different electrostatic energies from one face to another, causing the adhesion energies between the matrix and (100) and ($\bar{1}$00) faces of nanofibril to drop.

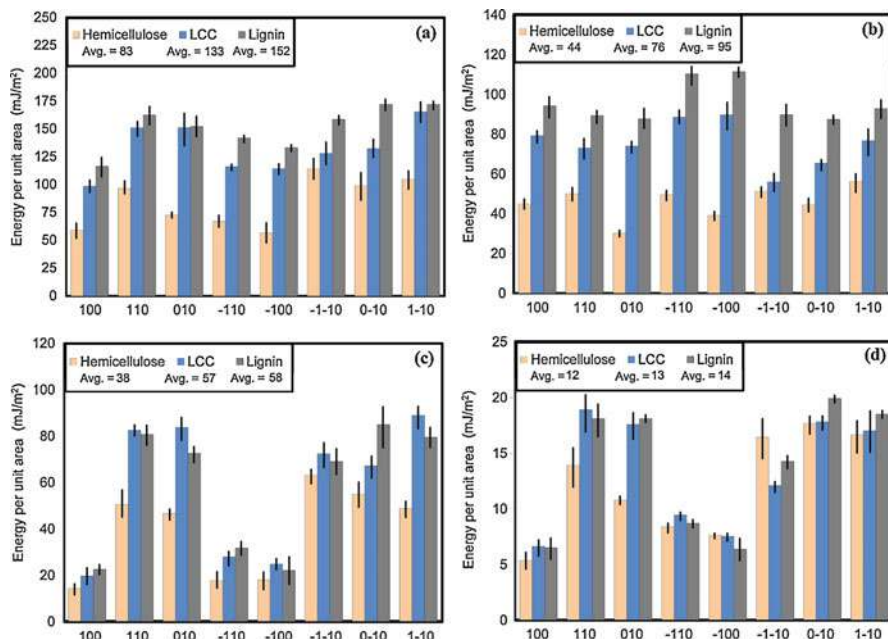
A closer look at the (100) and ($\bar{1}$00) face provides some insights into the weak hydrogen bonds between the faces and the matrix. Simulation result shows that the surfaces of (100) and ($\bar{1}$00) are covered with hydrogen atoms (white spheres). The hydrogen atoms are bonded either to oxygen or carbon. The hydrogen atoms connected to oxygen are less exposed because they stay closer to the surface, while the hydrogen atoms connected to carbon face outward and are configured for contact with adjacent layers. Therefore, since the accessibility of the hydrogen atoms in OH


Fig. 4 (**a**) The adhesion energy per unit area between different cellulose nanofibril faces and hemicellulose, LCC, and lignin computed from the molecular dynamics simulations. (**b**) The van der Waals energy per unit area between different cellulose nanofibril faces and hemicellulose, LCC, and lignin. (**c**) The electrostatic energy per unit area between different cellulose nanofibril faces and hemicellulose, LCC and lignin. (**d**) The hydrogen bond energy per unit area between different cellulose nanofibril faces and hemicellulose, LCC, and lignin

groups is less than that in CH groups, the overall hydrogen bond energy between these two faces and the matrix diminishes.

This adhesion study proves that the weakest interaction between cellulose nanofibril and LCC occurs at the (100) and ($\bar{1}$00) faces. However, the question of which interface is the weakest link in a microfibril still remains. To answer this question, we need to calculate the other possible locations where defects may occur. Figure 5 shows a schematic of a nanofibril in a matrix of LCC that is woven around both crystalline and amorphous regions. In this structure, the stress can either detach layers of LCC/LCC, interfaces of LCC/crystalline cellulose, and LCC/amorphous cellulose or fracture the cellulose nanofibril.

The weakest adhesion energy between cellulose nanofibrils and LCC was found to be around $106 \pm 8\,\text{mJ/m}^2$. This energy is less than the energy between the two layers of LCC in the matrix, which was estimated at about $160 \pm 29\,\text{mJ/m}^2$. The adhesion energy between LCC and the amorphous region of nanofibrils was close to the adhesion energy of amorphous cellulose/amorphous cellulose interface which were estimated to be 54 ± 10 and $44 \pm 6\,\text{mJ/m}^2$, respectively. Therefore, the amorphous region of nanofibril has the lowest adhesion energy in the system.
Fig. 5 The adhesion energy per unit area between different interfaces, present in a possible nanostructure of bamboo microfiber. The adhesive interaction energy at the interface of LCC layers is the highest among all the regions. The amorphous regions exhibit the lowest adhesive interactions; hence, their interface strength is likely to determine the strength of overall strength of bamboo microfibrils

4   Effect of Humidity on Mechanical Properties

Another component of the cell walls is water, which is known to have profound effects on the mechanical properties of wood. At the cell wall level, nanoindentation studies have shown that the longitudinal elastic modulus of S2 secondary layers in wood cell wall decreases with increasing moisture content (MC) (Yu et al. 2011b; Bertinetti et al. 2015). The results in these studies support the assumption that the moisture-sensitive matrix is responsible for the change in modulus of elasticity. In order to fully understand the plasticization effect of moisture on the individual wood cell wall constituents, Cousins measured the elastic moduli of extracted lignin and hemicellulose (Cousins 1976, 1977, 1978). He observed a small increase in elastic modulus of lignin from MC of 0.0% to 3.6% and linear regression at the higher MC. For hemicellulose, up to 10% MC, the loss of modulus is small, but from 10% to nearly 70%, MC the elastic modulus decreases by nearly three orders of magnitude. In another attempt, to understand the mechanism of water interactions with wood cell walls, Kulasinski et al. employed molecular dynamics simulations and showed that increasing MC above 10% decreases the stiffness of amorphous cellulose, noticeably (Kulasinski et al. 2015). Their results suggest that the moisture is adsorbed in hemicellulose and the interfaces of cellulose/hemicellulose, while no sorption occurs in the ordered cellulose (Kulasinski et al. 2014a).

In order to study the effects of humidity, nanoindentation was used to investigate the anisotropic moisture-dependent elastic moduli of bamboo fiber cell

walls (Youssefian and Rahbar 2015). Fiber wall elastic moduli were assessed using a Hysitron (Minneapolis, Minnesota, USA) TriboIndenter equipped with a Berkovich probe following the procedures in Jakes et al. (2015). Specimens were conditioned in absorption inside the enclosure for at least 36 h at room temperature (24–26 °C) under each RH, and the RH was maintained during the experiments.

Youssefian and Rahbar (2015) showed that the nanoindentation elastic moduli and the differences between the transverse and longitudinal surfaces agree well with previous work performed under ambient lab conditions (Jager et al. 2011). These results show that the longitudinal elastic modulus remained considerably higher over the range of MCs tested. The longitudinal elastic modulus is strongly influenced by longitudinal modulus of cellulose microfibrils, which provides higher modulus of elasticity due to its partly crystalline structure.

Distinguishable differences were also observed in the shapes of the elastic modulus curves with MC, and these differences are of most interest in the paper to gain new insights into the fiber wall structure-property relationships. The transverse elastic modulus continuously decreases almost linearly with increasing moisture content at the rate of 0.35 GPa per 1% moisture content from 7.9 to 2.6 GPa. In contrast, the longitudinal elastic modulus initially increases from an average value of 19.1 GPa at 0.5% moisture content to maximum of 19.4 GPa at approximately 3% MC and then decreases to 14.6 GPa at 14.5% with a rate of 0.4 GPa per 1% moisture content. A slight increase at low MCs has also been observed in bulk wood elastic moduli parallel to the grain, but elastic moduli perpendicular to the grain decrease consistently with increasing MC even at low MCs (Green et al. 1994).

This simplified definition of the stiffness of the potential energy indicates that strong short-range potential energies connect atoms with stiffer interactions than weak long-range potential energies. As a result, covalent bonds connect atoms with higher stiffness than hydrogen bonds and hydrogen bonds with higher stiffness than other nonbonded potential energies. In materials such as ordered cellulose in which external loads predominantly struggle against C-C and C-O, covalent bond potential energies dominate the elasticity and escalate the elastic modulus to relatively high value ($E_X = 11$–57 GPa, $E_Y = 50$–57 GPa and $E_Z = 110$–200 GPa) (Oliver et al. 2004; Jager et al. 2011; Green et al. 1994; Buehler et al. 2008). For amorphous materials such as the fiber cell wall matrix constituents, covalent bonds do not play significant roles, whereas hydrogen bonds primarily influence the elasticity, causing relatively low modulus elasticity of 6.93 GPa. Since water molecules with capabilities of interfering with hydrogen bond network are more likely to alter the elastic response of the matrix than the ordered regions of cellulose microfibrils, we focus our study on the influence of water molecules on hydrogen bond energies and nanostructures of bamboo fiber matrix and its constituents. Simulation results show that lignin and LCC have lower number of hydroxyl groups and are less hydrophilic compared to hemicellulose (Diddens et al. 2008). Therefore, the influence of water molecules on the hydrogen bond network of lignin, LCC, and hemicellulose should be different. In order to explore the different responses

of the matrix constitutes to absorbed moisture, atomistic simulations have been used as a powerful tool to elucidate the variation of the molecular interactions and nanostructures.

4.1   Variation of Elastic Modulus as a Function of Humidity

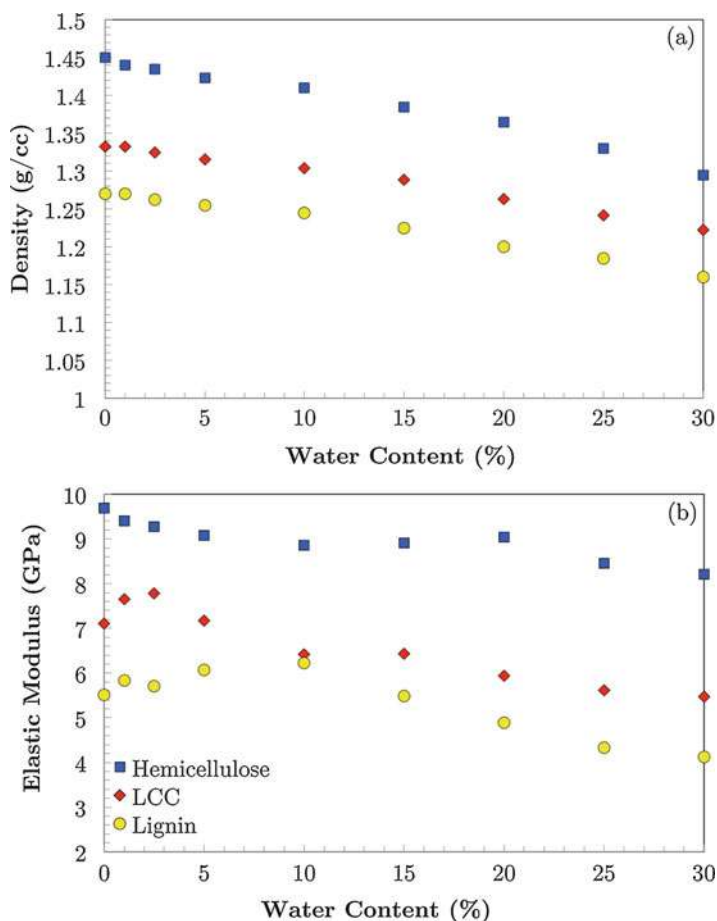
Figure 6 elucidates the variations of the density and modulus of elasticity of hemicellulose, lignin, and LCC with MC. Hemicellulose with higher density than lignin and LCC exhibits more sensitivity to water molecules. Introducing a small


Fig. 6 Variation of density and elastic modulus of hemicellulose (blue), lignin (yellow), and LCC (red) with increasing MC using molecular dynamics simulations. Hemicellulose density constantly decreases with growing MC, whereas LCC and lignin are resistant to the variation of density at very low MC. Hemicellulose elastic modulus constantly decreases with increasing MC, whereas LCC and lignin elastic moduli increase at low MC and then decrease (Youssefian et al. 2017)

amount of water (less than 2.5%) into dry LCC and lignin does not change their densities significantly, whereas hemicellulose density decreases notably. As the water molecules continue permeating into these polymers, their densities decrease almost linearly. The elastic modulus of hemicellulose drops almost linearly with increasing water content, whereas lignin and LCC elastic moduli increase at low water content (less than 10%) and decrease afterward. The peaks in elastic moduli are at 2.5% and 10% MC for LCC and lignin, respectively. When water molecules permeate into the polymer, they enhance the elastic modulus of the material. Once the number of water molecules inside the material reaches a certain level, the effect of water molecules becomes regressive, and the modulus of elasticity starts to decrease.

Comparison between the shapes of the moisture-dependent elastic moduli from the nanoindentation experiments and simulation results reveals interesting similarities. The transverse nanoindentation elastic moduli have a similar shape to the hemicellulose simulations, and the longitudinal nanoindentation elastic moduli have similar shape to the LCC and lignin simulations. This suggests that the nanostructure of fiber is organized in such a way that when compressed in the direction perpendicular to the cellulose microfibrils, hemicellulose, or possibly the similarly structured amorphous cellulose, has more influence on the elastic response than lignin. Conversely, in the direction parallel to the cellulose microfibrils, the lignin has a larger effect than the hemicellulose on the elastic response.

The intermolecular energies between particles in a material play an important role in determining its molecular structure that intimately dictates the physical properties such as density and elastic modulus. Since hydrogen bond interactions are both short range and angle-dependent, their impacts on structuring of polymers are significant. In hemicellulose and lignin, due to their high number of hydroxyl groups, the consequences of hydrogen bond energies are amplified, especially when interacting with water molecules. Studying variation of hydrogen bonds with water content allows us to capture important physics of water-polymer interactions with a minimal need for experimental inputs. Hence, we start with investigating the total hydrogen bond energies of hemicellulose, LCC, and lignin in different MC. All three materials exhibit almost the same progressive trend of total hydrogen bond energies when the water content increases. Nevertheless, hemicellulose shows higher total hydrogen bond energy than LCC and lignin due to the larger number of hydroxyl groups.

In an effort to investigate the conformational change of the hemicellulose, LCC, and lignin with increasing MC, the hydrogen bond energies between merely polymer chains are calculated. At low MC, the diminution of hydrogen bond energies indicates that hydrogen bonds are being broken by water molecules. Higher than 10% MC, the lignin and LCC curves go to almost a plateau, indicating a saturation point for hydrogen bond rupture process. Higher than 10% MC, the growth of hydrogen bond energies between water molecules increases significantly. This suggests that water molecules tend to create hydrogen bond with other water molecules and aggregate at high water content. The salient growing trend of this graph below 10% MC shows that the water molecules tend to form hydrogen bonds

with polymer chains at low MC. Taken all together, the results suggest that at low MC the hydrogen bonds between the polymer chains and water molecules seem to be more favorable than water-water hydrogen bond interactions. At higher MC, however, water molecules tend to make hydrogen bond with other water molecules and form nano-droplets inside the materials.

In order to analyze the evolution of hydrogen bond characteristics with increasing water molecules, radial distribution functions (RDFs) between water molecules and hydroxyl groups of hemicellulose, LCC, and lignin were calculated. The observed variations in dihedral conformation and internal structural variables are the results of the dynamics of nonbonded interactions like hydrogen bonding, electrostatic, and van der Waals interactions. The results suggest as the MC increases, water molecules tend to form hydrogen bonds with other water molecules rather than the polymer chains. Nonetheless, there is a significant difference between hemicellulose and lignin RDFs. Unlike hemicellulose, lignin peaks drop suddenly after 10% water content. This suggests that lignin nanostructure is saturated after 10% MC. LCC also follows the lignin behavior.

The other difference between lignin and hemicellulose response to water molecules is the height of the peaks. The higher peaks on lignin diagram indicate higher probability of finding the water molecules around the reaction site on lignin chains than that of hemicellulose. Therefore, lignin tends to interact with a larger fraction of introduced water molecules than hemicellulose. This is due to the position of functional groups adjacent to the hydroxyl groups. The lignin hydroxyl groups are mostly parts of well-spread hydroxymethyl groups that are extended out from the main chains. The hemicellulose hydroxyl groups, however, are parts of xylose groups, where two hydroxyl groups attach directly to the main chains and are localized on pyranose rings. Lignin hydroxyl groups are more exposed to and more accessible by water molecules than those of hemicellulose hydroxyl groups. Hence, although the hemicellulose structure contains more hydroxyl groups, lignin hydroxyl groups are more efficient in making hydrogen bonds.

Studying the fractional free volumes (FFVs) of a material can bring a deeper insight into understanding the nanostructure and the transport behavior of nonporous amorphous polymers. FFV can be defined as the ratio of the specific free volume (v_f) to the total specific volume (v_T). v_f can be calculated by subtracting the occupied volume (v_{OC}) from the total volume, $v_f = v_T - v_{OC}$. Therefore, the FFV can be calculated from, $FFV = 1 - v_{OC}/v_T$.

To calculate fractional free volume of lignin, hemicellulose, and LCC, Bondi has been used to compute the occupied volumes by the particles. Bondi estimated the occupied volume from the packing density of molecular crystals at $0\,K$ to be approximately 1.3 times the van der Waals volume (v_W) of the repeat unit of the polymer which can be reliably estimated from group contributions (Thran et al. 1999; Bondi 1966). Here, we have used a method developed by Zhao et al. for fast calculation of van der Waals volume as a sum of atomic and bond contributions (Zhao et al. 2003). In this method, which is termed as Atomic and Bond Contributions of van der Waals volume (VABC), the only information needed

for calculating the v_W is the atomic contributions and the number of atoms, bonds, and rings as follows:

$$v_W = 14.71N_O + 20.58N_C + 7.24N_H - 5.92N_{\text{Bonds}}$$
$$- 14.7N_{\text{ARings}} - 3.8N_{\text{NARings}} \quad (5)$$

where N_O, N_C, N_H, N_{Bonds}, N_{ARings}, and N_{NARings} are numbers of oxygen, carbon, hydrogen, bonds, aromatic rings, and nonaromatic rings, respectively. The oxygen, carbon, and hydrogen atoms have been assumed to be represented by hard spheres with a radius derived from the van der Waals radius of respective atoms ($r_C = 1.7\,\text{Å}$, $r_H = 1.2\,\text{Å}$, $r_O = 1.55\,\text{Å}$) (Batsanov 2001).

The number of bonds can be simply calculated by,

$$N_{\text{Bonds}} = N - 1 + N_{\text{ARings}} + N_{\text{NARings}} \quad (6)$$

where N (the total number of atoms) is the summation of all atoms in the system. Therefore, Eq. 5 can be modified to,

$$v_W = 8.79N_O + 14.93N_C + 1.32N_H - 20.62N_{\text{ARings}}$$
$$- 9.72N_{\text{NARings}} + 5.92. \quad (7)$$

Although VABC approach has proven to provide useful correlative and even predictive capabilities, its capabilities have not been fully proven for organic compounds. Since in our models water molecules have a major contribution in the expansion of the nanostructure, we have employed a more accurate and more complicated theory for computing the occupied volume by Connolly (1985). Connolly method analytically calculates the solvent-excluded volume of a molecule by a direct determination of the volume enclosed by the solvent accessible surface. In this method, the molecules are modeled as a static collection of hard spheres (with van der Waals radii) which completely exclude a spherical probe representing a solvent molecule. As the probe rolls over the van der Waals surface, it creates a Connolly surface that is a combination of three kinds of surfaces: convex, saddle, and concave. The total solvent-excluded volume of the molecule is the summation of all these surface pieces. Here, the volume of each polymer was calculated with Connolly method using a probe radius of $0\,\text{Å}$ which returns the van der Waals volume of carbohydrates.

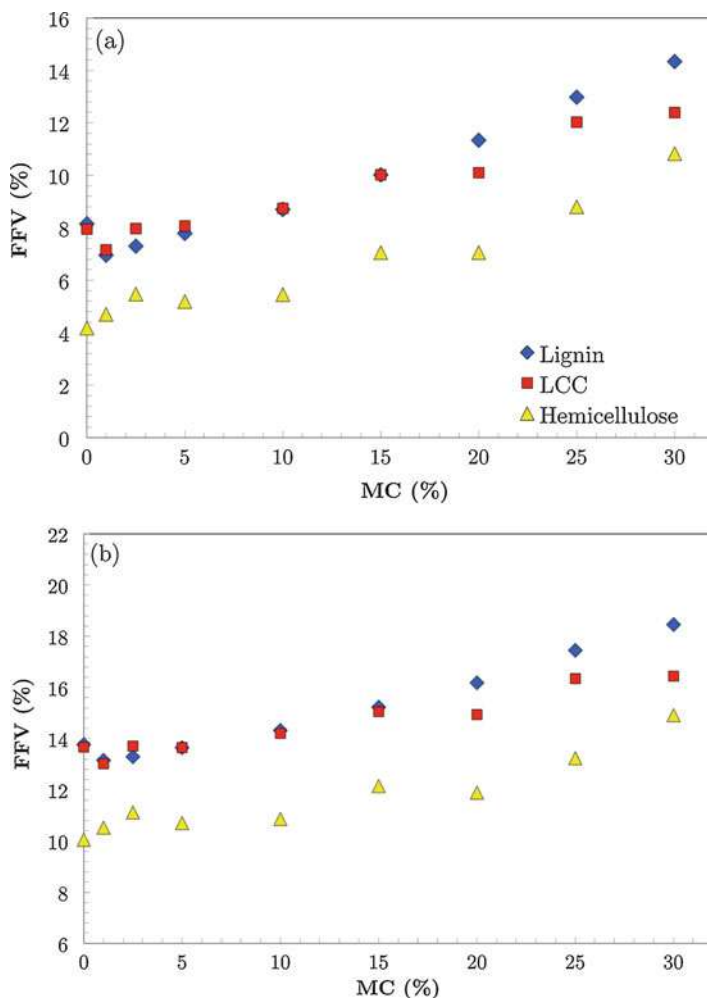
Figure 7 shows the variation of FFV with MC for lignin, LCC, and hemicellulose, calculated by VABC and Connolly methods. Although at higher MCs, VABC estimates FFV at higher values than Connolly, both approaches show the same trend for all three materials. The lignin FFV in dry condition is about 14%. Introducing water into lignin decreases the free volume down to 13% at 2.5% MC, followed by a linear increase to 20% around 30% MC. Hemicellulose, however, exhibits different


Fig. 7 Variation of fractional free volume (FFV) of hemicellulose, lignin, and LCC calculated by (**a**) VABC, (**b**) Connolly method using the results of the molecular dynamics simulations. Lignin and LCC have more free space for water molecules to fit in. As the water molecules are introduced to the system, they fit into the free volume between polymer chains and reduce FFV at low MC. Hemicellulose has denser structure. Adding water molecules to this system expands the volume and increases the portion of free volume, even at low MC (Youssefian et al. 2017)

response to increasing water molecules. Dry hemicellulose has an FFV around 10%, indicating a denser structure than lignin and LCC. Introducing water into the hemicellulose structure increases the portion of free volume to 12% rapidly followed by a linear increase up to 17% at 30% MC. The FFV value of LCC drops to 13% once the water is introduced into the system and then increases linearly with growing MC. This behavior seems to be influenced more by lignin than hemicellulose.

The different trends of variation of lignin and hemicellulose FFV with increasing MC indicate different influence of water molecules on the nanostructure of these materials. Hemicellulose with a dense hydrogen bond network has denser molecular structure than lignin. Upon the permeation of water molecules into hemicellulose molecular structure, free volume of this material increases because the system expands rapidly to create enough space for water molecules to fit in. Lignin with lower number of hydroxyl groups forms a different molecular structure with more free space available for water molecules to fit to. At low MCs, water molecules take spaces between the lignin polymer chains and decrease the free volume of this material. After 10% MC, however, the nano-droplets are formed in lignin, and free volume linearly increases with increasing MC.

5 Summary

Bamboo, a grass, with stiffness-to-weight and strength-to-weight ratios higher than steel and concrete is a wonder of nature. In this chapter we presented a comprehensive analysis of the mechanical properties of bamboo along with toughening mechanisms and models. We show at the molecular level that the bamboo microfibrils that are the main source of strength and stiffness. The microfibril nanostructure is composed of crystalline and amorphous cellulose in the matrix of lignin-carbohydrate complex (LCC). In this nanocomposite, hemicellulose provides the stiffness, while lignin binds strongly to cellulose faces and provides the strength. We also show that the role of humidity is significant in bamboo microfibrils. Addition of large volume of water (more than 10% water content) reduces the overall density and stiffness. However, addition of 1% water molecules to the system does not change density at nanoscale and increases the elastic modulus of in the longitudinal direction. We have shown this is probably due to the relatively larger fractional free volume in the structure of lignin, and subsequently LCC, at low moisture contents. This universal phenomenon is important in understanding the mechanics of these wood-based materials. It must be noted that more accurate force field can indeed improve the quality of these prediction and understanding of the physics of the complex bamboo system. Hence, development of new reliable force field that can more accurately capture the dynamics of cellulose, hemicellulose, and lignin especially at finite temperature can certainly advance this frontier in this field.

materials. Lignocellulosic biomass is the main component of cell walls in plants, and it is basically composed by cellulose, hemicellulose, and lignin. Among the three, lignin is of special interest, since it is the second most abundant natural polymer after cellulose and the main natural source of aromatic compounds. Effective lignin valorization is therefore a key challenge in the development of integrated biorefineries, and many strategies are being researched to successfully utilize it. Within this framework, this chapter presents a revision of current state of the art in multiscale modeling of lignocellulosic biomass (especially lignin), as well as an overview of molecular simulations that have helped understanding lignocellulosic biomass structure to develop new depolymerization strategies to enable the production of biomass-derived materials.

1   Introduction

Lignocellulosic biomass is an essential natural source for producing sustainable chemicals, materials, and fuels in a circular economy. Unlocking the potential of such resource requires however to address the fundamental challenge of economically degrading biomass into its basic constituents, i.e., cellulose, hemicellulose, and lignin. Once this is achieved, cellulose and hemicellulose can be decomposed into sugars for further processing and fermentation, while lignin arises as a raw material for the production of aromatic chemicals and biomass-derived materials. The current state of the art of biomass technology points to the valorization of lignin as the bottleneck for the successful development of integrated biorefineries. Therefore, many efforts are focused on developing sustainable lignin-related technologies, and accordingly lignin is the main goal of the current chapter.

   Lignin is the second most abundant polymer provided by nature after cellulose and the most abundant natural material composed mostly of aromatic moieties. It is a highly heterogeneous biopolymer, mainly constituted by three types of aromatic monomers known as monolignols: hydroxyphenyl (H), guaiacyl (G), and syringyl (S). These monolignols generate the 3D amorphous lignin structure by means of oxidative coupling reactions (Beckham et al. 2016). Monolignols derive from the bioconversion of L-phenylalanine through a series of conversion steps that involve multiple enzymes. The final result is a hard and glassy material at room temperature, which becomes soft above its glass transition temperature (80–100 °C) (Petridis et al. 2011b). It is very recalcitrant, with several vital roles in lignocellulosic biomass, such as providing mechanical strength and rigidity, participating in the water conduction system, or as defensive barrier against microbial, enzymatic, and chemical degradation (Sangha et al. 2012b). Lignin is usually obtained as a waste product from the pulp and paper industry, and with the expected advent of lignocellulosic biorefineries, the amount of waste lignin available is expected to increase dramatically. Due to the unique chemical properties of lignin, mainly devoted to its aromatic backbone, much interest has been placed on the production of materials from it. Some potential high-value lignin-derived

products are low-cost carbon fibers, plastics, composites, additives for cement, dust suppression agents, drilling fluids for oil recovery, polymeric foams, phenolic resins, biodispersants, surfactants, and membranes or aromatic chemicals (Calvo-Flores et al. 2015).

Understanding lignin structure and composition is crucial for deciphering biosynthetic pathways, producing plants with more easily degradable cell walls, and developing better technologies for depolymerization (see Fig. 1). However, decomposing lignocellulosic biomass into its basic components to produce such a wide range of materials requires a deep fundamental understanding of biomass structure, as well as polymerization and degradation mechanisms. Furthermore, isolating and characterizing lignin is one of the major challenges in current biomass technology, and therefore, complementary theoretical approaches can greatly assist to reach beyond experimental limitations. Modeling and simulations at different lengths from nano- to macroscale have helped indeed the development of depolymerization strategies to produce lignin-derived materials. Multiscale modeling can be used to predict the physicochemical properties of lignocellulosic biomass, as well as its components, including lignin. It has helped to provide insight into lignin structure, reactivity, and intermolecular interactions with lignocellulosic biomass components, to shed light into better degradation processes (Sangha et al. 2012b).

The choice of an appropriate computational method always depends on the specific molecular system under study, as well as on those questions to be answered. For dynamic processes that imply relatively large molecular systems and long (in a molecular context) time scales, molecular dynamics (MD) simulations can provide useful information from nanoscopic to mesoscopic length scale. When the study implies reactivity, reaction mechanisms, or electronic properties, quantum mechanical (QM) calculations are required, and the computational cost significantly increases. When it comes to molecular modeling and simulations, there is always an intrinsic trade-off between the desired level of accuracy and the computational cost of the calculations. This usually limits the size of the model system under study, and it is, in the end, the main criteria for selecting a computational method. A scheme summarizing the different methods that are used in lignocellulose multiscale modeling, along different time and length scales, is shown in Fig. 2.

The following sections provide an overall view of the different studies that have contributed to a better understanding of lignocellulose structure, properties, and degradation. Furthermore, it covers extensively how these methods, and the results derived from them, are helping the development of degradation strategies for the production of materials from lignocellulosic biomass. We cover both QM calculations and MD simulations of lignocellulosic biomass, with special focus on lignin, since we understand that this material is the cornerstone that could unlock the development of future integrated biorefineries. In conjunction with multiscale modeling techniques, we also review the experimental approaches that are currently applied and investigated to degrade biomass, and lignin, to its fundamental building blocks.

2   Ab Initio and Computational Chemistry Modeling of Fundamental Building Blocks of Lignocellulose

In the case of lignocellulosic biomass, as it happens with any materials system under study, large part of the challenge when performing computational chemistry calculations comes from the selection of the method that provides accurate results in a reasonable amount of time. Computational chemistry is much about adequated approximations, and that also includes modeling biomass components. As many of us already know, ab initio methods are the most accurate, but also the most computationally demanding approaches. In this regard, it is commonly accepted nowadays that density functional theory (DFT) is almost as accurate yet less computationally demanding than purely ab initio methods to calculate the electronic structure of molecules and materials. In addition, semiempirical QM methods also provide an efficient approach for calculating molecular structures and their properties. Below, we review some of these DFT approaches that have been undertaken to understand the structure of lignocellulosic biomass and especially of lignin.

Within DFT, B3LYP hybrid functional has been the most widely used across all areas of computational chemistry, including lignocellulosic biomass (Mostaghni et al. 2013), although a relatively new generation of DFT methods with that

improve accuracy and dispersion corrections are nowadays taking over B3LYP's overwhelming domain, e.g., ωB97X-D or Minnesota density functionals.

Within this context, QM calculations have been used to investigate the structure, electronic properties, and reactivity of monolignols, dehydrodilignols, and other lignin-like compounds. Back in 1996, Garver (1996) applied semiempirical MO methods to calculate minimum energy structures and energy barriers for bond rotations of lignin models represented by trimer acetoguaiacyl-dehydro-diisoeugenol methyl ether. This was complemented by Dos Santos (2001) in a study that used semiempirical methods to perform a conformational analysis of similar lignin model systems. Later in 2000, Russell et al. (2000) studied lignin formation mechanism by comparing the properties of lignin to synthetically produced polymers. In a similar direction, Durbeej and Eriksson (2005b) study dehydrogenated dilignols. They reported spin populations to characterize the electronic distribution of unpaired electrons and to correlate such distribution with the observed linkage ratios. Their results clearly pointed out a prevalence of the radical in the phenolic oxygen, partially explaining the prevalence of β–O–4 linkage in nature. In later works (Durbeej and Eriksson 2003, 2005a), the authors described the geometry and stability of dilignols considering some frequent linkages, β–O–4, β–5, β–β, β–1, 5–5, and 5–O–4, highlighting the intramolecular hydrogen bonding as a key factor for stabilizing the different conformers. These studies were the first attempts to describe the reaction mechanism for dilignols formation. Similarly, Parthasarathi et al. (2011) analyzed the main dissociation tendencies of a diverse set of lignin linkages encompassing 65 lignin model compounds. More recently, radical coupling reactions for different lignin linkages were investigated in an extensive computational study performed by Sangha et al. (2012a). Natural bond orbital (NBO) analysis was used to quantify the spin densities, and this was completed by providing reaction enthalpies of monolignol dimerization for the main linkages in lignin, β–O–4, β–5, β–β, β–1, 5–5, and 5–O–4. Additional studies implemented Monte Carlo conformational search to find the lowest energy conformers for each dilignol, including solvent effects. These results showed that β–O–4, β–5, β–β linkages are the most energetically favorable. In the same direction, Watts et al. (2011) studied lignin polymerization with focus on potential mechanisms that lead to the formation of α–linkages. They also employ B3LYP hybrid functional to calculate thermodynamic data, pointing out that the most probable mechanism for the formation of α–linkages occurs by the formation of α radical monolignols hydroxylated in the C$_{\beta}$– and in the presence of H$_2$O$_2$.

Moreover, taking into account that lignin structures are rich in aromatic functional groups, computational studies where monolignols and dilignols interact with each other require the implementation of electron dynamic correlation to describe π–orbitals. The development of dispersion-corrected functionals enabled further studies in the field. In 2006, there was a valuable advance in DFT methods with the publication of M05-2X hybrid functional that takes into account the noncovalent interactions. Chen and Sarkanen (2010) used the dispersion-corrected M05-2X hybrid functional to study the possible arrangements between a radical monolignol and a lignin model. Their results pointed out that noncovalent forces rule the

polymerization steps, where a co-facial arrangement between the radical monolignol and lignin substructures is preferred due to π–stacking between aromatic groups. The authors also highlight that such noncovalent interactions prevail over hydrogen bonding, substituent interactions, and solvent effects. With focus in the lignin β–O–4 linkage bond, Lim et al. (2013) studied model compounds to estimate the efficiencies of single electron transfer-promoted photochemical and enzymatic C–C bond cleavage reactions. Their results show that the radical cations derived from less alkoxy-substituted dimeric β–O–4 linkage models undergo more rapid C_1–C_2 bond cleavage than those of more alkoxy-substituted analogues. Further insight was also provided by Sánchez-González et al. (2017), by analyzing the formation mechanism of β–O–4 linkages with quantum theory of atoms in molecules (QTAIM) and noncovalent index (NCI) analysis to quantify noncovalent interactions between reactants. They pointed out the importance of hydrogen bonding and π-stacking interactions in the stabilization of transition states that control the polymerization mechanism of lignin.

The interactions among the three main components, cellulose, hemicellulose, and lignin, were studied to examine the hydrogen bonding network of cellulose–hemicellulose systems and the covalent bond linkages of hemicellulose–lignin systems (Zhang et al. 2011). In combination with experimental data from X-ray photoelectron spectroscopy (XPS), Haensel et al. (2012) applied DFT to estimate the valence band structure of cellulose and lignin. They proved valence band analysis supported by DFT as a powerful basis for a detailed interpretation of spectroscopic data. The comparison with experimental, and in particular with sum frequency generation–vibrational spectroscopy (SFG-VS) for crystalline cellulose inside intact lignocellulose, showed that dispersion-corrected DFT-D2 underestimates the distances between hydrogen-bonded oxygen atoms compared to the experimentally determined values (Lee et al. 2013).

As expected by the limitations imposed by the computational cost of the methods, all these studies have been mainly focused on the structure, electronic properties, and reactivity of monolignols, dehydrodilignols, and other small lignin-like model compounds.

3 Molecular Dynamics and Larger-Scale Models of Lignocellulosic Components

As we discussed already, a proper description of lignocellulosic biomass requires a multiscale approach that is able to describe all key fundamental features of such hierarchical material along different length scales. This multiscale description implies not only the abovementioned ab initio and DFT calculations but also larger-scale models that help in understanding the structure of cellulose, hemicellulose, and lignin, as well as their integration into lignocellulosic biomass. Ab initio and DFT methods are computationally too expensive to simulate the behavior of molecular systems in such larger scales, and therefore MD simulations arise here as the most

suitable choice to reach larger model sizes that still retain the details required to achieve the intended atomistic description of fundamental features.

MD simulations of wood have helped in understanding the structure and molecular deformation mechanisms (Jin 2015). In the context of MD simulations of complexes between lignocellulose components, Shevchenko and Bailey (1996) studied the lignin–carbohydrate complex (LCC) of living plants and soil humic materials by considering model linear chains of lignin, in the presence of carbohydrate linear structures. MD simulations also require the selection of models systems, yet larger than those employed in QM calculations. The results pointed out by these authors show that a helical conformation of lignin chains can accommodate the carbohydrate ribbon structure inside, stabilizing the LCC without covalent bonds. A similar work was presented by Houtman and Atalla (1995), where the adsorption of lignin oligomers in a polysaccharide surface matrix was studied. This work pointed that lignin can be adsorbed at the surface of cellulose microfibrils, leading the polymerization of the lignin–polysaccharide complex. Additionally, the nature of the polysaccharide matrix was shown to induce a selective binding with preferred orientations, affecting the architecture of the hemicellulose in the cell wall. In connection with hemicellulose, one of the most useful advances for modeling lignin–hemicellulose complexes was achieved through the development of WallGe, a Fortran program to build virtual cellulose-hemicellulose networks by stochastic self-assembly. This approach also provided a way to predict the mechanical properties finite element analysis (Kha et al. 2010). Within a similar context, a modeling of lignified secondary plant cell walls adapted to grass was applied to systems composed of cellulose, xylan, water, and lignin (Charlier and Mazeau 2012). More specific to xylan, as the most relevant component in hemicellulose, MD simulations help understand the mechanism of thermal decomposition of hemicellulose (Huang et al. 2013).

Despite these studies on LLC, lignin–cellulose and lignin–hemicellulose complexes, stand-alone models for lignin are of special importance due to the relevance of this lignocellulosic component, and therefore, the amount of literature on the topic is especially significant. Some of the first MD studies on lignin were performed by modeling β–O–4-linked dimeric and oligomeric model compounds (Simon and Eriksson 1995). Similar methods were used to characterize the conformational behavior of dilignols formed by the most abundant linkage present in lignin, the β–O–4 linkage.

In 2009, Petridis and Smith (2009) presented a first parametrization of molecular mechanics force field for lignin, based on QM data of model compounds. Partial atomic charges were derived using the electrostatic potential fitting from methoxybenzene–water interactions. Dihedral parameters were optimized by fitting to critical rotational potentials, and bonded parameters were obtained by optimizing vibrational frequencies and normal modes. This parametrization paid special attention to properly describe the β–O–4 linkage by considering the partial atomic charges of the atoms involved in it. This work opened new perspectives for computational simulations of lignocellulosic biomass, since, together with the

existing force field for polysaccharides, it enabled more accurate full simulations of lignocellulose (Petridis and Smith 2009). The same authors used neutron scattering experiments and MD simulations to reveal that lignin aggregates are characterized by a surface fractal dimension that is invariant under change of scale from ∼1 to 1000 Å (Petridis et al. 2011a). This work and a complementary study on the temperature-dependent structure and dynamics of individual softwood lignin polymers in aqueous solution helped to understand the role of lignin as residual that hampers an effective hydrolysis of plant biomass in cellulosic ethanol production (Petridis et al. 2011b). In a similar direction, replica-exchange MD have been used to characterize the globule-to-coil transition for a softwood-like lignin biopolymer in a tetrahydrofuran (THF)–water cosolvent system, at temperatures at which the cosolvent undergoes a de-mixing transition (Smith et al. 2016).

Furthermore, Besombes and Mazeau (2004) used CHARMM force field to study the influence of hydrogen bonding and steric effects of methoxide groups in the conformational characteristics of such linkage and the relative stability of *erythro-* and *threo-* forms. This study was later complemented by the same authors to further analyze the assembly of cellulose and lignin (Besombes and Mazeau 2005a). They consider a molecular model of a cellulose crystal corresponding to the allomorph Iβ. The model was selected to exhibit different surfaces that mimic the carbohydrate matrix present in native wood cell wall. In a second part, they extended their previous computational investigations by considering more complex systems, looking for evidence of organization of lignin molecules at the interface with cellulose (Besombes and Mazeau 2005b). Surface coverage of cellulose, molecular mass, and lignin structural features were some of the parameters taken into account to examine their influence on the associative interactions between cellulose and lignin. An additional step was taken by Beste (2014) by selecting the most common linkages to perform MD simulations with a reactive force field (ReaxFF) to describe lignin degradation into carbon fibers.

Going up in the scale of simulations, it is worth mentioning the implementation of experimental measurement of the intra-ring properties of loblolly pine (*Pinus taeda*) to provide inputs to finite element models using both solid layers and cellular layers to represent longitudinal tracheids. This was used to investigate the effect of considering wood strands as two-layer composites consisting of earlywood and latewood, or intra-ring, layers (Hindman and Lee 2007).

The complexity of the hierarchical structure along different large scales, together with computational limitations, has called for the implementation of new methodologies in the field, as, for example, the use of quantum mechanics/molecular mechanics (QM/MM) that has been proved successful in simulating different kinds of biomolecular systems (Senn and Thiel 2009). Combined QM/MM approaches have become indeed the method of choice for modeling reactions in many biomolecular systems. As it happens with the previously discussed DFT methods, the limitations imposed by the computational cost MD simulations, when it comes to the size the models, have not hampered the production of very useful information to support better degradation strategies as we discuss below.

4 Downstream: Multiscale Modeling to Assist Pyrolysis, Hydrothermal Liquefaction, Depolymerization, and Upgrading

From previous sections on structural QM and MD modeling of lignocellulose and lignin at different length scales, it has been shown that a plethora of approaches have provided significant amount of information on the structure, chemical bonding, and molecular-scale features of lignocellulosic biomass. All this fundamental knowledge has been proved very useful in developing the polymerization processes that we will describe in this part of the chapter. These experimental techniques, largely supported by modeling and simulation, help the actual valorization of those materials that are produced by degrading biomass to simpler building blocks, i.e., downstream processing. This section aims at connecting these ab initio and MD simulations with state-of-the-art experimental approaches for depolymerizing lignocellulosic biomass, as well as providing a quick introduction to those upgrading strategies that follow biomass degradation. It also includes some references to the kinetic modeling that has been done to simulate mass and heat transfer that occur during pyrolysis and hydrothermal processes.

4.1 Valorizing Lignocellulosic Biomass

As we have already pointed out, prior to the valorization of lignocellulosic biomass into any kind of material, it is necessary to break down its structure into its main biochemical fractions: cellulose, hemicellulose, and lignin (see Fig. 3). Effective methods to separate biomass into pure streams of its biochemical constituents are important for the valorization of any lignocellulosic biopolymer. For example, during the enzymatic hydrolysis of cellulose to produce bioethanol, 50% of the enzymes tend to bind nonproductively to lignin, thus decreasing the degree of conversion of cellulose. Thus, several methodologies are available for the isolation of lignin streams, e.g., acid hydrolysis, alkaline hydrolysis, hydrothermal degradation, or ionic liquids, and some modeling have been devoted to understand the fundamental mechanisms that control lignin–cellulose and lignin–hemicellulose interactions. Once a lignin stream is obtained, it can be used as raw feedstock for producing lignin-derived materials, e.g., carbon fibers or graphitic porous carbons. In many other cases, the valorization of lignin into usable materials requires additional depolymerization steps that yield monomers or small oligomers, hence the importance of modeling these smaller fragments that can be recovered and directly used, i.e., catechol, phenol, or be subjected to a second valorization step by means of biological or chemical methods, in order to upgrade the depolymerized fragments into high-value materials.

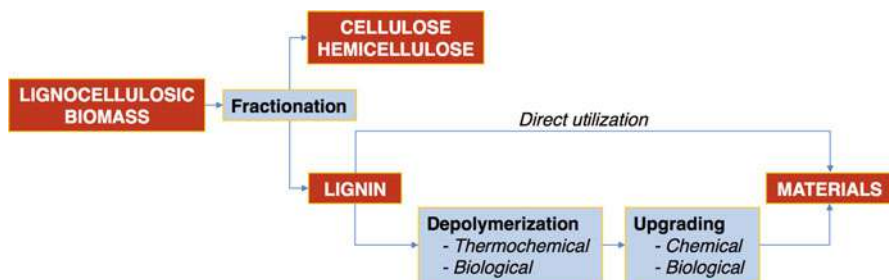
Lignin depolymerization is a challenging process, due to the presence of a handful of chemical linkages with different strengths in the structure of lignin, as it has


Fig. 3 The pathway from lignocellulosic biomass to lignin-derived materials

been discussed in the previous sections. Conventional depolymerization methods for lignin can be generally divided into (thermo)chemical or biological. The main (thermo)chemical routes include pyrolysis and hydrothermal/solvothermal processing (sometime aided by base catalysts), whereas biological depolymerization is mainly related to the use of extracellular enzymes secreted by ligninolytic organisms (mainly fungi) capable of degrading the aromatics structure of lignin (see Fig. 4).

When it comes to modeling, most of the work in the field has been done concerning the pretreatment, drying (Zhao et al. 2015), and pyrolysis of lignocellulosic biomass, which usually implies large-scale empirical modeling of the kinetic mechanisms, in the solid phase for biomass pyrolysis and in gas phase for secondary reactions of released products. This includes mathematical models of porous reactive mediums to study the processes of heat and mass exchange, drying, and ignition (Loboda et al. 2015), as well as to simulate heat and mass transfer in liquid, vapor, and bound water movement during drying processes (Jia 2008). Some multiscale models of hydrothermal pretreatment methods have been also developed, starting from the microscale level where chemical reaction takes place followed by the mesoscale level, in which the diffusion in lignocellulosic material is the main process, and finally the macroscale level where the mixing and bulk diffusion are important (Ali-Hosseini and Nilay Shah 2009). There are also some multiscale computational models that even scale up to the design and optimization of industrial plants that are devoted to the pretreatment of biomass (Colin et al. 2016). Moreover, jointly with plant bioengineering, the pathways for the biosynthesis of lignin can be understood and modified to design novel, artificial lignin variants that are more easily converted into materials, either directly or through strategies that involve depolymerization and subsequent upgrading. For instance, it has been reported that the side chains of the monolignols can be varied without compromising the lignification process (Vanholme et al. 2012).

To understand the enzymatic deconstruction of cellulose, Beckham et al. (2011) have provided extensive work on understanding the molecular-level mechanisms that enzymes employ to deconstruct plant cell walls. These authors discussed path
Fig. 4 Multiscale modeling guides the design of strategies for lignin depolymerization as well as new insights about lignin biosynthesis

sampling methods to measure rates of elementary steps of enzyme action, coarse-grained modeling for understanding macromolecular, cellulosomal complexes, methods to screen for enzyme improvements, and studies of cellulose at the molecular level. They have pointed out simulations as a complementary tool to understand carbohydrate-active enzymes and plant cell walls, which will enable industrial processes for the production of advanced, renewable fuels.

4.2   Direct Conversion of Lignin to Materials

Lignin can be directly subjected to chemical processes in order to produce several types of materials, such as carbon fibers for composite reinforcement or porous activated carbons with applications in energy storage, water purification, or CO_2 capture and sequestration. Lignin-derived carbon fibers can be obtained through different methods, like dry and wet spinning or melt spinning. This is typically followed by a stabilization process of the spinned lignin fibers (normally in an oxygen atmosphere) followed by a high-temperature treatment in an inert atmosphere (Beste 2014). Prior to these, lignin can be conditioned to improve the properties of the final carbon fibers, either chemically (e.g., acetylation, hydrogenation, or phenolation) or biologically. Moreover, the different monolignols that constitute lignin present different thermostabilization properties when forming carbon fibers, and thus the mechanical properties of the carbon fibers can be improved by adjusting the blending ratio of the various monolignols. Another way of valorizing directly lignin after its isolation is its hydrothermal carbonization (HTC). Here, mixtures of lignin and water are subjected to high pressures and temperatures. Under such conditions, water acquires properties very different from those at atmospheric conditions: i.e., high ionic product or reduced electrical conductivity and density. Despite the high thermal stability of lignin, HTC turns it into a solid material with a more condensed aromatic character and with properties that resemble those from brown coal. The resulting product has also a higher glass transition temperature and a higher thermal stability. During HTC, the β–O–4 linkages are mostly hydrolyzed, and the propyl side chains from the monolignol units are partially cleaved. Dealkylation and demethylation also take place, and more catechol-like units are obtained. The addition of catalysts (e.g., H_2SO_4 or Fe^{2+}) can enhance these reactions.

At this stage, modeling can be a useful tool here to understand the oxidative thermal conversion of lignin (Beste 2014) and how the different linkages between monolignols behave under this process (see Fig. 5). Theoretical studies of bond dissociation energies for lignin model compounds have been also performed for six prevalent linkages (β–O–4, α–O–4, 4–O–5, β–1, α–1, and 5–5) by using density functional theory methods (Huang et al. 2015). Some quantum MD studies have helped understanding fragment distribution of thermal decomposition of lignin monomer (Endo et al. 2008) as well as monomer and dimers of lignin from thermal decomposition (Kato et al. 2008).

Fig. 5 Lignin-derived products are currently produced through biological and thermochemical processes
4.3   Thermochemical Depolymerization Processes

Lignin pyrolysis is carried out at high temperatures during short reaction times in an inert atmosphere, turning lignin into a liquid product with a complex mixture of hundreds of phenolic monomers and oligomers (Kawamoto 2017). It can be performed in the presence of catalysts, such as zeolite, in order to increase the selectivity toward certain products, like BTX (Li et al. 2015). It behaves differently, depending on the biomass type used. Softwood generates guaiacol-like phenols as main products, whereas hardwood tends to generate syringol and phenolic monomers and oligomers. Pyrolysis is a radical reaction, and hence the pyrolysis products tend to present stability issues and be prone to repolymerization. Hydrothermal processes take advantage of the special properties of water under sub- and supercritical conditions to break down lignin into smaller (even monomeric) aromatic molecules, such as catechol or guaiacol. Many of these molecules are useful building blocks for a bio-based chemical industry, perfumes, pharmaceuticals, or building blocks in organic synthesis. Under such conditions, water becomes highly reactive and breaks down the lignin structure. The presence of a liquid medium causes a dilution in the biomass feedstock, thus reducing the repolymerization of the reaction intermediates. A variation of this process includes the addition of a base to the aqueous or organic solvent (Erdocia et al. 2014), which has proved to lead to higher yields of the liquid product. Other organic solvents (e.g., acetone, ethanol, tetralin) (Breunig et al. 2018) can be used instead of water. The process is termed then solvothermal conversion. These organic solvents act as an in situ source of hydrogen or as hydrogen shuttle for the reaction. For instance, formic acid is reported to decompose under high pressure and temperature, yielding atomic hydrogen (Gasson et al. 2012). Under these conditions, lignin is quickly depolymerized, and the presence of atomic hydrogen in the reaction medium can cap the radicals generated during the process, thus avoiding subsequent polymerization reactions. Variations of the hydrothermal/solvothermal

process might include the use of heterogeneous catalysts or high-pressure hydrogen atmospheres (Breunig et al. 2018).

Modeling of pyrolysis is a multicomponent, multiphase, and multiscale problem of kinetic modeling of pyrolysis and combustion of biomass, which includes modeling of bio-oil and therefore a comprehensive description of kinetic and transport processes, both at the particle and the reactor scale (Ranzi et al. 2017). The models can provide information on heat of reaction, reaction products concentration, and reactants accumulation (Roman et al. 2011).

Blasi (2008) reviewed the state of the art in modeling chemical and physical processes of wood and biomass pyrolysis, indicating critical issues that require further investigation. Additional and very detailed reviews on biomass pyrolysis were provided also by Sharma et al. (2015), where they described operational and environmental challenges associated with pyrolysis at different scales, e.g., particle level, multiphase reacting flow, reactor performance, process integration and control, and by Anca-Couce (2016) with a focus on individual reaction mechanisms of cellulose, hemicellulose, and lignin and recent advances in understanding the fundamental reaction pathways. They demonstrated that a multiscale consideration of pyrolysis on multiple levels – specifically, on molecular, particle, and reaction levels – is required to accurately describe biomass pyrolysis.

More fundamental knowledge on reaction mechanisms during pyrolysis has been achieved by DFT calculations of model compounds (Kawamoto 2017), reaching a better understanding of the molecular mechanisms involved in lignin pyrolysis/gasification and guiding the development of better systems that overcome issues with low product selectivity.

4.4   Biological Depolymerization Processes

The first thing to remember when discussing depolymerization strategies is that the chemical bonds in lignin are rather stable, making them difficult to degrade by microbes. However, there are a few microorganisms in nature that encode metabolic pathways to break down lignin. These organisms are typically fungi that degrade lignin through two types of extracellular enzymes: laccases and peroxidases. These enzymes break down the lignin structure into aromatic radicals that subsequently cleave other lignin linkages (C_α–C_β, alkyl-aryl demethoxylation, and aromatic ring cleavage) by means of nonenzymatic reactions (Beckham et al. 2016). It has been reported that bacteria can also express those enzymes and degrade lignin (Bugg et al. 2011). However, both fungi and bacteria degrade lignin very slowly, which hinders their industrial implementation. Tools provided by synthetic biology and metabolic engineering (e.g., directed evolution or enzyme resurrection) (Alcalde 2015) can be of use to enhance the lignin degradation rate, making these microbes more prone for industrial implementation. Other issues of concern for the biological depolymerization of lignin are the need of a redox environment and aerobic conditions to operate, which demands a continuous supply of H_2O_2 and O_2.

From a modeling standpoint, the enzymatic biodegradation of lignin in soil by various microorganisms has been reviewed recently by Datta et al. (2017), with

focus on fungi and bacteria capable of producing ligninolytic enzymes. They state that very little is known about the degradation of lignin in soil, and they envision new efforts to identify new lignin-degrading microbes and thorough study of their genomics, biochemistry, and proteomics in the coming years.

As it happens with other protein-related areas, modeling can be applied to optimize the interaction of lignin with the enzymes (laccases, peroxidases) secreted by microbes. This can provide on the one hand guidelines for tailoring the lignin substrate to optimize its enzymatic degradation and, on the other hand, for tailoring the enzymes for optimized bioconversion or for expanding the substrate specificity for biological funneling during the upgrading of depolymerized lignin liquors (Beckham et al. 2016).

In any case, it is clear that understanding lignin-degrading reactions of ligninolytic enzymes is a challenge in which modeling has provided useful inputs by calculating binding affinities, intermediates, reaction energy profiles (Chen et al. 2011), as well as oxidation mechanisms using QM calculations (Elder 1997).

In the case of peroxidase, MD simulations have been the most used method to provide information on peroxidase behaviors in solution (Gerini et al. 2003), and the structure of peroxidase (Banci et al. 1994), as well as the effect of calcium ions on it (Banci et al. 1996). More recently, QM/MM methods have shed light into the intrinsic mechanisms that rule the interaction of tryptophan radicals in the long-range electron transfer of lignin peroxidase and lignin peroxidase-like systems (Bernini et al. 2012).

For plant and fungal laccases, some molecular docking and MD analyses have helped in unraveling the differential enzymatic catalysis with respect to lignin biosynthesis and degradation (Awasthi et al. 2015). Also, the factors affecting product distribution in laccase-catalyzed oxidation reactions have been studied by a combination of experimental and computational approaches (Lahtinen et al. 2013).

4.5   Chemical and Biological Upgrading of Depolymerized Lignin

The depolymerization products from lignin can be upgraded to other materials in two different ways: through chemical and biological processes. In both cases, the main challenge is that lignin depolymerization usually yields a complex slurry of aromatic compounds (Beckham et al. 2016) with very different reactivities.

Chemical processes for upgrading depolymerized lignin include, among others, classical chemical reactions such as alkylation, acylation, carboxylation, halogenation, or oxidation. There is even an industrially established process for the production of vanillin from lignin through chemical oxidation (Araújo et al. 2010). Lignin can be used as additive or substitutive feedstock for the production of adhesives, such as polyurethane foams or urea-formaldehyde resins. But lignin presents two issues that hinder their use as additives for adhesives: its wide range of molecular weights and its relatively low reactivity due to the presence of methoxy groups that suppress the reactivity of the aromatic rings. Most of the research is being devoted to enhance the reactivity of those aromatic rings, mainly by demethylating monolignols to produce polyols (Ferhan et al. 2013).

Some research is being done on the modeling side for studying the properties of lignin-derived adhesives (Lopez-Albarran et al. 2017). Using ReaxFF simulations, it was shown that the type of mono- and oligolignol precursors used to generate the adhesives affects their mechanical properties (i.e., the Young's modulus), and their results correlated quite well with experimental values.

The biological upgrading of depolymerized lignin offers the possibility of obtaining different types of products: molecules that maintain the aromatic ring from the phenolic monomers (e.g., vanillin (Lahtinen et al. 2013)), ring-opened species generated through aromatic catabolic pathways, or products obtained through central metabolic routes, where the microbes use "upper pathways" to funnel the carbon flux of the handful of aromatic materials coming from lignin depolymerization and convert them into central intermediates (e.g., protocatechuate or catechol) that then can be used by the microbes to produce energy storage compounds, such as TAGs or PHAs (Beckham et al. 2016). An interesting approach is to develop a one-pot system in which the enzymes that depolymerize the lignin into low molecular weight compounds work in concert with microbes that take up those low molecular weight compounds and convert them into high-value products. This is being developed at NREL under the name of Lignin Consolidated Bioprocessing (Salvachua et al. 2015). It is a process intensification strategy that reduces the number of unit operations needed and the capital expenses, due to the synergistic interaction between extracellular enzymes and microbes. Moreover, the intracellular accumulation of high-value compounds facilitates their recovery from the broth, as those products do not need complex separation processes from the lignin depolymerization liquor. Conversely, cells can be separated from the fermentation broth and subsequently lysed to recover their intracellular metabolites. Several studies have proved that bacterial species (e.g., *Pseudomonas putida* strains, acinetobacter ADP1 or *Rhodococcus jostii*) (Salvachua et al. 2015) can make use of the liquor obtained after depolymerizing lignin to produce polyhydroxy alkanoates (PHAs). These can be used as source of various materials, such as bioplastics for films, coating, biocompatible drug-delivery systems, and biomedical materials, among others (Linger et al. 2014).

5 Concluding Remarks

As we have seen, understanding lignin structure and composition, as well as its integration with cellulose and hemicellulose into the hierarchical structure of lignocellulosic biomass, is crucial for deciphering biosynthetic pathways, producing plants with more easily degradable cell walls, and developing better technologies for biomass depolymerization.

Computational chemistry calculations and molecular simulations along different scales of lignocellulosic biomass provide atomistic details, yet scalable predictions, on the structure energetics of reactions, and depolymerization processes involving lignin, cellulose, and hemicellulose, many of which still elude current experimental techniques.

Large part of the challenge when performing computational chemistry calculations comes from the selection of the correct methodology that provides accurate results in a reasonable amount of time. Thus, QM calculations have been mostly used to investigate the structure, electronic properties, and reactivity of monolignols, dehydrodilignols, and other small lignin-like model compounds. Nevertheless, the limited size of the models has not hampered the production of many useful information on the early stages of lignin polymerization, as well as the mechanisms for its degradation. The same statement applies to MD simulations to support better degradation strategies. Therefore, QM calculations and MD have provided extensive fundamental insight that result in improved technologies for biomass conversion.

In the future, the development of better molecular mechanics force fields, the use of more advanced QM/MM methods, and most importantly, the increased computational power provided by cloud computing, together with the implementation of new machine learning algorithms for speeded-up multiscale modeling and simulations, are expected to dramatically increase our understanding of lignocellulosic biomass structure, biosynthesis, and degradation. This includes atomistic models of the material but also large-scale empirical modeling of the kinetic mechanisms to study the processes of heat and mass exchange, drying, and ignition, as well as to simulate heat and mass transfer.

Unlocking the potential of lignocellulosic biomass is crucial to develop integrated biorefineries in a circular economy. However, it requires addressing fundamental challenges in economically degrading biomass into its basic constituents. A synergetic combination of multiscale modeling and process engineering is most definitely the way to achieve it.

Contents

Abstract

Reservoir crude oils consist of dissolved gases, liquids, and dissolved solids, the asphaltenes. For 40 years, gas-liquid equilibria of crude oils have been treated with cubic equations of state, variants of the van der Waals EoS. However, asphaltenes had eluded a similar thermodynamic treatment. Recently, the molecular and nanocolloidal structures of asphaltenes in crude oil have been developed and codified in the Yen-Mullins model. With sizes known, the gravity term clarifies and can be added to the Flory-Huggins polymer solution theory, yielding the Flory-Huggins-Zuo (FHZ) EoS. Measurement of gradients of crude oils vertically and laterally in reservoirs is best accomplished with "downhole fluid analysis" (DFA). Interpretation of asphaltene gradients with the FHZ EoS allows determination of the extent of thermodynamic equilibrium of reservoir crude oils. Equilibrated crude oils imply flow connectivity in reservoirs, addressing one of the most important uncertainties in reservoirs. Disequilibrium fluid gradients in reservoirs imply ongoing fluid processes in geologic time. Specification of many of these processes in reservoir case studies has led to

a newly formalized discipline, "reservoir fluid geodynamics" (RFG). Many reservoir concerns are addressed utilizing RFG analyses including reservoir connectivity, viscosity gradients, solution gas gradients, variable productivity index, tar mat formation, and sluggish aquifer support. The combination of new science embodied in the Flory-Huggins-Zuo EoS and the Yen-Mullins model and new technology, DFA, has led to an explosion of applications through reservoir fluid geodynamics.

1   Introduction

Reservoir crude oils are a complex mixture consisting of dissolved gases, liquids, and dissolved (or colloidally suspended) solids, the asphaltenes as conveyed in Fig. 1. As such, the physical and chemical properties of reservoir hydrocarbons can vary enormously, for example, from dry natural gas to immobile tar (Mullins 2008). The economic value and the methods of production and processing all depend on the composition of the oil especially regarding these three phases, gas, liquid, and solid. In addition, there can be important and deleterious chemical constituents of the reservoir fluid such as CO2, H2S, and Hg. It is essential to know the properties of the crude oil in order to know whether to produce the reservoir fluid. For production, a variety of concerns must be addressed to develop production methods, gas handing facilities, flow assurance processes, and methods of reservoir pressure support. All of these concerns depend critically on the properties of the reservoir fluid. In addition, the reservoir fluid properties can change dramatically vertically and laterally in the reservoir. Such fluid variation must also be understood for implementation of optimal production planning. Moreover, remote sensing such as seismic imaging is ineffective in the determination of properties of the reservoir hydrocarbons with the exception of some ability to identify light hydrocarbon fluids in the reservoir. Consequently, it is necessary to acquire fluid samples prior to production; there is no substitute.

Figure 2 shows a series of "dead" oil samples from a single reservoir from deepwater Gulf of Mexico (Elshahawi et al. 2009). This figure shows clear differences in fluid colors, with lighter colors near the top of the reservoir and darker colors near the bottom. The color difference reflects large differences in asphaltene

Fig. 1 Reservoir crude oils consist of dissolved gas, liquid, and dissolved (or colloidally suspended) solids, the asphaltenes (Mullins 2008). All economics and all production methods depend on the composition of the hydrocarbon
Fig. 2 (Left) Huge color and GOR gradients in crude oil composition are observed in oil samples within a single connected reservoir, deepwater Gulf of Mexico (Elshahawi et al. 2009). (Right) The areal map of the reservoir is shown with contour lines which also represent different gas-oil ratios (GORs). Four well locations are shown. The methane stable carbon isotope ratios indicate a greater fraction of thermogenic gas lower in the reservoir and a greater fraction of biogenic gas toward the top (Elshahawi et al. 2009)

content of the fluids. In addition, gas-oil ratios (GORs) of the corresponding live oil samples vary enormously from 8000 to 1800 scf/bbl (standard cubic feet of gas per barrels of oil at 1 atm and 60 °F), further demonstrating the wide range of fluid composition encountered in a single reservoir(Elshahawi et al. 2009; Zuo et al. 2016). (Dead crude oils have been flashed to 1 atmosphere thereby losing dissolved gases; live crude oil contains its dissolved gases as in the reservoir at elevated pressures.)

Figure 2 shows that the carbon isotope varies throughout the reservoir, indicating that there are two sources of methane in this reservoir and that primary biogenic methane in this reservoir is substantial. (Primary) biogenic methane is generally enriched in ^{12}C typically about $\delta^{13}C = -68‰$, while thermogenic methane resulting from the catagenesis of kerogen is typically in the range of $\delta^{13}C = -40‰$ (Hantschel and Kauerauf 2009; Tissot and Welte 1984). Consequently, this reservoir experienced a mixture of biogenic methane and crude oil. (Primary biogenic methane corresponds to biodegradation of organic matter in sediments; secondary biogenic methane is from biodegradation of crude oil.)

In addition to fluid complexities, the reservoir can possess innumerable complexities associated with the rocks or "formations" which comprise the hydrocarbon-bearing formations and the sealing formations which trap the hydrocarbon. The
Fig. 3 The upper and lower surfaces of an oil reservoir, deepwater Gulf of Mexico (Mullins et al. 2007a). Wells are drilled to obtain required information about fluid and rock formation properties for consideration of possible economic production of crude oil. Reservoirs are large, and well penetrations are few when major decisions must be made. Methods of interpolation and extrapolation for fluid and formation properties are required

overall size of the reservoir is of immediate concern and is addressed by seismic imaging. Nevertheless, the quality of seismic imaging degrades with depth and with intervening salt and other irregular structures. In addition, key concerns such as the extent of fluid flow or "connectivity" throughout the reservoir cannot be addressed adequately by remote sensing. Consequently, wellbore data is critical to understand formation properties in addition to fluid properties. Figure 3 shows the upper and lower surfaces or horizons of a reservoir, in excess of 20,000 ft below sea level and with a water depth in excess of 4000 ft (Mullins et al. 2007a). Several wells are depicted that were used to perform reservoir evaluation. After favorable results, development wells were subsequently drilled. This reservoir is tilted from basin distortion; faults in the reservoir are evident in seismic imaging. It is imperative to determine the extent of flow connectivity across the reservoir.

Even if faults are identified in seismic imaging, it can remain unclear whether the fault is sealing or transmissive. In addition to flow connectivity or its inverse "compartmentalization" in a reservoir, there are many other concerns associated with the rock formations. The existence of "baffles" which act to divert fluid flow but which are not pressure seals can have a significant impact on production rates and aquifer sweep in production. Baffles are particularly hard to identify prior to production. The extent of aquifer pressure support and sweep are of major production concerns. There are a large variety of concerns regarding the petrophysical properties of the rock formations. Porosity, permeability, oil saturation, and their variations throughout the reservoir must be understood; well log data is essential to address the extensive range of fluid and rock properties of interest.

Downhole Fluid Analysis, Asphaltene Thermodynamics, and Reservoir Fluid Geodynamics. In order to understand fluid distributions in reservoirs, it is critically important to measure fluid gradients accurately. Downhole fluid

analysis (DFA) within oil wells affords this opportunity (Mullins 2008). Thermodynamic modeling enables projection of fluid properties away from wellbores over large reservoirs. In particular, the recent development of the thermodynamics of asphaltene gradients has led to powerful new methods of reservoir evaluation. Moreover, this asphaltene modeling applied to DFA gradient data can be used to identify fluid equilibrium throughout reservoirs. Equilibrated fluids indicate connected reservoirs giving new ways to address a major industry concern. When the fluid columns are not equilibrated, there are often processes taking place in geologic time that preclude equilibrium. This has led to the recent formalization of a new technical discipline, "reservoir fluid geodynamics," accounting for fluid redistributions and phase transitions in reservoirs after trap filling. To understand present-day realizations of reservoirs, it is important to understand their evolution in geologic time. This chapter treats many aspects of these new developments.

2   Wireline Well Logging and Downhole Fluid Analysis (DFA)

In a typical scenario, a tool package is lowered into the well on a cable or "wireline" shortly after a well is drilled. In this circumstance, the wellbore is "openhole" meaning uncased in the well section of interest which intersects the reservoir. That is, there is no steel casing placed in this section of the well. In openhole conditions, the well is filled with drilling mud which maintains higher borehole pressure than that in penetrated permeable formations, thereby preventing blowouts, the uncontrolled entry of formation fluids into the well. The drilling fluid contains clay, thus its name drilling mud, which acts to form a mud cake on permeable formations thereby preventing excessive fluid loss from the wellbore into the formations. Nevertheless, some drilling fluid "filtrate" leaks into permeable zones thereby contaminating formation crude oils. Oil-based muds (OBM) are commonly used, and OBM filtrates are miscible with reservoir crude oils making OBM filtrate contamination a significant concern (Mullins 2008). Water-based muds are much less problematic for acquisition of crude oil samples.

Oil wells provide the opportunity to measure all manners of properties; whole cores can be acquired addressing key geological concerns. Petrophysical logs can be run and include high-resolution imaging, nuclear magnetic resonance, neutron scattering, gamma ray scattering, phase and amplitude response at many electromagnetic frequencies, and phase and amplitude response at many acoustic frequencies (Ellis and Singer 2008), all providing a wealth of information about the formation primarily near the wellbore. Fluid samples can be acquired using an openhole sampling tool such as the Schlumberger MDT (Zimmerman et al. 1989, 1990).

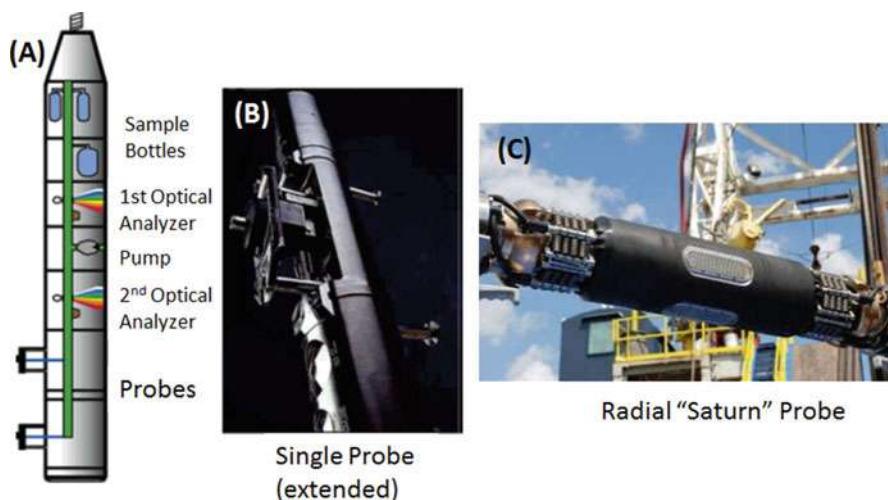
To acquire a sample of formation fluid in openhole, a tool is lowered into the well on a wireline cable; Fig. 4 depicts the Schlumberger MDT (Modular Formation Dynamics Tester) used for this purpose (Mullins 2008; Zimmerman et al. 1989, 1990; Kazakevich et al. 2016). DFA tools are mounted onboard the


Fig. 4 (**a**) Schematic of the MDT fluid acquisition and analysis tool for openhole wells (Zimmerman et al. 1989, 1990). Probes interface with permeable formations for fluid extraction using pumps. Optical fluid analyzers (DFA tools) and high-pressure sample bottles are depicted (Mullins 2008; Zimmerman et al. 1989, 1990). (**b**) A photograph of a "probe" with a protruding steel tube that is pressed firmly against the borehole wall to make hydraulic communication with permeable zones in the oil well to extract formation fluids. (**c**) Photograph of the Schlumberger radial Saturn probe where fluid entry occurs at four symmetrically placed ports in the middle of a rubber packer, which contact the borehole wall when deployed (Kazakevich et al. 2016)

MDT and enable accurate measurement of fluid properties and their variations within the oilfield (Mullins 2008). First, DFA identifies the presence or absence of drilling fluid filtrate that can leak into permeable zones and contaminate reservoir crude oil (Mullins 2008). Pumping fluid out of the formation for extended times by the MDT, for example, a few hours, is frequently required to greatly reduce or eliminate contamination of the crude oil by OBM filtrate. DFA is used to monitor the extent of OBM contamination; crude oils generally have solution gas and/or asphaltenes, while OBM filtrate generally has neither (Mullins 2008; Mullins et al. 2000). This distinction along with knowledge of the typical time rate of change of contamination allows real-time determination of contamination during the pumping process (Mullins 2008; Mullins et al. 2000). Many different probe types are available that make contact with the borehole wall. This enables sample acquisition and DFA to be performed in a large variety of formations including unconsolidated sands, low-permeability formations, and formations with extensive drilling filtrate invasion (Kazakevich et al. 2016).

Asphaltene content is determined in DFA by measuring the electronic absorption of the oil in the visible and near-infrared spectral ranges (Mullins et al. 1992; Mullins and Zhu 1992; Kharrat et al. 2013). Figure 5 shows the optical absorption spectra of many dead crude oils. Plotting optical density (OD) on a log plot versus

photon energy shows that all crude oils exhibit the same slope. This behavior is reminiscent of the Urbach tail from solid-state physics and relates to the constant ratio of small to large bandgap components in all crude oils (Mullins et al. 1992; Mullins and Zhu 1992).

The two-stretch overtone region provides the opportunity to estimate the gas-oil ratio (GOR) of live crude oils (Mullins et al. 2001; Dong et al. 2002; Agthoven et al. 2002; Fujisawa et al. 2002). Figure 6a shows linearity of the spectra of methane, heptane, and a mixture of the two. The NIR peaks of methane, methyl, and methylene groups are readily resolvable using optical hardware compatible with the downhole environment (Mullins et al. 2001; Dong et al. 2002). Figure 6b shows the CH two-stretch overtone region of methane, a series of live crude oils, and a dead crude oil. Large spectral differences are seen in both the methane peak and "oil" peak for the crude oils. Figure 6c shows the correlation of GOR with OD ratios for many crude oils. A variety of interpretation algorithms are available to obtain the GOR from a live crude oil using NIR spectroscopy (Mullins et al. 2001; Dong et al. 2002). In addition, other analytes such as CO_2 can be measured using NIR spectroscopy in situ in oil wells (Agthoven et al. 2002).

DFA measurements also include density and viscosity measurements using the response to some form of mechanical vibrating object that interacts with the MDT flowline fluid. For example, the ringdown (loss) of a mechanical oscillator in fluid is greatly impacted by fluid viscosity (Sullivan et al. 2009; Etchart et al. 2008), and the reduction of resonant frequency of a mechanical oscillator is greatly impacted by the surrounding fluid density (Sullivan et al. 2009; Etchart et al. 2008.) Figure 7 provides a schematic of the Schlumberger in situ fluid analyzer (IFA) which is a module of the MDT that performs advanced DFA (O'Keefe et al. 2007).

DFA is performed on a fluid flow stream in the MDT flowline (cf. Fig. 4); visible and near-infrared spectroscopy are the methods of choice for downhole measurement of crude oil composition (Mullins 2008). Reservoir and MDT flowline pressures can exceed 30,000 psi; but this pressure is readily handled in high-pressure optics cells (with sapphire windows). Reservoir temperatures can be 175 °C or more; the primary impact of this temperature on DFA measurements is on optical detectors. The use of InGaAs detectors with bandgaps corresponding to a wavelength of 1.7 μ or slightly longer limits the thermal noise to acceptable levels. Aside from affecting fluid density, reservoir pressure and temperature do not impact the fluid spectra significantly (Fujisawa et al. 2002). To keep optical density values within a good range for crude oils, a pathlength of 2 mm is typically used in DFA tools (Mullins 2008).

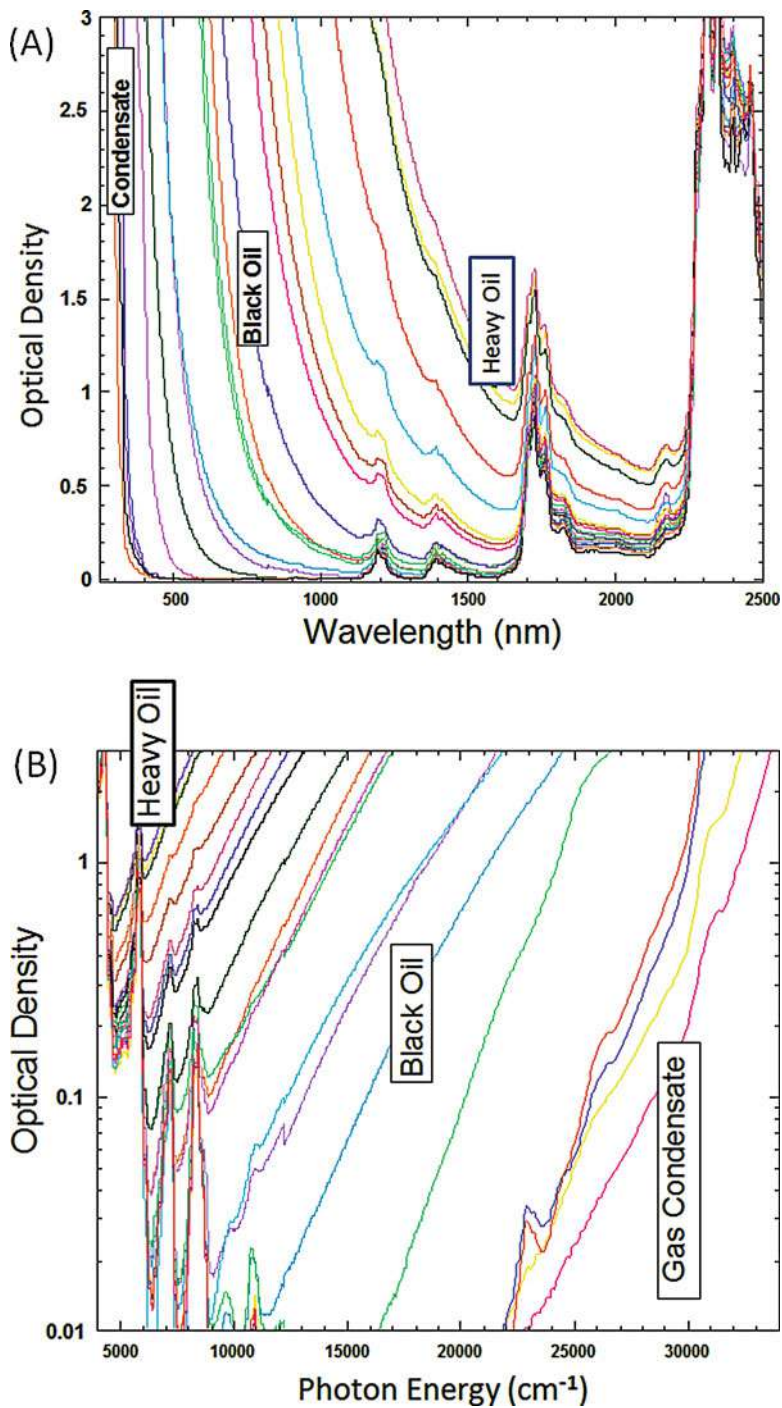
Laboratory Two-Dimensional Gas Chromatography (GC×GC). DFA provides the concentrations of dissolved gases, liquids, and dissolved solids of reservoir crude oils. The corresponding gradients are very amenable to a thermodynamic treatment. It is desirable to perform a detailed compositional analysis of the crude oils, especially with a geochemical interpretation, to compare with the thermodynamic analysis.


Fig. 5 (continued)

Gas chromatography (GC) is a powerful tool to separate complex molecular mixtures for compound identification and quantification. Conventional GC uses a single capillary column coated with a stationary phase that influences how compounds are separated by a combination of properties such as molecular weight, volatility, polarity, or polarizability. GC has been very useful for analyzing complex mixtures, such as crude oil, and for resolving many individual compounds of interest. However, conventional GC has limited utility for unresolved complex mixtures (UCMs) in weathered and biodegraded oils and overlapping or interfering peaks that impede compound identification and analysis. In contrast, comprehensive two-dimensional gas chromatography (GC×GC) adds a second column after the primary column with a different stationary phase to separate compounds according to two combinations of physicochemical attributes. GC×GC offers advantages over conventional GC in separating highly complex mixtures, such as crude oil, into thousands of fully resolved individual compound peaks and with low variability in response factors between compounds (Nelson et al. 2006, 2016; Frysinger and Gaines 2001). Compound peaks in GC×GC are less affected by coeluting components due to higher peak capacity and increased resolving power (Frysinger and Gaines 2001). In a common configuration of columns, GC×GC separated components according to their molecular weight (first axis) and polarizability (second axis). Those properties are particularly diagnostic of RFG processes such as biodegradation, water washing, and thermal maturity, making GC×GC a natural complement to DFA for RFG analysis (Nelson et al. 2006).

GC and GC×GC with flame ionization detection (FID) offer advantages of quantitative detection of peak abundances, reproducibility, and increased sensitivity. GC-FID is used to examine the overall *n*-alkane distribution followed by GC×GC-FID for simultaneous detection of saturated and aromatic compounds plus establishing chemical retention maps. Compounds in GC and GC×GC-FID are identified through the use of standard materials, retention times, and comparison with literature. To fully understand the identity of unknown compounds in chromatograms, time-of-flight mass spectrometry (TOFMS) is coupled with GC×GC permitting identification of compounds with fragmentation patterns matching with known components in various compound libraries. GC×GC-TOFMS is used to assign retention times to compounds that are then used in GC×GC-FID measurements for quantitative analysis of individual peaks. Figure 8 is an example of GC×GC analysis shown below for a crude oil acquired in the Llanos basin, Colombia (Bartha et al. 2015).

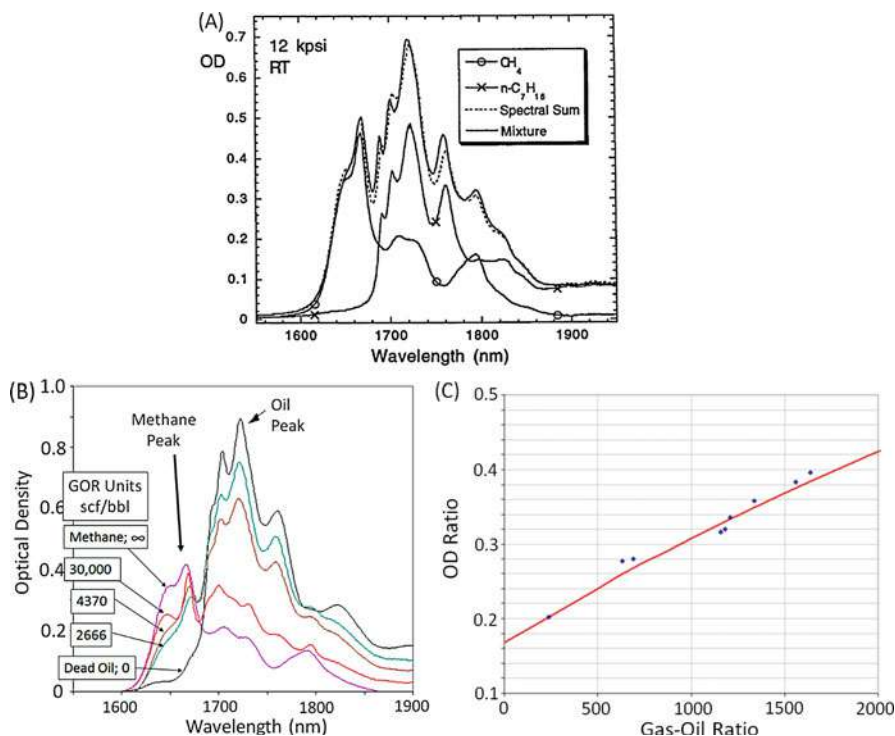
Fig. 5 (**a**) The optical absorption spectra of dead crude oils (at 1 atmosphere). There is a huge and systematic variation of crude oil color among different crude oils. (**b**) Optical density on a logarithm plot versus photon energy yields parallel, straight electronic absorption edges, which is reminiscent of the Urbach tail (Mullins and Zhu 1992; Kharrat et al. 2013). The coloration of an oil is a linear function of asphaltene content (Mullins et al. 2007a; Kharrat et al. 2013)


Fig. 6 (**a**) Two-stretch overtone for selected hydrocarbons showing largely separable peaks dominated by methane (1650 nm), methyl (1700 nm), and methylene (1725 nm) groups (Mullins et al. 2001). These peaks add linearly in compositional mixtures (Mullins et al. 2001; Dong et al. 2002). (**b**) Spectra of methane, live crude oils (with dissolved gases), and dead oil (Dong et al. 2002). (**c**) The optical density (OD) ratio of the oil peak to methane peak correlates with GOR (Mullins et al. 2007a). This spectral analysis is used to estimate GOR downhole using various algorithms (Mullins et al. 2001; Dong et al. 2002)

3   Thermodynamic Modeling of Reservoir Fluids

With these chemical evaluation tools of DFA and complementary laboratory methods, the chemical properties of oil samples can be resolved with great accuracy. Nevertheless, the ability to interpret fluid properties between wells and extrapolate fluid properties where no wells exist is critical to oilfield development planning. Naturally, thermodynamic equations of state are the first step in this process.

Crude oils in reservoirs can exhibit significant vertical and lateral compositional gradients. In general, the most important gradients relate to GOR and asphaltene content. GOR gradients are important because many production parameters relate to this variable. Economic value depends critically on GOR; in certain oilfield settings, gas cannot be transported so is not economic. In production, handling high-pressure gas is a major concern, while liquids are relatively easy to handle; again, GOR is key.
Fig. 7 The in situ fluid analyzer (IFA), an advanced DFA tool that is a module of the MDT (O'Keefe et al. 2007). This tool performs near-infrared and visible spectroscopy with a filter spectrometer and a grating spectrometer. Gas detection and fluorescence detection are also performed. Fluid density, viscosity (not shown), pressure, and temperature are also measured

Frequently, it is desirable to maintain reservoir pressure in excess of the saturation pressure of the oil because the appearance of newly formed gas bubbles in porous media results in a decline of the formation oil relative permeability. In addition, because gas has much lower viscosity than liquid, it can flow preferentially, leaving valuable liquids behind in the formation. The saturation pressure of an oil is closely related to its GOR. For these and other reasons, it is important to understand and model GOR gradients. Various so-called cubic equations of state (EoSs) such as the Peng-Robinson equation are very effective at modeling GOR gradients as well as the gas-liquid-phase behavior of crude oils and have been in use for 40 years (Peng and Robinson 1976). The various cubic EoSs that are used for live crude oils are variants of the familiar van der Waals EoS. There are many excellent treatments of the cubic EoS applied to crude oil (Peng and Robinson 1976; Høier 1997; Høier and Whitson 2001). Of course, equation of state modeling applies only for crude oil in thermodynamic equilibrium, and many reservoirs are not equilibrated. Nevertheless, the cubic EoS provides a good starting point.

For equilibrated crude oils, large GOR gradients are expected only for high GOR crude oils because they are compressible (Peng and Robinson 1976; Høier 1997; Høier and Whitson 2001). Hydrostatic head pressure of the oil column creates higher pressure toward the base of the column. For compressible crude oils, this higher pressure causes higher density toward the base of the column. The density gradient causes lower-density components such as methane to accumulate toward the top of the column. Thus, the density gradient creates a compositional gradient. In contrast, low GOR crude oils are not very compressible; the hydrostatic head pressure of the oil column does not induce a density gradient. Consequently, equilibrated low GOR crude oils have fairy homogeneous GORs (Høier 1997; Høier and Whitson 2001). For so-called black oils with their limited GORs, and for heavy oils with low GORs, the cubic EoS has limited application. Indeed,
Fig. 8 GC×GC chromatogram of a Colombian oil from the Llanos basin (Bartha et al. 2015). The excellent resolving power allows chemical specificity of many peaks. Here, *n*-alkanes are dominant indicating no biodegradation. In addition, 25-norhopanes are much more prominent than the corresponding hopanes, indicating severe biodegradation. Two crude oil charges entered this reservoir; the first was severely biodegraded after emplacement. The second lighter charge entered the reservoir after subsidence and heating of the reservoir beyond 80 °C, thus deactivating and killing the microbes. Petroleum system modeling gives concurring results (Bartha et al. 2015). The loss of naphthalene is due to water washing of the crude oil; the aquifers in the Llanos basin are extremely active (Bartha et al. 2015)

the properties of black oils and heavy oils are defined in great measure by their asphaltene content, not their GOR. It is important to employ an EoS for asphaltene gradients to understand reservoirs and contained fluids.

Asphaltene Nanostructures and the Yen-Mullins Model. The development of an EoS for asphaltene gradients requires knowledge of the size of asphaltene structure in reservoir crude oil. The force F of gravity g must be understood to model reservoir fluids. Newton's second law of motion, $F = mg$ in a gravitational field, requires the mass m of the object. For asphaltenes, this was previously unknown, thus precluding a first-principles EoS for asphaltene gradients in reservoirs. Indeed, even the molecular weight of asphaltenes was unresolved over several orders of magnitude (Mullins et al. 2007b, 2008a). The first measurement of molecular diffusion of asphaltenes utilized time-resolved fluorescence depolarization (TRFD) and showed that asphaltenes are small molecules, with predominantly one polycyclic aromatic hydrocarbon (PAH) per molecule (Groenzin and Mullins

1999, 2000). The TRFD measurements only involve dissolution of the asphaltenes under very mild conditions. Laser desorption, laser ionization mass spectrometry (L^{2}MS) compared 23 "island" model compounds (one PAH per molecule), and "traditional archipelago" model compounds (multiple PAHs per molecule, linked by alkane chains) with asphaltenes and confirmed asphaltenes are dominated by island molecular structure (Sabbah et al. 2011). More recently, a group at IBM Zurich obtained ultrahigh-resolution images of asphaltenes (Schuler et al. 2015, 2017a). The analysis of hundreds of molecular images in ten diverse samples with all kinds of asphaltenes showed the lack of even one traditional archipelago molecule (Schuler et al. 2015, 2017a). Figure 9 shows an example of imaging an asphaltene molecule. In addition, this group proved the ability to image a variety of traditional archipelago molecules (Schuler et al. 2017b). Evidently, traditional archipelagos are not observed in asphaltenes because they are not present. In particular, the nondestructive transfer from a rapidly heated wire to a cold surface of individual asphaltenes without fragmentation was validated. Most importantly, experiments were performed to validate that the imaging methods could resolve traditional archipelago molecules (Schuler et al. 2017b). Excellent images were obtained of 1,2-di(pyren-1-yl)ethane with no fragmentation at all despite the presence in this molecule of one of the weakest C–C bonds, the ethane linkage with bond strength 65.2 kcal/mol (Schuler et al. 2017b).

At low concentrations, the asphaltenes form a true molecular solution in toluene. With increasing concentration, nanoaggregates form. The critical nanoaggregate concentration (CNAC) has been observed by a variety of methods including high-Q ultrasonics (Andreatta et al. 2005a, b), NMR diffusion (Freed et al. 2009), DC-conductivity (Zeng et al. 2009; Goual et al. 2011), centrifugation (Goual et al. 2011; Mostowfi et al. 2009), and AC-conductivity (Sheu et al. 2007). The CNAC is about 100 mg/liter in toluene. In addition, several of these methods that are sensitive to the change in Stokes drag upon nanoaggregate formation (NMR, DC-conductivity, centrifugation) verify that the aggregation number is quite small. Surface-assisted laser desorption ionization mass spectrometry (SALDI-MS) has been used to measure the aggregate mass, and knowing the molecular weight from L^{2}MS, the aggregation number is obtained. The resulting aggregation number for asphaltenes is approximately 7 (Wu et al. 2014a, b; Pomerantz et al. 2015). Combined small-angle X-ray scattering (SAXS) and small-angle neutron scattering (SANS) confirm the small size of the nanoaggregate (Eyssautier et al. 2011, 2012a, b). In addition, the divergence of the SANS and SAXS cross sections showed that the core of the nanoaggregate is enriched in aromatic carbon (high Z), while the periphery is enriched in hydrogen (lowest Z), thus alkane (Eyssautier et al. 2011, 2012a, b). The SAXS and SANS data is consistent only with the island molecular architecture; only island structures can exhibit an aromatic core and peripheral alkane. Archipelago molecular structures would place alkane carbon in the core and aromatic carbon in the periphery in contrast to measurement of asphaltenes.

With a further increase in concentration, nanoaggregates form clusters. The critical concentration of cluster formation (CCC) was shown from the aggregation kinetics (Anisimov et al. 1995; Yudin and Anisimov 2007), DC-conductivity (Goual
Fig. 9 Extraordinary experimental determination of the structure and a particular molecular orbital of an asphaltene molecule (Schuler et al. 2015). Top: atomic force microscopy (AFM) images of the asphaltene molecule with slightly different experimental parameters. Bottom: Left, scanning tunneling microscopy (STM) imaging of the lowest unoccupied molecular orbital (LUMO) of the asphaltene molecule. Right, molecular orbital theory of the same LUMO, excellent agreement is obtained (Schuler et al. 2015). Images of hundreds of molecules have been reported using these methods (Schuler et al. 2015, 2017a) for diverse asphaltenes. "Island" molecular architecture dominates, and the few archipelagos found are only with a direct aryl linkage between PAHs (Schuler et al. 2015, 2017a). In ten diverse asphaltene samples, not one traditional archipelago molecule is found with PAHs linked with alkane chains (Schuler et al. 2015, 2017a) even though such molecules can be readily transferred and imaged (Schuler et al. 2017b)

et al. 2014), and centrifugation (Goual et al. 2014); the CCC is roughly 3 g per liter in toluene. Small cluster aggregation numbers are shown in several NMR studies (Korb et al. 2013; Dutta Majumdar et al. 2013, 2015, 2017). In addition, the combined SAXS and SANS study showed the existence of a fractal cluster (Eyssautier et al. 2011, 2012a, b). All these techniques are consistent with small aggregation numbers of roughly eight nanoaggregates for the cluster. Detailed accounts of asphaltenes and several reviews of asphaltene science are available (Mullins 2011; Mullins et al. 2014).

The molecular structures and hierarchical nanocolloidal structures, the nanoaggregate and cluster, are represented in Fig. 10 known as the Yen-Mullins model
Fig. 10 The Yen-Mullins model of asphaltenes (Mullins 2010; Mullins et al. 2012). The dominant molecular structure with a single PAH ("island" architecture) is shown on the left. In dilute solution, asphaltenes are dispersed as a true molecular solution. At higher concentrations, asphaltenes form nanoaggregates with aggregation number of about 6. At yet higher concentrations, clusters of nanoaggregates form with an aggregation number of about 8

(Mullins 2010; Mullins et al. 2012). With the size of asphaltene structures resolved, the gravity and other terms can be developed in an equation of state for asphaltene gradients.

Hildebrand Solubility Parameter and the Hansen Solubility Parameters. The Hildebrand solubility parameter δ is a numerical value that indicates the relative solvency behavior of a specific solvent or solute. It is derived from the cohesive energy density of the solvent or solute, which in turn is obtained from the heat of vaporization ΔE per unit molar volume V.

$$\delta = \sqrt{\frac{\Delta E}{V}} \tag{1}$$

The Hildebrand solubility parameter can be decomposed into three constituent solubility parameters accounting for the three dominant intermolecular interactions of organic compounds: polarizability (known as the dispersion force) δ_D, polarity δ_P, and hydrogen bonding δ_H (Hansen 2005).

The PAH core of asphaltenes is fluffy and polarizable. Alkanes have lower polarizability. Teflon is even lower polarizability, thus is not at all chemically sticky. Helium atoms have almost no polarizability which is why helium does not liquefy until the temperature is 4 °K. Polarizability of helium atoms would incorporate the $n = 2$ electronic shell which has an excitation energy of 26 eV, thus negligible polarizability.

Polarity refers to molecules that have a permanent dipole moment. Carbon and hydrogen have nearly equal electronegativity, so compounds made of these two elements are nonpolar. Alkanes and aromatic compounds have no dipole moment with rare exception (such as azulene). In contrast, oxygen and hydrogen have very different electronegativity so bonds made of these two elements are quite polar

(e.g., water). Asphaltenes are dominantly carbon and hydrogen, and the dominant heteroatom is sulfur which is typically in nonpolar groups. Asphaltenes might contain a few percent nitrogen and oxygen, which give asphaltenes a bit of polarity.

H-bonding (or hydrogen-bonding) compounds refer to compounds that are involved with this special, strong bond. Water molecules form strong hydrogen bonds, and consequently water remains liquid at unusually high temperatures for compounds of such small mass. All compounds that form H-bonds are polar, but the converse is much less true.

$$\delta^2 = \sqrt{\delta_D^2 + \delta_P^2 + \delta_H^2} \tag{2}$$

The projection of the Hildebrand solubility parameter into three orthogonal Hansen solubility parameters is shown in Fig. 11 (Hansen 2005). In chemistry "like dissolves like"; the specific condition of two compounds being mutually soluble is that their Hildebrand solubility parameters should be similar. Moreover, each component of their respective Hansen solubility parameters should also be similar.

In Fig. 11, this condition of similar solubility parameters is graphically represented by a sphere centered on the solubility parameter of a given compound. Points inside the sphere represent similar solubility parameters to the given compound, thus are soluble. Points outside the sphere are insoluble in/with the given compound.

Green points Fig. 11 represents compounds soluble in the given compound (inside the sphere) with similar Hansen components. Red points represent compounds with very different Hansen components; thus they are insoluble with the given compound (Hansen 2005).

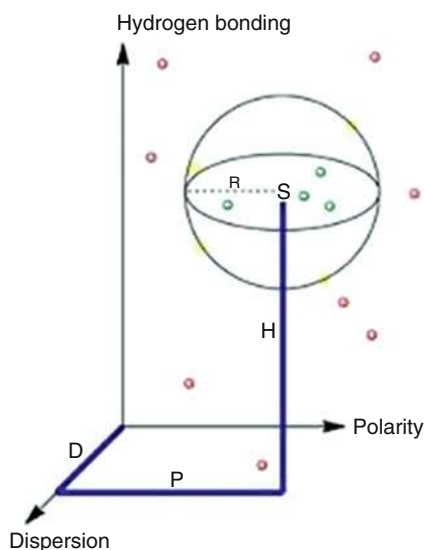
Fig. 11 Graphical representation of the Hildebrand solubility parameter (S) for a given compound projected into the three Hansen components, dispersion (D), polarity (P), and hydrogen bonding (H). The chemistry axiom "like dissolves like" dictates that only compounds within the sphere of radius R shown centered on S will be soluble with the given compound


Table 1 Hildebrand and Hansen solubility parameters

Compound	Hildebrand δ (MPa$^{1/2}$)		Hansen parameter	
		$\delta_{Disp.}$	δ_{Pol}	δ_{H-bond}
Alkanes				
n-pentane	14.5	14.5	0	0
n-heptane	15.3	15.3	0	0
n-dodecane	16.0	16.0	0	0
Aromatics				
Benzene	18.6	18.6	0	2.0
Toluene	18.2	18.0	0	2.0
Naphthalene	20.3	19.2	2.0	5.9
Hetero compounds				
Acetone	20.0	15.5	10.4	7.0
Ethyl alcohol	26.5	15.8	8.8	19.4
Phenol	24.1	18.0	5.9	14.9
Acetic acid	21.4	14.5	8.0	13.5
Carbon disulfide	20.5	20.5	0	0.6
Acetonitrile		15.3	18.0	6.1
Teflon	12.4	–	–	–
C8F18	12.6	–	–	–
Water	47.8	15.6	16.0	42.3
Asphaltenes	20.4	19.5	4.7	4.2

A table of Hildebrand and Hansen solubility parameters is instructive. Teflon and other perfluorocarbons are known to have very low intermolecular interactions which is why Teflon is a preferred coating in cookware; nothing sticks to it. A value of 12.4 (MPa)$^{1/2}$ for Teflon in Table 1 is seen to correspond to such a low intermolecular interaction (not shown but almost entirely the polarizability component). In contrast, Table 1 shows that water with its strong intermolecular interaction has a Hildebrand solubility parameter of 47.8 (MPa)$^{1/2}$. Teflon and water establish the range of Hildebrand parameters from very weak 12 (MPa)$^{1/2}$ to very strong 48 (MPa)$^{1/2}$ for condensed phase. Moreover, water is dominated by H-bonding, a strong and spatially directional bond. Alkanes, the dominant component of crude oil, are seen to have Hildebrand parameters 16 (MPa)$^{1/2}$ somewhat above Teflon, and those of aromatics are somewhat above the alkanes. Moreover, Table 1 shows that the alkanes and the aromatics are dominated by the simple, weak polarizability forces.

The solubility parameters of the asphaltenes are very similar to those of aromatics. Indeed, asphaltenes are defined to be toluene soluble and thus must have solubility parameters similar to that of toluene. Note that the difference between the solubility parameters of asphaltenes and alkanes are sufficient to dictate no solubility. The solubility parameters of toluene and asphaltenes are dominated by the weak and simple polarizability component. The asphaltenes do have a component of

polarity and H-bonding, but these contributions are small especially considering it is the square of each component that contributes to the Hildebrand solubility parameter (Eq. 2).

Table 1 shows that the solubility parameter of asphaltenes is dominated by the polarizability term (Redelius 2005). This fact is often overlooked when elaborate supramolecular assemblies are proposed for asphaltenes with binding associated with hydrogen bonding, organometallic complexes, and the like. In fact, polarizability dominates consistent with a stack of PAHs (Eyssautier et al. 2011, 2012a, b; Mullins 2010; Mullins et al. 2012).

Methane has low intermolecular interaction but is not listed in Table 1 because the molar volume is very dependent on temperature and pressure making the numeric value of solubility parameter somewhat arbitrary (cf. Eq. 1). Nevertheless, addition of methane to crude oil results is a decrease in solubility parameter because both the density decreases and methane has low intermolecular interaction.

The Flory-Huggins-Zuo Equation of State. With this understanding, we can now examine the FHZ EoS. The FHZ is generally written as a ratio of ODs, optical densities, as measured by DFA tools. The ODs correspond to the strength of oil color at a specific wavelength. The color OD measurement is linear in asphaltene content. However, we do not assume a constant of proportionality, so the exact asphaltene content is not determined. For the OD ratio, the proportionality constant cancels; thus the FHZ EoS is written in terms of the OD ratio. The FHZ provides a thermodynamic expression for the DFA measured asphaltene gradients.

The FHZ EoS (below) takes into account three forces that result in asphaltene gradients: gravity, entropy, and solubility. The variables k, ϕ, v, δ, T, g, ρ, and h are Boltzmann's constant, volume fraction, molecular or particle volume, solubility parameter, temperature, earth's gravitational acceleration, density, and depth, respectively. Subscript a denotes the properties of asphaltenes; subscripts h_1 and h_2 stand for the properties at depths h_1 and h_2, respectively.

Gravitational gradients result from density difference or negative buoyancy between asphaltenes and the remainder of the oil, with relatively dense asphaltenes accumulating toward the bottom of the reservoir. This term contains Archimedes buoyancy $V_a \Delta \rho g$ where V_a is the volume of the asphaltene species from the Yen-Mullins model, $\Delta \rho$ is the density contrast between asphaltene and the oil, and g is earth's gravitational acceleration. Archimedes buoyancy multiplied by height h is the gravitational potential energy. The FHZ EoS includes the Boltzmann distribution for gravity, exp(-mgh/kT), where mgh (or more accurately $V_a \Delta \rho g h$) is the energy required to lift the asphaltene particle to height h from the bottom of the reservoir, and thermal energy kT is doing the lifting, k is Boltzmann's constant and T is temperature.

$$\frac{\phi_a(h_2)}{\phi_a(h_1)} = \exp\left\{ \frac{v_a g\,(\rho - \rho_a)\,(h_2 - h_1)}{kT} + \frac{v_a}{kT}\left[(\delta_a - \delta)_{h_1}^2 - (\delta_a - \delta)_{h_2}^2 \right] \right.$$
$$\left. + \left[\left(\frac{v_a}{v}\right)_{h_2} - \left(\frac{v_a}{v}\right)_{h_1} \right] \right\}$$

$$(3)$$

The solubility term utilizes the solubility parameter δ discussed above and depends on the difference in solubility parameters of the oil and asphaltene at different heights in the column. GOR can change for crude oils at different heights in the column, and this yields a difference in liquid-phase solubility parameter which can produce large changes in asphaltene concentration. Thus, for oils with high solution gas, asphaltene concentration will be low. For oils with large GOR gradients, such as equilibrated condensates and oil columns undergoing gas entry by diffusion, there will also be a large gradient in asphaltenes (or heavy ends).

The entropy term employs ratios of the molar volumes of crude oil and asphaltene at different heights. This term tends to be small so is often neglected. Essentially the entropy term is related to the statistical permutations of arranging solute and solvent.

The Flory-Huggins-Zuo equation of state (FHZ EoS) has been used in conjunction with the Yen-Mullins model in approximately 40 oilfield studies very successfully. This methodology will be reviewed in the next section. In addition, the Yen-Mullins model coupled with the (simple) Langmuir EoS has found significant utility associated with oil-water interfacial characterization (Rane et al. 2013, 2015). This capability in the more demanding arena of interfacial science lends credence to the related formalisms applied to bulk crude oil.

4 Reservoir Evaluation and Reservoir Fluid Geodynamics

Reservoir fluid geodynamics (RFG) is the name given to account for processes which hydrocarbon reservoir fluids undergo after (and during) reservoir trap filling (Mullins et al. 2017). ("Geodynamics" has been used by geologists to describe evolution of the formations (Miall 2000), and "fluid geodynamics" has been used to account for magma flows in the mantle within geodynamic treatments.) RFG includes processes long studied by geochemists including biodegradation and water washing (Peters et al. 2005). Nevertheless, even for these processes, use of equation of state modeling greatly clarifies a detailed spatial accounting of fluid properties and their variations within the reservoir. In particular, incorporation of the FHZ EoS and its reliance on the Yen-Mullins model have been very revealing of all manners of complexities in reservoir as established in many reservoir case studies. Figure 12 shows a schematic of a timeline with different disciplines indicated. Petroleum system modeling provides the timing, type, and volume of fluids entering the reservoir. Reservoir fluid geodynamics accounts for the many processes that can redistribute and alter the fluids and cause phase transitions such as tar formation. Simulation modeling then accounts for production in a present-day setting.

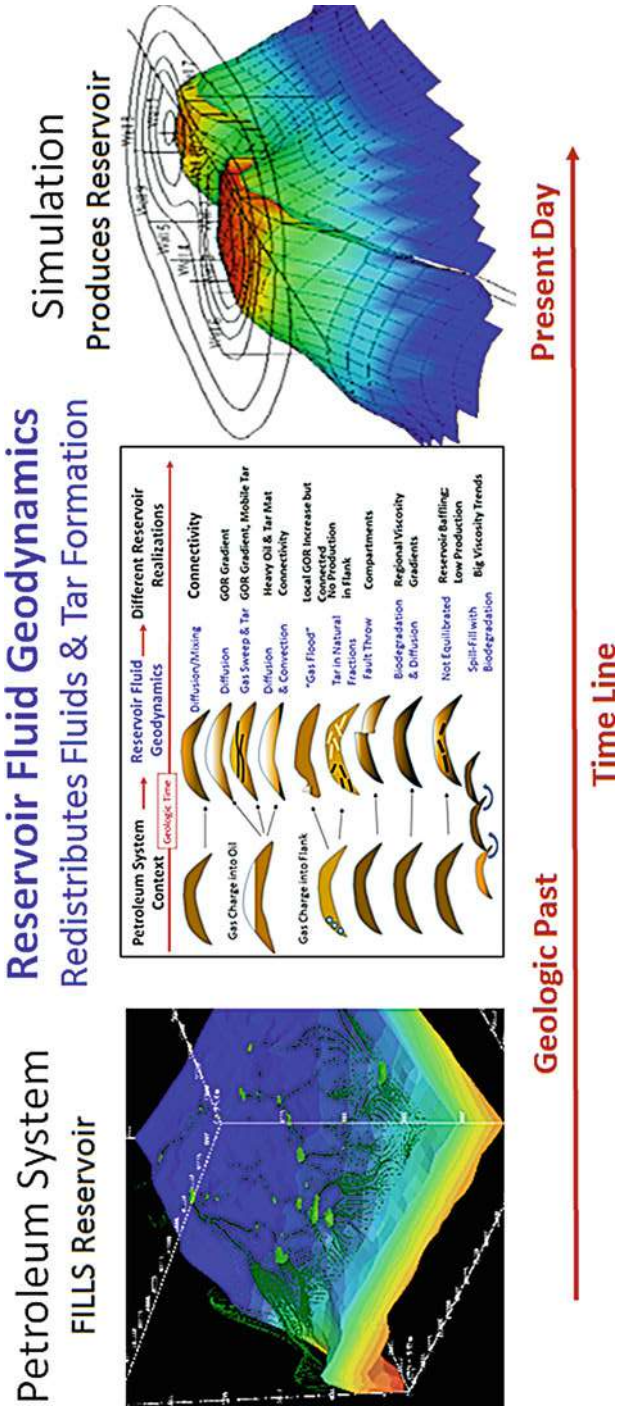
Compartmentalization and Connectivity. One of the most important concerns is the extent of reservoir "connectivity" or its inverse, compartmentalization (Mullins 2008). A compartment must be intersected by a well for drainage. A reservoir might consist of one or a few large compartments. For reservoirs that exhibit good connectivity, few wells are required. For reservoirs consisting of many small compartments, many wells are required for drainage. When well costs are high, compartmentalized reservoirs can be uneconomic. An industry study


Fig. 12 A timeline showing the different disciplines. Petroleum system modeling accounts for the timing, type, and volume of fluids that enter the reservoir. Reservoir fluid geodynamics, a newly formalized discipline, accounts for the many processes that redistribute fluids within the reservoir and that account for phase transitions such as tar formation (Mullins et al. 2017). Simulation then accounts for reservoir production in present day

concluded that 75% of deepwater reservoirs in the Gulf of Mexico underperformed in both rate of production and ultimate oil recovery, primarily due to unrecognized compartmentalization (Mishra et al. 2014). A large variety of sealing barriers separating compartments can be present in oilfield reservoirs. Some barriers correspond to (sealing) faults that are observed in seismic imaging. Seismic imaging is inherently low resolution so that layers or objects that are much smaller than 10 m thick are difficult to resolve. Other sealing barriers are not only invisible to seismic imaging, they can even be invisible to wireline petrophysical logging measurements performed in oil wells which often have a resolution of centimeters (Andrews et al. 2001). Indeed, such "invisible" barriers can even hold off 2000 psi of depletion pressure differential (Andrews et al. 2001).

Compartmentalization. One method to reveal compartmentalization is to perform pressure surveys. In an oil column, the pressure increases with depth according to the fluid density, so a pressure gradient is always obtained. In a new, unproduced field, if two formations are not in pressure communication, then they are not in flow communication and represent two separate compartments. Similarly, if a well intersects two oil-bearing formations, and the oil in the upper formation has a higher concentration of asphaltenes, then the formations are likely not connected as asphaltenes are negatively buoyant in crude oil.

Figure 13 shows an example of a highly compartmentalized series of oil-bearing sandstone layers (sands) in a single well. Pressure measurements show Sand A is isolated from Sand B, Sand C is isolated from Sand D, and Sand E is isolated from Sand F. DFA color measurements show the oil in Sand A has three times the asphaltene content as the oil in Sand B below it; clearly these are not connected. The oil in Sand B has more asphaltene than the oil in Sand C. The asphaltene difference is large between Sand C and Sand D, so lack of connectivity is plausible. Sand D has more asphaltene than Sand E below it; thus they are isolated. Combining the pressure and DFA color data shows the sands are all isolated from each other; the oil company ceased all activities in the field due to this conclusion (Mullins et al. 2007c, 2008b).

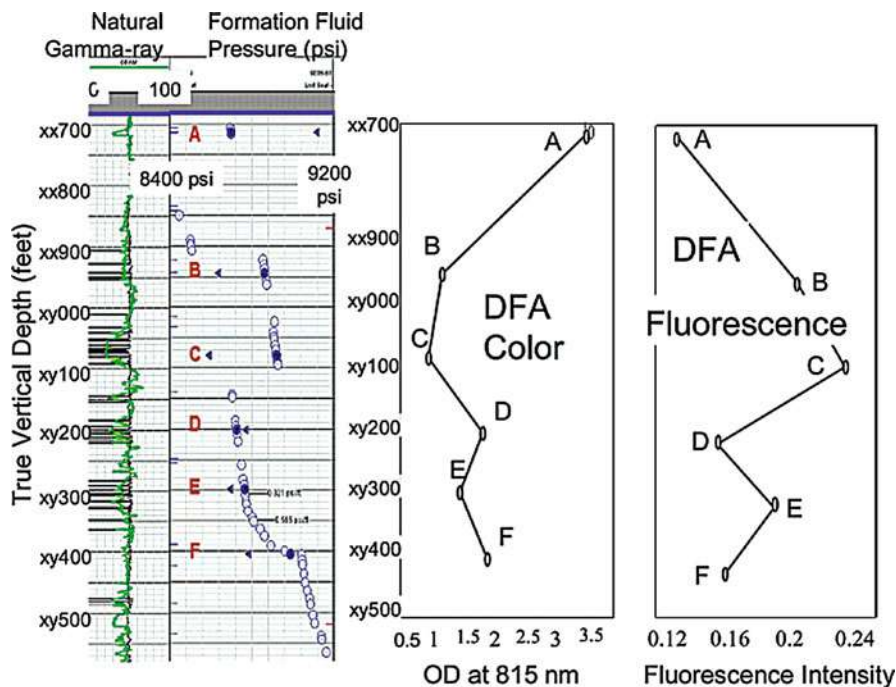
Dead crude oils were obtained from most of these zones to look for detailed compositional differences. No significant differences could be detected in the heavy ends using ultrahigh-resolution mass spectroscopy (Mullins et al. 2007c), nor in the liquid phases using comprehensive two-dimensional gas chromatography (GC×GC) (Mullins et al. 2008b). The crude oils have very similar chemical components but differ mostly in their asphaltene fractions (Mullins et al. 2007c, 2008b). That is, the chemical constituents in each phase are very similar as shown by high-resolution analytical chemistry. What differs is the overall concentrations of the different gas, liquid, and solid constituents; DFA measurements are well suited to analyze these fractions. With DFA measurements, there is minimal sample handling reducing sample transfer problems that can arise, especially in remote, offshore locations. In addition, the DFA tools within a well have the same time, operating engineer, temperature, calibration, and baselines, such that many systematic errors cancel in establishing fluid gradients.


Fig. 13 Well log data from deepwater Gulf of Mexico (Mullins et al. 2007c, 2008b). The exact depth is confidential, thus the leading xy in depth. Six stacked sandstone formations are intersected (A,B,C,D,E and F) with intervening shale zones with slightly higher gamma ray signal (green curve). Formation pressures with gradients are shown. DFA-measured coloration at 815 nm for six sampling points is shown. Fluorescence is also shown and is higher for crude oils of lower color (asphaltene content). Both pressure and DFA color measurements show significant compartmentalization; the oil company ceased any activity in this reservoir due to this conclusion

Nevertheless, the more important issue is to identify the good news of connectivity (better economic value), not just the bad news of compartmentalization (lower economic value). While pressure measurement can conclusively demonstrate the bad news of compartmentalization, it is not definitive to establish connectivity. Pressure connectivity is a necessary but insufficient condition to establish flow connectivity in production time frames (years to 10 years) (Mullins 2008). Indeed, in the industry-wide study showing the huge problem with unrecognized compartmentalization in deepwater Gulf of Mexico, all of the fields had extensive pressure surveys (Mishra et al. 2014); pressure measurement is grossly inadequate to establish reservoir connectivity. The cause of the shortcoming is simple: very little mass transfer between two compartments is needed to equilibrate pressure. A leaky seal between two compartments can act as a conduit for a little mass transfer equilibrating pressure in geologic time, but leaky seals are not adequate to handle significant oil flow in production time.

Connectivity and Equilibrated Asphaltenes. The equilibration of asphaltenes in a reservoir requires extensive mass flow, likely both during and post trap filling. Consequently, if asphaltenes are equilibrated across a field, the field is likely connected. Many oilfield case studies have established that equilibrated asphaltenes imply connectivity in a production time frame (Mullins 2008; Zuo et al. 2013). Figure 14 shows examples of equilibrated asphaltenes involving all three structures in the Yen-Mullins model as well as heavy resins for a light condensate (Zuo et al. 2013).

Figure 14a shows a heavy-end gradient in a light condensate (Zuo et al. 2013). In this case, the DFA color measurement was close to zero throughout the visible spectral range; thus, the DFA fluorescence measurement was used (Zuo et al. 2013). For low concentrations of fluorophores and chromophores, the fluorescence intensity is linear in concentration of fluorophores, which in this case are the heavy ends of a resin. For another light condensate, the predominant fluorophore was identified as perylene (Juyal et al. 2011), and the corresponding molecular dimension of perylene is used in the FHZ EoS analysis in Fig. 14a. Indeed, perylene fluorescence gave this oil a blue appearance under normal illumination; a photograph of this condensate under visible illumination is shown in Fig. 14a as an inset.

Fig. 14b is a heavier condensate with a molecular dispersion of asphaltenes. The asphaltenes across the field were shown to be equilibrated; however, the dissolved gas was *not* equilibrated across the field. The reservoir had two separate anticlinal structures, each with a gas cap and with different GOCs. The field was put into production and was proven to be connected; equilibrated asphaltenes again are associated with reservoir connectivity. The GOR was not equilibrated due to a gas charge (gas and oil charge into reservoir that has previously) filling different amounts of gas into the two anticlines. Equilibration of the two GOCs by diffusive methane transport across the field is a very slow process. In contrast, the asphaltene content of saturated crude oils is not impacted by further gas-phase addition to the reservoir. (Saturated crude oils are at their bubble point and cannot hold more solution gas.) Figure 14c, d show two oilfields with black oils; black oils have moderate GORs and moderate asphaltene content. Black oils almost always have asphaltenes dispersed as nanoaggregates (Zuo et al. 2013). Fig. 14e shows a heavy oil; heavy oils have asphaltenes dispersed as clusters (Zuo et al. 2013).

Asphaltene 2 nm Nanoaggregate Equilibration Across a Reservoir. A recent reservoir case study, deepwater Gulf of Mexico, allows a close look at asphaltene equilibration (Chen et al. 2017). Two wells were drilled in a middle Pliocene oilfield, and DFA data was acquired in two stacked sandstone formations (cf Fig. 15). Samples were acquired and extensive laboratory measurements were made (Chen et al. 2017).

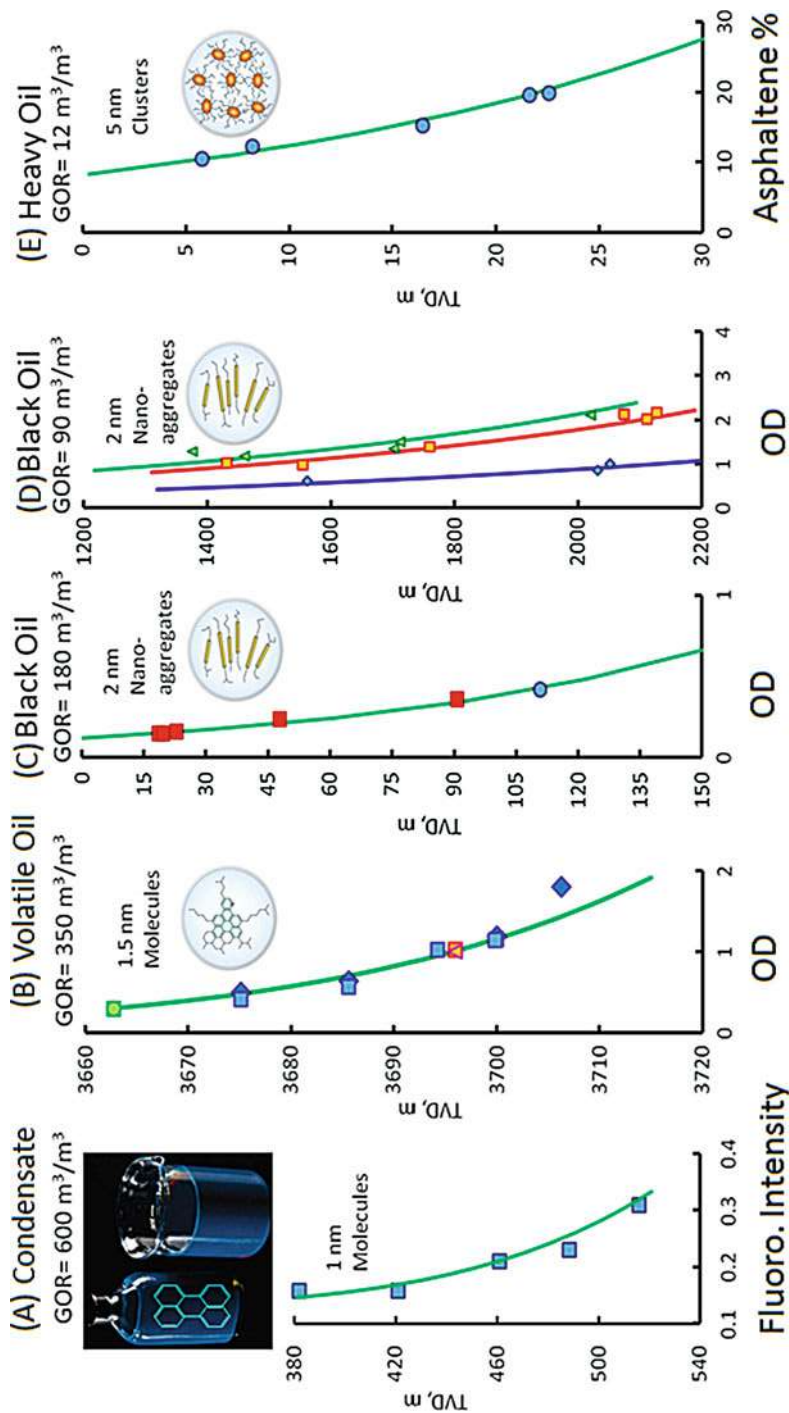
Figure 15 shows that the asphaltene gradients in each sand are consistent with an equilibrium distribution of asphaltene nanoaggregates; the asphaltene gradients match the FHZ EoS with asphaltene nanoaggregates. Moreover, the two asphaltene gradients are offset from each other except at the top of the reservoir. The implication of the offset is that the intervening shale layer is laterally extensive but


Fig. 14 Equilibrated asphaltenes imply reservoir connectivity as shown in five oilfields examples; in all cases, production proved the connectivity prediction to be correct (Zuo et al. 2013). These five examples also involve the three species of the Yen-Mullins model as well as heavy resins for a light condensate
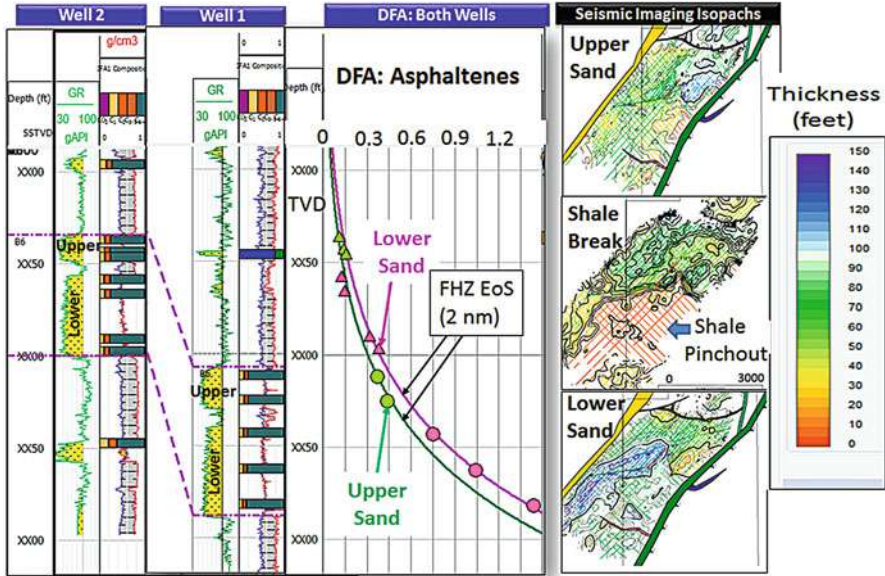

Fig. 15 A deepwater reservoir with two stack sands, for the most part separated by an laterally extensive shale layer (Chen et al. 2017). Two wells were drilled in this reservoir separated by roughly 1 km. Track 7 (DFA asphaltenes) shows each sand has equilibrated asphaltenes implying flow connectivity across the field. The two asphaltene curves are offset indicating the intervening shale layer is laterally extensive. Track 1, depth (the leading xx's are to conceal the absolute reservoir depth). Track 2, the natural gamma ray log (GR) of Well 2 which identifies sand formations (yellow). Track 3, horizontal bars with locations of DFA and sampling depths in Well 2. Green is oil, blue is water, yellow is methane, orange is other hydrocarbon gases. Track 4, the natural gamma ray log (GR) of Well 1 which identifies two sand formations (yellow). Track 5, horizontal bars with locations of DFA and sampling depths in Well 1. Also shown are the seismic "isopach" images showing the thickness over an extended lateral area of the upper sand, intervening shale layer, and the lower sand (Chen et al. 2017)

possibly pinches out (disappears) near the crest of the reservoir. This is consistent with the thickness "isopach" models of the shale shown in Fig. 15 (Chen et al. 2017).

Production history matching and reservoir simulations of production for 12 months of production are consistent with all conclusions from the asphaltene gradient analysis (Chen et al. 2017). Production is considered ultimate arbiter determining the connectivity profile of reservoirs (Chen et al. 2017). The agreement in this reservoir between predictions based on thermodynamics and 1 year of production is a strong validation for the FHZ EoS and the Yen-Mullins model.

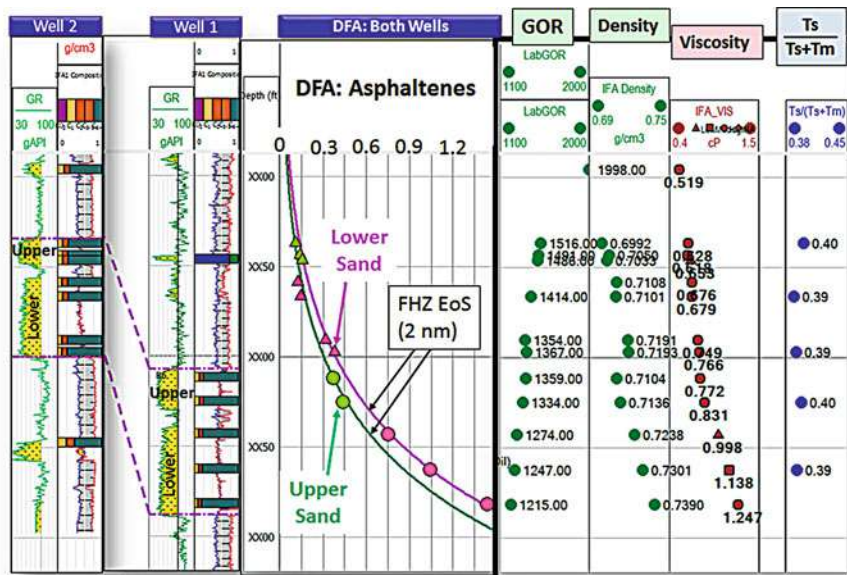
Figure 16 shows that the fluid gradients of GOR, fluid density, and viscosity are consistent with the interpretation of equilibrated asphaltene gradients. However, these other fluid gradients are not as clearly identified as being equilibrated as the asphaltene gradients; often the asphaltene gradients convey the most useful information. The thermal maturity biomarker ratio Ts/(Ts + Tm) shows no gradient


Fig. 16 The same reservoir as depicted in Fig. 15. Tracks 1–6 as described in figure caption for Fig. 15 (Chen et al. 2017). Fluid measurements of Track 7, GOR (from the lab); Track 8, IFA-measured density; Track 9, IFA-measured viscosity. Track 10, thermal maturity biomarker ratio Ts/(Ts + Tm) (Chen et al. 2017)

(Chen et al. 2017). This oil reservoir appears to have had a single charge of oil, thus, lacking various fluid complexities and providing a somewhat simplified case of testing asphaltene thermodynamic modeling (Chen et al. 2017).

Asphaltene 5 nm Cluster Equilibration Across an Oil Reservoir. When asphaltene concentrations are high, asphaltenes are dispersed as clusters, not nanoaggregates. An example of this is observed in a giant reservoir in Saudi Arabia. The reservoir is a four-way sealing anticline – a turtle shell structure (see inset in Fig. 17 with eight well locations). There is a black oil of a few percent asphaltene content in most of the field. At the bottom of the oil column, there is a 60 m vertical heavy oil rim around the entire 100 km periphery of the oilfield. This heavy oil is underlain by a 10 m thick tar mat; this represents a massive accumulation of asphaltenes. Figure 17a shows the asphaltene content as a function of depth in this oil column.

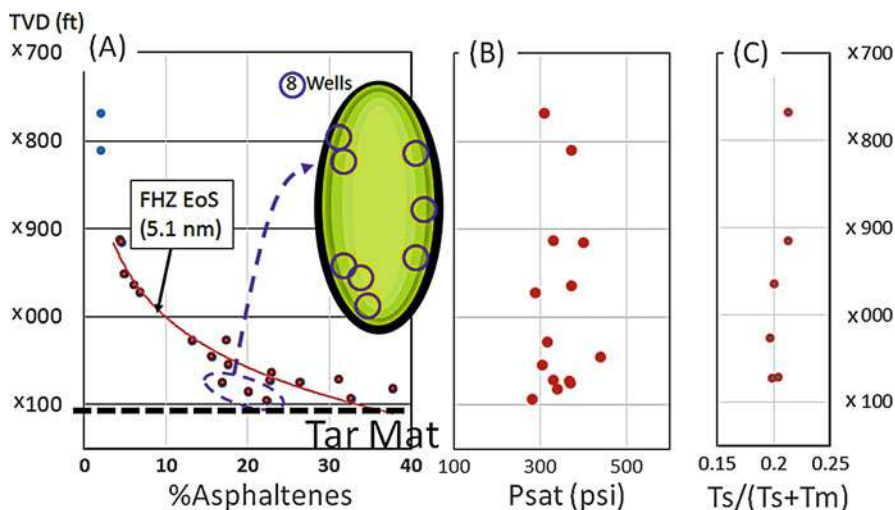
Figure 17 shows in dramatic fashion consistency of the heavy oil gradient matching the FHZ EoS with asphaltene clusters over a 100 km perimeter of the oilfield with a factor of ten variation of asphaltene concentration. Similar heavy oil gradients have been observed elsewhere (Mullins et al. 2013). Moreover, the implication of asphaltene equilibration is reservoir connectivity over this large field, and that is known from production (Mullins et al. 2013). As expected from successful application of the Yen-Mullins model and the FHZ EoS, there is no


Fig. 17 (**a**) Asphaltene concentration versus true vertical depth (TVD) in the heavy oil rim of a large oilfield. The asphaltene gradient matches the FHZ EoS with 5.1 nm clusters (vs. 5.0 nm nominal) with no other adjustable parameters around the 100 km perimeter of the oilfield. The equilibrated asphaltene cluster gradient implies connectivity which has been confirmed in production (Mullins et al. 2013). (**b**) There is no record of this huge asphaltene gradient in the saturation pressure (Psat). The saturation pressure is low and invariant. (**c**) The thermal maturity biomarker ratio Ts/(Ts + Tm) varies only slightly; the asphaltene gradient is not due to a thermal maturity gradient

variation in the asphaltene chemistry with regard to molecular weight (Pomerantz et al. 2013), nanoaggregate aggregation number (Pomerantz et al. 2013), or sulfur chemical speciation throughout the heavy oil column (Wu et al. 2014b). The only way to model this giant asphaltene gradient with an invariant liquid phase is to use a gravitational gradient of asphaltene clusters as given by the FHZ EoS (Mullins et al. 2013; Pomerantz et al. 2013; Wu et al. 2014b; Forsythe et al. 2015).

The heavy oil in the rim in Fig. 17 did not arise as a thermal maturity variation; the ratio of the thermal maturity biomarkers Ts/(Ts + Tm) is almost invariant, and there is no biodegradation (Forsythe et al. 2015). This massive accumulation of asphaltenes giving rise to the 60 m vertical heavy oil column underlain by a 10 m tar mat arose from instability of incompatible charges into the reservoir followed by asphaltene migration to the base of the reservoir. With such a large accumulation of asphaltenes, it is fairly easy to detect this occurrence in reservoir evaluation. Nevertheless, the asphaltene instability did not remove all asphaltenes from the oil.

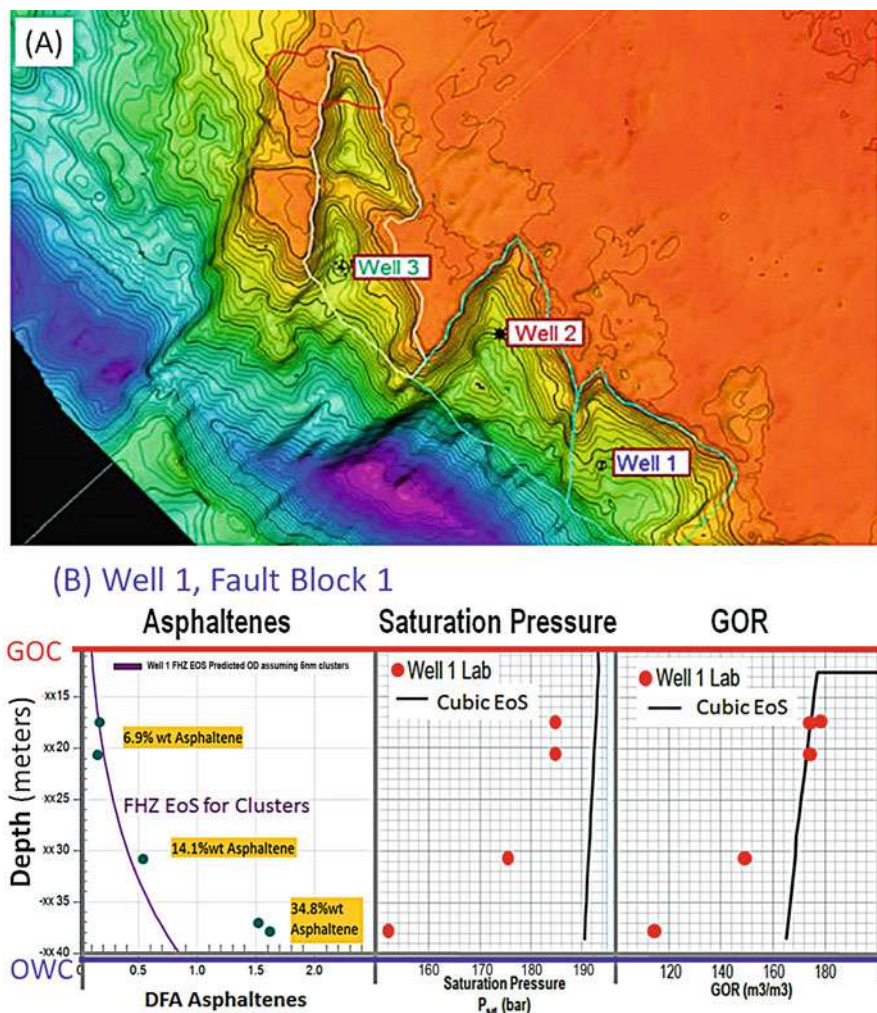
Validation of Reservoir Fluid Geodynamics. Another oilfield study showed a variety of complexities associated with a late gas charge into oil reservoirs. Indeed, this study proves the validity of RFG because three reservoirs exhibit totally different reservoir realizations even though they all had the same petroleum system process of a gas charge into oil (Achourov et al. 2015; Pfeiffer et al. 2016, 2017).


Fig. 18 (**a**) Areal contour map of the Norwegian continental shelf showing three adjacent fault blocks, each with one well (Achourov et al. 2015; Pfeiffer et al. 2016). (**b**) The vertical well in Fault Block 1 has both a gas-oil contact (GOC) and an oil-water contact (OWC); thus, all fluid migration is vertical and measurable within this well. The asphaltene gradient is very large and in disequilibrium; the data points do not match the FHZ EoS. In addition, the asphaltene content in the oil at the base of the column is 35%; this is a heavy oil. The saturation pressure (Psat) and GOR exhibit large, disequilibrium gradients; they do not match the cubic EoS

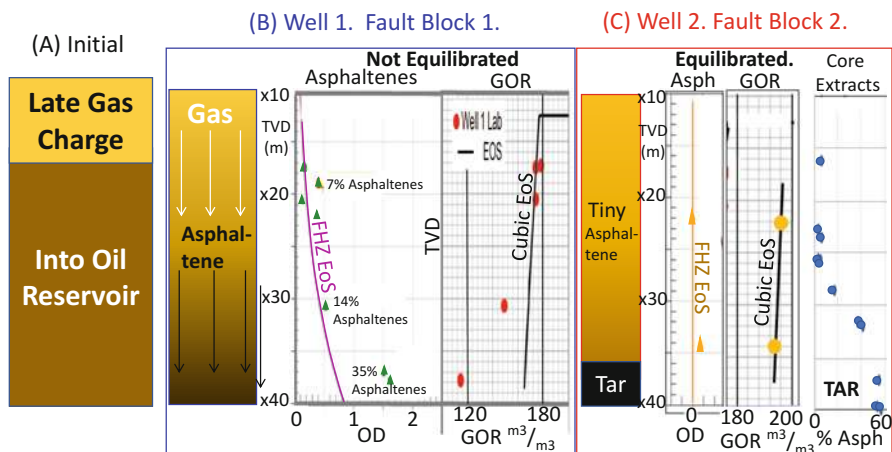
Fig. 18a shows the areal contour map on the continental shelf of Norway of three adjacent fault blocks, each with one well. Fault blocks are very large blocks of rock, often many kilometers in extent, created by tectonic and localized stresses in the Earth's crust. Fault blocks are often seen in seismic imaging.


Fig. 19 (**a**) The initial condition after charge of a density-stacked gas on top of an undersaturated oil (Achourov et al. 2015; Pfeiffer et al. 2016). (**b**) Fault Block 1, schematic of gas diffusing into oil increasing GOR at the top of the oil column; this causes asphaltenes migration to the base of the column. (**c**) Schematic of the completion of the RFG processes of gas diffusion and asphaltene migration down. The solution gas is high and equilibrated in Well 2. The asphaltene content is very small and equilibrated in Well 2. The asphaltenes migrated to the base of the oil column and underwent phase separation forming a tar mats seen in analysis of core extracts (Achourov et al. 2015; Pfeiffer et al. 2016, 2017)

Figure 18b shows that the oil column is in disequilibrium in Well 1 (Achourov et al. 2015; Pfeiffer et al. 2016). The asphaltene gradient is very large and does not match the FHZ EoS with clusters; there are no larger stable colloidal particles in crude oil. In addition, the saturation pressure and GOR also exhibit large, disequilibrium gradients. The crude oil at the bottom of the column has a high asphaltene concentration of 35%; thus is heavy. Well 1 has both a GOC and an OWC; thus, all fluid migrations are vertical and observable within this vertical well. This contrasts the frequent occurrence of tilted reservoirs, where the GOC is not only vertically displaced but also laterally displaced from the OWC so vertical wells often insect only one of these contacts. The issue arises as to why this column is in disequilibrium considering the very small vertical distances that are involved, just tens of meters. In all three fault blocks, that late gas charge is thought to be Pleistocene, limiting the time duration for establishing equilibrium. To address this question further, it is best to also consider the adjacent Fault Block 2.

"Movie" of Tar Mat Formation. Figure 19 shows that Well 1 is undergoing the process of gas diffusion into the oil column from the top, while the asphaltenes are migrating down away from high solution gas oil (Achourov et al. 2015; Pfeiffer et al. 2016). Well 2 shows the completion of this process in geologic time. The asphaltenes migrated to the base of the column increasing their concentration. Gas diffused to the base of the column increasing solution gas. Both fault blocks had this process initiate at about the same time; the question arises what slowed
Fig. 20 Scanning electron micrograph obtained from the tar zone in Well 2 (Pfeiffer et al. 2017). The asphaltene-enriched phase is a smooth, cracked material that is conformally attached to rock surfaces. Void space that is oil filled in the reservoir is also evident. The tar mat consists of two organic phases; once the asphaltene phase seals sufficient numbers of pore throats, permeability becomes negligible (Pfeiffer et al. 2017)

equilibration in Fault Block 1. The answer is obtained in measurement of both vertical permeability and oil production rates (Achourov et al. 2015; Pfeiffer et al. 2016). Well 1 was shown to have much lower vertical permeability by pressure interference testing (Pfeiffer et al. 2016). In addition the production rates in Well 1 are ten times lower than Well 2 after accounting for viscosity differences of the oils (Pfeiffer et al. 2016).

Most of the asphaltenes at the base of the oil column in Well 2 have undergone phase separation. Figure 20 shows an SEM from this tar zone showing an asphaltene-enriched phase and a void space that is filled by oil in the reservoir; the tar mat consists of two organic phases (Pfeiffer et al. 2017). The asphaltene phase adheres conformally to the rock surface which is consistent with heterogeneous nucleation. However, asphaltenes are nanocolloidal with huge surface area; thus, there is no standard homogeneous nucleation difficulty associated with formation of new surface energy in single-phase true molecular solutions. Instead, a plausible explanation for the heterogeneous nucleation observed here is due to the slow kinetics of reaction-limited aggregation known for floc formation from asphaltene clusters versus the relatively rapid rate of collisions with pore walls.

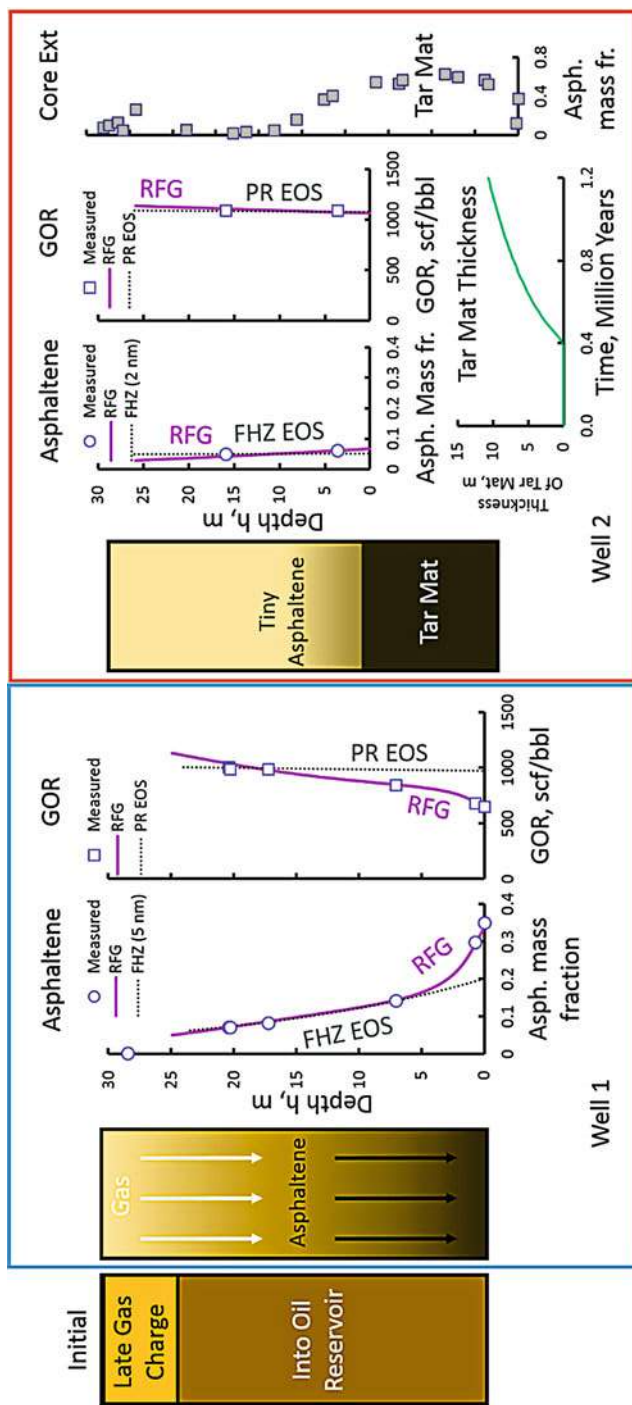
Figure 21 shows the application of a single RFG model to Wells 1 and 2 (Zuo et al. 2017). The single model accounts for the disequilibrium gradients of both GOR and asphaltenes in Well 1. The same RFG model also accounts for the equilibrated GOR and asphaltene gradients as well as the thick tar mat in Well 2. The major difference between the wells (and fault blocks) is the vertical permeability in the model. Well 1 is known to have low vertical permeability, and Well 2 is known to have higher vertical permeability in accordance with vertical


Fig. 21 A single RFG model accounts for present-day fluid and tar distributions in two adjacent fault blocks in an oilfield (cf. Fig. 19) (Zuo et al. 2017). The initial condition of a late gas charge into an undersaturated oil applies to both fault blocks. The RFG model incorporates gas diffusion into the oil, asphaltene migration away from high solution gas downward in the oil column, and asphaltene phase change. Well 1 is in the middle of these processes in geologic time, thus not equilibrated. Well 2 shows the final stage of this process (Zuo et al. 2017)

pressure interference testing (Achourov et al. 2015; Pfeiffer et al. 2016). Moreover, much higher production rates were obtained from Well 2 than Well 1 in accord with the higher permeability of Well 2 (Achourov et al. 2015). From a production standpoint, this RFG model is addressing many important concerns including the spatial distribution of asphaltenes and solution gas, thus oil viscosity and the presence or absence of a tar mat which has a huge impact on pressure support and aquifer sweep. Understanding the evolution of the fluid column greatly improves the understanding of present-day fluid and tar distributions (Zuo et al. 2017). This understanding is essential for optimal field development planning.

Well 3 in Fault Block 3 in this oilfield exhibits a very complex behavior of deposited asphaltenes. At this point, modeling can only account for the observations above the shale break as shown in Fig. 22.

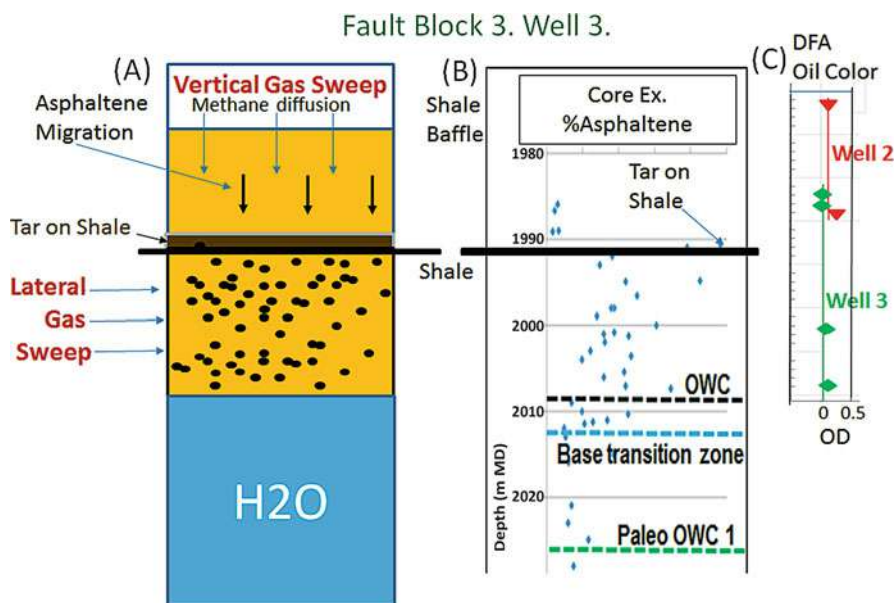
Figure 22 shows a complex distribution of deposited asphaltenes for Well 3 in Fault Block 3 (Pfeiffer et al. 2016). The fluids and pressures are equilibrated above and below the shale layer; thus, it is likely the shale is not a sealing layer but is a baffle and pinches out away from the wellbore. Above the shale layer, the late charge of gas density-stacked above the liquid and diffused down into the oil column. This


Fig. 22 Well 3 log data (Pfeiffer et al. 2016). (**a**) Schematic of the processes that led to complex asphaltene deposition observed in core extracts. Above the shale baffle, the same process occurs as in Well 2. Methane diffused down driving the asphaltene onto the shale baffle as a phase-separated material. Below the shale baffle, methane diffusion from above is impeded, and lateral gas sweep causes local deposition of asphaltene throughout the core with no tar mat at the base (Pfeiffer et al. 2016). (**c**) Little asphaltene remains in the oil due to the high GOR (~1200 scf/bbl). The asphaltenes, GOR (not shown), and pressure (not shown) are equilibrated from top to bottom in the oil column; the shale layer is a baffle, not a seal (Pfeiffer et al. 2016)

caused the asphaltenes to migrate onto the shale break where they became trapped (ponded as in a shale bowl) and underwent phase separation to form a thin tar mat. The tar mat is thin because there is only a small oil column above this shale break; thus little asphaltene was available to accumulate (Pfeiffer et al. 2016).

Below the shale break, gas could not diffuse from above. In this section of the well, the asphaltene is deposited throughout the column; moreover, there is no tar mat because there was no vertical migration of asphaltenes. This has been attributed to lateral gas sweep into the reservoir (Pfeiffer et al. 2016). Lateral gas sweep means that a significant lateral variation of fluid properties exists within a permeable formation. The origin of such variations is often associated with recent entry of new hydrocarbons, potentially gas, into the reservoir from the flank of a field (Achourov et al. 2015; Pfeiffer et al. 2016; Uchytil et al. 2016). With lateral migration, the asphaltenes cannot migrate downward away from the gas front; they become trapped locally and undergo phase transition. Lateral sweep of charge fluids has been incontrovertibly established by a black oilfield with a late gas charge (Uchytil et al. 2016). Lateral sweep of charge fluids is particularly likely if the well is located near the charge point of the reservoir, as is the case here for Well 3 (Pfeiffer et al. 2016; Uchytil et al. 2016).

These three adjacent fault blocks all experienced a late gas charge into oil reservoirs. However, the post charge evolution of these fault blocks led to three entirely different reservoir realizations in present day. Major production concerns of oil production rate, aquifer sweep, and type of produced fluid all depend on these different post charge processes and which are all described within a reservoir fluid geodynamics framework.

5   Conclusions

In this chapter, we have described the combination of new technology (downhole fluid analysis) coupled with new science (the first equation of state for asphaltene gradients) which have enabled the recent formalization of a new technical discipline "reservoir fluid geodynamics." Several oilfield case studies are presented elucidating major production concerns within a universal RFG workflow. Einstein stated "the most incomprehensible thing about the universe is that it is comprehensible." In our own microcosm of oilfield reservoirs, the same sentiment applies. We have shown here that measurements of asphaltene nanostructures apply to reservoirs at a length scale of 100 km. Laboratory measurements of asphaltene molecular diffusion at the nanosecond time scale apply to asphaltene diffusion in reservoirs in the tens of million years' time frame. The applicability of this extrapolation over roughly 14 orders of magnitude in both space and time dimensions is unexpected and remarkable. Reservoir fluids are not stochastic in nature; they are well behaved. The Flory-Huggins-Zuo equation of state is basically simple in that it employs a single "chemical" parameter, the Hildebrand solubility parameter each for the solute (asphaltenes) and solvent (live crude oil). The FHZ EoS is used with the specification of the asphaltene particle size from the Yen-Mullins model. The straightforward

approach enables broad understanding of many reservoir concerns over great space and time. The combination of this thermodynamic approach with exacting analytical chemistry methods and geochemical interpretation produces robust results. When new technology is combined with new science, great accomplishments come into view.

Multiscale Modeling of Cohesive-Frictional Strength Properties in Cementitious Materials

68

Steven D. Palkovic and Oral Büyüköztürk

Contents

Abstract

Computational modeling has been a valuable tool for studying the role of molecular structure and chemical composition in cementitious materials. A significant challenge is linking these molecular details to macroscale properties that define the durability of the material. This objective requires a holistic multiscale approach that translates the essential physics across atomistic (~ 1 nm), mesoscale (~ 100 nm), and microstructural (~ 100 μm) length scales. Recent studies have identified the importance of cohesive-frictional interactions on the material strength development. Cohesive-frictional materials exhibit a higher strength under compression than tension loading and a shear strength that increases when an external confinement is applied. These concepts are well

established for cementitious materials at the macroscale where they are routinely implemented in plasticity and strength models for structural design. However, macroscale phenomenological models are unable to identify the underlying structures and interactions that are the driving force behind this fundamental system response. In this chapter, observations from molecular dynamics (MD), discrete element method (DEM), and finite element method (FEM) modeling at multiple length scales are described to further understand the role of cohesive-frictional interactions in the strength development of cementitious materials.

1   Introduction

Cementitious materials like cement paste, mortar, and concrete are widely used because of their low cost and adaptability to a wide range of mix ingredients. This sensitivity to raw material inputs provides an opportunity for engineers to produce sustainable and durable materials for resilient infrastructure. Sustainable building materials require the incorporation of locally available additives such as fly ash, blast furnace slag, and volcanic ash in lieu of ordinary Portland cement (OPC) (Lothenbach et al. 2011). OPC is the component of cementitious building materials with the highest embodied energy demand, and its production currently accounts for up to 6% of global carbon emissions (Marland et al. 2017). The influence of additives on cementitious materials is difficult to predict and currently requires a trial-and-error approach to evaluate different combinations of constituents. Furthering our understanding of the role of additives at multiple length scales will reduce uncertainties and enable the design of sustainable materials that meet the performance requirements of a building or structure.

Computational modeling provides a powerful tool for establishing structure-property relationships within hierarchical materials. Nanoscale models provide significant insights for the principal hydrated phase of OPC-based materials, calcium-silicate-hydrate (C-S-H), that form more than 60% of a cement paste's volume (Double et al. 1978) and have a strong influence on the overall elasticity, strength, and long-term performance (Bernard et al. 2003; Pichler et al. 2009; Vandamme and Ulm 2009). C-S-H is a nanostructured material that has characteristic features spanning orders of magnitude in length scales which evolve dynamically with time. This material complexity provides a significant challenge for researchers attempting to use a bottom-up multiscale approach to establish connections between nanoscale behavior and engineering properties at the macroscale.

In this chapter, recent studies on the mechanical strength development of cementitious materials spanning from 10^{-10} to 10^{-2} m are discussed, with a particular focus on changes in cohesive-frictional behavior. A cohesive-frictional material exhibits a strength asymmetry in compression and tension and has a shear strength that is dependent on the confinement applied through an external normal stress or hydrostatic pressure. This behavior has been known for decades at the macroscale, where Mohr-Coulomb or Drucker-Prager models are used to predict the material strength envelope and plastic deformation behavior (Chen 2007). However, an

understanding of the features and length scales that control the origin and evolution of cohesive-frictional properties requires a holistic multiscale approach (Palkovic et al. 2016). This is accomplished through computational modeling that employs molecular dynamics (MD), discrete element methods (DEM), or continuum finite element methods (FEM) depending on the model size and features included. Information from lower-scale models are used to determine the appropriate model assumptions and inputs at larger scales. By understanding the critical aspects of cohesive-frictional strength development in cementitious building materials, more sustainable and durable structures can be obtained.

2   Hierarchies in Cement Paste

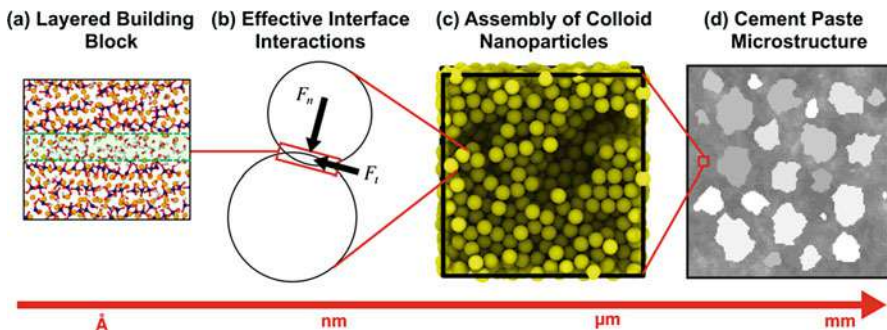
Cement paste is the matrix phase in larger-scale composites like mortar and concrete. Therefore, it is an appropriate starting point for developing a multiscale framework for cementitious building materials. Cement paste is a heterogeneous mixture of hydrating phases, mineral inclusions, and pores. The essential model features and length scales are summarized in Fig. 1. Models smaller than 1 μm focus on the nanostructured C-S-H phase. C-S-H is composed of colloidal nanoparticles with an internal layered structure of calcium-silicate layers separated by an interface containing water molecules, hydroxyl groups, and counter ions (Richardson 2008). This layered configuration provides a building block for studying the influence of atomistic structure and chemical composition on nanoscale interactions (Hou et al. 2015; Qomi et al. 2014). Forces within the layers and from the surrounding electrostatically charged pore solution influence the assembly, pore structure, and mechanical properties of colloidal nanoparticles (Ioannidou et al. 2014, 2016;


Fig. 1 Multiscale description of cement paste. (**a**) A layered building block describes the molecular structure which changes with varying chemical composition. (**b**) The effective behavior of this interface can be used to describe interparticle forces between C-S-H colloids. These forces include a normal component (F_n) for cohesive interactions and tangential component (F_t) for the shear resistance between particle pairs. (**c**) These particles assemble to form mesoscale solid-pore structures of colloids interacting through cohesive-frictional forces. (**d**) At larger scales, C-S-H behaves as a continuous material within a cement paste microstructure (Palkovic 2018)

Masoero et al. 2012). These colloids have a size ranging from 3 to 15 nm (Chiang et al. 2012; Jennings 2008; Skinner et al. 2010) and assemble to form a fibrillar pore network (Ioannidou et al. 2014). The arrangement and interactions of colloidal assemblies control the mesoscale behavior of C-S-H that bridges between discrete models and continuum descriptions. Continuum behavior is input to cement paste microstructure models as constitutive relationships that homogenize the discrete features of the material. Microstructure models consider the local distribution in strength and stiffness of hydrated phases that has been measured experimentally through statistical indentation (Constantinides and Ulm 2007). In the following sections, computational modeling is applied to study the development of cohesive-frictional properties within these structures.

3 Molecular C-S-H Interfaces

At the smallest length scales, all matter is composed of atoms which interact through intermolecular forces that are dependent on chemical composition and molecular structure. Nanoscale models must account for the discrete nature of materials at submicron length scales where classical continuum theories can no longer be applied.

For cement paste, atomistic modeling has been used to investigate the internal layered structure of C-S-H colloids. These models are based on the mineral phase tobermorite, which is systematically modified by introducing defects to the crystalline structure to match experimental chemical composition, silica chain connectivity, degree of hydration, and density measurements (Pellenq et al. 2009). These models frequently incorporate the reactive force field ReaxFF (Van Duin et al. 2001), which was parameterized through density functional theory (DFT) simulations (Manzano et al. 2012b). Reactive force fields are capable of capturing the formation and breaking of bonds, water dissociation, and atomic charge fluctuations during a simulation (Manzano et al. 2012a, 2013).

A C-S-H structure with a calcium/silicon (Ca/Si) ratio of 1.70 is studied because this composition is typical of what is produced during the hydration of OPC mixtures (Hou et al. 2015). The structure consists of relatively crystalline layers separated by a disordered interface (Bauchy et al. 2014). Under shear loading, the interface allows for strain localization while the more ordered layers experience little deformation. This is shown in Fig. 2 by calculating the local atomic shear strain as the overall structure is subjected to a linearly varying affine shear strain. The heterogeneous response to homogeneous deformation indicates that the interface is the limiting region for shear loading. This is further confirmed by the agreement in strength properties obtained for direct and affine shear loading, where direct shear loading is used to constrain localization within the interface (Palkovic et al. 2015). Other researchers have attributed this to a "lubricating" effect of water molecules which screen the interactions of adjacent calcium-silicate layers (Pellenq et al. 2009).
Fig. 2 (**a**) Two-dimensional view of a representative C-S-H atomic structure with Ca/Si of 1.65, with the interlayer region shown by the highlighted region. Atoms are colored by element type, with orange for Ca, purple for Si, red for O, and gray for H. (**b–f**) System response to applied affine shear (ε_{xz}), with atoms colored by the magnitude of local atomic shear strain. Atomic shear strain localizes within the water-filled interface region as the calcium-silicate layers remain relatively undeformed (Büyüköztürk and Palkovic 2017)

The response of the molecular C-S-H structure to external confinement is measured by applying a compressive strain normal to the plane of the interface (Palkovic et al. 2017b). Figure 3 shows that the interfacial shear strength increases with a greater magnitude of applied compressive strain. This response is characteristic of cohesive-frictional materials and can be quantified using a Mohr-Coulomb strength model given by

$$\tau_n = \mu\sigma_n + c \tag{1}$$

where τ_n is the shear strength and σ_n is the normal stress along the maximum shearing plane. The Mohr-Coulomb model is defined by two constants that vary for different material systems, the internal friction coefficient μ and cohesion c. The shear strength can be determined by averaging the fluctuations of the system response during the relatively perfectly plastic flow regime that occurs for all models after approximately 0.25 strain.

The strength envelope and resulting Mohr-Coulomb model for the average of five molecular C-S-H structures with a Ca/Si ratio of 1.7 is shown in Fig. 4. The Mohr-Coulomb fit provides a cohesion of $c = 2.6 \pm 0.2$ GPa and $\mu = 0.14 \pm 0.01$. The internal friction coefficient is consistent with other amorphous materials such as 0.12 for a metallic glass (Lund and Schuh 2003) and 0.07–0.16 for a polymer glass (Rottler and Robbins 2001). This suggests that the magnitude of μ is related to the disordered structure within the interface region and is less dependent on the atomic bonding which greatly differ for a metal, polymer, and C-S-H system. Amorphous materials exhibiting strength asymmetry and a dilatant response under
Fig. 3 Octahedral stress-strain for molecular C-S-H structures with an initial strain applied normal to the plane of the interface (ε_n). The horizontal lines show the average octahedral flow stress for strain higher than 0.25 that is used to determine the cohesive-frictional strength envelope

shear loading are believed to undergo plastic deformation through non-affine shear transformations (Argon 1979). A shear transformation is the rearrangement of groups of atoms that occurs under loading to relieve the buildup of internal stress. Atoms surrounding the shear transformation apply a restraining force that increases the shear load necessary to initiate the shear transformation and results in a shear strength dependency of the material confinement. The repeated stress drops observed under shear loading (Manzano et al. 2012a; Pellenq et al. 2009), and the measurable internal friction coefficient in Fig. 4, are consistent with shear transformations occurring within a disordered water-filled interface of the molecular structure as the origin of plastic deformation and cohesive-frictional behavior in C-S-H. The influence of cohesive-frictional properties at larger scales is investigated in Sects. 4 and 5.

4 Colloidal C-S-H

The computational complexity of a reactive force field limits the system size to approximately 10^4 atoms. To reach larger length scales, coarse-graining must be used to determine effective interactions that reduce the model degrees of freedom and allow for modeling of larger-scale structures. For colloidal C-S-H, the interface region that limits the strength and deformation behavior of the molecular structure is a natural choice to parameterize larger-scale interactions. One study developed a
Fig. 4 Shear strength as a function of normal stress along the maximum shear plane for molecular C-S-H. A Mohr-Coulomb model is fit to the strength envelope that is tangent to the Mohr's circle for different magnitudes of confinement using least-squares linear regression

Lennard-Jones pair potential that was modified to account for particle of dissimilar size while also incorporating the shear rupture strain and elastic stiffness of the interface region (Masoero et al. 2012). However, a molecular dynamics pair potential like the Lennard-Jones function cannot sustain shear forces for interacting particle pairs, in disagreement with atomistic simulations of the layered C-S-H structure.

4.1   Cohesive-Frictional Force Field (CFFF)

To provide more realistic interface interactions, Palkovic et al. (2017a) proposed a cohesive-frictional force field (CFFF) that incorporates aspects of adhesive contact mechanics (Derjaguin et al. 1975) which are implemented through numerical techniques developed for discrete element modeling (DEM) (Cundall and Strack 1979). In this force field, frictional forces between contacting particles are calculated to represent the cohesive-frictional behavior of the interface. This tangential force F_t is based on the shear stiffness of the interface up to a maximum value given by a Mohr-Coulomb limit as

$$F_t(r) = \min\left[8\Delta_t G_e a, \;\; \mu F_n + \pi c a^2\right] \tag{2}$$

where r is the center-to-center spacing of interacting colloids, $G_e = G/(2(2 - v))$ is the effective shear stiffness from the interface shear modulus G and Poisson's ratio v, Δ_t is an increment of tangential displacement, F_n is the normal force between colloids, μ is the internal friction coefficient, and c is the interface cohesion. The tangential force varies with the contact area between colloids $a = a_0 + \sqrt{D_e (D_0 - r)/4}$, where $D_e = 2D_i D_j/(D_i + D_j)$ is the harmonic mean of particles D_i and D_j and $D_0 = (D_i + D_j)/2$ is the average particle size defining the equilibrium spacing. The adhesive component of the contact radius $a_0 = \sqrt[3]{3\pi D_e^2/(32 E_e)}$ is given by the Derjaguin-Muller-Toporov (DMT) theory and is a function of w the work of adhesion and $E_e = E/(2(1 - v^2))$ the effective normal stiffness given by the Young's modulus E and Poisson's ratio v. DMT is a continuum theory that considers interactions between smooth spherical particles. As a result, the contact area is an upper bound for atomically rough C-S-H colloids.

The normal force-displacement function was derived by fitting a three-parameter exponential function to the tension and compression behavior of the atomistic C-S-H structure (Palkovic et al. 2017a). This pair potential was then extended to spherical colloids of varying diameters by considering interacting harmonic springs in series. The final pair potential normal force relationship is given by

$$F_n(r) = \frac{\pi E D_e (r - D_0) \left(1 + e^{-\alpha}\right)}{4 \left(1 + \exp\left(\frac{\alpha(r-D_0)}{D_0 \varepsilon_u} - 1\right)\right)} \tag{3}$$

where E is the Young's modulus that controls the compressive and initial stiffness of the pair potential, ε_u is a strain parameter that offsets the position of the maximum cohesive force, and α is a dimensionless parameter that controls how brittle or ductile the function behaves. Figure 5 compares Eq. 3 with the Lennard-Jones

Fig. 5 Comparison of interparticle force-separation curves for average particle sizes of 3, 6, and 9 nm for a polydisperse Lennard Jones (LJ) (Masoero et al. 2014), Eq. 3 with a constant strain parameter of 4.3%, and a size-dependent strain parameter calculated with Eq. 4 (Palkovic et al. 2017a)
function that was modified to account for polydisperse particles of varying diameter. Two forms of Eq. 3 are shown, (i) with a constant strain parameter $\varepsilon_u = 4.3\%$ and (ii) with maximum adhesive force predicted by DMT theory $F_n^{\max} = \pi E w D_e / 2$. A maximum adhesive force can be enforced with a size-dependent strain parameter, which for $\alpha = 2$ is given by

$$\varepsilon_u = \frac{2w\alpha}{E D_0 \left(1 + e^{-\alpha}\right)}. \tag{4}$$

The reduced adhesive force obtained when applying the size-dependent strain parameter defined in Eq. 4 shows better agreement with atomic force microscopy (AFM) measurements (Lesko et al. 2001; Plassard et al. 2004), and the lower tensile strain is consistent with dynamic rheology experiments (Nachbaur et al. 2001). The pair potential shown in Fig. 5 uses a Young's modulus $E = 61.3$ GPa, Poisson's ratio $v = 0.28$, $\alpha = 2.0$, and adhesion energy $w = 1.72$ N/m^2 (Bauchy et al. 2015) that were measured directly from the molecular C-S-H structure (Palkovic et al. 2015, 2017a). These inputs are used to investigate the mechanical response of colloid assemblies in Sect. 4.2.

4.2   Mechanics of Colloidal C-S-H

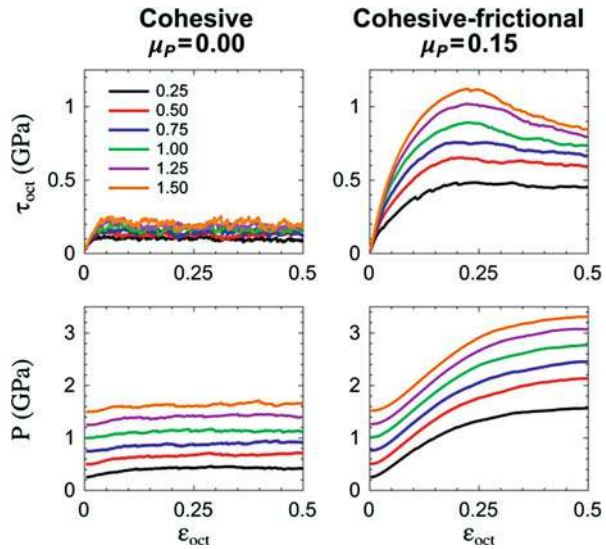
The CFFF allows for the investigation of the role of molecular behavior within colloidal assemblies of C-S-H particles through the fitting of force field inputs. On the order of hundreds of nm, small-angle scattering experiments indicate that models should consider polydispersity through varying colloid sizes and long-range particle correlations (Allen et al. 2007). Recent studies have assumed that particle sizes are given by a uniform random distribution with minimum diameter D_m and maximum diameter D_M, which can be defined by a normalized polydispersity parameter $\delta = (D_M - D_m) / \left(\sqrt{3}\,(D_M + D_m)\right)$. Polydispersity influences the system packing density (Masoero et al. 2012), which nanoindentation has shown exists across a broad range of densities due to varying gel and capillary porosity (Constantinides and Ulm 2007). The model packing density for N spherical particles is given by $\eta = \left(\sum \pi D_i^3/6\right) / V$, where D_i is the diameter of particle i and V is the total volume of the simulation cell. Dense C-S-H configurations are generated by randomly inserting colloidal particles with a Monte-Carlo algorithm to progressively fill an initially empty simulation cell. These colloidal configurations represent dense regions within the open C-S-H network that have been studied with a Yukawa potential that captures long-range repulsion in the charged solution (Ioannidou et al. 2014). Table 1 provides an overview of the model parameters considered for subsequent analysis. When cohesive-frictional interactions are considered, a shear modulus $G = 25.6$ GPa and Mohr-Coulomb strength envelope given by $\mu = 0.15$ and $c = 2.6$ GPa of the molecular interface are utilized.

δ	D_m	D_M	L	η	N
	(nm)	(nm)	(nm)		(particles)
0	5.0	5.0	43–65	0.50–0.65	583–2769
0.29	3.0	9.0	51–77	0.55–0.70	831–6296
0.38	3.0	15.0	51–78	0.60–0.74	576–4364

Table 1 Mesoscale C-S-H systems considered. The number of particles N is given for the smallest and largest packing density η
Fig. 6 Colloidal C-S-H response to shear deformation for systems with the same packing density and polydispersity but varying coefficient of friction (μ_P). Particles are colored by the local atomic shear strain (Palkovic 2018)

The influence of cohesive-frictional interactions is significant under large deformations. The local particle shear strain at varying magnitudes of overall shear deformation is shown in Fig. 6 for a polydisperse model with $\delta = 0.29$ and $\eta = 0.70$. Models with purely cohesive interactions ($F_t = 0$) exhibit localized deformations throughout the C-S-H structure. When cohesive-frictional interactions are included, a more distributed strain pattern and lower magnitude of local strain are observed.

The local strain patterns are consistent with the calculated stress-strain response of C-S-H structures under external confinement shown in Fig. 7. Colloidal models are first compressed to an initial pressure P_0 using an NPT ensemble at 300 K and pressures ranging from 0.25 to 1.50 GPa. Pure shear loading is then applied in an NVT ensemble with strain increments of 0.1% up to a maximum value of 50%. After each strain increment, a MD relaxation of 50,000 timesteps of 2.5 fs is applied with averaging of the Cauchy stress tensor performed over the final 10% of the relaxation time. Cohesive-frictional interactions result in a significant increase in octahedral stress, an extended elastic regime, and a more dilatant response compared to purely cohesive models. The stress-strain response also shows a smoother behavior, with less frequent stress drops that are likely associated with shear transformations of colloidal particles. These simulations suggest that shear resistance between interacting colloids results in a more continuous response as frictional forces resist the applied deformation and increase the resistance to local particle rearrangements that facilitate plastic deformation.

Fig. 7 Octahedral stress (τ_{oct}) and hydrostatic pressure (P) as a function of applied octahedral shear strain (ε_{oct}) and initial hydrostatic pressure P_0, for a colloidal C-S-H model with polydispersity $\delta = 0.29$ and packing density $\eta = 0.70$ but with varying internal coefficient of friction (μ_P). Models use a size-dependent strain parameter calculated with Eq. 4, but identical loading conditions that use CFFF interactions with a constant strain parameter are provided in Palkovic et al. (2017a)


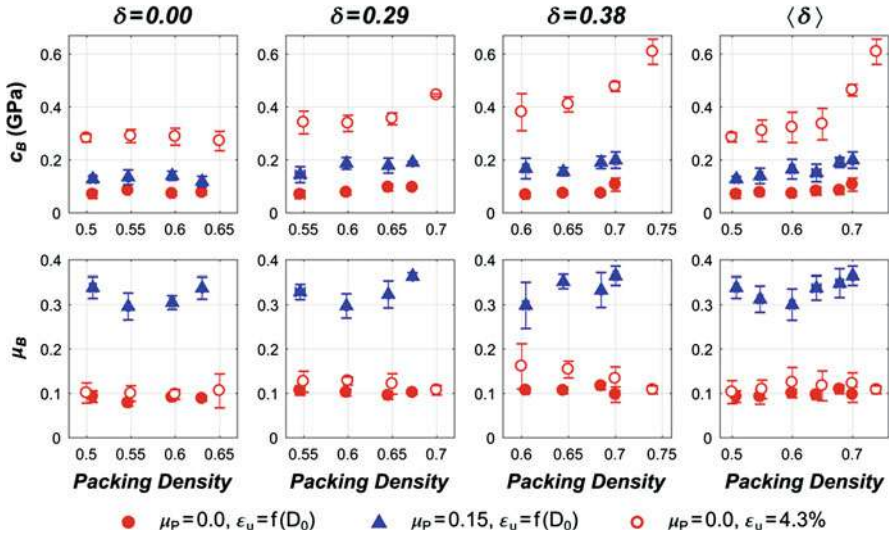
The bulk Mohr-Coulomb strength envelope for the colloidal C-S-H structures can be determined from C-S-H models subjected to varying hydrostatic pressure. These bulk properties are appropriate for material volumes on the order of hundreds of nm and can be compared with the molecular interfaces measured previously. The bulk cohesion c_B and internal friction coefficient μ_B are calculated as a function of polydispersity, packing density, and different particle normal interactions in Fig. 8. Polydispersity has a limited influence on the Mohr-Coulomb strength properties, and results are averaged over all polydispersity values $\langle \delta \rangle$ for a given packing density to make trends more apparent. Stronger adhesive forces between particles as a result of a constant strain parameter ($\varepsilon_u = 4.3\%$) lead to a significant increase in c_B. These models also reach greater packing densities because the significant tensile residual stresses that accumulate during model generation lead to densification during subsequent NPT relaxation that is performed prior to mechanical loading. Comparing models with the same size-dependent strain parameter given by Eq. 4, cohesive-frictional interactions lead to significant increases in both c_B and μ_B. Models that neglect shear forces between particles exhibit a similar bulk μ_B, regardless of the strength of adhesive forces, and the value ranges from 0.10 to 0.15 which is a similar magnitude to the layered molecular structure. This is attributed to the disordered structure that is exhibited by both the interfacial region of molecular C-S-H and overall colloidal assembly. However, when frictional forces are included, the shear resistance between particles greatly amplifies the overall shear strength and dilatant response of C-S-H. Prior simulations of cohesive-frictional models with a constant strain parameter showed even higher values of μ_B approaching 0.6 (Palkovic et al. 2017a). Experimental measurements of c_B and μ_B are not available in the literature, but we can investigate their influence within microstructural models described in Sect. 5 to compare with macroscale experiments.


Fig. 8 Mohr-Coulomb bulk strength properties of colloidal C-S-H models with varying polydispersity (δ), packing density, radial strain parameter (ε_u), and internal coefficient of friction (μ_P). Data points and error bars represent the average and standard deviation of four or more samples for each combination of δ and packing density. Results are also averaged for the same packing density but varying polydispersity ($\langle\delta\rangle$). Results with stronger adhesive forces obtained from (Palkovic et al. 2017a)

5   Cement Paste Microstructure

At larger scales ($>1\,\mu$m), the discreteness of underlying features such as the layered molecular structure or assemblies of colloidal nanoparticles is homogenized. As a result, the material behaves according to continuum mechanics which can be modeled using finite element methods (FEM). In the FEM, the mechanical response of a material domain under prescribed boundaries and loads is approximated across local finite elements using polynomial interpolation functions (Bathe 2006). The discretization of the material domain with regions of varying material properties allows for the modeling of a discrete microstructure. The challenges for developing finite element models of cement paste are the random and heterogeneous nature of the material which complicates the determination of a realistic microstructure geometry and interactions between phases. A new approach is to combine statistical nanoindentation concepts (Ulm et al. 2007) with random field modeling techniques (Torquato 2013) to produce random field finite element method (RF-FEM) models of the cement paste microstructure (Palkovic et al. 2018). This methodology allows for the generation of three-dimensional realizations that match experimental measurements on hardened cement paste samples with varying mix composition and hydration degree. Cohesive-frictional interactions can be input

within the constitutive models describing plasticity of hydrated phases like C-S-H. An overview of the method and application on an OPC material are described in Sects. 5.1 and 5.2, respectively.

5.1   Random Field Finite Element Method (RF-FEM) Models

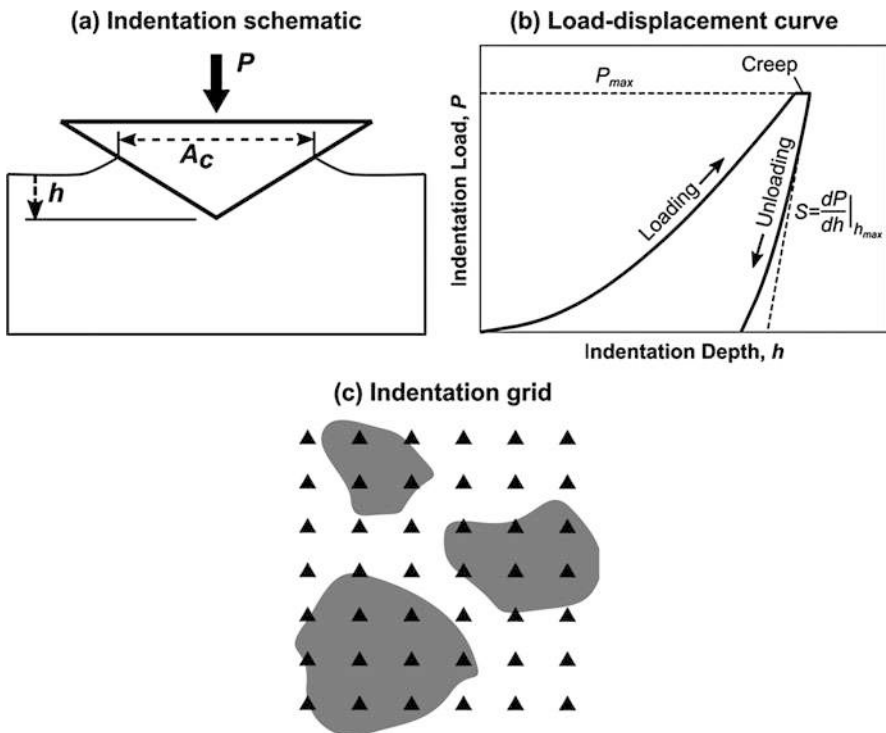
Statistical indentation allows for the measurement of the distribution of mechanical properties in a heterogeneous composite. The overall procedure is summarized in Fig. 9. An indentation test uses an axisymmetric stylus to deform an elastic-plastic substrate. The normal force P acting on the stylus is monitored as a function of the indentation depth h below the undeformed surface (Oliver and Pharr 1992). During loading, the indented material responds through predominantly plastic deformation as a permanent impression is formed on the sample surface which is characterized by the indentation hardness given by


Fig. 9 (**a**) Indentation of an elastic-plastic material with an axisymmetric stylus. (**b**) Load-displacement curve for a cementitious material obtained from each indentation. (**c**) Statistics are obtained by randomly sampling a composite with an indentation grid (Palkovic et al. 2018)

$$H = \frac{P_{\max}}{A_c} \tag{5}$$

where $P_{\max}$ is the maximum applied force and A_c is the projected contact area. The material is assumed to respond elastically when the load is removed, so that the elastic stiffness can be measured with the indentation modulus:

$$M = \frac{\sqrt{\pi} S}{2\sqrt{A_c}} \tag{6}$$

where $S = \frac{dP}{dh}\big|_{h_{\max}}$ is the unloading stiffness measured at the maximum indentation depth $h_{\max}$.

Statistics on mechanical properties are obtained by randomly sampling a microstructure using a grid of indentation tests. Local mechanical properties can be obtained if the volume of material probed during the indentation satisfies scale separability laws given by $0.01 < h_{\max}/D < 2 \cot \theta$, where D is a characteristic size of the microstructure and θ is the half-angle of the stylus ($\theta = 70.3°$ for a Berkovitch tip) (Constantinides et al. 2006). For cement paste, researchers have proposed a maximum indentation depth of 200 to 500 nm based on approximately 5 nm colloids as the smallest feature size and homogeneous regions of hydration product extending 5 or more μm as the largest microstructural feature (Ulm et al. 2010).

Statistical indentation measurements are presented in Fig. 10a for a hardened OPC paste with a water-to-cement (w/c) ratio of 0.35 that was aged for 28 days before being submerged in acetone to retard hydration. The average indentation depth was approximately 315 nm, within the proposed scale separability criteria. The results are analyzed to separate the porous hydration products that form a continuous matrix and inclusion phases that are suspended within the matrix. Hydration products include C-S-H, calcium hydroxide, and ettringite that exhibit a lower strength and stiffness than more crystalline inclusion phases like Portland cement grains. A maximum mechanical threshold of $H \le 3$ GPa and $M \le 75$ GPa is used to separate hydration products from inclusions. This threshold is based on statistical indentation testing on cementitious materials of varying (w/c) ratio that were analyzed with Gaussian mixture models to determine mechanical properties of local phases (Vandamme et al. 2010) and atomistic models of the molecular C-S-H structure excluding gel and capillary pores (Qomi et al. 2014). The resulting indentation modulus and indentation hardness distributions are shown in Fig. 10b–c. The inset of these figures shows the separated hydration products, along with a lognormal probability density function (PDF):

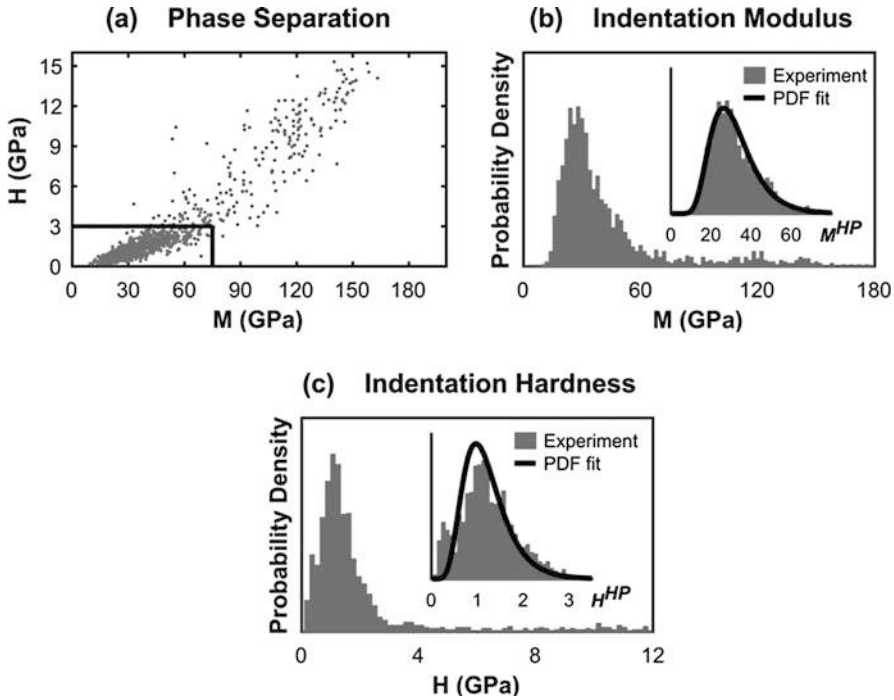
$$p^{HP}(\boldsymbol{x}) = \frac{1}{s_N \sqrt{2\pi \boldsymbol{x}}} \exp \frac{(\ln \boldsymbol{x} - m_N)^2}{2s_N^2} \tag{7}$$


Fig. 10 Analysis of nanoindentation results for random field modeling. (**a**) Porous hydration products are separated based on maximum indentation properties of M ≤ 75 GPa and H ≤ 3 GPa. (**b**) Indentation modulus distribution and (**c**) indentation hardness distribution from 1600 tests on an OPC sample. The insets show the separated hydration products and a lognormal probability density function (PDF) calculated for this subset of data (Palkovic et al. 2018)

calculated for the indentation properties using the mean m_N and variance s_N^2 of the associated normal distribution given by $\ln p^{HP}(x)$. The mean and variance of the lognormal distribution are obtained using $m_{LN} = \exp\left(m_N + s_N^2/2\right)$ and $s_{LN}^2 = \exp\left(2m_N + s_N^2\right)\left(\exp\left(s_N^2\right) - 1\right)$. For the OPC material tested, the moments of the indentation modulus are $m_{LN}^M = 31.8$ GPa and $s_{LN}^M = 11.7$ GPa and for the indentation hardness are $m_{LN}^H = 1.22$ GPa and $s_{LN}^H = 0.52$ GPa.

The measured mechanical property distributions are input within existing random field techniques to generate spatially correlated random fields that have an overall distribution of mechanical properties matching the values measured with nanoindentation. Overbars are used to differentiate the local material properties input within RF-FEM models and the effective microstructure properties obtained from simulations (e.g., $\widetilde{E}$ for local Young's modulus and E for effective microstructure Young's modulus). To be suitable with FEM, indentation properties are converted to an isotropic material model. The indentation modulus can be converted to the Young's modulus E using (Johnson 1987)

$$\frac{1}{M} = \left[\frac{1-v^2}{E} + \frac{1-v_s^2}{E_s}\right]^{-1} \tag{8}$$

where $v_s = 0.07$ and $E_s = 1140$ GPa are the Poisson's ratio and Young's modulus of a diamond-tipped Berkovitch stylus. The indented material Poisson's ratio is taken as 0.28 for hydration products and 0.30 for inclusion phases (Bernard et al. 2003). A Mohr-Coulomb plasticity model given by Eq. 1 can be calculated from the measured indentation hardness using

$$H = \frac{c}{\mu} \sum_{k=1}^{6} (a_k \mu)^k \tag{9}$$

where a_k are fitting coefficients that depend on the geometry of the stylus (Ganneau et al. 2006). Colloidal modeling shows that Mohr-Coulomb properties are dependent on the presence of cohesive-frictional interactions between particles. To study this effect at the microstructural scale, local internal friction coefficients $\widetilde{\mu}_B$ ranging from 0.09 to 0.47 are investigated. With this approach, a material with the same indentation hardness distribution can have varying local cohesive strength $\widetilde{c}_B$ based on the assumed internal friction coefficient. Inclusion phases are assumed to remain elastic because of their higher strength, so no yield criterion is applied.

RF-FEM geometry is generated according to a covariance function that defines the correlation of the random field based on spatial separation $r = \|x_i - x_j\|$ between position x_i and x_j in the three-dimensional grid used to define the random field. The covariance function is given by

$$B(r) = s_N^2 \exp\left(2\,|r|\,/L_c\right) \tag{10}$$

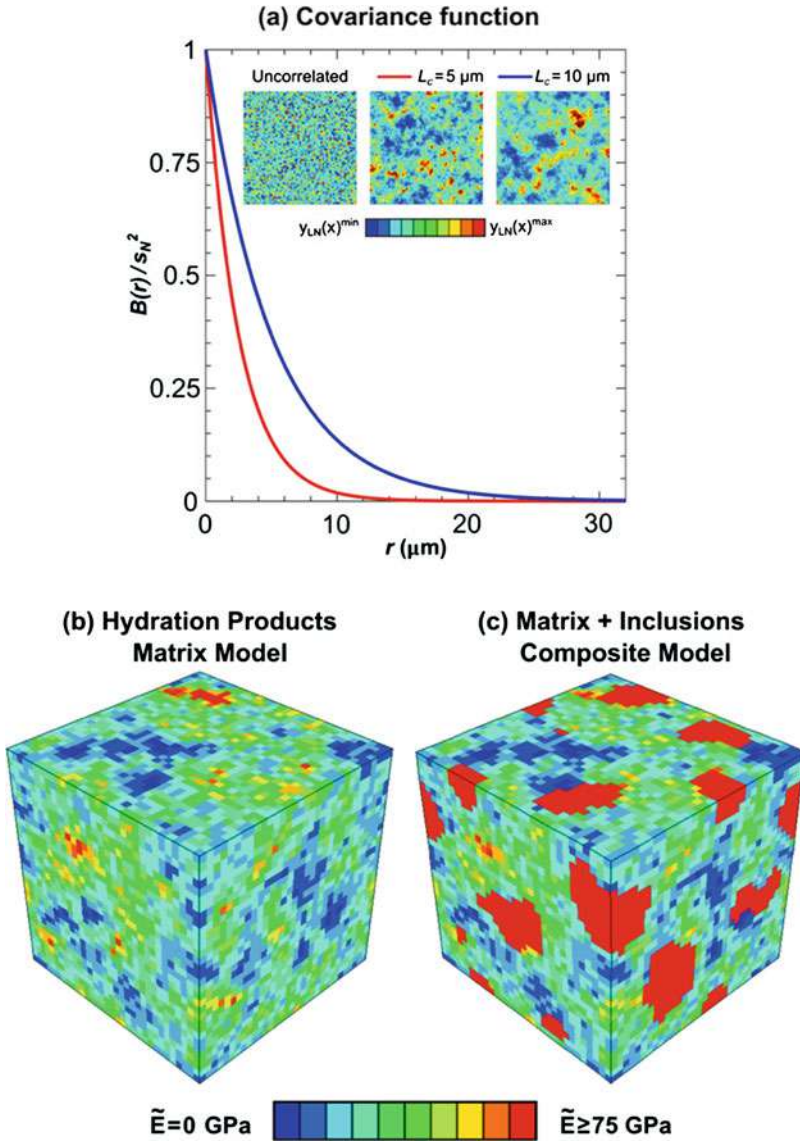
which is defined by the variance s_N^2 of the measured mechanical property PDF and the correlation length L_c. An increase in correlation length results in larger correlated regions within the microstructure. A periodic Gaussian random field $y_N(x)$ is generated with a fast Fourier transform (FFT) algorithm (Roberts and Teubner 1995) and then transformed to the desired lognormal random field using $y_{LN}(x) = \exp\left(m_N + y_N(x)\right)$, where m_N is the mean of the measured mechanical property PDF. This procedure results in a correlated random field representing the continuous matrix of cement paste with an overall mechanical property distribution that is based on nanoindentation measurements of the hydration products. A composite model representing the complete cement paste microstructure can be obtained by inserting inclusion phases of random size, shape, and position within the periodic material domain. The Young's modulus of inclusions is taken from a uniform distribution spanning from 60 to 160 GPa. The influence of the covariance function on the random field geometry is shown along with examples of a representative matrix and composite model in Fig. 11. Additional details regarding the implementation of random field models are described elsewhere (Palkovic et al. 2018).


Fig. 11 RF-FEM model development. (**a**) The spatial geometry of the continuous matrix is set by the covariance function. The local Young's modulus distribution is shown for a representative (**b**) matrix and (**c**) composite model (Palkovic et al. 2018)

Fig. 12 Response of 25 realizations of matrix and composite RF-FEM models to uniaxial compression with varying confinement and local internal friction coefficient. (**a**) Uniaxial stress-strain response along the loading axis. (**b**) Relationship between volumetric strain and applied axial compressive strain (Palkovic et al. 2018)
5.2 Mechanical Response of Cohesive-Frictional Microstructural Models

RF-FEM models are subjected to uniaxial compression with varying magnitudes of lateral confinement. Confinement is applied through a constant normal stress applied to opposing faces of the cubic model domain. Results for 25 realizations of matrix and composite models with varying local internal friction coefficient $\tilde{\mu}_B$ are shown in Fig. 12. The uniaxial stress-strain ($\sigma_{33} - \varepsilon_{33}$) relationship shows an initial elastic regime followed by perfectly plastic behavior after yielding. Models with a higher $\tilde{\mu}_B$ show a decreased compressive strength and less sensitivity to random field geometry and are more strongly influenced by confinement. The material volumetric response is also highly dependent on $\tilde{\mu}_B$. All models show an initial decrease in volumetric strain ε_v associated with compaction, followed by a dilatant response after yielding. More dilation is observed for models with higher $\tilde{\mu}_B$. When inclusions are added to the heterogeneous matrix, a small increase in the uniaxial compression strength is observed with little change in volumetric behavior.

The compressive strength as a function of confinement can be used to evaluate the effective cohesive-frictional properties of the microstructure. The Mohr-Coulomb fit for a representative matrix and composite material at low and high $\tilde{\mu}_B$ is shown in Fig. 13. Comparing matrix and composite models, the macroscale internal friction coefficient of the homogenized microstructure is not influenced by the presence of inclusions. The macroscale values are also almost unchanged from the local

Fig. 13 Mohr-Coulomb strength properties of a representative matrix and composite microstructure model with varying local internal friction coefficient $\tilde{\mu}_B$ (Palkovic et al. 2018)
internal friction coefficient input for the yield criterion of hydration products. This observation is true for models with varying correlation length, model size, and measured lognormal PDFs (Palkovic et al. 2018). These findings suggest that microstructural features do not strongly influence the effective internal friction coefficient. Therefore, it is the layered molecular structure and colloidal interfaces that control the inelastic dilatancy and plasticity of cementitious materials.

Microstructure models are compared with uniaxial compression experiments by calculating the porosity intrinsic to hydration product measurements obtained with nanoindentation. Nanoindentation tests satisfying scale separability for cement paste probe a material volume on the order of 1 to 2 μm, which is large enough to include gel and smaller capillary pores (Chen et al. 2010). The internal porosity can be estimated using a self-consistent micromechanical model which is commonly given by (Constantinides and Ulm 2007)

$$P^{SC} = \frac{1}{2}\left(1 - \frac{\langle M^{HP}\rangle}{M^{HP}_{\max}}\right) \tag{11}$$

where $\langle M^{HP}\rangle$ is the expected value of the measured indentation modulus distribution and $M^{HP}_{\max} = 75$ GPa is the threshold value used to separate phases. Applying Eq. 11, the porosity of matrix models is 29%, while the porosity of composite models is 25% if we assume no porosity within inclusion phases. The porosity of 5-cm cement paste cubes is calculated using empirical relationships for OPC materials that are dependent on the sample w/c ratio and hydration degree (Nielsen

Fig. 14 Comparison of uniaxial compression experiments on 5-cm cement paste cubes with microstructure model simulations for matrix and composite models
1993). The comparison of models and experiments is shown in Fig. 14 for varying local internal friction coefficients. Models with higher $\widetilde{\mu}_B$ show better agreement with macroscale experiments as a result of the decreased local cohesive strength of hydration products in the cement paste matrix. Triaxial loading experiments on cement paste and mortar materials that are converted from a Drucker-Prager to Mohr-Coulomb cohesive-frictional strength model find a macroscopic friction coefficient ranging from 0.42 to 0.60, providing further confirmation of model results (Heukamp et al. 2001, 2003).

6   Summary and Future Directions

This chapter tracks the development of cohesive-frictional interactions within cementitious materials from molecular to microstructural scales. The Mohr-Coulomb strength properties that were calculated at each length scale are summarized in Table 2. These values are specific to the parameter of the models shown and will vary depending on the force fields, interactions, and structures considered. However, the main observations and trends are expected to be applicable to a broad range of cementitious materials.

   At molecular scales, the disordered water-filled interface within the atomistic structure of C-S-H provides a region for strain localization that is the origin of

Table 2 Cohesive-frictional properties across length scales of cement paste

Model	Scale	μ	c (MPa)	Comments
Molecular	~1 nm	0.05–0.15	2500–4000	Cohesive-frictional behavior originates within the interface between calcium-silicate layers, likely due to shear transformations of disordered region
Colloidal	~100 nm	0.30–0.40	5–200	Amplification of μ due to shear resistance of particle interactions. Reduced c from gel porosity, capillary porosity, and adhesion energy of interactions
Microstructure	~100 μm	0.42–0.60	5–50	Properties are dominated by the cohesive-frictional inputs of hydration products forming a matrix. Inclusions and randomness of microstructure affect c, but not μ

Notes: Range of molecular values from unpublished models with Ca/Si ratio varies from 1.1 to 1.9, whereas results in Sect. 3 use 1.70. Colloidal results are based on models with adhesive strength limited by adhesion energy. Microstructure values are based on experimental and simulation observations, which suggest that a higher friction coefficient of cementitious materials is appropriate

cohesive-frictional behavior. This system response is attributed to shear transformations, a mechanism of plastic deformation for amorphous materials at low temperatures and strain rates. When cohesive-frictional properties are included in larger-scale interactions between colloidal C-S-H particles, the additional friction forces resist shear deformations and distribute strain throughout the material. As a result, there is a significant amplification of the bulk friction coefficient describing the inelastic dilatancy and strength asymmetry in compression and tension. The amplified friction coefficient is in better agreement with macroscale triaxial loading experiments of cement paste (Heukamp et al. 2001). Microstructure models suggest that this is because cement paste is insensitive to μm-scale features such as the presence of low volume fraction of inclusions, correlation length of hydration products, and random variations within the material microstructure. Therefore, it is the nm-scale behavior at molecular interfaces and colloidal interactions within hydration products that dominate the cohesive-frictional behavior of cementitious materials.

The development of this multiscale computational description of cementitious materials spanning from 10^{-10} to 10^{-2} m provides new possibilities for future exploration. Promising areas include the parameterization of the CFFF with molecular models of C-S-H with different chemical composition. This is especially important for understanding the role of additives which introduce additional aluminum, magnesium, and sodium ions within the atomistic structure (Lothenbach et al. 2015; Puertas et al. 2011). Using a CFFF model developed for multiple

molecular C-S-H structures allows for mixtures of colloidal C-S-H chemistries to establish chemo-mechanical relationships. Colloid geometries can also be modified to be more representative of experiments by using elliptical particles in lieu of idealized spheres. For this objective, the radial pair potential for calculating normal forces between particles could be replaced with a Gay-Berne potential that considers the necessary shape and orientation parameters (Yu et al. 2016). Finally, future research can extend microstructure models to larger scales to consider mortar and concrete. Cement paste is the matrix phase in these materials; however, the larger-scale fine and coarse aggregates do not participate in hydration reactions, and an interface transition zone (ITZ) may exist with a reduced strength and stiffness that must be considered within FEM models (Buyukozturk et al. 1972; Hillemeier and Hilsdorf 1977; Scrivener et al. 2004). Future developments in numerical modeling will provide further insights on the mechanisms controlling macroscale behavior in cementitious materials to enable the design of more sustainable and durable cementitious building materials.

Modeling the Structural Development and Mechanics of Complex Soft Materials

Modeling the Structural Development and the Mechanics of Complex Soft Materials: Overview

69

Emanuela Del Gado and Roland J.-M. Pellenq

Contents

Abstract

The materials discussed in the chapters of this section are apparently very different from each other (ranging from soft gels to cement and clays), but they all share structural and dynamical complexity that cover a range of length scales. Distinct computational approaches are required for the different length scales or timescales, and a statistical analysis of spatiotemporal fluctuations is crucial

to develop a deeper fundamental understanding of the material properties. Here we provide an overview of the different chapters, to highlight the connections between them and outline the emerging scientific questions.

1   Introduction

Most of the materials of interest in our everyday life and in the technological world have structural and dynamical complexity that extends over a wide range of length scales and has enormous impact on the material behavior (response to environmental changes, evolution over time etc.), posing formidable challenges to rationalizing and predicting it. Modeling and computational approaches need to address such complexity, in order to provide meaningful answers and insight. Soft materials like gels are an example and have emerged as pivotal in technologies ranging from food to personal care, smart electronics, or biotechnologies, because they can be easily processed (they can be easily stretched, squeezed, or made to flow, Fig. 1) and they have tunable mechanical properties (▶ Chap. 70, "Mechanics of Soft Gels: Linear and Nonlinear Response"). Materials such as cements or clays are not usually regarded as soft since they are mainly used in their hardened state, but it is when they are soft, while solidifying or setting, that their final microstructure develops and their distinctive properties emerge (▶ Chaps. 71, "Mesoscale Structure and Mechanics of C-S-H"; ▶ 72, "Nanoscale Composition-Texture-Property-Relation in Calcium-Silicate-Hydrates"; ▶ 73, "From Microscopic Insight to Constitutive Models: Bridging Length Scales in Soft and Hard Materials"). In all cases, disentangling structure development, dynamics, and mechanics over different length scales is needed to achieve an adequate understanding of the material properties and hence to be able to predict them.

The chapters in this section revolve around this theme: how can modeling and computational approaches include enough details of the chemistry and of the microscopic structure to capture the essential and distinctive features of such complex materials? What is the appropriate level of details needed? In which conditions can more abstract and coarse-grained or mesoscale models provide useful

Fig. 1 Complex materials, soft and hard. This section covers modeling and computational approaches for materials soft as food and hard as concrete. Crucial for all those materials is to be able to capture the development of the microstructure when they solidify. As in glasses, the resulting microstructure lacks long-range order and features frozen-in stresses that have impact on the mechanics

insight and how? How can the insight and understanding gained through modeling and computational studies contribute to the technological and societal concerns that these materials carry?

2 Microstructural and Dynamical Complexity: From Food to Cement

Gels typically comprise a soft, porous and prevalently elastic matrix or solid network interspersed in a fluid (which can be a simple Newtonian liquid or a more complex viscoelastic medium). In many cases, the porous matrix is self-assembled from colloidal or larger units that can also be aggregates, fibers, or bundles hierarchically organized. The units that compose the large-scale structure of these materials are, therefore, already complex to start with (e.g., in most gels of interest for food the colloidal units are proteins), and the additional level of organization into larger-scale structures can add further layers of complexity. Modeling and computational approaches that start from an atomistic description of these materials are typically limited to a very narrow range of length scales that are far from covering the structural, dynamical, and mechanical properties emerging from the larger-scale structure and used in the engineering applications. Coarse-grained models and numerical approaches that do not provide an atomistic description but are able to capture the essential ingredients of the self-assembled, larger-scale structure (e.g., size distributions of pores, aggregates, etc.) are therefore extremely important to unravel the relationship between microstructural features and material behaviors (▶ Chaps. 70, "Mechanics of Soft Gels: Linear and Nonlinear Response"; ▶ 71, "Mesoscale Structure and Mechanics of C-S-H"; ▶ 73, "From Microscopic Insight to Constitutive Models: Bridging Length Scales in Soft and Hard Materials"). All materials of interest are structurally amorphous solids, and their microstructures correspond to non-equilibrium, metastable states that have frozen-in stresses that depend on the material history. As a consequence, the way the microstructure develops has a significant impact on the material properties and hence has to be properly incorporated in the modeling. The chapters in this section give several insightful examples of how the structural disorder, the complexity in terms of length scales covered, and the history dependent nature of the microstructure, can be taken into account.

Concrete and cement do not come to our mind when discussing *soft* gels. Nevertheless, they are relatively close to soft gels, while cement is setting and its nanoscale amorphous structure is further developing and densifying (▶ Chap. 71, "Mesoscale Structure and Mechanics of C-S-H"). In fact, as cement dissolves in water the dissolution of the calcium silicates contained in the powder produces, among other hydration products, calcium-silicate-hydrates (C–S–H), the material at the origin of cement cohesion and concrete strength. During cement hydration, nanoscale C–S–H clusters (or particles) aggregate into gels that constitute the basis of the hardened cement paste used for constructions. The C–S–H gels are extremely cohesive and constitute the main binding agent in concrete, therefore crucial

to the material mechanical performances. Although various other compounds are present in concrete, the C–S–H are already chemically complex, since they exist with a range of different stoichiometries and are amorphous (▶ Chap. 72, "Nanoscale Composition-Texture-Property-Relation in Calcium-Silicate-Hydrates"). Their microstructure and properties result from a complex and strongly non-equilibrium aggregation process. Two of the chapters in this section cover the most recent advances in modeling and computational approaches for cement hydrates. In particular they represent a good example of how concepts developed for other materials, such as high-performance glasses or colloidal gels, have helped scientists develop novel fundamental understanding and insights into cement and concrete.

A common feature in the materials discussed in the next chapters is certainly the presence of frozen-in stresses, which develop as the material solidifies (▶ Chap. 73, "From Microscopic Insight to Constitutive Models: Bridging Length Scales in Soft and Hard Materials"). The internal stresses that develop during cement hydration and setting can have manifestations as extreme as swelling and shrinkage of the incipient solid and even lead to cracking. They are known to have an impact on the durability of the final product. In softer gels, the presence of frozen-in, localized stresses can be more subtle, but it is clearly revealed by the progressive aging of their mechanical properties as well as by the strain localization that characterize their mechanical response even at small deformations, in the linear response regime. Understanding how frozen-in stresses develop during solidification of amorphous materials and how they interplay with an imposed deformation to determine the mechanical response is one of the outstanding challenges in material science and technologies. Think, for example, 3D printing technologies, where one needs to finely control the final properties of the printed layers as the material is being squeezed out of a nozzle (e.g., as in direct writing), flows, and re-solidifies (Chandrasekaran et al. 2018). Controlling and suitably designing the rheological response of the ink (from soft gels to cement) is essential. To do so, a deeper understanding of the basic mechanisms that regulate the emergence and the evolution over time of the frozen-in stresses is needed. The chapters in this section analyze the problem of stress localization in amorphous structures at different levels: for example, through the atomistic disorder in C–S–H nanoparticles and through the mesoscale texture of C–S–H gels in ▶ Chaps. 71, "Mesoscale Structure and Mechanics of C-S-H," and in ▶ 72, "Nanoscale Composition-Texture-Property-Relation in Calcium-Silicate-Hydrates," or through the spatiotemporal statistical analysis of density and stress fluctuations in aging soft gels in ▶ Chap. 70, Mechanics of Soft Gels: Linear and Nonlinear Response". Different levels of description of the material at play require different methodologies, and you will find in this section a discussion of relevant techniques and strategies that could be applied to a variety of different materials. The area of computational mechanics and rheology for this type of complex materials is still nascent, but it has a great potential to connect the microstructural description of the material (even if simplified or coarse-grained) to its rheological response in a way that is still mainly inaccessible through experiments. In particular, the possibility to describe *local* stresses and strains in
Fig. 2 Microstructural complexity in soft and hard materials. Casein gels are the basis of yogurt products: on the left a SEM image on the left a SEM image of acidified casein gel, prepared as in (Leocmach et al. 2014), courtesy of T. Divoux. Atomistic simulations highlight the structural complexity of high-performance glasses (center) (Bauchy et al. 2017). On the right, a TEM image of the nanoscale structure of cement hydrates. (Reprinted from Del Gado et al. 2014)

response to different types of deformation and deformation rates can radically deepen the current understanding of the mechanics of soft complex materials and in particular of their nonlinear behavior, as discussed in ▶ Chap. 70, "Mechanics of Soft Gels: Linear and Nonlinear Response". While these aspects are here mainly analyzed for soft gels, the next step ahead is to transfer the new concepts and insights gained across materials and technologies (Fig. 2).

Constructing methods and strategies to bring the microscopic information (e.g., chemical composition, atomistic description etc.) into coarse-grained models and, from there, into the continuum level description of the materials is an open, outstanding question. You will see it appear through in all the chapters of this section and discussed more thoroughly in ▶ Chap. 73, "From Microscopic Insight to Constitutive Models: Bridging Length Scales in Soft and Hard Materials," where we sketch a possible strategy. The modeling and computational difficulties to be faced are many and vary depending on the specific material and on the specific engineering context. An important point is that, when materials have the multiscale complexity described in the examples you will see in this section, one needs to develop different approaches at different length scales, and therefore the main question becomes how to connect those approaches.

3   Conclusions

To summarize, the chapters of this section provide examples of how modeling and computational studies can indeed address the structural, dynamical, and mechanical complexity of technologically relevant real materials. They highlight the common traits of non-equilibrium conditions, structural disorder, and frozen-in stresses in a wide range of materials from soft gels to hard cement and unravel fundamental physical mechanisms (microscopic strain and stress localization, stress relaxation, etc.) that ultimately are at the origin of behaviors such as aging, creep, failure, or yielding. The workshop on "Physics of Dense Suspensions" held at the Kavli

Institute of Theoretical Physics of UCSB in 2018 hosted a number of events and several discussions focused on the very same issues. The progress made when addressing such issues is beyond the understanding of a complex material or of a complicated behavior, because the fundamental insights gained can be immediately fed into engineering questions with practical relevance. In the case of cement, the fundamental understanding of the physical chemistry and mechanics is required for new, greener technologies to develop and emerge. Given the volume of construction industry, the role that cement and concrete play in it and the overall environmental impact of cement production for concrete, new strategies to make the material and its production smarter and more sustainable are urgently needed.

Mehdi Bouzid and Emanuela Del Gado

Contents

Abstract

Soft gels are materials at the core of material technological innovation, and as such, they are constantly evolving to meet different requirements in terms of performance, reliability, durability, and environmental impact. Despite many progresses made in the case of polymer gels, a consistent theoretical framework for the relationship between the microscopic structure and the mechanical properties of a wide range of materials ranging from colloidal gels to protein and biopolymer gels is still lacking. A multitude of different phenomena are

observed – aging, strain stiffening, creep, banding, and fracture – that are difficult to control and properly tune to design the material properties. Here we discuss how numerical simulations of suitably designed microscopic models can help develop novel insight into the microscopic mechanisms that underlie the complex dynamics of these versatile materials. We provide an overview of the computational approach we have recently developed and of the main outcomes obtained. Finally we discuss outstanding questions and future developments.

1   Introduction

Gels are amorphous materials composed of a liquid phase and an interconnected network like solid phase, which can be formed at very low solid volume fractions. They are widespread, both in nature and in industry – from the pharmaceutical industry (agar gel) to the construction sector (cement hydrate or aluminosilicate gels in cement) – or in everyday life: the bread gets its rubbery texture from the formation of an elastic network of gluten protein, and the formation of protein networks is vital for the successful production of cheese. All soft matter, in fact, from proteins (Lieleg et al. 2011) to colloids (Lu et al. 2008; Gao et al. 2015) and polymers (Chen et al. 2010), easily self-assembles into such weakly elastic solids (see some examples in Fig. 1). They generally present a heterogeneous structure which is the result of the coupling between the kinetics of aggregation, phase separation or demixing, and arrest of the microscopic dynamics (Trappe et al. 2001; Del Gado et al. 2004; Coniglio et al. 2006; Del Gado and Kob 2010; Varrato et al. 2012; Zia et al. 2014).

The solidification process typically induces mechanical heterogeneities and hence internal stresses in the material, which then affect its properties in the long term (Cipelletti and Ramos 2005; Maccarrone et al. 2010a; Guo et al. 2011; Angelini et al. 2014; Bandyopadhyay et al. 2004). Weaker regions, for example, may yield via the sudden and irreversible rupture of bonds between the particles, which can be triggered by thermal fluctuations, while other regions densify. These "micro-collapses" or other aging processes can affect the stability of the material and the reliability of its performance (the mechanical strength of a gelled product can decay, for example, or batteries composed of colloidal gels may fail due to a progressive conductivity loss favored by aging (Youssry et al. 2013; Duduta et al. 2011; Helal et al. 2016; van Doorn et al. 2018)). The mechanical properties of the gel, therefore, depend on both the solidification protocol and the age of the sample. These problems are, in most of the cases, treated empirically because of the lack of fundamental understanding.

Even without the aging, it would be difficult to disentangle the impact of the structure, the dynamics, and the mechanical response in soft gels, because of the topological complexity of the solid network and of the microscopic relaxation mechanisms involved. The microscopic dynamics of gel networks is strongly cooperative and nonlocal (Colombo et al. 2013) due to the coupling among processes occurring over different lengthscales, a fact that has traditionally made theory, experimental, and computational investigations extremely challenging. Capturing
Fig. 1 (**a**) Snapshot of a colloidal particle gel (PMMA). (Reprinted from Tsurusawa et al. 2018). (**b**) A biopolymer gel (Fibrin). (Reprinted from de Cagny et al. 2016), (**c**) bright-field TEM images of calcium-silicate-hydrates C–S–H. (Reprinted from Del Gado et al. 2014)

the mechanics of soft gels and their intrinsically nonequilibrium and nonlinear nature requires bridging the lengthscale of the contacts between the particles to the lengthscale of the particles themselves and to the lengthscales relevant to the mechanics of the networks, which can include much larger structures. In addition, the presence of the fluid that can flow between the deformable pores contributes to the mechanical complexity (de Cagny et al. 2016). Under an imposed load or deformation, a multitude of different phenomena are observed – aging, strain stiffening, creep, banding, and fracture – that are difficult to rationalize, control, and properly tune to design the material properties. A key question to ask, to address this complexity, is whether or not there can be common microscopic underpinnings for the relaxation/deformation mechanisms that lead to aging at rest and to the mechanical response for different types of gel. In the last years, novel technologies have allowed experimentalists to combine rheology with imaging (Cerbino and Trappe 2008; Arevalo et al. 2015), ultrasound velocimetry (Gallot et al. 2013), interferometry (Mao et al. 2017), or spectroscopy (Ruta et al. 2012; Eberle and

Porcar 2012; Maccarrone et al. 2010b; van der Kooij et al. 2018; Aime et al. 2018b). Combining such approaches with computational studies and numerical simulations creates new unique opportunities to fill the gap between the macroscopic rheological behavior of the materials and their micro- and even nanoscale structure/dynamics and provides novel significant insights to develop advanced theories and constitutive models (Nicolas et al. 2018; Fielding 2014; Bouzid et al. 2018a).

In this chapter, we give an overview of new insights that can be gained through judiciously designed computational studies and models and of how the progress made can help understand at a more fundamental level the dynamical and mechanical complexity of soft gels. Building on the results obtained, we discuss how to tackle outstanding questions and how to bridge the microscopic picture obtained toward mesoscale or continuum level theories. The chapter is organized as follows: in Sect. 2, we present the computational approach we have recently developed for investigating the dynamics and the mechanics in a soft gel model. In particular this approach has been helpful to unravel the different nature of dynamical fluctuations in soft gels, depending on the internal stresses and the elasticity of the material, as discussed in Sect. 3. The mechanical response and its connection with the microstructure are discussed in detail in Sect. 4. Finally, in Sect. 5, we draw conclusions of the progress made so far and review some of the outstanding questions.

2 Computational Approach and Numerical Model

In the need to deepen our understanding of the interplay between the complex microstructure, the emerging dynamics, and the mechanical response of soft gels, numerical simulations play an increasingly important role. A key reason is the unique capability of computational methods to integrate different levels of complexity in a controlled manner. In condensed matter physics, the theories aimed at explaining macroscopic experimental observations are very rarely ab initio (Marx and Hutter 2009). They are based on simplified hypotheses, integrating a conceptual representation, covering a certain scale in time or space. The numerical simulations make it possible either to verify the validity of a theory by simulating the materials within the specific framework of the hypotheses used or to test the validity of the hypothesis of the theory, and to better understand their emergence, by simulating the material on a more microscopic scale. Ab initio numerical approaches are mainly useful when the microscopic details are sufficiently simple, but in most of other cases, coarse-grained approaches are more versatile and powerful. Being able to vary, in a continuous and parametrized way, the different microscopic properties is a big advantage of the numerical methods, because it makes it possible to offer a field of systematic studies out of reach of the experimental systems and, thus, to help to reveal new explanatory concepts.

Particle-based and molecular dynamics inspired approaches have proven effective, in the last few years, to unravel the dynamics and nonlinear mechanics of gel networks, thanks to large-scale simulations that can help disentangle the dynamical

processes at the level of the network structure and their contribution to the material's linear and nonlinear response (Colombo and Del Gado 2014b; Bouzid and Del Gado 2018; Bouzid et al. 2018a; Landrum et al. 2016; Jamali et al. 2017; Boromand et al. 2017; Di Michele et al. 2014; Varga and Swan 2018; Padmanabhan and Zia 2018). In these types of approaches, gels are described in terms of their microscopic discrete building blocks, typically particles, grains, or small aggregates in colloidal gels or flocculated suspensions. With a suitable model for the effective interactions between the particles, the time evolution of the system is obtained by integrating the many-body equations of motion for the whole set of microscopic degrees of freedom (typically, center of mass positions and velocities of the particles). The simulations therefore necessarily contain the following ingredients: (i) a model that describes the interactions between the particles, usually in terms of an interaction potential $\mathscr{U}(\mathbf{r}_i, \ldots, \mathbf{r}_N)$, where $\mathbf{r}_i$ represents the particle coordinates, and (ii) a numerical integrator, i.e., an algorithm that solves efficiently and precisely the equations of motion with a set of boundary conditions that corresponds to the specific problem of interest. The equations of motion can have different amount of details of the microscopic motion of the particles that compose the gel (from Brownian fluctuations to hydrodynamic interactions). With such an approach, one can introduce interactions between particles in a simple and controlled way and ask about the emergence, at various scales, of the constitutive properties of gels.

For the effective interactions, a number of approaches have been used in the literature to model soft gels, including short-range isotropic interactions typical of colloidal suspensions, valence-limited and patchy particle models that mimic small molecule or functionalized nanoparticle gels, and dipolar interactions that can lead to chaining and branching (Koumakis and Petekidis 2011; De Candia et al. 2006; Zaccarelli et al. 2006; Coniglio et al. 2004; Del Gado et al. 2004; Rovigatti and Sciortino 2011; Blaak et al. 2007; Ilg and Del Gado 2011; Eberle et al. 2011; Bianchi et al. 2015; Zia et al. 2014; Varga et al. 2015; Fierro et al. 2008). While these models mainly focus on the two-body short-range interactions that create the mechanical contact between particles at first, the emerging softness of the gel materials is the result of the sparse nature of the network structure, whose connections, on the other hand, need to be fairly rigid to support at least the gel own weight and a finite torque (Del Gado and Kob 2010, 2007; Pantina and Furst 2005, 2006; Ohtsuka et al. 2008; Colombo and Del Gado 2014a; Hsiao et al. 2012). We have therefore focused on a model where a short-range attractive well is combined with a three-body term, which imparts an angular rigidity to the gel branches, as to be expected in such open structures.

2.1   A Microscopic Model with Directional Interactions

We have developed a minimal model, considering particles (or small aggregates represented as particles) of diameter d that interact through a potential composed of two terms:

$$\mathcal{U}(\mathbf{r}_i, \ldots, \mathbf{r}_N) = \varepsilon \left[\sum_{i>j} \mathcal{U}_2 \left(\frac{\mathbf{r}_{ij}}{d} \right) + \sum_i \sum_{j>k}^{j,k \neq i} \mathcal{U}_3 \left(\frac{\mathbf{r}_{ij}}{d}, \frac{\mathbf{r}_{ik}}{d} \right) \right] \tag{1}$$

where $\mathbf{r}_{ij} = \mathbf{r}_j - \mathbf{r}_i$, with $\mathbf{r}_i$ denoting the position vector of the i-th particle and ε the strength of the attraction that sets the energy scale. The first contribution to $\mathcal{U}$ is a two-body potential à la Lennard-Jones, $\mathcal{U}_2$, which consists of a repulsive core and a narrow attractive well that can be expressed in the following dimensionless (and computationally convenient) form :

$$\mathcal{U}_2(\mathbf{r}) = A \left(\frac{a}{r^{18}} - \frac{1}{r^{16}} \right) \tag{2}$$

where r is the distance rescaled by the particle diameter d, while a and A are dimensionless parameters that control, respectively, the width and the depth of the potential well. The second contribution to $\mathcal{U}$ is a three-body term $\mathcal{U}_3$ that confers an angular rigidity to the interparticle bonds, which prevents the formation of dense clusters (Fig. 2). The idea is that once particles start to aggregate, their mechanical contacts can be more complex than the simple geometric contact between two perfect spheres represented by the attractive well $\mathcal{U}_2$ and, in particular, that there may be an energy cost associated to rotation of particles around each other in an aggregate made by more than two of them, due to inhomogeneity of their surfaces. For two particles both bonded to a third one and whose relative positions with respect to it are represented by the vectors $\mathbf{r}$ and $\mathbf{r}'$ (also rescaled by the particle diameter), $\mathcal{U}_3$ takes the following form:

$$\mathcal{U}_3(\mathbf{r}, \mathbf{r}') = B \Lambda(\mathbf{r}) \Lambda(\mathbf{r}') \exp \left[- \left(\frac{\mathbf{r} \cdot \mathbf{r}'}{rr'} - \cos \theta \right)^2 u^{-2} \right] \tag{3}$$

where B, θ, and u are dimensionless parameters. The radial modulation $\Lambda(r)$ that controls the strength of the interaction reads:

$$\Lambda(r) = r^{-10} \left[1 - (r/2)^{10} \right]^2 \mathcal{H}(2 - r) \tag{4}$$

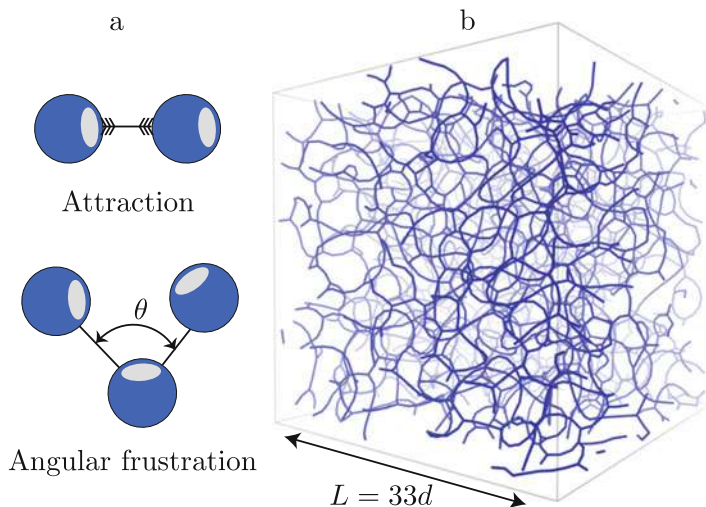
where r is the distance rescaled by the particle diameter d. $\mathcal{H}$ denotes the Heaviside function, which ensures that $\mathcal{U}_3$ vanishes beyond the diameter of two particles. The potential energy in our model depends parametrically on the five dimensionless quantities: A, a, B, θ, and u. Tuning these parameters leads to a variety of mechanically stable porous microstructures (Colombo and Del Gado 2014a), and the values chosen in the following ($A = 6.27$, $a = 0.85$, $B = 67.27$, $\theta = 65°$ and $u = 0.3$) are such that a disordered and thin percolating network starts to self-assemble for low particle volume fractions ($\phi \lesssim 0.1$) at $\varepsilon \simeq 20 k_B T$ (see the


Fig. 2 (**a**) Schematic representation of the interactions: two-body attractive part and the three-body repulsive one. (**b**) Snapshot of a gel network from the simulation with number density $\rho = 0.14$, which approximately corresponds to a solid volume fraction $\phi \simeq 7.3\%$ (the sample size here is $N = 5324$ particles). Each bond is represented by a segment, when the distance d_{ij} between two particles i and j is $d_{ij} \leq 1.3d$

snapshot in Fig. 2), with k_B the Boltzmann constant and T the room temperature. Typical values of d and ε for colloidal particles range, respectively, from $d \simeq 10$ to $100\,\text{nm}$ and from $\varepsilon \simeq 10$ to $100\,k_B T$.

With this model, we have performed molecular dynamics simulations, where the gel is composed of N particles each with a mass m in a cubic simulation box of size L. The simplicity of the model allows us to run large-scale simulations with up to $N \simeq 10^6$ particles, which is essential for a statistical analysis of the microscopic dynamics. The initial gel configuration is prepared with the protocol described in (Colombo and Del Gado 2014b), which consists in starting from a gaseous configuration at $k_B T/\varepsilon = 0.5$ and letting the gel self-assemble upon slow cooling down to $k_B T/\varepsilon = 0.05$ using Newton or Langevin equations of motion. In this temperature range, the self-assembled structures do not meaningfully depend on the specific microscopic dynamics used, and the Newtonian dynamics allows for shorter computational times. Nevertheless, once the gel has formed, the Langevin dynamics is obviously a much better choice for the dynamics overdamped by the solvent, which is typical of these materials (Colombo and Del Gado 2014a; Bouzid et al. 2017).

Once the gel is assembled, the kinetic energy is then completely drawn from the system (down to $10^{-24}\varepsilon$) by means of a dissipative microscopic dynamics:

$$m\frac{d^2\mathbf{r}_i}{dt^2} = -\nabla_{\mathbf{r_i}}\mathcal{U} - \eta_f \frac{d\mathbf{r}_i}{dt}, \tag{5}$$

where η_f is the damping coefficient associated with coupling of the particle motion to the surrounding fluid. We note that here and in the following, we always solve equations of motion that contain explicitly an inertial term with the mass m for computational convenience: integrating the equations with the inertial term allows us to use effective and precise numerical integrators (Frenkel and Smit 2002). On the other hand, the limit $m \rightarrow 0$ is the one relevant to colloidal gels in experiments, since in those systems the particle motion is completely overdamped and inertial effects are negligible. The timescales over which the particle motion is affected by inertia in our simulations are of the order of $1\tau_0 - 10\tau_0$ (for the values of m and η_f chosen). For a spherical colloidal (silica) particle of diameter $d \simeq 100$ nm and interaction strengths $\varepsilon \simeq 10k_BT$, the inertial timescale $\tau_0 = \sqrt{md^2/\varepsilon} \simeq 10^{-6}$ s corresponds to timescales (and lengthscales, in terms of particle displacements) that are not relevant to experiments (Bouzid et al. 2018a). In the following, we make sure to be in the overdamped regime of the dynamics by choosing large enough values of η_f (Colombo and Del Gado 2014a; Puosi et al. 2014).

We also note that what is still missing in the equations of motion we discuss (here and in the following) is a proper treatment of the hydrodynamic interactions that in principle can have a strong impact on the microscopic dynamics of soft gels. While a well-established rigorous framework is still under construction, recent works indicate that the role of (long range) hydrodynamics on the emerging microscopic dynamics of the gel network at rest and in the linear response regime may be relatively negligible (Varga et al. 2015; Varga and Swan 2018; Royall et al. 2015). The main difference detected so far is a slight shift of the gelation threshold (Varga et al. 2015), which could be also due to the limited size of the numerical samples, and a tendency to favor the formation of more open and anisotropic aggregates in the early stages of the aggregation, which may significantly modify the gel formation but seems to have little consequences for the long-time relaxation dynamics in the solidified gel (Varga et al. 2015; Royall et al. 2015). The explanation for such little effect could be in the fact that once the gel is formed, the main contribution to the stresses is through the gel structure, its elasticity, and the extended soft modes present. The latter are determined by the disordered network topology and involve lengthscales of the order of the sample size. Such contributions seem to dominate the gel response with respect to the hydrodynamics coupling, which would dominate only after a significant modification/rupture/destabilization of the gel structure has taken place. Further developments for the treatment of hydrodynamic interactions in such complex materials will help elucidate this point.

In all the simulations we discuss here, the timestep δt used for the numerical integration is $\delta t = 0.005$. Distances are expressed in terms of the particle diameter d, masses in units of m, the energy in terms of the strength of the attraction ε, and the time in the units of the characteristic timescale $\tau_0 = \sqrt{md^2/\varepsilon}$. From the particle number density N/L^3, we can compute an approximate solid volume fraction $\phi \simeq N\pi d^3/6L^3$. All simulations discussed here have been performed using a version of LAMMPS suitably modified by us (Plimpton 1995).

2.2   Computing Stresses and Mechanical Response

2.2.1   Stress Calculation

The average state of stress of the gel is given by the virial stresses as $\sigma_{\alpha\beta} = -\frac{1}{L^3} \sum_i s_{\alpha\beta}^i$, where the Greek subscripts stand for the Cartesian components x, y, z, L represents the size of the system, and $s_{\alpha\beta}^i$ represents the contribution to the stress tensor of all the interactions involving the particle i (Irving and Kirkwood 1950; Thompson et al. 2009). The latter contribution is calculated for each particle, by splitting the contributions of the two-body and the three-body forces according to the following equation:

$$s_{\alpha\beta}^i = -\frac{1}{2} \sum_{n=1}^{N_2} (r_\alpha^i F_\beta^i + r_\alpha' F_\beta') + \frac{1}{3} \sum_{n=1}^{N_3} (r_\alpha^i F_\beta^i + r_\alpha' F_\beta' + r_\alpha'' F_\beta'') \qquad (6)$$

The first term denotes the contribution of the two-body interaction, where the sum runs over all the N_2 pairs of interactions that involve the particle i. The couples (r^i, F^i) and (r', F') denote, respectively, the position and the forces on the two interacting particles. In the same way, the second term indicates the three-body interactions involving the particle i and two neighbors denoted by the prime and double prime quantities.

To evaluate the stress tensor at a mesoscale, we consider a coarse-graining volume v_{cg} centered around the point of interest $\mathbf{r}$ and containing around 10 particles on average and define the local coarse-grained stress based on the per-particle virial contribution as $\bar{\sigma}_{\alpha\beta}(\mathbf{r}) = - \sum_{i \in v_{cg}} s_{\alpha\beta}^i / v_{cg}$. For a typical starting configuration of the gel, the local normal stress $\bar{\sigma}_n = (\bar{\sigma}_{xx} + \bar{\sigma}_{yy} + \bar{\sigma}_{zz})/3$ reflects the heterogeneity of the structure and tends to be higher around the nodes, due to the topological frustration of the network. Note that here and in the following, we have been neglecting the kinetic contribution $-(1/L^3) \sum_i m_i \delta v_\alpha^i \delta v_\beta^i$ to the global stress tensor (from the fluctuations of the particle velocities with respect to the average), since we are mainly concerned with $\varepsilon \gg k_B T$.

2.2.2   Aging Protocol

We consider that breaking of network connections underlying the aging of the gel is more prone to happen in the regions where local stresses tend to be higher, as found also in Colombo et al. (2013) and Colombo and Del Gado (2014b). Hence aging at rest can be due to sudden ruptures of particle connections in the regions where the local tensile stresses are higher, as also suggested by experiments on ultraslow aging (Ramos and Cipelletti 2001). Such events become hardly observable on a reasonable simulation time window making it extremely challenging to study the aging regime (Colombo et al. 2013; Bouzid et al. 2017). In order to investigate the consequences of the ruptures on a timescale computationally affordable, we have devised the following dynamics: we periodically scan the local stresses in the gel structure and remove particle bonds where the local stress is the highest, with a fixed

rate Γ. In between breaking events, the gel evolution follows from the Langevin equations of motion:

$$m \frac{d^2\mathbf{r}_i}{dt^2} = -\nabla_{\mathbf{r_i}} \mathscr{U} - \eta_f \frac{d\mathbf{r}_i}{dt} + \xi_i(t), \tag{7}$$

where i refers to the particle and $\mathscr{U}$ is the interaction potential in Eq. (1). $\xi_i(t)$ is a random white noise that models the thermal fluctuations and is related to the drag coefficient η_f through its variance $\langle \xi_i(t)\xi_j(t') \rangle = 2\eta_f k_B T \delta_{ij}\delta(t-t')$. To be in the overdamped limit of the dynamics, η_f is set to 10 m/τ_0.

Recombinations of the gel branches are possible but just not observed at the volume fractions and for the time window explored here. The bonds progressively removed (by turning off the well in $\mathscr{U}_2$) are those whose contribution to the local normal stress $s_n^i = (s_{xx}^i + s_{yy}^i + s_{zz}^i)/3$ is the largest (prevalently bonds between particles belonging to the network nodes) (Bouzid et al. 2017) (see Fig. 3a). As the simulation proceeds, local internal stresses redistribute in the aging structure of the gel, and the locations of more probable connection rupture (as well as their number) change over time. All simulations presented here for the aging have been performed with a rate $\Gamma = 0.04\tau_0^{-1}$, corresponding to removing only $\sim$5% of the total network connections over the whole simulation time window.
Fig. 3 (**a**) Illustration representing an irreversible elementary process in the aging simulations: breaking of a bond highlighted in green. A snapshot of the gel network is visualized using the bonds between particles, and the colors refer to the displacement field u after the bond breaking, for a network with thermal fluctuations (**b**) and for an athermal gel (**c**). We have identified the range of parameters for which changing the rate (having kept all other parameters constant) does not modify the outcomes and the emerging physical picture discussed in the following. In addition to the data shown here, we have also varied the density of events, keeping fixed the criterion used for cutting (i.e., we cut the network connections corresponding to the largest tensile contributions to virial stresses). In fact, the rate of cutting events chosen for the data shown here has been chosen in a range such that the typical interval between two cutting events Γ is quite smaller than the relaxation times associated to the stress redistribution following the bond cutting. Hence many breaking events contribute to the structural relaxation that we discuss. Since for the aging we are interested to the case in which all dynamics are extremely slow (i.e., to very low temperatures in the simulations), the range of values for Γ that satisfy this condition is relatively wide. Increasing the rate corresponds to breaking a larger fraction of the total bonds initially present and hence also to increasing the density of events underlying the network rearrangements and the stress relaxation. Overall, the same results are recovered as long as the $\tau_r = 1/\Gamma$ between two rupture events allows for at least partial stress relaxation, varying Γ over nearly two orders of magnitudes. If the cutting rate is much higher, the rate may eventually disrupt the elastic strain field in the material leading to damage accumulation and spreading (Bouzid et al. 2017).

2.2.3   Start-Up Shear

To determine the gel mechanical response to a start-up shear test, each particle configuration can be submitted to a series of incremental strain steps in simple shear geometry (Colombo and Del Gado 2014b). In each step, we increase the cumulative shear strain by an amount $\delta\gamma$ by first applying an instantaneous affine deformation $\Gamma_{\delta\gamma}$, corresponding to simple shear in the xy plane, to all particles:

$$\mathbf{r}'_i = \Gamma_{\delta\gamma}\mathbf{r}_i = \begin{pmatrix} 1 & \delta\gamma & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \mathbf{r}_i \qquad (8)$$

The Lees-Edwards boundary conditions (Lees and Edwards 1972) are updated as well, to comply with the increase in the cumulative strain. The configuration $\{\mathbf{r}'_i\}$ is no longer a minimum of the potential energy (being the material amorphous) (Alexander 1998), and the small deformation step induces unbalanced internal forces. Hence we relax the affinely deformed configuration by letting the system free to evolve in time while keeping the global strain constant:

$$\mathbf{r}''_i = \mathscr{T}_{\delta t}\mathbf{r}'_i \,. \qquad (9)$$

where $\mathscr{T}_{\delta t}$ is the time evolution operator for a specified time interval δt and given by the damped dynamics:

$$m\frac{d^2\mathbf{r}_i}{dt^2} = -\eta_f\frac{d\mathbf{r}_i}{dt} - \nabla_{\mathbf{r}_i}U\,, \tag{10}$$

where m is the particle mass and η_f the coefficient of friction. After n steps, the cumulative strain is $\gamma_n = n\,\delta\gamma$, and the gel configuration is

$$\mathbf{r}_{i,n} = (\mathscr{T}_{\delta t}\Gamma_{\delta\gamma})^n\,\mathbf{r}_{i,0}\,, \tag{11}$$

where $\{\mathbf{r}_{i,0}\}$ denotes the configuration of the starting inherent structure.

   This procedure is similar to the *athermal quasistatic* (AQS) approach extensively used to investigate the deformation behavior of amorphous solids (Tanguy et al. 2002; Maloney and Lemaître 2006; Fiocco et al. 2013), with the main difference that, instead of using an energy minimization algorithm after each affine deformation step, we follow the natural dynamics of the system (with a viscous energy dissipation) for a prescribed time interval δt. We can therefore define a finite shear rate $\dot{\gamma} = \delta\gamma/\delta t$ for the deformation we apply. Disregarding effects due to the particle inertia, the microscopic dynamics (10) introduce a natural timescale $\tau = \eta_f d^2/\varepsilon$, corresponding to the time it takes a particle subjected to a typical force ε/d to move a distance equal to its size. Indicatively, if we consider a typical aqueous solution of colloidal particles with a diameter $d \approx 100\,$nm and an interaction energy $\varepsilon \approx 10 k_B T$ (Koumakis and Petekidis 2011), the characteristic time is $\tau \approx 10^{-4}\,$s; in such a system, imposing a shear rate of $0.1\,\mathrm{s}^{-1}$ would correspond to a numerical shear rate of $\dot{\gamma}_s = 10^{-5}\tau^{-1}$.

2.2.4 Small Amplitude Oscillatory Rheology

To determine the gel viscoelastic properties, the particles are submitted to a continuous shear strain $\gamma(t)$ in the xy plane according to the following equation:

$$m\frac{d^2\mathbf{r}_i}{dt^2} = -\nabla_{\mathbf{r}_i}\mathscr{U} - \eta_f\left(\frac{d\mathbf{r}_i}{dt} - \dot{\gamma}(t)y_i\mathbf{e_x}\right) \tag{12}$$

In order to measure the frequency and the strain dependence of the first-harmonic storage G' and loss modulus G'', we impose an oscillatory shear strain on the system, i.e., the shear strain is modulated periodically according as $\gamma(t) = \gamma_0\sin(\omega_i t)$, and we use Lees-Edwards boundary conditions while applying the deformation.

   By monitoring the shear stress response of the material $\sigma(t)$ over time, we can extract the viscoelastic moduli. The storage and loss moduli can be computed from the stress response with the following expressions:

$$\begin{aligned} G'(\omega_i) &= \mathscr{R}e\left\{\frac{\tilde{\sigma}(\omega_i)}{\tilde{\gamma}(\omega_i)}\right\} \\[2mm] G''(\omega_i) &= \mathscr{I}m\left\{\frac{\tilde{\sigma}(\omega_i)}{\tilde{\gamma}(\omega_i)}\right\} \end{aligned} \tag{13}$$

where $\tilde{\sigma}$ and $\tilde{\gamma}$ are the Fourier transforms of the stress and strain signals, respectively (Macosko 1994). The whole viscoelastic spectrum is then reconstructed by performing a discrete series of tests at various frequencies, also known as "frequency sweep."

We note that the drag term used in Eq. (12) is chosen for computational convenience, but a more accurate (Galilean invariant) option would be to have the drag term depend on the relative velocities of particles within a certain range from a given one (Salerno et al. 2012; Vasisht et al. 2019), which requires longer computations. Nevertheless, the correction due to this inaccuracy seems to be negligible in all cases discussed here, since the stresses, and the related dynamics, are dominated by the interparticle interactions and the structure topology, and the correction due to the different drag term does not significantly modify the behaviors analyzed in the following.

3   Elastically Driven Dynamics upon Aging

After the gelation, the microscopic dynamics of gels slows down considerably. The nanometric size of their building blocks makes gels sensitive to thermal fluctuations, resulting in a rich and complex relaxation processes that are associated with spontaneous and thermally activated processes. The study of how these different dynamical processes emerge at rest and how the mechanical response depends on the microstructure is relevant to several applications, since the progressive aging that such materials undergo over time has a dramatic impact on their functionalities. In aging soft solids such as gels, the microscopic dynamics is expected to be akin to slower than exponential (or stretched exponential) dynamics in super-cooled liquids or glasses, due to its strongly cooperative nature fundamentally controlled by the structural disorder, as shown in several experimental and simulation studies (Segre et al. 2001; Manley et al. 2005; Bandyopadhyay et al. 2004; Jabbari-Farouji et al. 2007; Krall and Weitz 1998; Del Gado et al. 2004; Del Gado and Kob 2007; Fierro et al. 2008; Abete et al. 2008; Angelini et al. 2014; Chaudhuri et al. 2015). Nevertheless, over the last few years, time- and space-resolved measurements have often found evidence of dynamics faster than exponential (so-called compressed exponential dynamics), intermittency, and abrupt microstructural changes, raising the question of whether the aging dynamics in gels may be controlled, instead, by stress relaxation through elastic rebound of parts of the material, after local breakages occur in its structure (Cipelletti et al. 2000; Ramos and Cipelletti 2001; Bellour et al. 2003; Angelini et al. 2013; Mansel and Williams 2015; Ruta et al. 2014; Harden et al. 2012; Chung et al. 2006; Bouchaud 2008; Ferrero et al. 2014; Gao et al. 2015; Godec et al. 2014; Chaudhuri and Berthier 2017).

The difficulty to study the aging and characterize the slow relaxation processes in gels (both in experiments and in simulations) comes from the required timescales which are extremely long. The procedure briefly described in Sect. 2.2.2 allowed us to overcome some of the difficulties: we could scan the gel network and artificially remove the connections where tensile stresses are higher, to mimic the aging process

(Fig.3a) (Bouzid et al. 2017). Using that procedure, we could characterize the stress redistribution in the network during the aging and systematically vary the amount of thermal fluctuations to elucidate how the coupling between elasticity and thermal fluctuations may qualitatively change the microscopic dynamics. Figure 3b, c show the differences in the displacement field caused by breaking connections in the same gel network in the presence of different amounts of thermal fluctuations, whereas Fig. 4a–c display the initial stress heterogeneities, the stress redistribution, and the stress fluctuations during the aging. The microscopic picture that emerged from our study points to a major role played by the architecture of the network, its elasticity, and the stress heterogeneities built in upon solidification (Fig. 4a). The timescales governing stress relaxation, respectively, through thermal fluctuations and elastic recovery are key: when thermal fluctuations are weak with respect to enthalpic stress heterogeneities, the stress can still partially relax, after the breaking of network connections, through elastically driven fluctuations. Such fluctuations are intermittent, because of strong spatiotemporal correlations that persist well beyond the timescale of the simulations (Fig. 4b, 4c) or of the experiments. Hence in these conditions ($\varepsilon/k_B T \simeq 0$) the elasticity built into the solid structure controls the microscopic displacements, and the time correlations of density fluctuations decay faster than exponential, as reported in experiments and hypothesized by theories (Cipelletti and Ramos 2005; Bouchaud 2008). Brownian motion driven by thermal fluctuations, in fact, disrupts the spatial distribution of local stresses and their persistence in time, therefore favoring a gradual loss of correlations and a slow evolution of the material properties. The insight gained in this study helped us rationalize apparently contrasting findings and clarify that in elastic soft materials the presence of large stress heterogeneities can favor faster than exponential and intermittent microscopic dynamics. In addition to affecting the time evolution and the material properties rest, these dynamic processes interact with an imposed mechanical deformation and can therefore be decisive for the mechanical response of this class of soft solids.

4   Mechanical Response

A macroscopic constitutive law for soft gels, i.e., the theory capturing how stresses are related to deformations, velocities, and possibly density in these materials, is still fundamentally lacking. As an example, we give the constitutive law of a Hookean homogeneous elastic solid. In this case, the stress tensor takes the form:

$$\sigma_{\alpha\beta} = K\varepsilon_{\ell\ell}\delta_{\alpha\beta} + 2G\varepsilon_{\alpha\beta} \tag{14}$$

K represents the bulk modulus and G the shear modulus. ε_{ij} is the strain tensor of the material with respect to its reference state (Landau and Lifshitz 1986), while α and β indicate the Cartesian components. Following the same reasoning, when describing the flow of the materials in response to a rate of deformation
Fig. 4 (**a**) A snapshot of the initial colloidal gel network for $k_B T/\varepsilon = 0$ and at low volume fraction $\phi = 7\%$, showing the interparticle bonds represented by a segment. The colors indicate the local normal stress $\tilde{\sigma}_n$, using red for tension and blue for compression. (**b**) The corresponding P.d.f of the time series of the normal stress fluctuations $\delta\sigma = \sigma_{xx} - \langle\sigma_{xx}\rangle$: in the regime dominated by frozen-in stresses (red), the stress fluctuations are elastically driven and intermittent in nature. (**c**) Main frame: The stress fluctuation autocorrelation function measured over the whole simulation for the fully thermal regime $k_B T/\varepsilon = 10^{-3}$ (blue), the intermediate $k_B T/\varepsilon = 10^{-4}$ (green), and the for $k_B T/\varepsilon = 0$ (red). Inset: Time series of the normal stress fluctuations $\delta\sigma$ over all the simulation for the athermal sample showing the aging of the structure. (e.g., due to imposed shear Fig. 7), the constitutive relation can be constructed from the strain rate tensor:

$$\dot{\gamma}_{\alpha\beta} = \frac{1}{2}\left(\frac{\partial u_\alpha}{\partial x_\beta} + \frac{\partial u_\beta}{\partial x_\alpha}\right) \tag{15}$$
Fig. 5 Log-log scale: schematic representation of the different macroscopic responses of gels to an imposed shear deformation rate (**a**) or shear stress (**b**)

Where u_α and x_α are, respectively, the components of the velocity vector and the position along the α axis. A fluid is characterized by its viscosity η, defined as the ratio between the stress and the strain rate, and the simplest example is a Newtonian fluid, for which the stress tensor takes the form:

$$\sigma_{\alpha\beta} = (g\dot{\gamma}_{\ell\ell} - P)\delta_{\alpha\beta} + 2\eta\dot{\gamma}_{\alpha\beta} \tag{16}$$

where $\delta_{\alpha\beta}$ is the Kronecker symbol, P is the normal stress, and g is zero for an incompressible fluid. For Newtonian fluids, the viscosity is independent of the shear rate as well as the time. The only stresses created by the flow are the shear stresses that cancel out immediately when the flow stops. Any deviation from these properties is a sign of non-Newtonian behavior.

Once a gel has solidified from an initial fluid solution, its mechanical response is typically visco-elasto-plastic (Alexander 1998; Nicolas et al. 2018), with the prevalence of one behavior or the other depending on the nature of the deformation and on the observation time (Fig. 5).

4.1   Linear Response of Soft Gels

For small deformations, the response of gels is viscoelastic (regime I in Fig. 5), often exhibiting a power law frequency dependence of the elastic (G') and the viscous (G'') moduli over a wide range of frequencies (Fig. 6), reflecting a wide distribution of time and lengthscales over which the internal structures of the gel can also relax some of the residual stresses frozen-in upon solidification. These viscoelastic characteristics have been observed experimentally in a wide range of gel materials for which the porous nature of the structure can promote contraction or dilation during shear, suggesting a nontrivial coupling between the transmission of normal
Fig. 6 (**a**) Elastic modulus G' (red) and viscous modulus G'' (blue) vs. frequency f for a carbopol gel. (Reprinted from Lidon et al. 2017). (**b**) Elastic modulus G' (squares) and viscous modulus G'' (circles) from the numerical simulations in Bouzid et al. (2018b)

and tangential forces (Ng and McKinley 2008; Caggioni et al. 2007; Jaishankar and McKinley 2014). For biopolymers networks such as collagen, G' decreases (the system becomes softer) if the system has been previously subjected to compression and increases if it is subjected to tension (Van Oosten et al. 2016). On the other hand, it has been shown that agar gels contract upon solidification (Mao et al. 2016) and that such tendency to contract is usually associated to a tendency of the material to stiffen under larger strains (Tabatabai et al. 2015; Broedersz and MacKintosh 2014; Feng et al. 2015). The changes in volume during gelation are typically coupled to

heterogeneities of internal stresses, whose consequences on the mechanical response of the material could then be controlled by adjusting the processing or preparation conditions (e.g., through the rate of confinement or gelation).

Using the model introduced in Sect. 2, recent numerical investigations have been able to reproduce these linear mechanical features (Fig. 6) and also provide a constitutive parametric model able to capture the linear response (Bouzid et al. 2018a). Classical constitutive models based on combinations of Hookean springs and dashpots, such as the Maxwell or Kelvin-Voigt model, are not able to capture the frequency dependence of the moduli (Macosko 1994). To describe these power laws, one can add different mechanical elements (Maxwell or Kelvin-Voigt) in series or in parallel, which will result in creating additional modes of relaxation of the system. This method is questionable because of the large number of elements necessary to model all the relaxation modes. A different approach is based on proposing a *fractional* model, which uses instead a spring-pot element, originally introduced by Scott Blair (Blair and Veinoglou 1944; Blair 1944) and recently applied with success to a broad variety of soft viscoelastic materials (Jaishankar and McKinley 2012; Bouzid et al. 2018a; Aime et al. 2018a).

4.2   Nonlinear Response

Upon increasing the imposed deformation, the rheological response of soft gels has strongly nonlinear characteristics, corresponding to regimes II and III in Fig. 5: soft gels can flow as yield stress fluids or fracture as solids (see examples in the cartoons of Fig. 7). The strongly nonlinear transient regimes preceding yielding or fracture are poorly understood and constitute an active area of research. In addition, the yielding or fracturing can be reversible, with the material regaining its elasticity once brought to rest, or irreversible.

Numerical simulations are a powerful tool to overcome experimental limitations and challenges, complementing them effectively. For example, imaging the structure and, at the same time, applying a deformation is not always possible, whereas simulations can be obviously more effective in connecting the structure to the
Fig. 7 Illustrations of different non-linear behaviors: (**a**) Shear band with two distinct shear rates $\dot{\gamma}_1 \neq \dot{\gamma}_2$. (**b**) Fracture in the bulk. (**c**) Loss of adhesion between the gel and the wall: sliding on the walls

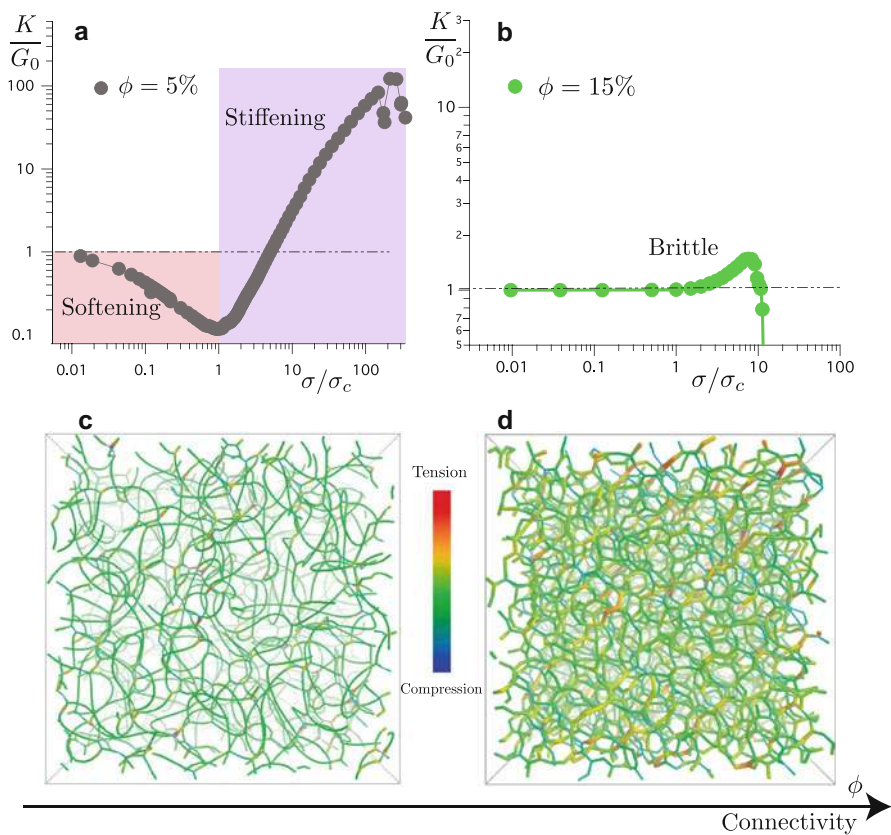
mechanical response and in addressing specific microscopic mechanisms. Using the approach described in Sect. 2, for example, we have recently provided novel insight into how regimes (I–III) in Fig. 5 are sensitive to the complexity of the architecture of the network and dependent on the rate of deformation. The simulations (Fig. 8) have shown that for tightly connected networks, with smaller and more homogeneously distributed pores, the stresses can be redistributed more uniformly under the action of a mechanical load, promoting almost simultaneously rupture of many connections and favoring crack growth. Conversely, a softer and more sparsely connected network, in the same type of gel, favors the localization of the stresses and their redistribution through the abundant low frequency modes, possibly delaying microstructural damage and cracks growth to much larger deformations


Fig. 8 The differential modulus K normalized by the elastic modulus G_0 as a function of the normalized shear stress σ/σ_c, for $\phi = 5\%$ (**a**) and $\phi = 15\%$ (**b**). Snapshots of the gel network extracted from the simulations at a volume fraction $\phi \simeq 15\%$ (**c**) and $\phi \simeq 5\%$ (**d**). Each bond is represented by a segment, when the distance d_{ij} between two particles i and j is $d_{ij} \leq 1.3d$. The color code shows the value of local tensile or compressive stresses, while the thickness is proportional to the stress amplitude. (See also Bouzid and Del Gado 2018)

(Bouzid and Del Gado 2018). Such distinct behaviors could be associated, in regime (II), to distinct dependencies of the nonlinear modulus K (obtained by deriving the shear stress σ with respect to the imposed deformation γ in the start-up shear tests described in Sect. 2) on the shear stress generated in the model materials under load (see Fig. 8). In sparse networks, extended soft modes can favor softening followed by a localization of the stresses and a progressive stiffening of the material (Figs. 8a, c). In our softer gels, the stiffening is characterized by a power law of the form $K \sim \sigma^{3/2}$, very similar the behavior of semiflexible polymer networks (Broedersz and MacKintosh 2014; Feng et al. 2016). For more homogeneously connected networks, where the gel branches are less flexible, the nonlinear response features also a progressive hardening (which is strongly rate dependent) and $K \sim \sigma$, indicating an exponential increase of the stress σ with increasing the imposed deformation γ, similar to the one observed in collagen fiber networks (Licup et al. 2015; Arevalo et al. 2015). Finally, denser networks composed of small homogeneous pores have a stronger tendency to be brittle (Fig.8b, d). It has also been shown that the ductility of the mechanical response and the reversibility of the damage accumulated under deformation can be modified by changing the flexibility of the gel branches (for a fixed network topology) and by pre-stressing the gel structures (Feng et al. 2018). Interestingly enough, in all these cases, the amount of microscopic structural anisotropy that can be induced in the gel network through deformation (and that can be quantified, for example, via a fabric tensor or a nematic order parameter suitably defined) seems a promising microscopic indicator of the nonlinear macroscopic response of different gels preceding yielding or fracture (Bouzid and Del Gado 2018; Jamali et al. 2017; Feng et al. 2015).

In the last plastic regime (III) of Fig. 5, the mechanical response depends more dramatically on the nature of the system, the specific mode of deformation (e.g., imposed stress vs deformation rate), but also on the nature of the interactions between the material and the boundaries (walls), as previously sketched in Fig. 7. Experiments show that the rupture can take place in bulk (casein-type, (bio)-polymer gels) or at the wall with a loss of adhesion and slip (agar gels, carbopol microgels, microgels of p-NIPAm, collagen, etc.) (Meeker et al. 2004; Divoux et al. 2015; Bonn et al. 2017). In spite of such complex diversity, experimental data also provide several indications that the coupling and the dynamics of localized (and correlated) plastic events may be the underlying common denominator in the transition from regime II to III. Indeed, in a variety of colloidal gels, it has been shown that in the transient regime (II) before flowing or fracturing (III), the dynamics is very intermittent in time and heterogeneous in space, featuring avalanche patterns (Kurokawa et al. 2015): in start-up shear experiments, for example, the yielding may proceed via successive drops during which the flow is spatially and temporally heterogeneous (Fig. 9a–c).

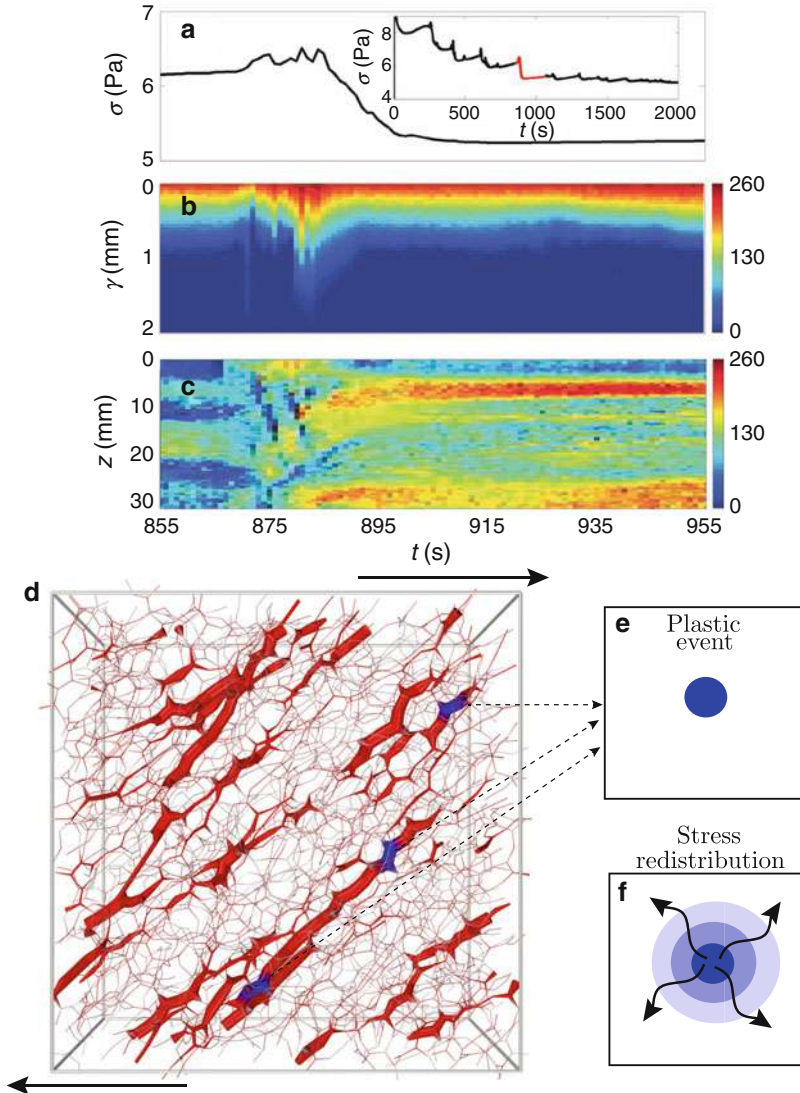
Recent experiments were able to detect a local acceleration of the microscopic dynamics before fracture and an enhancement of the plastic activity (Aime et al. 2018b). Start-up shear numerical simulations, using the approach described above, have indeed shown that the pre-yielding or pre-failure regime is dramatically rate


Fig. 9 Shear start-up experiment (imposed deformation) on a colloidal gel performed in a polished Taylor-Couette cell (Kurokawa et al. 2015). (**a**) The shear stress as a function of time for one stress drop (the red part of the full-time evolution shown in the inset), preceding the material fluidization. (**b**) and (**c**) are spatiotemporal intensity maps of the velocity field in the radial (**b**) and vertical (**c**) direction. (**d**) Snapshot from a numerical simulation of the model colloidal gel network discussed in Sect. 2 under shear. The thicker strands are the ones where the local tensions are larger than 60% of the maximum tensile stress. The blue indicates where breaking will happen. (Reprinted from Colombo and Del Gado 2014b). (**e**) Schematic view of the stress localization before a localized plastic event occurs inducing a nontrivial stress redistribution (**f**) across the network
Fig. 10 Creep experiment (imposed stress σ) on a casein gels. The temporal evolution of the strain γ, for different values of shear stress σ (**a**). Three regimes are observed: an elastic regime at short time, followed by a visco-plastic regime, and finally an acceleration before rupture. (**b**) The time associated with the rupture τ_f as a function of the applied stress in a logarithmic scale, with each point corresponds to an independent creep experiment, carried out at a constant stress. The gel breaks faster when the applied stress is higher. (**c**) Snapshot of the gel before failure at $t = 0.99\tau_f$, showing regularly spaced cracks. (Reprinted from Leocmach et al. 2014)

dependent because of the coupling between the deformation rate and the dynamics of stress redistribution following localized plastic events (typically irreversible rupture of the gel connections) in a given gel network (Fig. 9d–f). Because of such coupling, the evolution at moderate or higher rate can lead to a more gradual yielding, where the dynamic correlation between the plastic events is mainly dominated by the imposed rate. Upon deforming the material at slower rate, instead, the stress redistribution dynamics in the network can itself trigger localized plastic events which are even more spatially and dynamically correlated and can enhance density fluctuations or mechanical heterogeneities in the material, eventually promoting fracture or flow instabilities (Colombo and Del Gado 2014b; Zhang et al. 2017) (Figs. 9 and 10).

In protein gels like casein, a plastic regime characterized by the clear emergence of cracks follows the initial linear viscoelastic response (Fig. 9). The resulting deformation grows as a power law over time, similar to Andrade's creep law for hard solids (Andrade 1910), and the dynamics eventually accelerates toward a catastrophic rupture (Leocmach et al. 2014, Fig. 10). The fracture time also decreases as a power law with applied stress, reminiscent of the Basquin's law of fatigue typical of hard solid as well (Basquin 1910). If the case of crystalline solids seems well understood in terms of the interaction of defects (dislocations) within the material (Csikor et al. 2007), the microscopic origin in the case of amorphous materials, and in particular for soft gels, is far from being clear, but it can be connected to the existence of localized plastic events, which act as microscopic precursors of the macroscopic failure (Aime et al. 2018b; van der Kooij et al. 2018).

5 Conclusions

Computational studies of judiciously designed models can uniquely complement new experimental approaches to provide insight into the microscopic underpinnings of the mechanical response of soft gels. Here we have given an overview and examples of recent progress in this area. The key idea is to use relatively simple but microscopic models that can include structural disorder and have complex spatiotemporal fluctuations and correlations naturally emerge from the microscopic interactions. The use of computational methods allows for solving the many-body equations of motion of interest and obtains the full spatiotemporally resolved dynamics that underlies the mechanical response of these complex materials. This comes at the cost of a few simplifications (from the very limited account of the chemical details of the specific materials to the very crude description of the solvent in which the gel matrix is embedded). We have shown that, in spite of them, one can obtain significant novel insight into the nature of the stress fluctuations acting upon aging of the material structure, into the nontrivial microstructural origin of the linear response, and into how the gel connectivity and network topology can modify dramatically the nonlinear behavior all the way to the material failure. On the one end, current challenges from the computational and theoretical side are in developing further models and approaches that can better and more efficiently capture the hydrodynamics interactions, include factors that are usually neglected but very important in experiments such as geometry and boundaries in the mechanical tests, and obtain a more quantitative understanding of the different effective interactions relevant to different material chemistry, beyond existing theories. On the other end, the results discussed here already constitute an interesting starting point to construct mesoscopic constitutive models that naturally emerge from the spatiotemporal evolution of the microstructure and its interplay with the external deformation and the deformation rate. The outstanding questions, for building such models, concern the relevant microstructural variables and the associated dynamics to be included in a continuum mechanics description of the constitutive behavior. The analysis of the spatiotemporal fluctuations, non-affine rearrangements, and local plastic events that we have briefly discussed in this chapter can help understand what are such microstructural variables and dynamics. Finally, the insight gained through studies of the type discussed here has the potential to unravel the interplay and dynamical coupling among microstructural evolution and stress redistribution in soft gels when crossing over from regime II to III in Fig. 5, providing important cues into long-standing issues such as microscopic precursors of failure, origin of creep, and hardening/toughening/self-healing mechanisms in soft materials.

Mesoscale Structure and Mechanics of C-S-H

71

Katerina Ioannidou

Contents

Abstract

Cement is the most used building material on earth, yet its properties are inexactly understood and not fully controlled. Cement hydrates named C-S-H (Calcium-Silicate-Hydrate) are the most abundant phase in hydrated cement paste and are responsible for gluing all other hydration products and unreacted cement together. A source of complexity in modelling C-S-H is that the structure is amorphous, multiscale with fully interconnected porosity spanning from a few nm up to mm. The focus of this chapter is modeling approaches that allow connecting structure and mechanics of C-S-H at the mesoscale (the scale that spans from few nm up to the micron) from the early stages of hydration, the setting and up to the hardened cement paste. The modelling approach reviewed here is of reduced complexity based on coarse-graining with emphasis on the

effective interactions between C-S-H particles. It addresses the mesoscale of C-S-H and has provided a unified framework for understanding the microstructure of C-S-H and reconciling data from many different experimental techniques. A consistent picture is presented covering (1) the reactive solidification of cement, (2) the origin of the observed microstructure of C-S-H, and (3) its link to mechanics. This provides a powerful predictive tool for nanoscale design of cement.

1   Introduction

Cement paste is a multiscale porous material that exhibits distinct physical features at different length scales. The most abundant phase in hardened cement and responsible for its remarkable mechanical strength is the C-S-H (Calcium-Silicate-Hydrate). Initially C-S-H forms a soft gel that eventually hardens to glue all phases together. It is a rather complex phase (1) at atomistic level as it has variant stoichiometry, not well-defined molecular size or shape and (2) at meso- and macroscopic levels as it exhibits complicated topology of pores. A source of complexity in cement is that the structure is out-of-equilibrium, amorphous, multiscale with interconnected porosity. This complexity has major implications on the mechanical properties of cement and hence on the stability and durability of buildings.

The initial amount of water influences significantly the overall porosity of the material, the higher the w/c ratio the more porous the material. Initially the voids in cement are big and connected; however, as the hydration proceeds and the solid structure percolates, the pores reduce in size. Initially big capillary pores of μm are filling up with aggregating precipitates that contain a large amount of much smaller pores (1–100 nm). Proton nuclear magnetic resonance (NMR) spectroscopy has given interesting insight into the pore size distribution (Levitz et al. 2003; Korb et al. 2007; Chemmi et al. 2010). More specifically, experiments indicate the presence of pores of $2-5$ nm and $14-30$ nm, both associated with the C-S-H phase.

In the beginning of the previous century, Le Chatelier proposed that the anhydrous cement compound was dissolved in water and that the hydrated products precipitated from this solution in the form of interlocking crystals (Le Chatelier 1887). In the same period, Michaëlis attributed the cementing action to the formation and desiccation of a gel (Michaelis 1893). In the 1950s based on X-ray diffraction evidence, Bernal suggested that C-S-H has a layered structure related to a crystalline mineral, 1.1-nm tobermorite, and called it tobermorite gel (Bernal 1954). Today all these observations have been proved partially correct. Both small angle neutron scattering and statistical nanoindentation technique indicate that the C-S-H meso-texture is comprised of nanoscale colloidal particles that precipitate from the pore solution and aggregate in interlocking units of few nm, initially forming a gel and eventually an amorphous solid (Allen et al. 2004; Vandamme and Ulm 2009).

The structure of C-S-H does not show much order neither at the atomistic scale nor at the mesoscale. In the atomistic scale, tobermorite – a crystalline

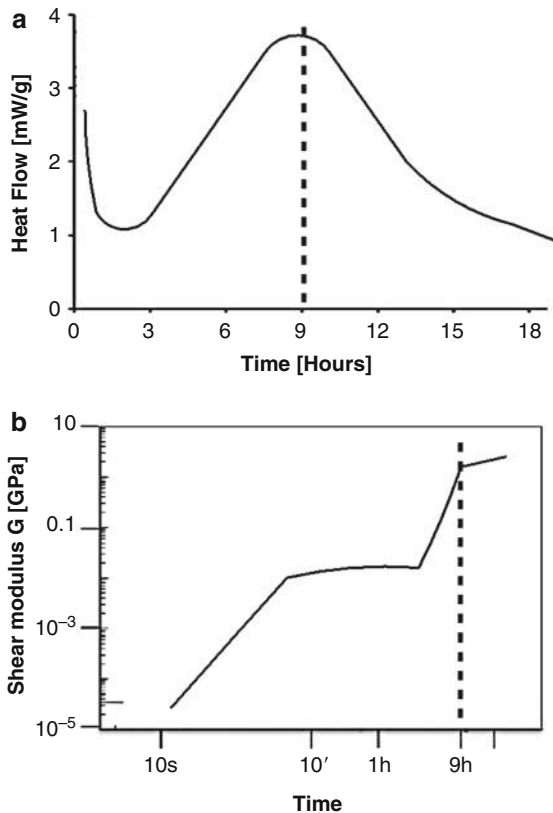
natural mineral – might form locally during cement hydration. However, most of C-S-H realizations have little order –expressed as calcium-silicate layers – and much disorder in the interlayers filled with calcium and water molecules (Pellenq et al. 2009). In certain chemical conditions, calcium-silicate layers may grow for several tenths or even hundreds of nm giving the impression under the microscope of a continuum uniform C-S-H phase organized in needles or sheets. In most cases, nevertheless, C-S-H appears chemically and texturally heterogeneous, showing amorphous aggregates interrupted by voids. This dyadic nature of C-S-H between particle and continuum has been the reason for debate over many years in the cement community.

Powers and Brownyard described the nano-colloid of C-S-H as a solid particle with inner crystalline structure and peculiar shape that is the basic building blocks of the C-S-H gel. This was based on evidence from water sorption isotherms and total and nonevaporable water (Powers 1958). Small angle neutron scattering (SANS) experiments of Allen provided the main indication of the colloidal nature of C-S-H (Allen et al. 1987). The colloidal particles in the cement paste have a characteristic length of ∼5 nm after the induction time and a correlation length ∼40 nm developing due to aggregation. Based on this, Thomas and Jennings introduced the idea that C-S-H is composed by particles aggregating with high and low packing density (Thomas and Jennings 2006). They also expanded their model to the formation of gel with pores of 1–2 nm, the so-called gel pores. Aggregation of C-S-H particles was also confirmed by atomic force microscopy imaging of a hydrating surface of alite and recent SANS experiments confirming the lamellar structure and determining the thickness of calcium silicate layers and of the water (Lesko et al. 2001; Chiang et al. 2012). From a modeling perspective, the introduction of a coarse-graining length, the C-S-H particle, facilitates the simulation of the material at larger length scales and over longer timescales.

In the following sections, a brief overview on cement hydration is given, focusing on the coupling of cement hydration to the mechanics of the C-S-H gel, and the mesoscale modelling approach is presented. The validation of the model with experiments is provided through the kinetics of growth, the mesoscale texture, and mechanics of C-S-H. This modelling approach for reactive solidification was thoroughly validated for hardened cement paste. Its main strength being the linking of cement's chemistry, via the effective interactions, to the growth of the microstructure and mechanics. Such an approach could be applied for other reactive solidification processes and also to address durability issues of cement due to in-pore solidification.

2   Cement Hydration: From Liquid to Stone

The transformation of fresh cement paste into soft and finally hard solid is intimately connected to the formation of C-S-H. During the process of hydration, numerous chemical reactions take place and different hydration products are formed. The main hydration processes are the dissolution of the reactive species contained

Fig. 1 Schematic representation of the time dependence of (**a**) the heat flow during hydration, typically obtained in isothermal calorimetry measurements and (**b**) the shear stiffness of cement paste during hydration and setting. The vertical red dashed line show the time that setting occurs


in the clinker (tri-calcium and di-calcium silicates – indicated as C3S and C2S, respectively) and precipitation of C-S-H with other minor hydration products. To fully react with water, cement needs to be mixed at least in a proportion of 42% (water to cement ratio – w/c). The full hydration process is completed in 28 days. However, the material has already solidified by the end of the acceleration period – the rheological setting – after which it reacts at very slow pace. A typical technique to follow the hydration reaction is by measuring the heat flow in isothermal calorimetry (Fig. 1a). From the changes of the heat curve, the hydration is usually divided into (1) an initial (∼30–60 mins), (2) an accelerating (∼8 h), and (3) a decelerating period of heat flow (Taylor 1997).

The growth of C-S-H changes significantly the rheology and the mechanics of the cement paste. Controlling the rheology of cement is crucial for several applications such as casting and transportation of cement. During setting, cement is a viscoelastic material, exhibiting characteristics of both solids and viscous fluids. In particular the way the mechanical strength develops and the crossing from the fluid-like properties to solid-like behavior are intimately connected to the hydration process. The complex time-dependent rheological response of cement

during the hydration is usually monitored by dynamic mode rheometry where the shear modulus versus the hydration time is obtained (Lootens et al. 2004). Three different regimes are observed in the measurements of the shear modulus of cement, as shown in Fig. 1b, the first increase of stiffness, a dormant period where the change of the elastic modulus is much weaker and the second increase of stiffness.

Almost immediately after cement is mixed with water, the shear modulus increases to 10^7Pa, which corresponds to the first increase of stiffness of Fig. 1b, and it is a clear sign of an initial gelation. At this point there are no reaction products, but the cement paste has a measurable yield stress. This first increase occurs when the clinker particles stick together and form a weak network, due to high ionic strength of the interstitial solution. At this stage, the gel structure is relatively weak and is easily destroyed by vibration, although, if not disturbed, it does not change during the next hours (Nachbaur et al. 2001). After this first weak gelation, the shear modulus stays at the plateau of 10^7Pa for nearly 5 h, which correspond to the plateau of Fig. 1b. The second increase of stiffness signals the setting of cement and its transformation into a solid material. The second increase of the shear modulus happens at the same time as the acceleration period of the hydration (see red vertical dashed line in Fig. 1a and b), when the initial network of clinker particles gets reinforced with C-S-H. The densification of the C-S-H around the clinker particles continues and, by the end of the second increase, when the acceleration period also ends, the shear modulus has reached the range of GPa due to the mechanical percolation of the C-S-H gel among what is left unhydrated of the clinker particles. Finally, further hardening occurs over periods from weeks to years due to further hydration and long-term rearrangements of the structure over different length scales.

3 Mesoscale Modeling for Reactive Solidification

The aim of mesoscale modeling is to capture the solidification process and reproduce a realistic porous texture that can be validated by different experimental observations of structural and mechanical characteristics of cement. This approach takes into account the out-of-equilibrium reactive nature of the material. By "mesoscale" one indicates lengthscales neither small enough to use atomistic approaches nor large enough to employ mean-field homogenization theories to investigate the relevant physics. Modeling techniques based on coarse-grained statistical physics provided a unified framework for understanding the structure and mechanics of a material as complex as C-S-H and can even suggest nano-scale design for enhanced and multifunctional cement formulations. Coarse-grained models allow investigating large lengthscales and longer timescales by reducing the degrees of freedom of the system and maintaining only the minimal essential constituents (Doi 2013).

3.1 The Colloidal Approach

C-S-H is known to precipitate as nanoscale particles in the pore solution upon mixing cement powder with water. During cement hydration, new C-S-H units are produced, due to the ongoing reactions; they interact with the existing ones, stick together, and form aggregates that eventually create a stress-bearing network, a gel that acts as a spontaneously densifying glue. The structural and mechanical properties of C-S-H gels are the results of a complex interplay between the precipitation kinetics, controlled by the evolution of the chemical composition and the dissolution of the clinker, and the effective interactions between the hydrates.

This approach uses coarser units than atomistic simulations in order to obtain the mesoscale structure of C-S-H that can span up to the micron scale. The building blocks are the C-S-H hydrates represented by colloidal particles of few nm. We consider an open system of precipitating and interacting colloidal particles within a small volume of a capillary pore of the fresh cement paste. The ionic solution of the capillary pore is supersaturated such that C-S-H hydrates can precipitate.

The statistical ensemble that captures this process is the grand canonical ensemble of constant $\mu V T$ condition, where μ is the chemical potential, V is the volume, and T the temperature. The simulations consist of a coupled Grand Canonical Monte Carlo (GCMC) and Molecular Dynamics (MD) scheme that accounts for particle insertion and the dynamics of the formed structures.

A particle can be inserted or deleted with a probability given by a Metropolis Monte Carlo (MC) scheme (Frenkel and Smit 2001)

$$P = \min\left[1, e^{\pm\beta(\mu_{exc}-\Delta U)}\right], \tag{1}$$

where k_b is the Boltzmann constant, T is the temperature, μ_{exc} is the excess chemical potential, and ΔU is the difference in the total potential energy of the particle configurations due to the insertion or removal of a particle. The chemical potential provides an effective description of the energy gain to create a new hydrate and thus accounts for the chemical environment of the pore solution. The probability of precipitation is obtained as the difference, at a fixed temperature T, between the change in the internal energy (due to inter-particle interactions, ΔU) and the free energy gain corresponding to the formation of a C-S-H hydrate (expressed through μ_{exc}). The chemical potential sets the equilibrium particle density that can be reached in the pore. Assuming that during cement hydration and C-S-H precipitation, the pore solution is always supersaturated, the chemical potential is chosen such that favors insertion and drives the system towards progressive densification.

To follow the microscopic dynamics of the microstructure growth, a hybrid scheme couples the GCMC insertion/deletion events to MD simulation (Ioannidou et al. 2014). The number of GCMC attempts over the number of MD steps defines the kinetic rate $R = N_{GCMC}/N_{MD}$, a parameter that characterizes the kinetics of precipitation in the experimental system. Structure and mechanics depends on how

fast precipitation takes place with respect to the timescale associated to structural relaxation of the C-S-H gel or amorphous solid that is progressively formed. The MD part of the simulations allows following the aggregation process and the restructuring as the precipitation proceeds.

Overall, the number of precipitated particles in the simulation box is the results of the effective interactions between particles, the chemical potential, and the imposed precipitation rate. This coarse-grained approach allows rationalizing the role of the rate (and therefore of the parameters that control it) in the development of the physical properties of the system and its interplay with the emerging cooperative processes due to the densification of the microstructure.

3.2   Effective Interactions

The choice of the effective interactions between precipitating particles is very important as it determines the local packing of particles and the mesoscale organization. For complex systems such as cement or clays, the potential of mean force (PMF) computed from atomistic models of two interacting C-S-H particles or clay platelets offers a route to upscale the chemistry of the particles surface and of the solution into a two-body interaction (Ioannidou et al. 2017a; Masoumi et al. 2017; Ebrahimi et al. 2014). The PMF is a free energy function of two interacting objects for specific thermodynamic conditions, i.e., pressure, temperature, ionic concentration, etc. Although an expensive computationally approach, PMF is useful for chemically complex materials as cement. For charged colloids, the electric double layer theory of Gouy and Chapman (GC), based on the solution of the Poisson–Bolzmann (PB) equation, describes the formation of the electric double layer when a homogenously charged surface is in contact with an electrolyte solution. The high surface charge of C-S-H particles and the divalent calcium ions in the pore solution make mean-field approaches such as PB nonapplicable (Pellenq and Van Damme 2004).

A combination of evidences points to the fact that the effective interactions between C-S-H nano-colloids result from a competition between a short-range attraction with a longer-range repulsion expressed as an attractive well and a shoulder (Ioannidou et al. 2014). Two similarly charged particles may generate attractive interaction because of correlations in the local concentration of ions due to thermal fluctuations. This has been known for more than 20 years (Kjellander et al. 1988; Valleau et al. 1991), and the suggestion that this may contribute to the cohesion of set cement was made more than two decades ago (Pellenq et al. 1997). Sufficiently strong electrostatic coupling in the electrolyte is necessary for attraction. The electrostatic coupling is evaluated from the colloidal surface charge density, the ionic charge and radius, the solvent dielectric constant (in an implicit solvent description), and the temperature. The PMF approach takes into account all these parameters and was able to predict the short-range attraction followed by a repulsive shoulder (Bonnaud et al. 2016). This was also confirmed by direct force measurements performed using a C-S-H covered atomic force microscopy (AFM)

tip and a C-S-H flat surface (Plassard et al. 2005). Investigation of different solution parameters showed that the calcium ion concentration controls the attraction to repulsion ratio. Recent measurement of hydrating cement volume changes showed that cement paste initially expands and later shrinks (Abuhaikal et al. 2018). They also suggest that the reason for this is the competition of attractive and repulsive interactions.

The effective interactions in cement are not homogeneous in space and time, but they depend strongly on the ionic solution surrounding the C-S-H particles. The AFM measurements suggest that in the beginning of hydration when calcium ionic concentration is low the repulsion is stronger, whereas eventually the attraction is taking over. In the mesoscale approach just introduced (Ioannidou et al. 2014), the effective interaction of two spherical C-S-H particles with diameter σ is defined as a combination of a short-range generalized Lennard-Jones (LJ) attraction and a long-range Yukawa repulsion (Israelachvili 1992):

$$
V(r) = 4 \epsilon \left[\left(\frac{\sigma}{r} \right)^{2\gamma} - \left(\frac{\sigma}{r} \right)^{\gamma} \right] + A \frac{e^{-\kappa r}}{r}, \tag{2}
$$

where r is the inter-particle distance, γ the exponent in the generalized LJ interaction, and κ the inverse screening length. The parameters ε and A quantify the relative strength of the attractive and repulsive interaction terms. The functions of Eq. 2 with all possible parameter values define a family of interaction potentials with an attractive minimum at $r = r_{min}$ and a repulsive barrier at $r = r_{max}$. A subfamily of potentials was considered with fixed $\gamma = 12$ and $\kappa^{-1} = 0.5\sigma$ and combinations of A and ε values such that the depth of the attraction well at r_{min} is fixed to $V(r_{min}) = -1k_BT$ and the height of the repulsive shoulder is between $0 < V(r_{max}) \leq 0.5\ k_BT$ (Ioannidou et al. 2016a).

The exact parameters depend on the time of hydration and the specific thermodynamic condition. In the next sections, we discuss results for three cases: the high shoulder HS ($A = 4$, $\varepsilon = 1.5$) representative of early stages hydration, the low shoulder LS ($A = 12$, $\varepsilon = 2.4$) representative of later stages hydration, and no Yukawa term LJ ($A = 0$, $\varepsilon = 1.5$) representative of the hardened cement paste. The three interaction potentials are displayed in Fig. 2. In all cases under consideration the attraction is short-ranged, i.e., the width of the attraction well is in the range between 0.1σ and 0.3σ. Monodisperse (Ioannidou et al. 2016a) and polydisperse (Ioannidou et al. 2016b, 2017b; Masoero et al. 2012) size systems were consider. In this approach, polydispersity is a way to introduce further heterogeneity in the system.

In the next section, we show that this type of approach made it possible to connect the time evolution of C-S-H growth and densification to textural and mechanical properties of hardened cement paste. In addition, although the hybrid GCMC-MD precipitation scheme was conceived to explore the nonequilibrium conditions, it helped to reveal the crucial influence of the underlying thermodynamically stable and metastable states (dictated by the effective interactions) on the out-of-equilibrium process of precipitation (Ioannidou et al. 2014, 2016a).

Fig. 2 Effective interaction of C-S-H particle in different thermodynamic conditions. A short-range 12–24 Lennard-Jones attraction is combined with a long-range Yukawa repulsion. The blue dashed-dotted line corresponds to HS, the red dashed line to LS and the black solid line to 12–24 LJ. The attraction to repulsion ratio ε/A depends upon the concentration of calcium cations
4   The Kinetics and Rheology of C-S-H Growth

The colloidal mesoscale approach for C-S-H precipitation captured for the first time consistently the kinetics of C-S-H growth and densification and at the same time provided a realistic time evolution of the microstructure (Ioannidou et al. 2014, 2016b). The simulations provide the volume fraction of the box occupied by C-S-H hydrates, and by analyzing the coordinates of the particles, correlation in the microstructure can be computed. Starting from C-S-H particles of size 3–10 nm, the mesoscale structures assembled by the precipitation simulation technique can reach up to 600 nm.

In more detail, the results display hydrates precipitation curves (time evolution of the volume fraction) that indeed reproduce the acceleration and deceleration regime typically observed in experiments and were able to correctly capture the effect of Ca^{+2} concentration on the hydration kinetics and the gel morphology (Ioannidou et al. 2014). The structural analysis of the C-S-H gels formed under precipitation showed that the different densification regimes are directly related to the aggregation process that is controlled by the underlying thermodynamics (Ioannidou et al. 2016a). As the volume fraction increases the local packing of the aggregates changes facilitating further precipitation, due to the change in the effective interactions. When the system is dilute, large elongated clusters quickly form and merge into a gel, whereas when the system becomes denser compact and locally denser domains are prevalent (Ioannidou et al. 2014, 2016a).

Figure 3 shows how the different effective interaction influences the formation of C-S-H gel at low volume fractions, as it appears in simulation snapshots. HS poten-
Fig. 3 Snapshots of C-S-H gels, with HS (left) and LS (right) effective interaction at volume fraction $\eta = 0.25$ produced by particle precipitation in the μVT ensemble. Only the bonds between the particles are depicted using lines. The color code corresponds to the number of nearest neighbors

tial, with a higher repulsive shoulder than LS, favors the formation of elongated thin strands, whereas LS enhances the close packing of particles. This has an effect on the pore size distributions since HS produced many smaller pores and LS instead favors large pores. Furthermore, tuning the out-of-equilibrium conditions via the kinetic rate R changes the degree of local order in the system (Ioannidou et al. 2014).

The mesoscale colloidal approach for reactive solidification allows to connect the changes of the physico-chemical environment, which dictate the evolution of the effective interactions, to the sizes of pores. Moreover, in the case of cement the fact that the effective interactions evolve from HS to LS and to LJ eventually specifically favors the early gel formation and its continuous densification. Such an approach helps rationalizing how cement attains its unique strength and contributes in the science-based design of the properties of cement and related materials.

A comparison with rheological measurement can also be achieved by evaluating the evolution of the shear modulus during the precipitation simulations of C-S-H particles. Shear tests were performed on configurations of different volume fractions and, using the resulting load curves, the evolution of elastic modulus during cement hydration can be determined as shown in Fig. 4. Hence, the mesoscale colloidal approach allowed us to build the connection among gelation kinetics, changes in the morphology of the microstructure, and rheological and mechanical properties of the material.

4.1 Mesoscale Texture and Mechanics of C-S-H in Hardened Cement Paste

A full validation of the C-S-H amorphous solid structures obtained from the colloidal approach was possible against a large set of available experimental
Fig. 4 Shear modulus as a function of the time for HS and LS at a high and low kinetic rate R. The simulation timescale is set up in agreement to Reference (Ioannidou et al. 2014). The experimental data, depicted by black circles, are from reference (Lootens et al. 2004) plotted in linear time

results ranging from electron-microscopy imaging, nano-indentation tests, small angle X-rays (SAXS) and SANS, NMR spectroscopy, and adsorption/desorption of nitrogen and water (Ioannidou et al. 2016b). The complex pore network and the structural heterogeneities inherent to cement paste naturally emerge from the effective cohesive interactions and from the nonequilibrium conditions of the precipitation simulation.

The voids and solids of the configurations obtained via mesoscale simulations were analyzed via pore size distribution and local volume fractions. This approach was able to capture the broad distribution of pore sizes up to two orders of magnitude. A large population of nanoscale gel pores (1–2 nm) and a broad distribution of larger mesopores (3–40 nm) form an extended pore network. Together with the continuous distribution of local solid packing fractions, this observation composes a new physical picture of cement (Ioannidou et al. 2016b).

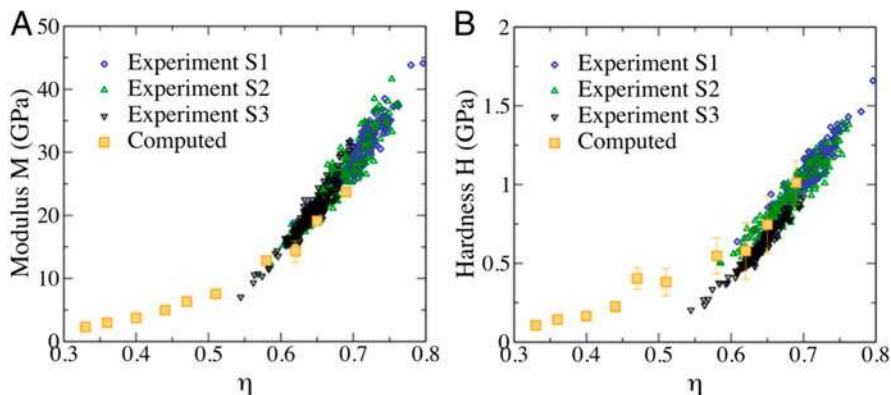
In more details, the meso-scale texture obtained is consistent with adsorption/desorption experiments, NMR, and with Powers-Brownyard classical relations estimating capillary and gel pore volumes. The SANS signal in cement paste has an intriguing q^{-3} behavior observed over an unusually large range of distances. This behavior was obtained also from calculations of the scattering intensity of the mesoscale configurations. By further analysis of the structure using chord length distributions, the explanation for the q^{-3} dependence was found in the interface of pore and solid matrix. It is due to a unique coexistence of a surface roughness of the capillary pores at the scale of 3–40 nm with a complex (fractal) pore network, all consequences of the interplay between the cohesive nano-scale effective interactions


Fig. 5 (**a**) The C-S-H modulus M and (**b**) the hardness H as a function of η for simulations and experiments from reference Ioannidou et al. (2016b))

and the out-of-equilibrium conditions in which the material forms during cement hydration (Ioannidou et al. 2016b). Due to the mesoscale approach for the first time, simulations data were able to explain the extended spatial correlations of cement.

Moreover, calculating the specific surface area using in-pore chord length distribution has allowed us to formulate a new perspective on water and nitrogen adsorption experiments and to reconcile literature data apparently contradictory (Ioannidou et al. 2016b). In fact, the calculations are consistent with the fact that drying conditions may determine which part of the pore population is actually accessible to the adsorbate and the existence of a thick, stable layer of water molecules in C-S-H may block, in some of the experiments, the access to nanoscale gel pores.

Mechanical properties of the C-S-H mesoscale configurations can also be computed. Figure 5 shows the modulus M and hardness H as a function of the volume fraction η in experiments on hardened cement paste and in simulations, showing an excellent agreement. In these experiments, portlandite and all other minor phases of cement have been carefully excluded and the data refer only to the C-S-H phase (Krakowiak et al. 2015). The C-S-H data were isolated from the cement samples by spatially correlating nano-indentation data and energy dispersive X-ray spectrometry and elemental mapping data. The comparison of these data highlights the fact the densest part ($\eta > 0.6$) of the material spans the whole structure in a complex, load-bearing network, which dominates the nano-indentation experiments (Ioannidou et al. 2016b, 2017b).

5   Conclusions

In this chapter, we provided an effective approach to reactive solidification applied to the problem of the formation and evolution of the C-S-H microstructure, the main binding phase of cement, at the mesoscale level (1–500 nm). A source of complexity

in cement, and more specifically in C-S-H, is that the structure is amorphous and develops over a range of length scales under out-of-equilibrium conditions. This issue has major implications in the mechanical properties of cement and hence in the stability and durability of buildings. In order to tackle this complexity, a minimalistic coarse-grained nanoscale model and computation approach for the C-S-H gel formation during the early stages of cement hydration was discussed. The use of a coarse-grained model makes this investigation possible by reducing the degrees of freedom of the system and maintaining only the minimal essential constituents. The main characteristics of the colloidal mesoscale approach are: the material consists of particles of few nanometer representing the main units of the C-S-H gel, the particles interact with effective forces arising from atomistic interactions, the formation and evolution of the gel microstructure is determined by the combination of statistical mechanics laws with the out-of-equilibrium conditions stemming from the complex chemical hydration reactions. This type of model can provide the time evolution of the C-S-H gel microstructure which can be analyzed and used for computing directly its structural and mechanical properties in excellent agreement with experimental measurements.

Abstract

The more than 20 billion tons of concrete, produced every year, is responsible for 5–7% of global anthropogenic carbon dioxide emissions. Yet, there is no other viable material that can substitute concrete to meet the need for civil infrastructure in the developed and developing countries. This leaves reducing concrete's carbon footprint as the only path forward to meet environmental targets. The strength and durability properties of concrete rely on the calcium-silicate-hydrate (CSH) phase that forms during cement hydration. Controlling the structure and properties of CSH phase is challenging, due to the intrinsic multiscale complexity of this hydration product that spans several orders of magnitude in length scale (from nanometers to microns). The existing lack in scientifically consistent insights into structure and properties of CSH has been the major obstacle to the development of greener formulations of modern concrete. In this chapter, we review how bridging general concepts from condense matter physics to cement and concrete research has revolutionized our contemporary understanding of the CSH phase and its making-up at the nanoscale, redefining this ubiquitous material described simultaneously as a spanning space continuous matrix and as a cohesive granular material that degrades and creeps over time.

1   Introduction

At the 21st Conference of Parties Climate Summit in Paris, the cement industry launched an action plan aimed to reduce its carbon emissions by 1 Gt by 2030. This plan identifies a range of actions that tackle emissions of the sector, including expanding the use of alternative fuels, developing new low-carbon cement formulations, looking into avoided emissions in concrete's use phase, and exploring novelties in the production process. This plan is envisioned to engage the building and infrastructure value chains to reduce the environmental footprint of cement and concretes as a sustainable and resilient construction solution.

Cement clinker particles are produced from a high-temperature (around 1500 °C) process that mixes limestone (calcium carbonate) and clay (alumino-silicate minerals) followed by a sintering step to form hard nodules called clinker that get finally ground into a fine powder. During this high-temperature treatment, several chemical

(**d**) Cement paste's texture at the engineering scale (Qomi et al. 2015)

processes, from the loss of free water to thermal decomposition, take place (Bensted and Barnes 2002; Taylor 1997). The clinker is then ground in presence of gypsum into a fine powder to produce the "Ordinary Portland Cement" (OPC) sac, the most commonly used cement type.

The hydration process begins soon after mixing cement powder with water. The clinker is rich in crystalline calcium silicates, mainly tricalcium silicate $(CaO)_3 SiO_2$ (or $C_3 S$ in cement chemistry notation, also called alite, that is, a chemically impure form of $C_3 S$) and dicalcium silicate $(CaO)_2 SiO_2$ (or $C_2 S$ also called belite, that is, a chemically impure form of $C_2 S$), and reacts with water to form the calcium-silicate-hydrate (CSH) phase, calcium hydroxide $(Ca(OH)_2)$, and hydrated calcium aluminates (AFm and AFt phases) (Taylor 1997). Note that, in cement chemistry notation, "C" stands for CaO, "S" for SiO_2, and "H" for H_2O. It is now clear that the CSH phase is a *cohesive*, *glassy*, *porous*, *multiscale*, *nonstoichiometric compound* (by nonstoichiometric, we indicate that different CSH chemistries can coexist within the same set paste). See Fig. 1 for CSH and cement paste's schematic representation across length scales. CSH's stoichiometry is usually accounted for through the Ca/Si ratio also called the C/S ratio that ranges between 1.0 and 2.0 and distributed around C/S = 1.7. At the very nanoscale, CSH is often described as an analog of a defective tobermorite, a layered hydrated calcio-silicate mineral (with C/S ratio ranging from 0.66 to 1.0, with several possible polymorphs) (Gartner 2004).

At the mesoscale (100 nm to 1000 nm), CSH appears to be an assembly of nanograins (on the order on 5 nm in size, with some size polydispersity (Gartner and Sui 2018; Popescu et al. 2003; Quillin 2001)) with two distinct textures called low-density (around 64%) and high-density (above 76%) – the first being located at the surface of the hydrating clinker grains, while the second corresponds to regions in-between clinker grains. From SEM experiments, the low-density phase is often described as being fibrillar, although the vacuum conditions of the SEM

observations might affect the texture of a fresh paste (Neubauer and Jennings 1996). Interestingly, the small-angle scattering response of CSH to X-ray or neutron diffraction exhibits an unusual Q^{-3} behavior that was explained only recently (Q being the norm of the momentum transfer vector corresponding to a $d = 2\pi/Q$ characteristic distance) (Santos et al. 2015). The 3D percolation of CSH in-between initial reactive clinker grains during the hydration process determines the overall rigidity threshold of the paste. Alite reacts fast with water so that, after 28 days, 70% of it has been replaced by hydration products (Taylor 1997). On the contrary, belite hydrates much slower – only 30% has reacted within the same amount of time. Note that the hydration of alite or belite produces CH, in addition to CSH; CH represents 15–20% of the cement paste volume under the form of large (10s of microns) size crystallites immersed in CSH.

In this chapter, we review how bridging general concepts from colloidal and glass physics to cement and concrete research has revolutionized our contemporary understanding of the CSH phase and its making-up at the nanoscale, redefining this ubiquitous material described simultaneously as a spanning space continuous matrix and as a cohesive granular material that degrades and creeps over time. This new route in understanding the CSH phase grew out from a combination of new experimental techniques together with an important effort in modeling and numerical simulations using statistical condensed matter physics as a unifying knowledge background allowing tackling the structural and complexity of the material over critical time and length scales. This framework provides a novel opportunity to scientifically design cement material properties and hence identify strategic issues that have the potential to transform cement production and use. The purpose of this chapter is (i) to give a holistic overview of the physical chemistry and mechanics of cement hydrate, as it develops during cement hydration and progressively solidifies; (ii) to frame the outstanding questions on cement hydrate structure and mechanics within the context of modern condensed matter physics of amorphous materials; (iii) to review the recent research developments in experiments, modeling, and simulations; and (iv) to analyze the new emerging questions and their possible implications for reducing the environmental impact of cement and concrete. In contrast to the existing reviews on this subject (see, e.g., J. Thomas et al. (2011)), we are addressing the large community of condensed matter physicists and material scientists, well beyond the traditional concrete research community. Our scope is to promote fundamental scientific understanding of cement hydrates' physics to encourage new research directions.

2 The Nanoscale Process of Hydration = Dissolution of Clinker + Hydrate Precipitation

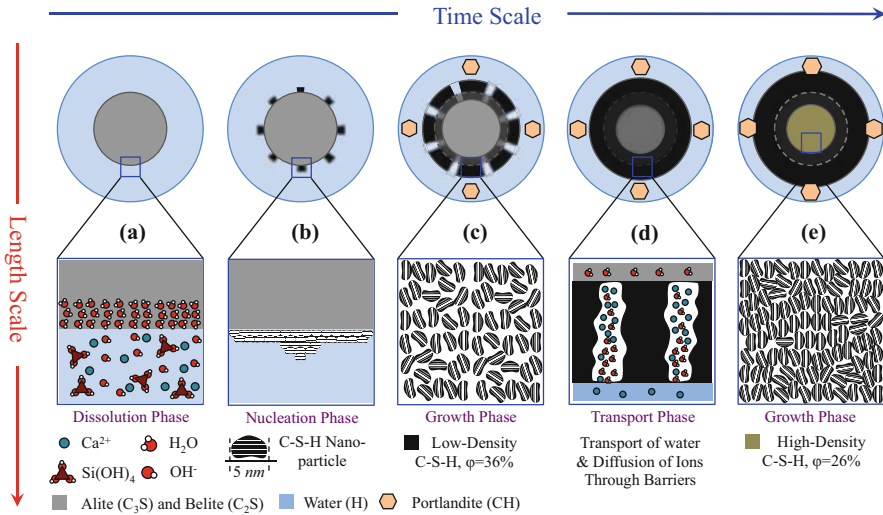
In this section, we focus on new and promising simulation approaches that advance the understanding of different phases of cement hydration products, mainly CSH. Figure 2 provides a schematic illustration of different stages of cement hydration


Fig. 2 The schematics of a five-stage idealized thought model of cement hydration that combines transport and boundary nucleation growth mechanisms. (**a**) Formation of a semi-impermeable layer around cement particles during the dormant period. (**b**) A symmetric nucleation of a constant number of CSH particles on the surface of cement particles. (**c**) An isotropic and self-similar growth of CSH nuclei with spatially constant but time-varying growth rate. (**d**) Overlapping of growing CSH nuclei and the coverage of the entire surface with hydrates which terminates the nucleation-growth process. (**e**) The uniform growth of CSH particles that is controlled chiefly by the inward transport of water and the outward diffusion of ions to the solution (see Rahimi-Aghdam et al. 2017)

including dissolution, nucleation, and growth (Rahimi-Aghdam et al. 2017). At the beginning of the hydration, the CSH grows loosely around the clinker phase starting from nuclei; later it densifies and glues together also the crystalline phases. The morphology of CSH can vary from globules to fibril or foil-like depending on the initial conditions and the hydration stage (Richardson 2000). The initial composition of the cement powder, the water-to-cement (w/c, mass basis) ratio, and the relative humidity influence CSH structure. The fibril growth has been suggested to rise from the increased osmotic pressure that ruptures the preexisting CSH layer (Richardson 2000). Jennings and co-workers investigated the size and diameter of the needles formed under different conditions of relative humidity (Fonseca and Jennings 2010). It is also found in microscopy images that CSH grows in different directions. CSH grows both outward and inward the clinker particles, forming the so-called inner and outer product, respectively. The inner product occupies the space of the hydrating grain, and its structure is more compact and amorphous. The outer product is formed in the pore solution, and it is reported to form bumps, needles, or foils.

A complementary way to examine the cement paste's structure is by characterization and distribution of void spaces in the material. The initial amount of water influences significantly the overall porosity of the material; the higher

the w/c ratio, the more porous the material. Initially, the voids in the cement paste are large and connected; however, as the hydration proceeds and the solid structure percolates, the pores reduce in size and get disconnected. Initially large capillary pores of few μm are replaced by pores of few decades of nm at the later stages or cured paste. Proton NMR experiments provide information about the water movement and the porosity in cement paste (Korb et al. 2007b; McDonald et al. 2010; Muller et al. 2013a). More specifically, these experiments indicate that there are consistent pores of 2–5 nm and 14–30 nm, both associated with the CSH gel. In order to interpret the experimental findings of the CSH structure, models were developed based either on the hypothesis of the planar growth of naturally occurring tobermorite, jennite, and portlandite minerals or the aggregation of colloidal particles (Bullard et al. 2010). According to the first hypothesis, the CSH gel is formed by interconnected layers that are similar to mineral crystals (Daimon et al. 1977) following the cartoon representation proposed by Feldman and Sereda (1968), where the layers are irregularly stacked and water is trapped in between them or adsorbed in the free surfaces. This hypothesis could explain some properties of the nanostructure such as the observed variable composition of C/S ratio, the crystalline regions, and the amorphous layers, and they were validated by gas sorption properties, porosity, and shrinkage. Gartner et al. (2017) described the layers as narrow ribbon-like with random defects that make them wavy and cause them to separate and branch. The growth rate of these ribbons was considered exponential assuming that, due to the kinetics of the hydration, nucleation and growth of the new material happen at the extremities of the ribbons. Gartner suggested that the growth of the ribbons and their branching or impingement could correspond to the acceleration and deceleration regime, respectively, of the kinetic hydrations (Gartner 1997). The indication of the colloidal nature of CSH came with the small-angle neutron scattering (SANS) experiments of Allen in the 1980s (Allen et al. 2007). The scattering data of a hydrating cement paste showed a characteristic length of $\sim$5 nm after the induction time and a correlation length $\sim$ 40 nm developing due to aggregation (Allen et al. 1987). Based on these scattering measurements and sorption data, Jennings proposed a hybrid model of globules with a peculiar shape and inner structure. According to his first colloidal model (CM-I), these particles form aggregates with two different packing densities: high-density (HD) CSH and low-density (LD) CSH (Thomas and Jennings 2006). A further refinement of Jennings' model (CM-II) accounted for the smallest pores of the CSH arising from the internal structure of the globules that, like in the picture proposed by Feldman and Sereda (1968), are composed of tobermorite and/or jennite sheets and water. Therefore, the CM-II combines a layer-like structure into the colloidal-like description and accordingly interprets the adsorption isotherm experiments and processes like creep and shrinkage (Jennings 2000).

Recent papers (e.g., Scrivener et al. 2015; Thomas et al. 2011) provide a comprehensive review of modeling efforts on the cement hydration process over the past 40 years, covering different modeling approaches such as single-particle models, mathematical nucleation and growth models, and vector- and lattice-based approaches to simulating microstructure development. In this section, we took the step to consider advances in modeling based on modern solid-state quantum and

statistical physics and importing general concepts from colloid and glass science, which are critical to advance the science and engineering of cement paste.

2.1   Nanoscale Description of Clinker Surface Reactivity

The hydration of mineral surfaces is a critical process that involves multiple coupled chemical reactions as well as topological changes. These features make computational modeling of the hydration process very challenging. For cement clinker, most of the modeling effort concentrates on C_3S. The contact of C_3S with water leads to the hydroxylation of silicate particles and dissolution, releasing calcium and silicate ions in the solution. It has been shown that Ca^{2+} is the main parameter controlling the hydration kinetics and the stoichiometry and structure of the reaction products such as CSH. The concentrations of the solution ([CaO], [SiO$_2$]) do not vary independently during C_3S or cement hydration. In their recent work, Manzano et al. have used reactive force-field simulations to understand the surface properties, hydration, and dissolution of C_3S (Manzano et al. 2015). Furthermore, they showed that the computed static quantities, i.e., surface energies and water adsorption energies, do not provide useful insight into prediction of mineral hydration because these quantities do not account for major structural changes at the interface, when dynamic effects are included. As water reacts with the surface, significant topological changes take place modifying the surface structure, and the correlation with the surface properties is lost. Therefore, the authors concluded that the hydration of minerals couldn't be predicted from the static properties as has been traditionally done. Hence, including dynamics becomes necessary to observe topochemical reactions.

The hydration mechanism of the reactive surfaces of C_3S can be summarized as a reaction and hopping process. Water reacts with the surface oxygen atoms forming hydroxyl pairs. Then, protons penetrate into the crystal, hopping from surface to inner oxygen atoms following a Grotthuss-type mechanism. The protonation reactions break the calcium-oxygen bonds, and calcium desorbs from the bulk to the surface, forming inner- and outer-sphere complexes. Overall, the surface of the crystal evolves toward a disordered calcium-silicate-hydrate phase, and, as a result, the reaction rates homogenize. In addition, Manzano et al. (2015) also observed the formation of a stable icelike water monolayer driven by the peculiar underlying crystalline order of some C_3S surfaces that can inhibit hydration.

First-principles DFT-type calculations were employed for the first time by Durgun et al. (2012) to provide a fundamental understanding of the relationship between the reactivity of synthetic calcium silicate clinker phases and their electronic structure with the aim to shedding light on the wide range of hydration kinetics observed in different phases of calcium silicate. The authors showed that the high reactivity of C_3S is mainly related to the reactive sites around its more ionic oxygen atoms. C_2S does not contain these types of oxygen atoms, although experiments suggest that impurities may play a role in changing the reactivity of these materials. The electronic structure of a wide range of possible substitutions in both C_3S and C_2S shows that while the influence of different types of impurities on structural

properties is similar, their effect on reactivity is very different. These first-principles calculations suggest that the variation of electronic structure is mainly related to the formation of new hybridized orbitals and the charge exchange between the impurity atoms and the bulk material. These differences are shown to influence the reactivity in these materials, in good agreement with available experimental data. By quantifying the charge density localization of the VBM and CBM (valence band maximum and conduction band minimum, respectively) for a large set of potential substitutions, it was predicted that several candidates could influence the reactivity of C_2S.

Manzano et al. have used a combination of classical and quantum mechanical simulation methods to study the detailed physicochemical changes of C_3S and C_2S upon incorporation of Mg, Al, and Fe guest ions (Manzano et al. 2011). Using classical force-field methods, they considered random substitutions among possible sites and different compositions in order to identify the preferential substitution sites on the crystalline structures. Using quantum mechanical density functional theory calculations, the electronic structure of representative configurations has been computed to determine the potential impact of impurities on the reactivity. Simulations show that any crystallographic site within the unit cell is equally probable for the incorporation of guest ions and that there is not an optimal distance between them, when multiple incorporations occur. The rearrangement of the silicate groups' orientation and calcium coordination polyhedron allows for defect accommodation. Despite the change in orientation, the internal structure of the silica groups is kept unaltered, while the change occurs in the more flexible Ca-O distances. Manzano et al. (2011) found that C_2S tighter structure makes it more susceptible to structural changes when guest ions are incorporated. Regarding the reactivity, DFT calculations reveal that the reactive areas under nucleophilic and electrophilic attack change differently depending on the guest ion. Mg docking does not change the electronic structure appreciably, while Al and Fe do, thereby reducing the number of reactive sites. Aluminum, however, creates weak Al-O bonds that are therefore highly reactive, balancing the reduction of dissolution points. By contrast, iron dramatically decreases the reactive sites and introduces a strong Fe-O bond. This difference might induce a noticeable decrease in the dissolution rate with respect to the pure or the Mg- and Al-substituted alite and belite. Along the same lines, Huang et al. (Huang et al. 2015) combined first principles (DFT) and reactive molecular dynamic simulations, to provide a similar picture of the influence of Mg, Al, and Fe impurity species on the hydration reactivity of triclinic C_3S phase.

2.2 Nanoscale Modeling of CSH Precipitation from the Initial Electrolyte Solution

The formation of CSH out on the so-called pore electrolytic solution that exits in-between clinker grains as they dissolve remains an open question. Here, we describe the work of Dolado et al. (2011), who took the step to set a direct simulation

of CSH precipitation using molecular dynamic simulation using the Garofalini reactive potential for silica with the aim of reconciling the existing structural and colloidal/gel-like models. The key result of this work is the prediction of the formation of a branched three-dimensional CSH solid network with segmental branches (SB) of $\sim 3 \times 3 \times 6$ nm in size. These SB units of CSH are essentially glassy and do not reproduce the layered nanoscale texture that has been observed from many TEM experiments over the years. The reason behind this is most probably that the system got stuck into some local potential minima, being unable to overcome large energy barriers. There are two ways to overcome such drawbacks. The first would be to use a replica-exchange molecular dynamic approach (also often called parallel tempering (Sugita and Okamoto 1999)). The second strategy can build on the replica-exchange approach but will implement a coarse-grain description from a full atomistic description to basic relevant structural units such as silica tetrahedra and calcium ions in a dielectric continuum that represents the solvent, i.e., water in the case of CSH. For a good example of this approach, we refer the interested reader to the work of Chien et al. (2015). These authors have performed replica-exchange reaction ensemble Monte Carlo simulations to study the low-energy crystalline structures of a reactive model of silica. The implementation of replica-exchange Monte Carlo involves simulating several system copies, each with its own value of the equilibrium constant controlling silica condensation/hydrolysis reactions, which are essential for building higher-order network structures and eventually crystals. These replica-exchange simulations were found to traverse energy landscapes from amorphous to crystalline phases, yielding the dense silica polymorphs. The good predictive power of this approach is based on advanced statistical physics methods that open the door to future simulation studies of the free energy barriers controlling crystallization processes.

2.3 Origins of Cohesion Between CSH Grains and Its Evolution During Cement Hydration: Bridging from the Nanoscale to the Mesoscale

The bottom-up approach for multiscale modeling of cementitious materials integrates different scales of knowledge to accurately model relevant phenomena across multiple length and time scales. This approach provides a unique opportunity to develop a full predictive modeling and simulation framework for amorphous complex porous materials from molecular to engineering scales. Our starting point is the atomic structure from which, using the state-of-the-art interatomic potentials, one can derive the so-called potential-of-mean-force (PMF) between different phases using free energy perturbation approach within the framework of statistical physics. A PMF is a free energy function representing the interactions between objects at a given temperature along a pre-specified reaction path, sometimes also referred to as a collective variable. The PMF, therefore, is the key information piece allowing to coarse-grained physical-chemistry information within a mesoscale

model formulation. Such a coarse-grained modeling integrates atomistic response into interparticle potentials that fully describe the atomic interactions and enables us to reach much larger time and length scales.

The cohesion and stability of charged layers separated by an electrolyte solvent have long been discussed within DLVO theory framework. The DLVO theory combines the repulsive electrical double-layer interaction with the attractive van der Waals interactions (Israelachvili 2011). The repulsive electrostatic interaction is obtained by analytically solving the Poisson-Boltzmann equation of a system made of positive point charges between negatively charged surfaces. Designed for point charges, it is, therefore, a mean-field approach that ignores correlations in ionic positions and their fluctuations due to thermal agitation. Making use of the Poisson-Boltzmann equation, the electrostatic pressure P (i.e., the force per unit area, i.e., the derivative of the PMF with respect to the inter-colloidal distance) between two charged surfaces in function of the surface separation D is given by $P(D) = k_B T[C_{ion}(D/2) - C(\infty)]$ where k_B is the Boltzmann constant, T is the temperature, and $C_{ion}(D/2)$ is the cation concentration at the mid-separation. This pressure depends only on the increase in the ionic concentration at the center of the pore, and therefore its origin is entropic.

It is now known that a system of charged plates and counterions can generate strong attractive electrostatic interactions, the so-called ionic correlation forces (ICFs) (Pellenq et al. 1997, 2008; Pellenq and Van Damme 2004). The so-called primitive model was introduced in the 1980s to study such attractive forces. In the primitive model, the charged lamellae and the hydrated cations are represented by uniformly charged infinite planar surfaces and by charged hard spheres, respectively, while the solvent is represented by a dielectric continuum. Monte Carlo simulations in the framework of the primitive model showed that fluctuations of the ionic concentration in the interlayer space result in an instantaneous polarization and give rise to an attractive ionic fluctuation interaction, the so-called ionic correlation forces. Thus, the behavior of the system is governed by a competition between repulsive entropic forces and attractive energetic forces. For divalent or trivalent cations, the attractive energetic contribution can exceed the repulsive entropic fluctuations. For example, in the case of calcium counterions, attractive pressures are observed for pore sizes larger than 10 Å and explain the experimentally observed difficulty in complete exfoliation of calcium montmorillonite clay layers.

The primitive model has obviously its own limitations. The surfaces of the slit pore are assumed to be flat and uniformly charged; the ions are supposed to be fully hydrated and mobile, and the solvent is considered to be a dielectric continuum, the dielectric constant of which is that of bulk water. These hypotheses make the primitive model questionable, in particular at low surface separation. In this case, the molecular structures of the solvent and the surfaces have to be directly taken into account. Therefore, numerous works adopted a full-atomistic description to study, for instance, the intralamellar swelling of smectite clays (Ebrahimi et al. 2012, 2014) or cohesion between CSH layers (Bonnaud et al. 2016; Masoumi et al. 2017a, b). However, the computational cost of these atomistic simulations is very significant preempting coarse-grained simulations. Accordingly, it is necessary to

determine more precisely the complexity that needs to be introduced into the models of lamellar systems and the key physical ingredients responsible for the cohesion of such materials.

During cement hydration, the cement paste has a high ionic concentration of hydroxyl ions, resulting in 10 to 13 pH levels. These ions interact with the surface of the already formed CSH particles, thereby giving them high surface charge – on the order of one electron charge per $0.35 \ nm^2$ for fully ionized CSH. To compensate the highly negatively charged CSH surfaces, Ca^{2+} counterions gather in the vicinity of CSH surfaces forming an ionic cloud. These two characteristics of highly charged particle surface and divalent surrounding counterions make the interactions of CSH particles different than other colloidal systems. In weak electrostatic coupling conditions, it has recently become clear that the distribution of the ionic cloud of monovalent counterions cannot be described by the Poisson-Boltzmann equation that constitutes the part of the DLVO theory that deals with electrostatics in a mean-field fashion (Carrier 2013). This conclusion was drawn out from the primitive model describing ionic ICFs using explicit solvent (Israelachvili 2011; Pellenq et al. 1997, 2008; Pellenq and Van Damme 2004). In this case, ion-ion correlations should be considered explicitly. The excess counterions near a CSH surface may be correlated with a deficit of counterions in the opposite layer, giving rise to attractive ion-ion correlation forces. These ion-ion correlated density fluctuations give rise to an attractive force, akin to London dispersion forces that arise from correlations between instantaneous electronic dipoles.

This nonclassical feature of the double layer, inducing an attraction between two similarly charged surfaces immersed in an electrolyte, has been explored within the theory of equilibrium electric double layer, where two regimes can be distinguished (Attard 1996). The first regime is an attractive regime that occurs at small separation distances and in presence of multivalent ions. The forces in this case change from repulsive to attractive as the surface charge and pH increase. The second regime occurs at larger separations, and especially in case of multivalent ions, the force can be alternately attractive and repulsive depending on the electrostatic coupling. For highly charged surfaces such as that of CSH and the divalent counterions (Ca^{2+}), simulations and theory predict strong attractive force more than one order of magnitude larger than the van der Waals interactions. To account for the ion-ion correlations, the following models and simulations were performed treating ions explicitly (Jönsson et al. 2004, 2005; Pellenq and Van Damme 2004; Pochard et al. 2010). Within the mesoscale model, all ions are treated as point charges and the water as a dielectric continuum. Two parallel walls with smeared surface charge represent the opposite charged surfaces of CSH particles, and, in the pore solution between the two surfaces, there are Ca^{2+} and OH^- ions. All ions interact solely with Coulomb interactions and satisfy electroneutrality within the simulation cell. Monte Carlo simulations were performed in the canonical ensemble in order to calculate the ionic distributions and the osmotic ICF pressure (Jönsson et al. 2004; Pellenq et al. 1997; Pellenq and Van Damme 2004).

At this point, it is worth mentioning some numbers about the ionic concentrations in CSH that will manifest the high ion concentrations near the particle surfaces. The

bulk ionic concentrations at pH >11.6, when charge reversal occurs, hence when the forces become attractive, are of the order of 10^{-3} M, the average separation of the ions is 10 nm, and their electrostatic energy is much lower than their thermal energy. The range of electrostatic interactions in the solution is given by the Debye screening length that in this case is 4 nm and the Gouy-Chapman length that indicates the width of the confinement layer next to the surface is of the order of 0.1 nm (Jönsson et al. 2004, 2005; Pellenq and Van Damme 2004). Hence most counterions are confined in the vicinity of the surfaces, and this layer around the surface has a much higher ionic concentration than the bulk. The main finding of these simulations confirms the finding of AFM experiments, i.e., strongly cohesive forces appear in between the CSH particles.

At the sub-nanoscale, atomistic simulations have been recently performed within the CSH globules to evaluate the cohesion between the layers of tobermorite-like CSH using Hartree-Fock, quantum DFT, or force-field methods (Gmira et al. 2004; Pellenq et al. 2008; Pellenq and Van Damme 2004). The atomistic simulations have elucidated the role of interlayer calcium ions and have been used to compute the hydrogen bonding scheme of crystals such as jennite and tobermorite (Churakov 2009) or to investigate the cohesion of tobermorite layers (Gmira et al. 2004; Pellenq et al. 2008; Pellenq and Van Damme 2004). The mechanical properties and several spectral properties of the sub-nanometric structure of CSH could also be obtained (Manzano et al. 2013; Pellenq et al. 2009). Static ionic interactions govern the sub-nanoscale, whereas at larger length scales, dynamic correlations dominate due to charge fluctuations. Therefore, in the case of CSH, it all comes down to the evolution of the attracto-repulsive PMF that changes as the hydration proceeds: as more and more ions are getting stuck into solid phases (CSH and CH), the potential shoulder decreases, and in the case of the hardened paste, one is left with a single well PMF. Note that in the case of clay, the PMF could exhibit up to three minima corresponding to different water contents, in agreement with experiments (Ebrahimi et al. 2014).

Interestingly enough, recent full atomistic simulations have confirmed the role of ICFs in the case of tobermorite and CSH and provided reference PMFs that can be readily used for mesoscale simulations of CSH (Bonnaud et al. 2016; Masoumi et al. 2017a, b). See Fig. 3 for an all-atom PMF calculation between tobermorite layers using free energy perturbation technique. These PMFs, which are in quantitative agreement with AFM data (Plassard et al. 2005), measure the cohesion with CSH grains, as shown in the table below.

	Contact surface area (nm^2)	Cohesive pressure (GPa)
CSH model A (Bonnaud et al. 2016)	26.15	−0.9
CSH model B (Bonnaud et al. 2016)	26.15	−0.07
CSH model C (Bonnaud et al. 2016)	9.95	−1.0
Tobermorite model (Masoumi et al. 2017a, b)	26.54	−6.0
Exp. (Plassard et al. 2005)	64.00	From −0.6 to −3.0

Combining advanced statistical physics approaches with realistic PMFs for the simulation of cement precipitation and settings, Ioannidou et al. (2014, 2016) investigated at the mesoscale the development of CSH gels under out-of-equilibrium conditions using a realistic CSH grain-grain PMF (Ioannidou et al. 2014, 2016). These authors proposed a new model and numerical approach to follow the gel formation upon precipitation and aggregation of nanoscale colloidal hydrates, whose effective PMF interactions are quantitatively consistent with forces measured in

experiments at fixed lime concentrations and also with recent molecular simulations (Bonnaud et al. 2016; Masoumi et al. 2017a, b). In the work of Ioannidou et al., a Grand Canonical Monte Carlo (GCMC) scheme was introduced for the first time in order to mimic the precipitation events (of CSH grains) by *NVT* molecular dynamic simulation steps, which mimic a rate effect corresponding to the hydrate production set by the chemical environment. The simulated hydrate precipitation curve indeed reproduces the acceleration and deceleration regime typically observed in experiments correctly capturing the effect of lime concentration on the hydration kinetics and the gel morphology. The analysis of the evolution of the gel morphology indicates that the acceleration is related to the formation of optimal local dense packing that allows for growth of large and elongated aggregates. It is important to mention that this is the first prediction of the heat curve with no pre-assumed kinetic models that always contain ill-defined and/or unmeasurable parameters (Thomas et al. 2011). Overall, Ioannidou et al.'s efforts clarify the connection between the hydration kinetics and the changes of the gel morphology.

3 Hardened Cement Paste

At the microscale, many crystalline phases are observed in hardened cement paste together with the amorphous CSH. The most common crystal is the portlandite, which can grow up to several micrometers in the pore solution and close to the clinker surface. The size of the crystals depends on the temperature and w/c ratio. The ones growing in the pore solution under ideal conditions form hexagonal plates, whereas the ones growing close to the clinker surface are not perfectly shaped. Other crystal phases are the AFm and AFt that form needles of around 1 μm close to the clinker particles (Bullard et al. 2010).

3.1 Chemical Composition and Nanoscale Structure of CSH

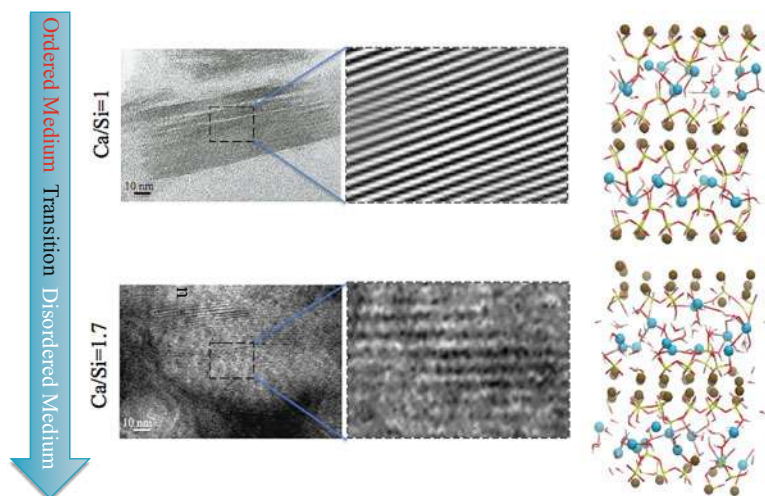
Many experimental techniques elucidate the structure of CSH at the nanoscale (Fig. 4). The main findings of the CSH's nanostructure come from analog models that interpret X-ray diffraction (XRD), sorption, shrinkage, NMR, and AFM experiments. In the 1950s, based on XDR evidence, Bernal (1954) suggested that CSH has a layered structure related to a crystalline mineral – 1.1 nm tobermorite – and called it tobermorite gel (Taylor 1993). In general, different types of CSH can coexist within a same cement hydrate paste with variable stoichiometry characterized by the water content and the calcium to silicon (Ca/Si) ratio that ranges from 1.2 to 2.3 with a maximum abundance at 1.7. The reason for the coexistence of all these different chemical compositions has to be established on proper thermodynamic grounds based on free energy arguments. CSH is usually described as amorphous due to its X-ray diffraction (XRD) pattern that shows few (and rather broad) peaks (Meral et al. 2011; Skinner et al. 2010). Tobermorite minerals have lamellar structure of calcium oxide layers connected on both sides by silicate chains


Fig. 4 The textural evolution of CSH with increasing Ca/Si ratio. At low Ca/Si ratio (Ca/Si = 1), both the TEM and MD simulations show ordered crystalline structure, in which calcium-silicate chain layers are distinctively very long. However, at high Ca/Si ratios (Ca/Si = 1.7), both TEM and MD simulations indicate defective structures that lead to a disordered glassy structure. For details, see Pellenq et al. (2009) and Qomi et al. (2014b)

following dreierketten arrangement, i.e., based on three silicate tetrahedra – two in the vicinity of the calcium oxide layer and one bridging to the next dreierketten group (Bonaccorsi et al. 2005). Note that, at C/S > 0.66, tobermorite layers acquire a nonzero negative charge with the hydrolysis of O-H bonds attached to silicate groups. This surface charge is then compensated by additional hydrated interlayer calcium ions.

It has been proposed that CSH could be made of crystalline tobermorite-like layers mixed with jennite, another layered calcio-silicates with C/S = 1.5, which is the base of the so-called T-J model of Richardson (Richardson 2008). Obviously, a mixture of compounds with C/S altogether less than 1.5 cannot account for the fact that the C/S distribution in CSH can average at 1.7. This explains why the idea of nanocrystalline portlandite was put forward. To date, no experimental evidence of such nanocrystalline portlandite has been found. More experimental findings for the chemical composition of CSH were provided by Nonat et al. when they investigated alite hydration with a special setting that allowed them to control the calcium hydroxide concentration in solution (Garrault et al. 2005, 2006; Nonat 2004; Plassard et al. 2005). They found that the calcium hydroxide concentration determines the Ca/Si ratio of the CSH and the formation of the CSH network. The evolution of the stoichiometry of CSH can be linked to the lime concentration of the solution. According to this, Nonat et al. categorized CSH into three classes with different C/S ratios and developed a predictive thermodynamic equilibrium model

based on bulk and surface mass laws that are reliable at local equilibrium conditions (Nonat 2004).

Solid-state nuclear magnetic resonance measurements of ^{29}Si-enriched triclinic C$_3$S enabled the quantitative monitoring of the hydration process in terms of transient local molecular composition, extent of silicate hydration, and polymerization. This provided insights into the relative influence of surface hydroxylation and hydrate precipitation on the hydration rate. When the rate drops, the amount of hydroxylated C$_3$S decreases, thus demonstrating the partial passivation of the surface during the deceleration stage. Moreover, the relative quantities of monomers, dimers, pentamers, and octamers in the CSH structure can be measured (Pustovgar et al. 2016).

In 2009, Pellenq et al. (2009) proposed a molecular model of CSH based on a bottom-up atomistic simulation approach that considers only the chemical specificity of the system as the overriding constraint. By allowing for short silica chains distributed as monomers, dimers, and pentamers, this CSH archetype of a molecular description of interacting CaO, SiO$_2$, and H$_2$O units provides for a realistic value of the C/S ratio (set at 1.65 and corresponding to the most abundant form of CSH in a cement paste). The mass density computed after Grand Canonical Monte Carlo simulation of water adsorption at 300 K is 2.43 g/cm^3 that comes very close to the CSH density measured by NMR (Muller et al. 2013b). Note that the densities of both tobermorite (Ca/Si = 0.83, ρ = 2.18 g/cm^3) and jennite (Ca/Si = 1.5, ρ = 2.27 g/cm^3) are significantly lower than that of CSH. Jennings et al. (Allen et al. 2007) using SANS measurements also determined the mean C/S ratio to be at 1.7 and the density of CSH at 2.6 g/cm^3 – a value that is a bit larger than that reported by McDonald et al., i.e., 2.45 g/cm^3 (Muller et al. 2013b). This discrepancy can be rationalized from the fact that it is necessarily an upper bound as the technique made no distinction between in-CSH grain structural water and adsorbed water at the surface of capillary pores. The simulated model of CSH, with a chemical composition of (CaO)$_{1.65}$(SiO$_2$)(H$_2$O)$_{1.75}$ (see Fig. 4), also predicts other essential structural features and fundamental physical properties amenable to experimental validation, which suggests that the CSH gel structure includes both glass-like short-range order and layered structure features of the mineral tobermorite. Additionally, the predicted mechanical stiffness, strength, and hydrolytic shear response compare well to experimentally measured properties of CSH using nanoindentation.

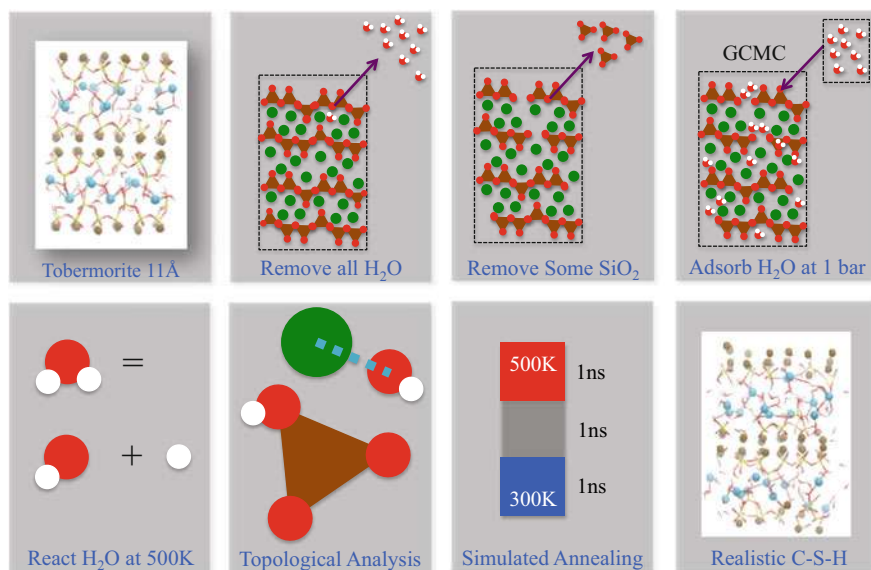
This work was then extended to studying all the possible chemical compositions of CSH measured in terms of C/S spanning from 1.2 to 2.1 (Qomi et al. 2014a). A database for the combinatorial screening of mechanical behavior was then obtained by creating an ensemble of atomic structures of CSH with each member characterized by a given value of the C/S ratio according to the multi-statistical physics-based method approach shown in Fig. 5. All the (150+) atomistic models were created consistently, according to the procedure in which randomly chosen electroneutral SiO$_2$ groups are removed from a pristine 11 Å tobermorite crystal structure under the constraint of a given C/S ratio. Subsequent molecular simulation steps in the course of this procedure accounted for the chemical reactivity of


Fig. 5 The eight stages of model construction. These stages are strictly followed 150 times to produce CSH samples with varying Ca/Si ratio ranging from 1.1 to 2.1

the silicate chains with water through the use of the ReaxFF empirical reactive potential.

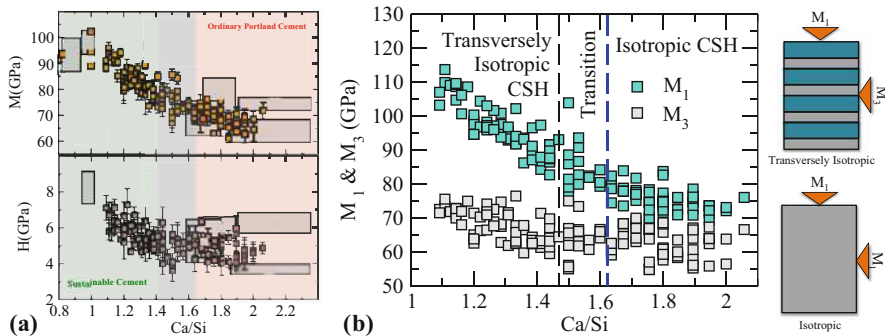
There models provide a quantitative means to relate the composition of CSH to its mechano-physical properties at the nanoscale. Figure 6 shows the dependence of mechanical properties of CSH to C/S ratio. Both the indentation modulus and hardness decrease as a function of C/S. The superior strength and stiffness required for reducing cement consumption can be envisioned with the altercation of the chemistry of CSH to lower C/S ratios. Recently, using high-pressure X-ray diffraction, it was shown that at low C/S ratios, the densification can increase the mechanical properties of CSH despite the increase in the defect content, and its possibilities were verified using atomistic simulations (Geng et al. 2017). Furthermore, it was shown that incorporation of aluminum in the molecular structure of CSH creates crosslinking between CSH layers, increasing its mechanical properties (Qomi et al. 2012). There is an important combinatorial aspect of this work as it is clear that, for a given C/S ratio, a (finite) number of atomistic configurations could be built, relaxed, and subjected to GCMC simulation of water adsorption. We mentioned earlier that the fact that the same CSH paste could host different local composition characterized by its C/S ratio had to be explained by an argument. Indeed, it is one of the main outcomes of the work of Qomi et al. (Qomi et al. 2014a; Qomi et al. 2015) that all CSH polymorphs for a given C/S ratio turn out to exhibit the same free energy (see Fig. 7 (Qomi et al. 2014b)). As expected, low C/S CSH polymorphs are found to be more stable than those at larger C/S indicating


Fig. 6 Mechanical properties of CSH. (**a**) The indentation modulus (M, orange squares) and hardness (H, brown squares) of CSH as a function of Ca/Si ratio. The results of the atomistic simulations are compared against nanoindentation results (gray squares). (**b**) CSH's anisotropy. At low Ca/Si ratios, the CSH has a transversely isotropic structure as indicated in the difference between M_1 and M_3. See Qomi et al. (2014b) for details

Fig. 7 Vibrational free energy of CSH models as function of Ca/Si ratio that indicates the presence of polymorphism in CSH structure (Qomi et al. 2014a and Qomi et al. 2015)
that tobermorite is more stable than CSH and that CSH over time should turn into tobermorite if silica sources are provided.

More interesting, for any given C/S value, all CSH polymorphs have the same free energy indicating that they have the same equal probability to occur whatever is the distribution of silica chunks in terms of monomers (Q^0), dimers (Q^1), and longer silica chains (Q^2). Note that the Q^n notation refers a SiO_4 tetrahedral unit that is surrounded by n bridging oxygen atoms (with $n = 1$–4). Hence, Q^0 indicates an isolated silica tetrahedron; Q^1 refers to end members in a silica chain, i.e., a dimer is therefore made of two Q^1-type silica tetrahedra; and Q^2 refers to silica tetrahedra that are in the core body of a silica chain, hence having two tetrahedra site as immediate neighbors, etc. Importantly, these nanoscale models of CSH were validated against a large body of experimental evidence ranging from water content (from drying experiments), Ca-OH bond content (from neutron scattering experiments), silica mean chain length (from solid-state ^{29}Si NMR), and total scattering function (as obtained from synchrotron-based X-ray spectroscopy) as

shown in Fig. 2 of Qomi et al. 2014a. The agreement between simulations and experimental results is impressive as there are no adjustable parameters in the simulation protocol. In particular, one should focus on the GCMC prediction of water content upon increasing amount of SiO_2 vacancies. This result remains unique and clearly indicates the validity of the approach: for every missing SiO_2 group, two water molecules can be docked in the CSH nanotexture – which is totally meaningful in terms of created volume accessible to water molecules based on a simple van der Waals radius argument. The use of the ReaxFF reactive force field further allowed some water molecules initially inserted in GCMC fashion to react and split into Ca-OH and Si-OH groups.

3.2 CSH at Large C/S Values: The Nano-portlandite Hypothesis and the Fate of Silica Monomers

Another very interesting point coming out of the texture analysis of the CSH models across the range of C/S values is that CSH's density increases as the C/S ratio increases, which was thoroughly confirmed by synchrotron scattering experiments (Soyer-Uzun et al. 2012). Interestingly, recent molecular simulations based on reactive interatomic potentials of tobermorite crystals doped with $Ca(OH)_2$ moieties contradict these experiments, hence disqualifying the "nano-portlandite hypothesis" that was put forward in order to account for CSH at the large C/S values in the T-J model of Richardson (Richardson 2004). We now focus on analyzing the fate of silica chunks in the nanoscale models of CSH across the span of C/S values. As shown in Fig. 2c of Ref. (Qomi et al. 2014a), the evolution of the silica mean chain length is well accounted for in the simulated models. Despite all prediction of the CSH models across the range of C/S values, the approach was highly criticized, in particular concerning the large number of silica monomers present at large C/S values, apparently contradicting the commonly accepted belief that Q^0 monomers were remains of hydrated clinker grains and that CSH only contains silica dimers, pentamers, and octamers. Figure 8 presents the average number of Q^0 (monomer) for a given family of CSH models at fixed C/S value as a function of the C/S ratio. There is a sharp transition at C/S = 1.5 where this number jumps from 3 +/− 1% to 14 +/− 2%. When convoluting this curve with the experimental C/S distribution, one obtains an average value of the number of monomers of around 6 ± 1%. This value is in very good agreement with the recent high-resolution NMR work of d'Espinose et al. (Pustovgar et al. 2016), who were able to quantity Q^0 fraction in CSH to be at 5 ± 2%. This confirms that silica monomers can exist in CSH up to some large amount and can be stable due to O-H covalent and/or O-Ca ionic bonds. Interestingly, the Si-O and Ca-O pair distribution functions for the CSH models at large C/S value are characteristic of oxide glasses, while at low C/S value, these are close to that found in crystalline tobermorite (Qomi et al. 2014a; Bauchy 2014; Bauchy et al. 2014b, c). The overall picture that emerges is that, at the nanoscale, CSH is a collection (of grains) of different chemistry (measured by the local
Fig. 8 The number of Q_0 as a function of Ca/Si ratio in CSH models

C/S ratio) – each grain having a structure reminiscent of layered tobermorite that gets more and more defective and hydrated as C/S increases locally inducing glassy atomic arrangements (Abdolhosseini Qomi et al. 2014a; Bauchy et al. 2014c). The transition between ordered and glassy was identified at C/S = 1.5 (Qomi et al. 2014a).

3.3   Anomalous Behavior of Confined Water in CSH

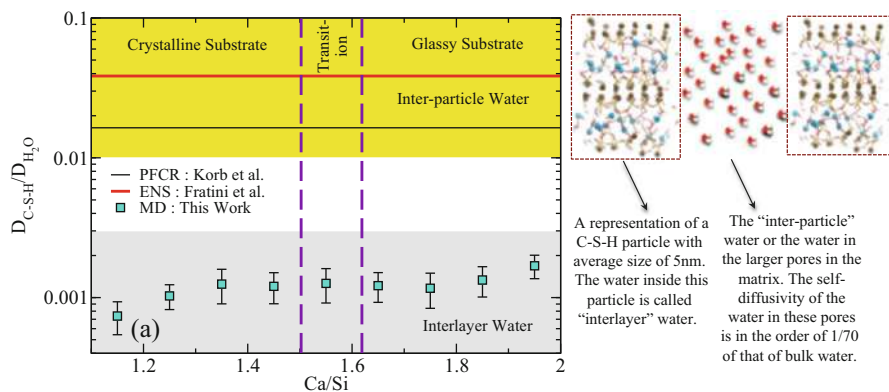
Despite the multidisciplinary interests in understanding water in confined geometries, our knowledge in the field of interfacial properties of water in such extreme confining conditions is still in a fledgling state. This is important as the confinement size and pore geometry directly affect the chemo-physical properties of water, e.g., a shift in dipole moment, hydrogen bonding, and transport properties – which are significantly different from those of bulk water. Equilibrium molecular dynamic (MD) simulations were performed on the 150+ models of CSH samples with the goal of understanding the structure and mobility of unreacted interlayer water molecules using the CSH-FF potential (Shahsavari et al. 2011) as it reproduces the structure and mechanics of CSH at varying stoichiometry. It was found that the mobility of water strongly depends on composition; namely, it increases with increasing C/S ratio by up to one order of magnitude (Fig. 9). However, over the whole range of C/S ratio values, the diffusivity of mobile water remains about 1/1000th of the bulk water. The increase in the probability of escaping the


Fig. 9 The self-diffusivity of water in the CSH structure. The self-diffusivity of water in the interlayer of CSH increases with increasing Ca/Si ratio. The diffusion coefficient of the nanoconfined interlayer water is three orders of magnitude less than that of bulk water (Qomi et al. 2014). The nanoconfined self-diffusivity of water is 70 times larger than those measured for CSH by Korb et al. (2007a) and Fratini et al. (2013)

dynamical cage with increasing C/S ratio physically explains the composition-dependent mobility in relation to the amount of protruding silica groups in the interlayer spacing of CSH. This brings forward the notion of "pocket-like," "patch-like," and "in-channel" diffusion at low, medium, and high C/S ratios, respectively.

The strong interaction with the CSH hydrophilic surfaces and their sub-nanometric defective texture reduces the self-diffusivity of mobile water molecules. Furthermore, the self-diffusivity of water in the interlayer is roughly ten times smaller than that observed in elastic neutron scattering and proton field-cycling relaxometry experiments, which both only probe the dynamics of water in CSH's mesopores. Hence, these experiments are not yet addressing the water dynamics inside the nanotexture of CSH. Finally, a correlation was found between the structural and dynamical properties, which arise from the anomalous behavior of water under pressure. Similar to the anomalous behavior of bulk water, the self-diffusivity of water in the nanotexture of CSH increases with the density. The confined water in CSH was shown to have higher self-diffusivity due to an increase in the escaping probability from the dynamical cage through reduction of diffusion energy barriers.

The consistent picture that emerges from these studies is that molecular water confined in the nanotexture of CSH is really part of the structure and does not behave at all as liquid water: water molecules vibrate around almost fixed interlayer calcium ion and show very limited translational diffusion. This translates into an anomalous diffusive behavior and very small value of the associated dielectric constant, even affecting the water dipole moment. Spanning across the data bank of atomistic models of CSH, it became clear that molecular water goes through

a hopping mechanism (from interlayer calcium ion to the next) with increasing self-diffusivity constant with increasing C/S values. However, these diffusivity constants remain 1000 less than that of bulk water. Obviously, this almost non-diffusive water does not arrange as ice. Interestingly enough, Korb et al. (2007a, b) measured a self-diffusivity constant for water molecules at the surface of the CSH grains defining capillary pores that is 60 less than that of the bulk. Therefore, it does totally make sense to find even lower self-diffusivity constant for water inside CSH grains. Recently, Morshedifard et al. showed that the non-asymptotic long-term deformation of creep, i.e., the so-called logarithmic creep, originates from increasing nanoconfined water content between the CSH layers (Morshedifard et al. 2018). They demonstrated that the viscoelastic deformation in CSH transitions to logarithmic creep by increasing the lubrication effect on adjacent CSH layers. This places a critical emphasis on the role of nanoconfined water on the durability of cementitious materials.

3.4 Thermal Properties of Cement Paste from the Nano- to the Macroscale

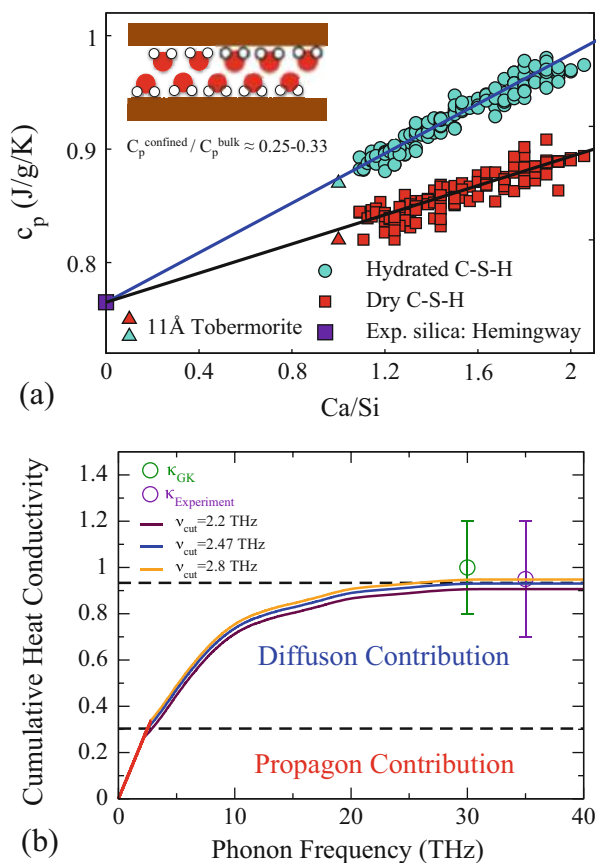
Having a set of realistic structure of CSH, Qomi et al. studied the thermal properties of cement paste via a multiscale bottom-up approach, starting from the nanoscale by calculating properties of individual constituent phases and connecting them to macroscale properties using mean-field homogenization theories (Qomi et al. 2015). At the nanoscale, the phonon density of states of CSHs, CH, β-C_2S, and C_3S and the components' atomic contributions were studied, and it was found that analogous to glassy materials, CSH exhibits excess vibrational states characterized by the boson peak at the low-frequency region. The position of the boson peak shifts to higher frequencies with increasing CSH density or, equivalently, by decreasing the C/S ratio. The specific heat capacity of dry and saturated CSH models increases linearly with the C/S ratio; see Fig. 10a. The apparent heat capacity of nanoconfined water in the interlayer spacing of CSH is determined to be significantly lower than that of bulk water at room temperature due to strong interaction with the calcium-silicate substrate. The thermal-conductivity tensor individual phases using the Green-Kubo relation were calculated and shown to be close to that of silica glass. The cumulative model thermal conductivity measurements are close to that of molecular dynamics and those back-calculated from the experiment (Zhou et al. 2017). Due to the glassy nature of CSH, only 30% of the total heat conduction stems from the phonon-like vibrational modes called propagans. The rest of the 70% heat conduction is carried out via the diffusive vibrational modes; see Fig. 10b. Furthermore, it was demonstrated that the variation of the macroscopic heat capacity of cement paste in terms of the hydration degree using mixture rules. The macroscopic heat capacity and thermal conductivity values predicted via our multiscale bottom-up approach were shown to be in good quantitative agreement with experiments.


Fig. 10 Thermal properties of CSH. (**a**) The heat capacity of CSH increases linearly with Ca/Si ratio (Qomi et al. 2015). (**b**) The cumulative thermal conductivity of CSH at Ca/Si = 1.7, which is close to that of molecular dynamics and those back-calculated from the experiment (Zhou et al. 2017)

3.5   Topological Constraint Theory

Concrete's mechanical properties are mostly controlled by the mechanical properties of its binding "glue," the CSH phase. However, the complex atomic structure of CSH makes it challenging to reveal the relationship between CSH's composition and its nanoscale mechanical properties. This lack of knowledge has likely severely limited our potential to significantly improve the mechanical properties of CSH. This is an account of the fact that CSH can exhibit a virtually infinite number of possible compositions (e.g., with varying C/S ratio) and that even small variations in its composition can drastically alter the properties of CSH as shown here above.

To this end, recent progress in glass science has recently resulted in some new insights into the relationship between CSH's atomic composition/structure and its

engineering properties. This analogy with glass science is based on the observation that cementitious materials and structural glasses share many similarities: (i) they are largely disordered, (ii) they exhibit fairly similar compositions (e.g., SiO_2, Al_2O_3, CaO, Na_2O, etc.), (iii) they are out-of-equilibrium (i.e., they "relax" toward a more stable state of energy over time), and (iv) they can present a virtually infinite number of possible compositions (i.e., unlike crystals, they do not have to satisfy any stoichiometry rules). Over the past decade, significant efforts have been devoted by the glass industry to nano-engineer novel glasses featuring optimized properties, especially to stimulate the development of fracture- and scratch-resistant glasses used as smartphone protective screens (Mauro et al. 2013).

In particular, topological constraint theory (TCT) has emerged as a powerful technique to predict the engineering properties of glasses based on their composition (Bauchy 2012; Mauro 2011; Phillips 1979). The idea of TCT is to reduce the complex, disordered structure of glasses into simple mechanical trusses, wherein nodes (the atoms) are connected to each other by some mechanical constraints (the chemical bonds). In atomic networks, such constraints comprise (i) the radial bond-stretching constraints, which maintain the bond length fixed around their average values, and (ii) the angular bond-bending constraints – which govern the interatomic angles. As such, TCT captures the important atomic topology that has a first-order impact on their macroscopic properties while filtering out less relevant structural details (Smedskjaer et al. 2010). In analogy with the stability of mechanical trusses, atomic networks can then be classified as flexible, stressed-rigid, or isostatic when the network of topological constraints per atom (n_c) is smaller, larger, or equal to three (i.e., the number of degrees of freedom per atom in 3D), respectively (see Fig. 11). Importantly, TCT was successfully used to predict the optimal composition of Corning® Gorilla® glass, which is now used on billions of smartphones and tablets around the world (Ball 2015).

3.6 Composition-Property Relationships in CSH

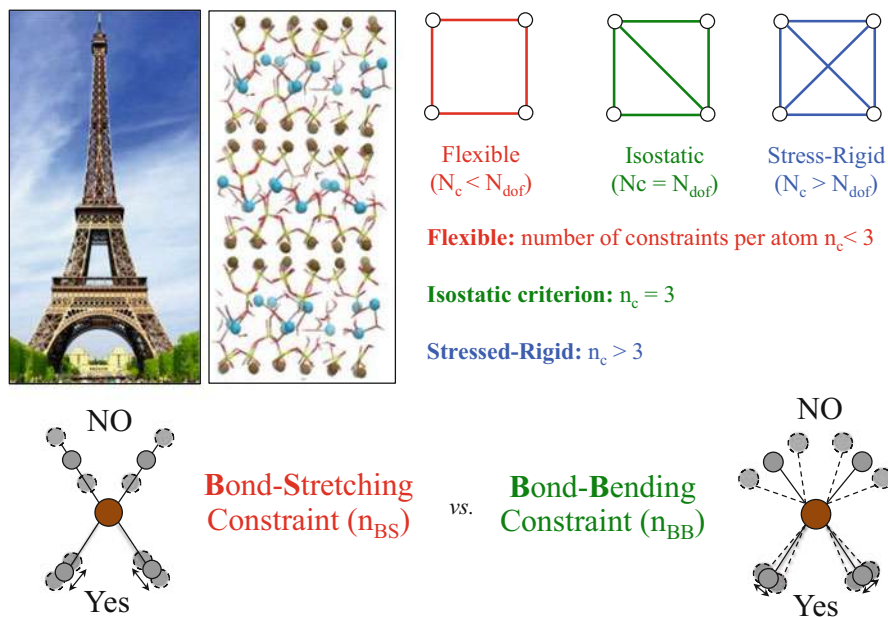
Recently, for the first time, TCT was applied to CSH to rationalize the relationship between its composition and properties. The rigidity state of CSH systems of varying compositions was identified by reactive molecular dynamic simulations (Bauchy et al. 2014a, 2015) using a well-established method (Bauchy et al. 2011; Bauchy and Micoulaut 2011). CSH was found to be flexible ($n_c < 3$) and stressed-rigid ($n_c > 3$) for Ca-rich and Si-rich compositions, respectively (see Fig. 12). These regions effectively delimit a series of optimally constrained ($n_c = 3$) CSH samples (gray region in Fig. 12). The knowledge of the topology of the atomic network of CSH was used to predict its hardness, in the very same fashion as the hardness of aluminosilicate glasses was predicted while designing Gorilla® glass (Bauchy et al. 2015; Smedskjaer et al. 2010; Zheng et al. 2017). The hardness was calculated using the new approach proposed by Qomi et al. by applying biaxial deformation to the molecular structure (Qomi et al. 2017). It was found that the hardness of CSH scales linearly with the number of angular bond-bending


Fig. 11 The notion of topological constraint theory. In this approach, the molecular structure of CSH is analyzed to that of trusses in structural analysis. The three states of rigidity of a mechanical truss, i.e., flexible, isostatic, and stressed-rigid. We also show an illustration of bond-stretching and bond-bending constraints
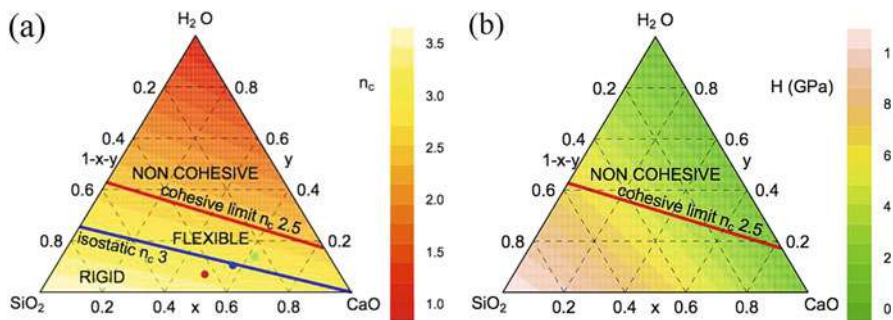
Fig. 12 Number of constraints per atom (n_c) in CSH as a function of the Ca/Si molar ratio. The gray area indicates the extent of the isostatic domain ($n_c = 3$). The inset shows the number of bond-stretching (BS) and bond-bending (BB) constraints per atom as a function of the Ca/Si molar ratio


Fig. 13 Ternary diagram showing the compositional dependence of (**a**) the number of constraints per atom and (**b**) the indentation hardness

constraints per atom (Bauchy et al. 2015). Based on this knowledge, the ternary map of CSH hardness was predicted (see Fig. 13). All the predictions were validated by nanoindentation tests. This ternary map of hardness can be used to pinpoint promising CSH compositions exhibiting targeted hardness values (see Fig. 13). Altogether, by simplifying the complex atomic network of CSH, TCT can be used to analytically predict composition-property relationships in CSH. This approach can be used to identify in silico promising CSH compositions that feature desired engineering properties.

3.7   Optimal Properties of Isostatic CSH Compositions

When analyzing the 150+ models of CSH spanning the range of possible C/S values through the prism of the so-called rigidity theory, it was striking to realize that the C/S = 1.5 composition was the turning point from stressed-rigid (at C/S >1.5) to floppy/flexible configurations (at C/S <1.5), that is, the composition threshold at which CSH exhibits a crystalline-to-glassy transition (see above). Due to its isostatic character, the particular composition at C/S = 1.5 is rigid but free of any internal stress (Bauchy et al. 2015). Based on previous observations regarding isostatic glasses, these compositions are expected to show optimal properties. Importantly, it has been shown that isostatic glasses (i.e., $n_c = 3$) feature (i) an optimal space-filling tendency, (ii) a minimum propensity for aging, and (iii) a maximum resistance to fracture (Boolchand et al. 2001; Varshneya and Mauro 2007). This is significant as, despite obvious advantages (low cost, ease of use, etc.), concrete's main drawback lies in the fact that it can break or creep over time.

As mentioned above, CSH was found to be isostatic (optimally constrained, $n_c = 3$) for Ca/Si =1.5. This isostatic state is obtained when the atomic is fully rigid (i.e., no internal modes of deformation) but free of any eigenstress (i.e., no mutually dependent constraints). Interestingly, it was observed that isostatic CSH samples exhibit maximum fracture toughness (see Fig. 14) (Bauchy et al. 2016).

Fig. 14 Computed fracture toughness of CSH as a function of the number of constraints per atom. The gray area indicates the range of composition for which CSH shows an isostatic character
This was shown to arise from the facts that flexible CSH samples ($n_c < 3$) exhibit low surface energy values, which makes them poorly cohesive, whereas stressed-rigid CSH samples ($n_c > 3$) show high brittleness since the high atomic connectivity prevents any local reorganization of the atoms to release stress. In contrast, isostatic CSH samples ($n_c = 3$) present the best compromise between cohesion and ability to show local plastic deformations and, hence, feature maximum fracture toughness (in line with what is observed for structural glasses).

In addition, isostatic CSH samples were also found to exhibit maximum resistance to long-term relaxation deformations (Bauchy et al. 2017; Pignatelli et al. 2016). This was explained by the facts that flexible atomic networks present some internal modes of deformation, which facilitate the activation of low-energy modes of relaxation upon loading. On the contrary, stressed-rigid systems are free of such floppy modes but present some internal eigenstress, which acts as a driving force stimulating relaxation (i.e., to achieve a more stable configuration that is free of any internal stress). Isostatic CSH compositions were also found to exhibit unusual thermal properties, dissolution kinetics, and resistance to irradiation (Krishnan et al. 2016, 2017; Pignatelli et al. 2016). Altogether, these results support the idea that CSH might behaves as a conventional silicate glass.

4   Conclusion

Overall, these results offer a self-consistent description of concrete at different scales: (i) electronic scale (DFT simulations), (ii) atomic scale (classical and reactive molecular dynamic simulations), (iii) colloidal scale (mesoscale simulations), and (iv) continuum scale (i.e., the scale that is accessible to experiments). Various upscaling techniques (e.g., "potential of mean force") or theories (e.g., topological

constraint theory) can now be used to seamlessly connect one scale to the next – by capturing the essential feature of a given scale and modeling it as a reduced-dimensionality input for the next scale. This approach offers a complete bottom-up description of calcium-silicate-hydrate – from electrons to continuum – with no adjustable parameters. We expect these models to facilitate the optimization of existing cementitious binders and accelerate the discovery of novel formulations with drastically improved properties. Altogether, these results also exemplify how a synergetic combination of experiments, simulations, and theoretical models – which mutually feed into and advance each other – can unlock the "genome" of concrete, that is, by identifying and deciphering how the basic structural building blocks of its atomic structure control its macroscopic properties. This effort also largely benefited from advances offered by various fields, including material science, condensed matter, statistical physics, and chemistry. Such an interdisciplinary is critically needed to solve the "material problems" facing the civil engineering community – a field that had largely relied on empiricism-driven routes in the past.

Abstract

Translating the insight gained through numerical simulations of microscopic models into information and predictions useful for engineering applications is a formidable task for complex and amorphous materials. Here we propose a strategy that builds on distinct dedicated approaches at different length scales and transfers the relevant information across them, to bridge from an atomistic description to a mesoscale mechanical model. We provide an overview of the fundamental concepts that underlie such strategy and two examples for engineering-relevant materials such as clays and cement hydrates.

1   Introduction

Novel breakthroughs in engineering materials depend crucially on understanding the microscopic physical processes underlying the development of amorphous structures and the related complex mechanical response. Being able to explain material properties in terms of their atomic structure is the ultimate goal for a mature branch of materials science, but it is far from being reached for amorphous materials: the mechanical properties of crystalline alloys are well understood in terms of microscopic heterogeneities in their structure – dislocations, grain boundaries, and interstitials – but an equivalent picture is lacking for amorphous materials. Translating the insight gained through microscopic models into information and predictions useful for engineering applications is therefore a formidable task. The idea that bridging the wide range of length scales involved can be achieved just by extending first-principle calculations over increasingly large samples, thanks to the continuum increase in power and capacity of computational resources, is far too simplistic and set to fail. The conundrum, in fact, is not to compute atomistic trajectories but rather to identify and disentangle distinct dynamical and mechanical processes that emerge at different length scales, depending on the complexity of the material structure. Solving this problem requires constructing models and analysis tools that unravel the fundamental physical mechanisms at the different relevant lengthscales, and devise the right strategy to pass the information across scales. For engineering applications, the ultimate challenge is to use the knowledge obtained at the microscopic level to formulate mesoscopic constitutive models that allow to predict the material behavior at engineering-relevant scales.

2   From Atomistic Approaches to the Potential of Mean Force: The Case of Cement Hydrates and Clays

Clay-based soils and cementitious materials have enormous practical relevance and implications for sustainable industrial technologies. The mechanics of clay-hydrates and calcium-silicate-hydrates (the main binding phase in cement), together with its evolution with changes in the physicochemical environment, is one of

the outstanding questions to control and design durability and sustainability of materials in civil engineering. Even at the atomistic level, those solids are extremely complex and require sophisticated models to capture their subnanoscale structure (Pellenq et al. 1997, 2009). In particular, the mechanics emerges from the mesoscale organization of nanoscale (colloidal) units, whose cohesion, in turn, is the results of subnanoscale effective interactions. Hence the most useful information to be extracted from the atomistic description of the material is the cohesion between the nanoscale units, which can be then translated into effective interactions for a model that describes their aggregation and phase behavior. From the atomic structure of a specific material, one can in fact derive the free energy function representing the effective interactions over a given length scale (the *Potential of Mean Force* or PMF). The PMF is the key piece of information needed in a coarse-grained description of the physical chemistry of a material and offers huge computational and modeling advantages as it allows for the upscaling of models and computational approaches with the possibility to retain the essential physicochemical processes of interest (Doi 2013; Frenkel and Smit 2001; Kumar et al. 1992; Pellenq et al. 1997; Bonnaud et al. 2016; Ioannidou et al. 2017a).

For both clay-hydrates and calcium-silicate-hydrates (at early stages of the hydration, where ions and small aggregates are still quite mobile in solution), the cohesion between the nanoscale units can be rationalized as the result of the net interactions between charged surfaces separated by a solvent containing counterions (Carrier 2013). This problem has been solved analytically, in certain conditions, by the DLVO theory that describes the combination of the repulsive electrical double-layer interaction (due to the accumulation of the counterions close to the charged surfaces) with the attractive van der Waals interactions (Israelachvili 1992). Within the DLVO theory, the analytical form of the repulsive electrostatic interactions is obtained by solving the Poisson-Boltzmann equation for a system made of positive point charges between negatively charged surfaces with the well-framed classical density functional theory approach. Designed for point charges, it is a mean-field approach that ignores the correlations in the fluctuations of the ionic positions. Making use of the Poisson-Boltzmann equation, the electrostatic pressure P (i.e., the force per unit area, or the derivative of the PMF with respect to the distance) between two charged surfaces as a function of the surface separation D is given by

$$P(D) = k_B T [C_{\texttt{ion}}(D/2) - C_{\texttt{ion}}(\infty)] \tag{1}$$

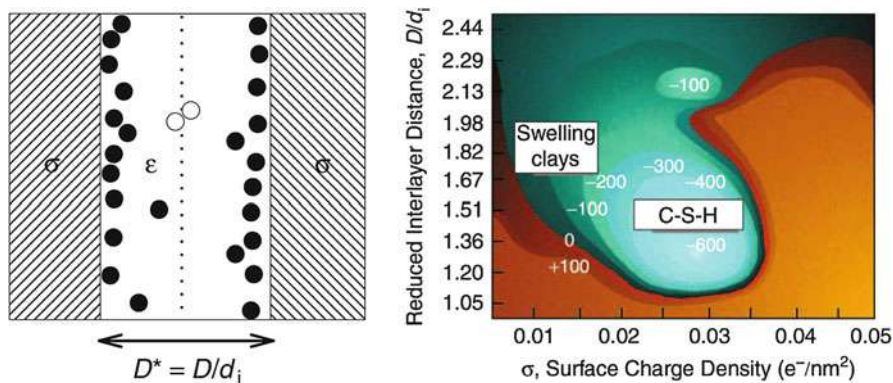
where k_B is the Boltzmann constant, T is the temperature, and $C_{\texttt{ion}}(D/2)$ is the cation concentration at the mid-separation. The PMF is simply the integral form of the pressure curve (typically integrated along the direction orthogonal to the two surfaces). This pressure depends only on the increase of the ionic concentration in the gap between the two surfaces, and its origin is the entropic contribution of an ideal gas of ions to the total stress (Israelachvili 1992). However, counterion fluctuations between charged surfaces can be affected by strong correlations that provide non-negligible contributions to the stresses on the surfaces: these are the so-called ionic correlation forces (ICFs) which can be strongly attractive even between


Fig. 1 Schematics and results of the primitive model (PM) from (Pellenq and Van Damme 2004). Left: Scheme showing the two uniformly charged walls separated by a dielectric continuum in which hydrated counterions are free to move. D is the interlayer separation and d is the ion diameter. equally charged surfaces and are not accounted for by DLVO theory (Pellenq et al. 1997, 2008; Pellenq and Van Damme 2004). ICFs can be computed numerically: in the primitive model (PM) introduced in the 1980s, the charged plane surfaces and the hydrated cations are represented by uniformly charged, infinite, and structureless planar surfaces and by charged hard spheres, respectively, while the solvent is represented by a dielectric continuum (see Fig. 1(a)). Monte Carlo simulations of PM have shown that fluctuations of the ionic concentration in the interlayer space result in an instantaneous polarization and can give rise to attractive ICFs. In particular, ICFs can become strongly attractive for divalent or trivalent cations, since in those cases, the attractive energetic contribution can exceed the repulsive entropic fluctuations by much. In the case of calcium counterions, present both in clays and calcium-silicate-hydrates, strong attractive pressures can be obtained at separations <10 Å (see Fig. 1(b)).

The primitive model has obviously its own limitations. The surfaces of the slit pore are assumed to be flat and uniformly charged; the ions are supposed to be fully hydrated and mobile; and the solvent is considered to be a dielectric continuum (typically the dielectric constant of bulk water would be used for clay or C–S–H). These hypotheses make the primitive model questionable in particular at small surface separations. In this case, the molecular structures of the solvent and the surfaces need to be taken into account to properly describe the emerging interactions. For weak electrostatic coupling conditions, corresponding, for instance, to sodium-based clays, it has been shown that the modification of PM to include the solvent explicitly (rather than through the bulk dielectric properties) leads to significant changes with respect to earlier findings, since the distribution of the ionic cloud of counterions cannot be properly described by the

Poisson-Boltzmann equation (Carrier 2013; Israelachvili 1992; Pellenq et al. 1997, 2008; Pellenq and Van Damme 2004). In the case of calcium-silicate-hydrates, to compensate the strong surface charge of C–S–H surfaces – on the order of one electron charge per 0.35 nm^2 for fully ionized C–S–H – Ca^{2+} counterions tend to accumulate even more in the vicinity of the surface. The two characteristics of strongly charged surfaces and divalent counterions make the interactions between C–S–H nanoscale units qualitatively different from clays and other weakly (or less strongly) interacting colloidal systems (Pellenq and Van Damme 2004). Overall, the basic picture that emerges from taking into account ionic positional correlations (with possibly an explicit description of the solvent if one wants to predict colloid cohesion quantitatively) is that the excess of counterions near a charged surface may be correlated with a deficit of counterions in the opposite same-charge surface, giving rise to net attractive ion-ion correlation forces. Such correlated density fluctuations of the ions lead to an attractive force in the same way as correlations between instantaneous electronic dipoles (due to the quantum fluctuations of the electron density around two argon atoms) give rise to London dispersion forces (Israelachvili 1992).

The possible attraction between two similarly charged surfaces immersed in an electrolyte has been explored within the theory of equilibrium electric double layer, where two regimes can be distinguished (Attard 1996): an attractive regime that occurs at small separation distances and in the presence of multivalent ions, where the forces change from repulsive to attractive as the surface charge and pH increase, and a second regime occurring at larger separations, where especially in case of multivalent ions the force can be alternately attractive or repulsive depending on the electrostatic coupling. The result is an effective interaction potential that can feature multiple minima separated by repulsive barriers. In the case of clays, the PMF can exhibit up to 3 minima corresponding to different water contents (Ebrahimi et al. 2012). When used in coarse-grained simulations of clay-platelets (Na-laponite) and parametrized with a Gay-Berne potential, the PMF obtained from atomistic calculations of the free energy of two Na-smectite clay-platelets in liquid water provided crucial information on the morphology of mesoscale aggregates and on mechanical properties of large particle assemblies, in good agreement with measurements in conventional 1D laboratory compression tests and nano-indentation measurements on natural clays and shale samples (Ebrahimi et al. 2014). In the case of C–S–H, the presence of a deep minimum and a repulsive barrier in the PMF, whose (respectively) depth and height change with increasing pH during cement hydration, was suggested by experiments (Garrault et al. 2005; Lesko et al. 2001) and supported by recent atomistic calculations (Bonnaud et al. 2016). Using such information from the PMF in a non-equilibrium molecular dynamics approach has allowed for novel insight into gelation and densification of cement hydrates (Ioannidou et al. 2014; Del Gado et al. 2014): the evolution of the PMF could be, in fact, responsible for the morphological changes of cement gels during hydration that are instrumental to reach the high density and mechanical strength needed for their technological function (Ioannidou et al. 2016a). Furthermore, the approach devised for C–S–H and based on PMF has proven able to provide quantitative

new understanding of mechanical and hygrothermal properties of cement gels, rationalizing experimental findings so far considered contradictory and opening the way to advanced material design (Ioannidou et al. 2016b, 2017b).

As stated above, the PMF-based approaches just described provided new opportunities to bridge the mesoscale features of those complex amorphous materials with the engineering-scale description. Recently, PMF-based lattice approaches have also been proposed, to capture the effective mechanical behavior of heterogeneous materials, using harmonic interactions inspired from beam-type stretch and bending interactions between a discrete set of mass points (Laubie et al. 2017). While traditional engineering approaches defined those interactions employing standard mechanical elements (Dormieux et al. 2006), such lattice approaches have clearly more to offer when set in the context of effective potentials. Closed-form calibration procedures for such interaction potentials can be derived for both the isotropic and the transverse isotropic elastic cases on cubic lattices, in the form of linear relations between effective elasticity properties and energy parameters that define the interactions. This framework provides a means to set methods based on lattice discretization of heterogeneous materials onto a path toward modeling the actual physics interactions between phases, within the limits defined by the geometric discretization of regular or irregular lattices.

3   Coarse-Grained Models and Microscopic Insight of Dynamical Processes

The effective interactions discussed above in terms of the PMF constitute the essential basic ingredients to investigate structure formation and kinetic arrest occurring in the amorphous solidification of materials on length scales much larger than the atomistic one. Those effective interactions can provide the basis to investigate the emerging mechanics and the rheology of such materials, using coarse-grained microscopic models and simulations that include fundamental features of specific materials (or class of materials) while simplifying the atomistic description. Such models and simulations allow for the large-scale numerical studies needed to unravel the connection between nanoscale structure and dynamics and the response on much larger length scales and timescales, typically relevant for engineering applications.

A coarse-grained microscopic model usually describes the material in terms of the nanoscale units (particles), their positions $\{\mathbf{r}_i\}$, and their collective interaction energy $U(\{\mathbf{r}_i\})$ (i.e., the result of the PMF). Such model can be used in molecular dynamics (MD) simulations, by integrating Newton, Brownian, or damped equations of motion to compute particle trajectories and velocities, forces and stresses, as well as the response to an externally imposed stress or deformation rate (Frenkel and Smit 2001; Allen and Tildesley 1987; Morriss and Evans 2013). Different types of degrees of freedom can be included in this type of description to account for the local anisotropy of the structural domains (or particle shapes) and of the interactions. They can also be added successively allowing for studies in which one can gradually investigate different degrees of complexity in the material description. All material-specific information are contained in the shape of $U(\{\mathbf{r}_i\})$ and in the

specific type of equations of motion that are chosen for a prescribed problem. The relative simplicity of such schemes allow for tackling the intrinsically many-body nature of the emerging mechanics and for using statistical mechanics to develop a bottom-up description of the macroscopic material properties.

Even when modeling the material simply as an assembly of point-like particles with U depending only on their relative distances, the variety of shapes of the effective interactions that emerge from surface forces and electrostatics between colloidal units in solution allows for a relatively wide variety of equilibrium and non-equilibrium microstructures. Hence, a variety of microstructural and mechanical heterogeneities in complex materials. Figure 2 shows some examples from different numerical studies, using effective interactions that can be derived from the PMF approach described in Sect. 2. The examples range from complex porous gel structures that result from competing short-range attraction and longer-range electrostatic repulsion (de Candia et al. 2006; Zhuang et al. 2016; Ioannidou et al. 2014, 2016a) to more spatially homogeneous amorphous assemblies of repulsive particles, where the size polydispersity allows for introducing structural disorder and the pair interaction strengths can be made size-dependent to account for local mechanical heterogeneities in the microstructure (Masoero et al. 2012, 2014).

3.1 Spatiotemporal Correlations and Non-affine Motion

From the single-particle trajectories obtained in the simulations just described, one can compute the spatiotemporal fluctuations of the microscopic dynamics, to quantify cooperative processes, and of the microscopic stresses, to analyze the role of related heterogeneities in the overall mechanical response. A space-

resolved analysis of the cooperativity of the microscopic dynamics can be obtained through an isoconfigurational analysis of particle trajectories (Widmer-Cooper and Harrowell 2007; Widmer-Cooper et al. 2009). Such approach, initially introduced to investigate dynamical heterogeneities in dense supercooled liquids, consists in generating an ensemble of MD trajectories from the same initial microscopic con-figuration and different initial velocities drawn from the same Maxwell-Boltzmann distribution. The distribution of particle displacements over this ensemble, at a fixed time, allows us to detect which particles and which parts of the structure are more likely to undergo the most significant displacements, and hence to be responsible for the overall structural relaxation. Figure 3 (left) shows an example of the spatial distribution of the dynamical heterogeneity in a 2D glassy alloy, modeled as a binary mixture of disks interacting through a purely repulsive soft effective potential and obtained with this method (Mosayebi et al. 2014; Widmer-Cooper and Harrowell 2006; Widmer-Cooper et al. 2008). Here, the dynamical heterogeneity is quantified by calculating the local Debye-Waller factors (DWF) of each particle. The DWF of the ith particle is defined as the isoconfigurational average of the variance of its position during a fixed time interval t^*, $DWF_i = \langle\langle(\mathbf{r}_i(t) - \langle\mathbf{r}_i\rangle_{t^*})^2\rangle_{t^*}\rangle_{\mathrm{iso}}$. Such analysis can be extended to low density, soft materials such as particle gels, but needs to be suitably modified. In the model colloidal gel shown in Fig. 3 in fact, one needs to filter out the large-amplitude particle vibrations for a given configuration

of fixed interparticle bonds, since they are far bigger than the amplitude of the cage rattling in a dense system. The problem can be solved by associating to any given network configuration a reference configuration, computed by constraining the interparticle bonds not to break and evaluating the average position of each particle during a simulation at constant temperature of the same model (Colombo et al. 2013; Colombo and Del Gado 2014). The distribution of intrinsic displacements over such isoconfigurational ensemble at a fixed time quantifies, for each particle, its tendency to undergo a significant displacement, thus contributing to the cooperative network restructuring. In Fig. 3 (right), the thickness of the gel strands indicates the parts of the network where the displacements responsible for the cooperative restructuring take place. These large displacements originate in regions where the stress accumulation favors the breaking of the gel structure and tend to propagate along the network. Gels may indeed contain weaker regions (where local stresses are higher and breaking is more likely to occur), and the simulations indicate that the consequences of bond breaking are nonlocal, with cooperative displacements involving parts of the structure that are relatively far away, in regions where non-affine displacements are more likely to concentrate under deformation. The mesoscale organization of the gel network has therefore a significant role, favoring stress build-up and bond breaking in densely connected regions. The occurrence and the spatial distribution of the non-affine motion in amorphous materials under deformation provides indeed useful insight into the mechanical response.

3.2   Micromechanical Consequences

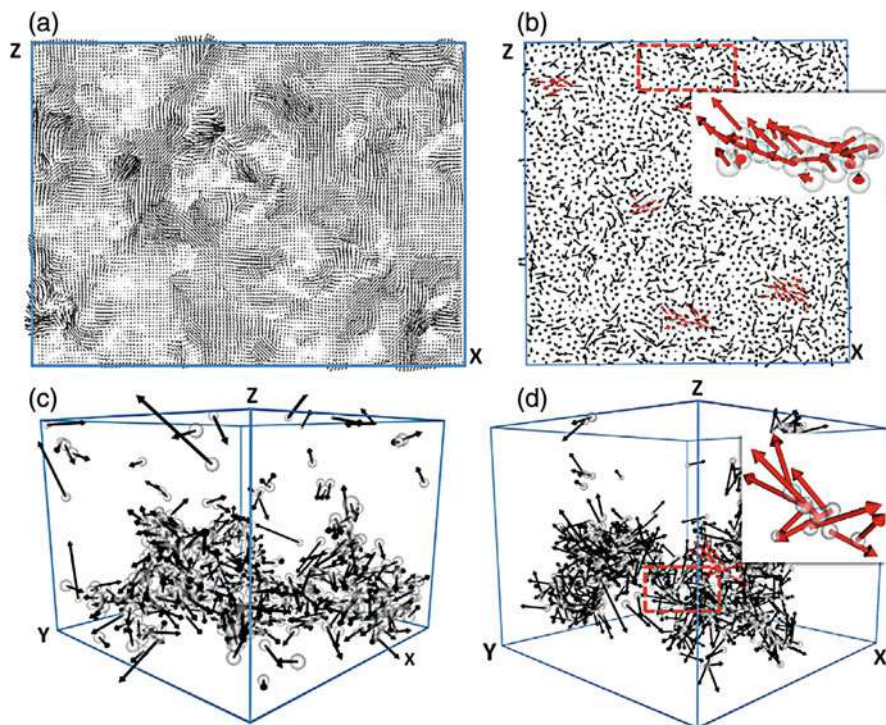
The spatiotemporal analysis of the microscopic dynamical processes just described can be also used to unravel the elementary non-affine rearrangements that can be at the origin of the material response to an external perturbation. Figure 4 shows the results of such spatiotemporal analysis in a 3D soft solid model that was sheared at constant rate (Vasisht et al. 2018). The analysis, in this case, is based on the spatial correlations of elementary microscopic rearrangements (EMR), which can be obtained from the local non-affine motion (computed subtracting the overall imposed flow). Interestingly enough, the EMR strongly depend on the deformation rate imposed to shear the material: the flow at high shear rates originates from a highly coordinated motion of small-particle clusters that move collectively in the same direction. Conversely, at low shear rates, the bulk flow emerges from non-affine rearrangements that take place over much larger correlated domains and trigger events later in time, due to the long-range elastic strain field of the initially solid amorphous material. The results of the simulations, in this case, have been directly tested in experiments that combine bulk rheology with confocal microscopy, as shown in the figure, where similar data on the non-affine motion and its spatiotemporal correlations can be obtained. The microscopic insights gained through the simulations suggest that the bulk rheological flow curve of the material can be associated to changes in the nature of the EMR. A quantitative analysis of the EMR indicates that the change in their spatiotemporal correlations may be at the


Fig. 4 Non-affine displacement maps for a compressed soft glassy material (experiments on the left and simulations using a coarse-grained model on the right in steady-state shear, respectively, at high rate (**a**) and low deformation rate (**b**). The arrows represent the non-affine displacement vectors. To highlight the localization of displacement vectors, the length of the vectors are amplified. Reproduced with permission from (Vasisht et al. 2018)

origin of the differences in the flow events when the material is sheared at different rates, in agreement with experiments. Recognizing the distinct and rate-dependent nature of the elementary excitations is a fundamental starting point for the development of microscopic theories and constitutive models. The microscopic quantitative information made available from coarse-grained simulations, on when and where local irreversible events are more likely to occur and non-affine displacements are localized, can then be incorporated into nonlocal constitutive models.

4   Toward Constitutive Models for Amorphous Materials

Connecting the different dynamical processes and their mechanical consequences to the emerging rheological properties is one of the crucial problems in the field. Figure 5 illustrates the challenge for the theoretical modeling posed by the largely different length and time scales. Is it possible to develop continuum
Fig. 5 Illustration of the multiscale problem of a sheared glass from the review of Rodney et al. (2011). (**a**) Localized plastic rearrangements from particle-based simulations (Tanguy et al. 2006). (**b**) Kinetic Monte Carlo simulations of a mesoscale model (Homer and Schuh 2009). (**c**) Constitutive law is used to simulate indentation with a finite element method (Su and Anand 2006)

equations starting from the underlying microscopic dynamics obtained from the approaches described in the previous sections? Usually when dealing with a large number of degrees of freedom with relatively simple local interactions, statistical mechanics is the tool of first choice to derive continuum descriptions by calculating ensemble averages. This technique usually allows to link directly all parameters in the continuum modeling to microscopic potential and dynamical parameters. However, in the case of driven glassy materials, we are dealing with strongly out-of-equilibrium dynamics in a complex potential energy landscape. Already the non-driven system might present out-of-equilibrium relaxation dynamics, also known as aging in glasses, and is as such nonstationary. The additional external forcing only adds to this complexity. Thus all standard tools from equilibrium statistical mechanics are not applicable, and the endeavor of starting from the whole set of microscopic degrees of freedom to derive macroscopic equations turns out to be a formidable if not impossible task.

4.1   Elastoplastic Models

To overcome these fundamental difficulties related to the complexity of the dynamics, a more phenomenological approach, known as elastoplastic modeling, has been proposed to bridge the gap between the different scales (for an extensive review, see Nicolas et al. 2018). Built upon ideas developed by Argon and Kuo 1979, who pioneered the understanding that macroscopic plastic deformation in dense disordered materials is induced by localized plastic events of a size of few particle diameters, models were proposed starting from the scale of the plastic regions (Bulatov and Argon 1994a, b; Baret et al. 2002), which implies an important coarse graining in space and in time. A dense particle assembly,

representing the amorphous solid, is divided into blocks of a size that is relevant to define a meaningful coarse-grained elastic modulus (Tsamados et al. 2009) together with fields of stress, elastic, and plastic deformation. This elastoplastic modeling approach depends crucially on the existence of localized plastic events, and the approach can thus only be valid in deeply jammed systems since close to unjamming dissipation mechanisms are known to become strongly nonlocal (Lerner et al. 2012).

An important ingredient of the elasto-plastic model is that an elastically deforming region in the material acquires a new reference configuration as a response to the external deformation, but also responding to the surrounding plastically deforming regions. This new configuration will differ from the original reference state by some *eigenstrain*. To simplify the problem further we will consider that the plastically deforming zones can be considered point-like at this coarse grained scale. In this limit only the far field response of the surrounding material to the locally deformed plastic inclusions can be considered. In the simplest formulation this response can be derived for a linear isotropic elastic medium, which is a good first order approximation of the complex problem. The mesoscopic model then involves the calculation of the elastic response of the surrounding medium to the forces that are exerted by the zones that have undergone a yield event. This calculation goes along the lines of a standard linear elasticity calculation, but we will omit the details of this technical point and we will give directly the final result that describes the response of the medium at point **r** to a yield event taking place at the origin using the propagator $\mathscr{G}$ given in Eq. 2.

Approximating the rearrangements corresponding to the local plastic events by a force quadrupole (Eshelby problem), one expects a four-fold quadrupolar symmetry for the inhomogeneous part of the stress propagator (Eshelby 1957) (see middle panel of Fig. 6). The form of this propagator for an infinite two dimensional medium reads in non-dimensional form

$$\mathscr{G}^{(\infty)}(r, \theta) = \frac{1}{\pi r^2} \cos(4\theta). \tag{2}$$

Elastic deformation   Plastic event   Stress redistribution
Fig. 6 Sketch of plastic deformation in amorphous media. Deformation occurs via elastic deformation, localized plastic events, and nonlocal redistribution of the elastic stress, potentially triggering other plastic events. (Reproduced with permission from Bocquet et al. 2009).

To model a yield stress material under steady shear with a fixed strain rate $\dot{\gamma}$, we start from a simple Maxwell-like description of the stress dynamics associated with a given element:

$$\partial_t \sigma(t) = \mu \dot{\gamma} - 2\mu \dot{\varepsilon}^{\text{pl}}(t) \tag{3}$$

where ∂_t denotes the partial time derivative, $\sigma(t)$ is the shear component of the stress tensor, μ is the shear modulus, and $\dot{\varepsilon}^{\text{pl}}(t)$ accounts for the change in the strain due to local yielding. To take into account the long-range effects of the plastic events, first predicted by Argon and Kuo (1979) and later evidenced in molecular dynamics simulations (Tanguy et al. 2006) and experiments on colloids (Schall et al. 2007), we change the above homogeneous equation to a field description with a stress propagator $G(\mathbf{r} - \mathbf{r}')$ accounting for the stress redistribution due to a plastic event:

$$\partial_t \sigma(\mathbf{r}, t) = \mu \dot{\gamma} + 2\mu \int d\mathbf{r}' \mathscr{G}(\mathbf{r} - \mathbf{r}') \dot{\varepsilon}^{\text{pl}}(\mathbf{r}', t) \tag{4}$$

To describe the deformation due to the plastic events, we model a Maxwellian viscoelastic-like relaxation of the material in the plastic state, i.e.,

$$\dot{\varepsilon}^{\text{pl}}(\mathbf{r}, t) = \frac{1}{2\mu\tau} n(\mathbf{r}, t) \sigma(\mathbf{r}, t), \tag{5}$$

where τ is the typical time for the stress release in the plastic phase and $n(\mathbf{r}, t)$ a local state variable. In the following, we refer to $n(\mathbf{r}, t)$ as local activity. We define $n(\mathbf{r}, t) = 0$ indicating the absence of a plastic event and $n(\mathbf{r}, t) = 1$ if the local region is in the plastic phase.

To incorporate the idea of a yield stress, we define the following stochastic dynamics for the state variable $n(\mathbf{r}, t)$ (see the left panel of Fig. 7). If the local stress exceeds a threshold value $\sigma(\mathbf{r}, t) > \sigma_y$, there is a finite probability to yield locally. The yielding rate is given by $1/\tau_{\text{pl}}$. Once yielded ($n(\mathbf{r}, t) = 1$), stress is redistributed using an appropriate stress propagator, and locally the stress is relaxing during a typical restructuring time τ_{el}. The rate to re-establish the elastic state ($n(\mathbf{r}, t) = 0$) is given by $1/\tau_{\text{el}}$. These dynamical rules are then discretized into a set of elastoplastic elements that occupy the nodes of a regular square lattice.

It has been shown that this very simplified cellular automata model for the mesoscopic elasto-plastic dynamics leads to many qualitative and semi-quantitative results, fitting the fluctuations and rheological measurements from experiments and microscopic simulations. Such cellular automata have been intensively studied in the framework of dynamical heterogeneities Martens et al. (2011) avalanche dynamics Talamali et al. (2011), shear-banding Martens et al. (2012), critical phenomena Lin et al. (2014) and transient creep dynamics Merabia and Detcheverry (2016), to name only few fields where they have been successfully used to understand the link between microscopic plasticity and the macroscopic mechanical response.
Fig. 7 Local stress dynamics. (**a**) Schematic representation of the local stress of an isolated site as a function of time. When the stress is larger than the thresholds, the site yields with a probability given by the plastic rate. While the site is active, the stress drops exponentially during a typical restructuring time until it becomes elastic again. The site is supposed to be isolated, to simplify the picture. In the completely connected model described in the main text, we would expect stress fluctuations due to the mechanical noise coming from the surrounding sites. (**b**) Stress change due to a single plastic event at the origin. The stress change at the origin is artificially set to zero to account for the visibility of the nearest neighbor changes. In reality the change at the origin is strongly negative. Reproduced with permission from (Martens et al. 2012). (**c**) Averaged displacement field caused by induced plastic events obtained from bidisperse Lennard-Jones particle simulations. Reproduced with permission from (Puosi et al. 2014)

4.2   Deriving Mean-Field Descriptions

The theoretical understanding of the yielding transition in athermally driven disordered systems is a highly challenging problem, and no consensus has been established even on the basic ingredients that should underlie coarse-grained descriptions of the nonlinear rheological response of yield stress materials (Sollich et al. 1997; Hébraud and Lequeux 1998; Falk and Langer 1998; Agoritsas et al. 2015; Lin and Wyart 2016).

A way to derive a phenomenological mean-field description from the above lattice model is to introduce the probability density $\mathscr{P}$ of local shear stresses $\sigma = \sigma_{xy}$ in regions of mesoscopic size W, while the material is sheared at rate $\dot{\gamma}$. The time evolution of $\mathscr{P}$ is given by

$$\partial_t \mathscr{P}(\sigma, t) = -G_0 \dot{\gamma}(t) \partial_\sigma \mathscr{P} - \frac{1}{\tau} \theta(|\sigma| - \sigma_c) \mathscr{P}$$
$$+ \Gamma(t)\delta(\sigma) + D(t)\partial_\sigma^2 \mathscr{P} \qquad (6)$$

where $\theta(x)$ and $\delta(x)$ denote, respectively, the usual Heaviside and delta distributions. The first term on the right-hand side proportional to the stress gradient of the probability density $\partial_\sigma \mathscr{P}$ accounts for the linear elastic response. The following term describes the loss in the probability density due to local yielding of overstressed regions above a critical stress σ_c at a rate given by $1/\tau$. It has been argued that the phenomenological parameter τ can be interpreted as the duration of a plastic event in the low shear rate limit (Agoritsas et al. 2015). The corresponding gain term is given in the third expression on the right-hand side, where the stress is set to zero after a yielding event with a rate given by the plastic activity rate

$$\Gamma(t) = \frac{1}{\tau} \int_{|\sigma|>\sigma_c} \mathscr{P}(\sigma, t)\mathrm{d}\sigma. \tag{7}$$

The last term encompasses the stress changes created through other yielding events in a mean-field manner, assuming that this mechanical noise can be approximated through a normal diffusion of the mesoscopic stresses. To describe this noise in a self-consistent manner, the HL approach (from Hébraud and Lequeux 1998) proposes that its amplitude should be related to the rate of plastic activity through a dimensionless coupling constant $\tilde{\alpha}$:

$$D(t) = \tilde{\alpha}\sigma_c^2 \Gamma(t). \tag{8}$$

This last relation introduces a nonlinearity into Eq. (6), since the rate of plastic activity itself depends on the probability density of the mesoscopic stresses. It is this coupling that renders the problem nontrivial and yields interesting results regarding the behavior of macroscopic quantities.

This model is known to exhibit a unique stationary state for a finite shear rate in the large time limit, where the probability density for the mesoscopic stresses becomes time independent. To determine the time-averaged macroscopic stress in the steady state, one averages over the mesoscopic stresses weighted by the corresponding steady-state probability density

$$\langle \sigma \rangle = \int \sigma \mathscr{P}(\sigma)\mathrm{d}\sigma. \tag{9}$$

Using appropriate units, we can write the equations in dimensionless quantities, expressing stress-related values in units of the local yield stress σ_c, time quantities in units of τ, the shear rate in units of $\sigma_c/(G_0\tau)$, and the stress diffusion coefficient in units of σ_c^2/τ, leaving only two independent dimensionless model parameters that determine the flow behavior, namely, the dimensionless shear rate and coupling constant $\tilde{\alpha}$.

The rheological results in the small shear rate limit for this model are well studied (Hébraud and Lequeux 1998; Olivier and Renardy 2011; Agoritsas and Martens 2017). For small enough coupling strength $\tilde{\alpha} < 1/2$, the HL model predicts a Herschel-Bulkley flow behavior of exponent $1/2$:

$$\langle \sigma \rangle \approx \sigma_Y + A\dot{\gamma}^{1/2}$$

for the time-averaged macroscopic stress in the steady state $\langle \sigma \rangle = \int \sigma \mathscr{P}(\sigma)\mathrm{d}\sigma$, with the two constants σ_Y (the dynamical yield stress) and A (the prefactor). Thus this very simplified model can already capture well the nonlinear behavior of the flow of yield stress materials. Moreover, it has also been shown that the typical transient dynamics during creep experiments can be qualitatively well reproduced using these modeling techniques (Liu et al. 2018).

5   Conclusions

The theoretical approach described in Sect. 4 captures many aspects of the complexity of the mechanics of amorphous solids and in particular their intrinsically nonlinear response. Particularly interesting to the discussion here is that, in principle, the more microscopic information obtained from the studies described in Sects. 2 and 3 can be included in such approach to bridge quantitatively the physics and physical chemistry of specific materials (Section 1) to the general theoretical formulation of their elastoplastic response (Section 4). While developments in this direction are still at a very early stage and far from being straightforward, a first remarkable example is shown in Fig. 7 (Puosi et al. 2014) which visualizes the averaged displacement field caused by induced plastic events obtained from a simple coarse-grained model for a glassy material, of the same type as the ones discussed in Sect. 3. The plot proves that the long-range strain field that is at the core of the elastoplastic modeling can be quantitatively obtained from a microscopic model. Along this line, various information on microscopic mechanical and dynamical heterogeneities, as described in Sects. 2 and 3, (and obtained through the approach described in Section 1), can be transferred into the parameters of the elastoplastic description (e.g., the distribution of local elastic moduli, local yield stresses, or characteristic relaxation times) to develop quantitative constitutive models that do not rely on ad hoc fitting parameters but truly bridge the relevant information over a dramatic range of length scales.

Nanomechanics of Materials: Overview

74

Ting Zhu and Dengke Chen

Contents

Abstract

Recent experiments on nanoscale and nanostructured materials, including nanowires, nanopillars, nanoparticles, nanocrystalline, and two-dimensional (2D) materials, have revealed a host of "ultra-strength" phenomena, defined by stresses in the material generally rising up to a significant fraction of the ideal strength – the highest achievable strength of a defect-free crystal.

Understanding the "ultra-strength" phenomena requires an in-depth study that integrates the nanomechanical experiment and modeling. Here we present an overview on the strength-controlling deformation mechanisms as well as the nanomechanical modeling studies for ultra-strength materials. The general concepts and principles are described, with a particular emphasis on the size, temperature, and strain-rate dependence of the ultra-strength phenomena. The chapters in this Part of the handbook are reviewed to highlight recent progress in the nanomechanical modeling of ultra-strength materials. Perspectives on the future study of nanomechanics of materials are discussed.

1   Introduction

An engineering revolution is currently under way in that small structures and devices are now being fabricated at the micrometer to nanometer scales. The reliability concerns of such small systems call for an understanding of the mechanical properties of materials at small length scales (Freund and Suresh 2003). This overview describes the general concepts and principles underlying the ultra-strength phenomena in materials with very small length scales. The chapters in this Part of the handbook are reviewed to highlight recent progress in the nanomechanical modeling of ultra-strength materials.

Ultra-strength phenomena are characterized by sample-wide stress levels reaching a significant fraction of the material's ideal strength, defined as the highest stress a perfect crystal can sustain without undergoing immediate structural transformation (Ogata et al. 2002, 2004; Li et al. 2007). There is an intimate relation between observable strength and the timescale of observation. It is difficult to avoid "observing" ultra-strength in molecular dynamics simulations because of the short simulation timescales, typically nanoseconds, for stress ramp-up. But in recent years, more and more ultra-strength behaviors are revealed in laboratory experiments, typically on the seconds-to-minutes timescale. This is often enabled by the small sample sizes, small microstructural length scales, or small probes.

1.1   Ultra-Strength Experiments

Recent years have seen rapid growth of experimental studies on ultra-strength material systems and phenomena. This is largely enabled by the refinement of nanoscale mechanical experiments, which allow one to study the near-ideal strength behavior quantitatively in a controlled fashion. Representative data of experimentally measured ultra strengths have been collected previously (Zhu et al. 2009). These data are either yield or fracture strengths measured from tension, compression, or bending experiments. Evidently, ultra-strength behavior can be considered as a GPa-level phenomenon, in contrast to the relatively low strengths (tens to hundreds of MPa) in coarse-grained hard materials.

1.2   Length-Scale Effect

The attainment of ultra strength can result from a length-scale effect. For coarse-grained crystals, the experimentally measured strengths are far below the theoretical values. The low strength arises because the sample usually has a large number of grown-in defects such as dislocations or cracks. In well-annealed crystals, the dislocation density is initially low but nonzero. It increases rapidly once deformation starts, due to, for example, double cross slip and Frank-Read-type multiplication processes. The yield strength is then limited by the resistance to dislocation motion, typically a factor of 100 below the ideal strength, or even more in coarse-grained samples.

The strength of materials with preexisting defects can be increased by reducing the characteristic length scales in materials. Generally, the strength-controlling length scale can be the sample size, grain size, layer thickness, or contact loading zone size. In crystals, the strengthening mechanism is typically based on the blockage or elimination of dislocations. Various detailed size-strengthening mechanisms will be reviewed later in this chapter.

1.3   Timescale Effect

Ultra-strength phenomena are also closely related to the observation timescale, as manifested by the dependence of strength on loading rate and temperature. To understand the strength, temperature, and timescale relationships, one needs to know the controlling deformation mechanism, which is the focus of this review. Then the kinetic rate theory can be used to link time and strength.

1.4   Rate Theory of Strength

A unit process of strength-controlling structural transformation can be characterized by two types of quantitative measures: the athermal strength limit and activation parameters. The former measures the zero-temperature structural stability limit at which the structural transformation occurs instantaneously without the aid of thermal fluctuations. The activation parameters, including activation energy and activation volume, characterize the probabilistic nature of transformation by thermal fluctuations when the applied load is below the athermal limit. Consider, as an example, thermally activated shear transformation at a given temperature T and applied shear stress τ. According to transition state theory (Vineyard 1957), the transformation rate is

$$\nu = N\nu_0 \exp\left(-\frac{Q(\tau, T)}{k_B T}\right) \tag{1}$$

where ν_0 is the trial frequency, N is the number of equivalent sites of transformation, $k_\mathrm{B}T$ is the thermal energy, and Q is the activation free energy whose magnitude is controlled by the local shear stress τ along with the temperature. The athermal strength limit corresponds to the critical stress, giving zero activation energy.

The sensitivity of transformation rate to stress can be measured by the activation volume Ω, defined as

$$\Omega = -\frac{\partial Q}{\partial \tau} = k_\mathrm{B}T\frac{\partial \ln \nu}{\partial \tau}. \tag{2}$$

Physically, the activation volume is proportional to the number of atoms simultaneously involved in a thermally activated process, such that it measures the individual (single-particle) and collective nature of a transition. Different rate processes may have drastically different characteristic activation volumes, e.g., $\Omega \sim 0.1b^3$ for lattice diffusion and $\Omega \sim 100$–$1000b^3$ for Orowan looping through forest dislocation intersections, where b denotes the magnitude of the Burgers vector. As a result, the activation volume can serve as an effective kinetic signature of the deformation mechanism. Importantly, the activation volume can be determined by both atomistic modeling and experiments, thus providing a useful link between the two approaches for revealing the strength-controlling mechanisms. In atomistic modeling, the stress-dependent activation energy and activation volume can be calculated in a robust and efficient manner by using the reaction pathway exploration approach such as the nudged elastic band method (Henkelman et al. 2000). In experiments, the activation volume is typically determined by measuring the strain-rate sensitivity.

2   Strength-Controlling Deformation Mechanisms

Because of the interposition of small length scales, the deformation of ultra-strength materials often operates in a source-limited and nucleation-controlled regime. We next review representative deformation mechanisms in ultra-strength materials. The critical role of activation volume is emphasized in understanding the strength-controlling mechanisms, as well as the size, temperature, and strain-rate dependence of material responses.

2.1   Dislocation Nucleation

Ultra strength can be achieved in a small volume of perfect crystal. At low temperatures, the strength of a perfect crystal is limited by dislocation nucleation in the bulk or from the surface, depending on the sample geometry and loading mode. Homogenous dislocation nucleation in the bulk crystal has been experimentally observed in the atomic model systems of bubble raft (Gouldstone et al. 2001) and colloidal crystal (Schall et al. 2006) and also in atomistic simulations (Li et al.

2002). In addition, displacement bursts in nanoindentation experiments have been associated arguably with homogeneous dislocation nucleation in a small and perfect volume beneath the nano-sized indenter tip (Li et al. 2002).

Athermal dislocation nucleation in a perfect crystal results from elastic instability at large shear stress; equivalently, it occurs when the energy barrier of nucleation vanishes. Because of the elastic softening effect at large deformation, the athermal threshold of homogeneous dislocation nucleation should be determined by using the theory of hyperelastic (i.e., nonlinear elastic) instability (Hill 1975). An atomistics-based hyperelastic instability criterion has been developed that balances the elastically softening modulus and the GPa-level high stress at large shear (Li et al. 2002). Using this criterion, the critical nucleation conditions at zero temperature can be accurately predicted, including the nucleation site, critical stress, and activated slip system. The athermal nucleation from a surface can be similarly modeled in the hyperelasticity framework with an appropriate description of the surface stress effect (Park and Klein 2007).

Increasing temperature can lower the strength because of thermal fluctuations in assisting dislocation nucleation. To understand the temperature and strain-rate dependence of dislocation nucleation, Zhu et al. (2008) have developed an atomistic model that integrates reaction pathway calculations and theoretical analyses based on transition state theory. Consider, as an example, surface dislocation nucleation in a Cu nanopillar under an applied constant strain rate. Because of the probabilistic nature of the thermally activated nucleation process, the nucleation stress has a distribution even if identical samples are used. The most probable nucleation stress is defined by the peak of the nucleation event frequency distribution. Based on this nucleation statistics-based definition, Zhu et al. (2008) developed a nonlinear theory to determine the nucleation stress as a function of temperature and strain rate. A key result is that the activation volume associated with the surface dislocation source is within 1–$10b^3$, much lower than that of bulk dislocation processes, 100–$1000b^3$. The physical effect of such small activation volume can be clearly seen from a linear version of the theory, giving an analytic formula of the nucleation stress

$$\sigma = \sigma_a - \frac{k_B T}{\Omega} \ln \frac{k_B T N \nu_0}{E \dot{\varepsilon} \Omega} \tag{3}$$

where σ_a is the athermal stress of instantaneous nucleation and E is Young's modulus. Notice that the nucleation stress σ has a temperature scaling of $T\ln T$ and the activation volume Ω appears outside the logarithm, so that the small Ω associated with a surface source should lead to sensitive temperature and strain-rate dependence of nucleation stress, as quantitatively shown in atomistic simulations (Zhu et al. 2008). In very small volumes, surface dislocation nucleation is expected to dominate, as evidenced by the experiment (Bei et al. 2008). As schematically shown in Fig. 1, the strength mediated by surface nucleation should provide an upper bound to the size-strength relation in nanopillar compression experiments; this upper bound is strain-rate sensitive because of the small activation volume.
Fig. 1 Illustration of the surface effect on the rate-controlling process and the size dependence of yield strength in micro- and nanopillars of diameter d under compression (Zhu et al. 2008)

2.2   Dislocation Exhaustion

What if mobile dislocations preexist in small-volume materials? Under such conditions, ultra strength can be achieved by dislocation exhaustion. This has been experimentally measured in crystals of very small dimensions where the few dislocations present cannot multiply sufficiently before they are annihilated at free surfaces. Greer and Nix (Greer and Nix 2006) measured the strength of Au pillars under uniaxial compression. For a pillar with a diameter as small as 300 nm, the compressive strength is increased to about 800 MPa, about 50 times higher than for bulk Au. Similar high strengths have been measured for both the single crystal Au pillars and the nanometer-sized ligaments in nanoporous Au (Volkert and Lilleodden 2006; Volkert et al. 2006). All of these experimental values are extremely high for Au, close to the theoretical predictions of ideal shear strength from ab initio calculations (Ogata et al. 2004).

Greer and Nix (2006) have explained the ultra strength in Au nanopillars based on the concept of dislocation starvation. Unlike bulk samples, dislocations in nanopillars can travel only very small distances before annihilating at free surfaces, thereby reducing the overall dislocation multiplication rate. Gliding dislocations leave the crystal more rapidly than they multiply, decreasing the overall mobile dislocation density. Such processes would lead to a dislocation-starved state requiring very high stresses to nucleate new mobile dislocations.

Shan et al. (2008) recently performed in situ compression experiments of submicrometer nickel pillars inside a transmission electron microscope (TEM). The experiments showed that the pillar structures contain a high density of initial defects

after processing but can be made dislocation-free by applying purely mechanical stress. This phenomenon, termed mechanical annealing, provides evidence of source-limited deformation, where the hardening occurs through the progressive exhaustion of dislocation sources, causing dislocation starvation.

2.3   Dislocation-Interface Interaction

In thin films and layered materials, the strengthening arises from the constraints of the surrounding substrate and layers (Kraft et al. 2002). Achieving ultra strength requires that the film and layer thickness be in the range of a few to a few tens of nanometers. Under such conditions, the dislocation-interface interaction is expected to play an important role in controlling the strength.

The effect of layer thickness on flow strength has been summarized by Misra et al. (2005) for metallic multilayers. They showed that a Hall-Petch-type model based on dislocation pileup is applicable at the submicrometer length scales. At the few to a few tens of nanometer length scales, confined layer slip of single dislocations is the operative mechanism; the strength is influenced by interface stress and interface dislocation arrays. As layer thicknesses are further reduced to a few nanometers or less, the strength reaches a peak in ultra strength. This peak strength is set by the interface resistance to single dislocation transmission.

The dislocation-interface interactions may govern not only strength but also ductility. For example, Lu et al. (2004) have reported experiments of an unusual combination of ultrahigh yield strength ($\sim$1 GPa) and high ductility ($\sim$14% elongation to failure) in ultrafine-grained copper (i.e., with a grain size of several hundred nanometers) containing layered nano-twins, typically tens of nanometers in thickness. While the ultrahigh strength can be attributed to the size-strengthening effect of thin twin lamellas, the mechanistic connection between the retained high ductility and twinned nanostructures is not fully understood.

In bulk nanocrystalline metals, tensile ductility is often limited by the onset of necking instability. This has been well studied at the continuum level. The central result is that the high strain-rate sensitivity and the high rate of strain hardening can both help delay the onset and development of necking, thereby promoting tensile ductility (Hart 1967). To connect the phenomenological theories with nanostructure-mediated plastic deformation, one needs to first determine the rate-controlling mechanisms. The experiment by Lu et al. (2005) showed that nano-twinned copper increases the rate sensitivity ($m \approx 0.02$) by up to an order of magnitude relative to microcrystalline metals with grain sizes in the micrometer range and a concomitant decrease in the activation volume by two orders of magnitude (e.g., down to $\Omega \approx 20b^3$ when twin lamellas are approximately 20 nm thick).

The mechanistic origin of decreased activation volume and increased rate sensitivity has been studied for the nano-twinned system (Zhu et al. 2007). Slip transfer reactions between the lattice dislocation and coherent twin boundary (TB) were analyzed. Using the free-end nudged elastic band method, minimum energy paths were determined for reactions of absorption, desorption, and slip transmission.

Predictions of yield stress, activation volume, and rate sensitivity were consistent with the experimental measurement. This agreement demonstrates that the slip transfer reactions at TBs are the rate-controlling mechanisms in nano-twinned copper.

Besides increasing the rate sensitivity, the dislocation-TB interaction causes an increase in the strain-hardening rate, which may play a key role in preserving the tensile ductility. The modeling study (Zhu et al. 2007) indicated that in contrast to the general high-angle grain boundaries in nanocrystals, which have a limited capacity of hardening, the coherent TB is quite hardenable as it gradually loses coherence during the initial stage of plastic deformation. This effective hardenability facilitates the accommodation of incompatible deformation between adjacent twins; it raises the resistance of plastic flow, promotes the strain hardening, and helps retain tensile ductility. Also, the coherent TB is more resistant to tensile decohesion compared to random boundaries and, therefore, can store larger amounts of deformation-induced incompatibility (interfacial dislocation content) before fracture occurs.

2.4   Deformation Twinning

In ultra-strength materials, the formation of deformation twins may dominate over dislocation slip. This has been observed by recent TEM experiments of nanocrystals (Dao et al. 2007). The preference for deformation twinning in nanocrystals can be understood by comparing the critical resolved shear stress (CRSS) needed to emit a perfect dislocation, τ_f, with the CRSS, τ_p, required to initiate the partial twinning dislocation to generate stacking faults and deformation twins (Chen et al. 2003). These CRSSs can be estimated by considering the energy balance between the elastic energy increase in expanding a boundary dislocation loop and the potential energy decrease associated with the work done by the CRSS. Assuming the source size is approximately equal to the grain size, d, the CRSSs for the emission of a perfect dislocation and twinning partials are given by $\tau_f/\mu = b/d$ and $\tau_p/\mu = b_p/d + \Gamma_{sf}$, respectively. Here, $\Gamma_{sf} = \gamma_{sf}/(\mu b_p)$, where γ_{sf} is the stacking fault energy and b_p is the magnitude of the Burgers vectors of a partial dislocation. Equating τ_f and τ_p gives the critical grain size $d_c = (b - b_p)/\Gamma_{sf}$, where the transition will occur from the plastic response dominated by perfect dislocations for large grains to the twinning and stacking faults controlled by plastic behavior for small grains. The estimated d_c is about 10 nm for aluminum nanocrystals.

It should be emphasized that the foregoing analysis of glide dislocations and deformation twins is based on the energy balance of expanding the existing boundary dislocations. As a result, their CRSSs only involve the material energetic parameter of stack fault energy, γ_{sf}, which characterizes the metastable stacking state of the lattice. Van Swygenhoven et al. (2004) have emphasized the importance of examining the generalized stacking fault energy curve, which additionally provides activation-related parameters such as unstable stacking energy γ_{us} and unstable twinning energy γ_{ut}. Along this line, Asaro and Suresh (2005) have performed the mechanics analysis of athermal emission of perfect dislocations

and deformation twins from the grain boundary. The athermal stresses derived incorporate naturally γ_{us} and γ_{ut}. Finally, it is noteworthy that the thermal activation of deformation twins has not yet been studied for understanding the temperature and strain-rate dependence of nucleation stresses at small length scales.

2.5   Fracture

Plastic flow and brittle fracture are competing deformation modes in ultra-strength materials. Bulk silicon is brittle, but silicon nanowires in tension can undergo large plastic deformation at room temperature (Han et al. 2007). A revealing analysis of brittle-ductile competition has been given by Dumitrica et al. (2006) for a perfect single-walled carbon nanotube. By molecular dynamics simulations at various temperatures T and at short timescale (about 0.1 ns), they identified two primary mechanisms: the "cool" mechanism of brittle fracture at low T and the "hot" mechanism of formation of Stone-Wales defects (i.e., dislocation dipoles) at high T. To explore the competition at long timescales, they have studied the energy landscapes governing the two processes. They found the brittle mode of bond breaking requires little thermal agitation; the fracture stress is controlled by the ideal tensile strength of the C-C bond. In contrast, the Stone-Wales defect formation by single-bond rotation sensitively depends on temperature, implying a small activation volume associated with this process. According to transition state theory, the activation energy under constant stress needs to be reduced to $Q = k_B T \ln(N \nu t)$ in order to observe the formation of Stone-Wales dipole over the test duration t (probability ~ 1). Dumitrica et al. (2006) have further calculated Q as a function of stress. Then, the stress needed to form the Stone-Wales dislocation dipole at different temperatures and times can be backed out from the formula of Q given previously. A breaking-strain map (Dumitrica et al. 2006) was predicted to provide useful guidance for the experimental study of temperature and strain-rate dependence of mechanical responses of carbon nanotubes.

The foregoing analysis has considered an idealized situation of competition between the brittle and ductile response in a perfect system (Dumitrica et al. 2006; Kang and Cai 2007; Belytschko et al. 2002). In an alternative scenario, such competition could occur at the crack tip in a system with a preexisting crack (Warner et al. 2007). In this case, bond breaking at the crack tip may have different temperature and strain-rate dependences. The analysis along the lines of Dumitrica et al. (2006) needs to be performed to better understand the brittle-to-ductile transition in ultra-strength materials.

3   Nanomechanical Modeling

Recent years have seen a dramatic increase in the nanomechanical modeling study for a variety of ultra-strength materials, including nanowires, nanopillars, nanopar-ticles, nanocrystalline, and 2D materials. The chapters in this Part of the Handbook

highlight recent progress in the computational modeling of nanomechanical behavior of ultra-strength materials. For example, Ogata (▶ Chap. 75, "First-Principles Modeling of Intrinsic Materials Strength") presents a chapter on the first-principles modeling of intrinsic material strength. He shows that the density functional theory calculations can provide a deep understanding of the effects of electronic structures and chemical bonding on the intrinsic strength of materials, which represents the upper bound of ultra strength. Li et al. (▶ Chap. 76, "Atomistic Simulations of Fracture and Fatigue in Nanotwinned and Amorphous Materials") present a chapter on the atomistic simulations of fracture and fatigue in nano-twinned and amorphous materials. They show that large-scale atomistic simulations can provide unique atomic-level insights into the controlling deformation mechanisms in nano-twinned and amorphous materials. Notably, nanomechanics of 2D materials has attracted considerable attention in recent years. In this section, Sorkin et al. (▶ Chap. 77, "Modelling of Defects and Failure in 2D Materials: Graphene and Beyond") present a chapter on modeling of defects and failure in 2D materials. They show that point defects and line defects can play a critical role in the mechanical behavior of graphene and other 2D materials. Park (▶ Chap. 78, "Mechanics and Electromechanics of Two-Dimensional Atomic Membranes") presents a chapter on the mechanics and electromechanics of 2D atomic membranes. He shows that atomistic simulations can effectively reveal the auxetic behavior in 2D materials. He also describes the new computational techniques that couple molecular dynamics, tight binding, and quantum transport for understanding how mechanical strain can impact the electronic properties of graphene kirigami. Overall, these chapters highlight the power of materials modeling for understanding and predicting the mechanical behavior of nanoscale and nanostructured materials.

4   Conclusions and Perspectives

In the past decade, we have seen a dramatic increase in experimental studies of ultra-strength materials and phenomena, driven by technological demands and projections. The high strength achieved often is caused by a scarcity of grown-in defects and the exhaustion of mobile defect population destabilized by close proximity to interfaces or surfaces, which consequently cause the strength to be defect nucleation controlled rather than propagation controlled. The plastic deformation in the ultra-strength regime is generally characterized by enhanced strain-rate sensitivity and temperature sensitivity. Mechanisms of strain hardening (or the lack thereof), interfacial structural evolution and decohesion, and tensile ductility are some of the issues that need to be further considered for comprehensive understanding of ultra-strength materials at low temperatures. Although temperature-controlled nanomechanical testing is still quite rare today, it is a direction for future growth. The chapters in this Part of the Handbook highlight recent progress in the computational modeling of nanomechanical behavior of ultra-strength materials.

Given the rapid development of both experimental and computational modeling capabilities in recent years, we expect a great advancement in the nanomechanics study of materials in the coming years. These studies will have a significant impact on our understanding of deformation mechanisms in ultra-strength materials, including diffusive and hybrid displacive-diffusive processes. The deformation mechanism maps (Frost and Ashby 1982) in the parametric space of stress, temperature, and strain rate will be obtained through coupled experiment and modeling. Such maps will enable the design of better ultra-strength materials to realize their latent mechanical properties to the full (Ma and Zhu 2017).

First-Principles Modeling of Intrinsic Materials Strength

75

Shigenobu Ogata

Contents

Abstract

Intrinsic materials strength, which is determined by the mechanical nature of the chemical bonds in materials, is essential and key information for developing ultra-strength and, moreover, ultra-toughness materials because a thorough control of the nucleation and migration of defects is necessary to develop these materials. Well-established first-principles approaches enable us to predict the intrinsic strength of materials, which should lead to the high-throughput design of ultra-strength and ultra-toughness materials. In this article, first-principles modeling of the mechanical nature of chemical bonding is discussed, followed by a discussion of first-principles modeling of the strength of a crystal lattice, which is useful for describing not only the intrinsic strength but also the deformation mechanism map of a crystal lattice.

1   Introduction

The strength of materials is predominantly determined by the mechanical nature of the materials' chemical bonds, although extrinsic factors such as the materials' size, shape, dimensions, microstructure, type, and density of defects, surface, interface, temperature, and strain rate may change their "measurable" strength. However, the upper limit of a material's strength, sometimes referred to as its ideal strength, is always limited by the intrinsic strength of its interatomic chemical bonds, which is uniquely determined by the atomic arrangement and atomic species within the Born-Oppenheimer approximation. The recent challenge in the development of ultra-strength materials (Zhu et al. 2009; Zhu and Li 2010) is how to approach the upper limit by controlling extrinsic factors. Therefore, first extracting and understanding the mechanical nature of chemical bonding and then modeling materials strength while taking into account the extrinsic factors is an intuitive approach for the predictive modeling and high-throughput design of materials strength from first principles. Currently, first-principles density functional theory (DFT) and related first-principles methods enable us to directly examine and study the mechanical nature of chemical bonding in materials and their lattice strength without empirical information, whereas direct experimental measurement is still difficult. In this article, I first discuss the mechanical nature of chemical bonding in materials based on bond stretchability and shearability concepts. These concepts lead to a concept of the intrinsic ductility of materials. I then discuss the strength of crystal lattices from the viewpoint of the Gibbs free energy landscape at zero Kelvin in a joint space of deformation/strain and atomic shuffling, which can be used to study the strength against lattice instabilities that leads to the initiation and nucleation of cracks and dislocations and the occurrence of deformation twinning and solid-solid transformations such as martensitic and Bainitic transformations.

2   Mechanical Strength of Chemical Bonding

The strain limit that chemical bonding can withstand can be defined as the mechanical strength of chemical bonding. In particular, two independent strain limits – specifically, the shear and tensile strain limits – are important for materials strength and plasticity (Foreman et al. 1951; Xu et al. 1995) because the shear-induced bond switching and bond angle-change and tension-induced bond breaking in perfect crystal and in lattice defects, such as dislocations, cracks, and boundaries, in defect-containing crystals actually determine a material's strength and plasticity. Therefore, shearability and tensibility are conveniently defined by the maximum shear and tensile strains at which a perfect crystal becomes unstable (Ogata et al. 2004), which are computable using first-principles DFT. Notably, because chemical bonding in the lattice defects may differ from that in perfect lattice, direct simulation of these lattice defects is necessary to precisely determine the mechanical nature of chemical bonding in defects. However, analysis using perfect crystal lattice, which is more convenient in first-principles computations, should still provide some essential information about the bonding response in defects to the strains.

More precisely, the shearability can be defined as

$$s_m \equiv \arg\max \sigma(s), \tag{1}$$

where $\sigma(s)$ is the resolved shear stress and s is the engineering shear strain in a specified slip system of a crystal. "arg max" is the arguments of the maxima. The tensibility is defined as

$$t_m \equiv \arg\max -P((1+t)V_0), \tag{2}$$

where $P(V)$ is the pressure-volume relation and V_0 is the equilibrium volume, $P(V_0) = 0$. The shearability and tensibility have been computed using first-principles DFT for various metals and ceramics (Ogata et al. 2004), including face-centered cubic (FCC) Ag, Cu, Au, ferromagnetic (FM) and paramagnetic (NM) Ni, and Al; body-centered cubic (BCC) W, Mo, and Fe (FM); hexagonal close-packed (HCP) Mg, Ti, and Zn; L1$_0$ TiAl and D0$_{19}$ Ti$_3$Al; diamond cubic C and Si; β-SiC, α-, and β-Si$_3$N$_4$; and B1 NaCl, MgO, KBr, and CaO. In these computations, incremental affine shear strains were imposed on each crystal along experimentally determined common slip systems to obtain the corresponding unrelaxed and relaxed energies and stresses, defined, respectively, by the conditions $\varepsilon_{ij} = 0$ except $s \equiv x/d_0$, with d_0 being the interplanar separation and x taken along the Burgers vector, and $\sigma_{ij} = 0$ except for the resolved shear stress. For α- and β-Si$_3$N$_4$, the common slip systems are unknown experimentally. Therefore, six systems for each phase are calculated, and the one with the lowest shear strength is used (Ogata et al. 2003). When the relaxed ideal shear stress σ_m^r normalized by G_r and the shearability s_m^r for different materials are plotted together (Fig. 1 (Ogata et al. 2004)), gaps are observed in the distributions of s_m^r between metals and covalent solids. Such gaps can also be observed when comparing the results of different works for elastic shear instability of metals (Krenn et al. 2001; Roundy and Cohen 2001; Ogata et al. 2002) and covalent solids (Roundy et al. 2001; Ogata et al. 2003). In addition, among the metals, the noble metals Au, Ag, and Cu and the more directionally bonded Al and BCC Mo, W, and Fe (FM) are at opposite sides of the distributions, which suggest that directional bonding allows for longer-range shear distortion of the bonds before peak resistance is attained. This behavior can be rationalized by observing that greater bond covalency results in a greater concentration of valence charge in nonnuclear-centered regions (Silvi and Gatti 2000; Mori-Sanchez et al. 2002), e.g., bond centers and other high-symmetry interstices, which can be verified through examination of the charge-density isosurface plots (see Fig. 3). These localized charge pockets would require a certain spatial arrangement among them for the total energy to be well-minimized. By contrast, if the valence charge density in the interstices is completely delocalized, then no such constraints would exist, and the energy barrier to shear would arise mainly from a misfit-volume effect. In FCC Cu and Ag, when the local interstice volumes completely recover their equilibrium values at the intrinsic stacking fault, the energy penalties are very low despite the "wrong" bond angles (Ogata et al. 2002). Consequently, a rather general interpretation of our results is that, for the rearrangement of charge
Fig. 1 Shearability (relaxed) (Ogata et al. 2004). The solid line indicates a unit slope, whereas the dashed line corresponds to a slope of $2/\pi$

density in response to mechanical deformation, bond-angle dependence brings about geometric constraints on the atomic configurations above and beyond the volumetric constraints. In the relaxed s_m^r, σ_m^r distributions (Fig. 1), ionic ceramics lie midway between directionally bonded metals and covalent solids; α- and β-Si$_3$N$_4$, being more ionic than SiC, also lie within this range (Ogata et al. 2003). However, in unrelaxed shear (Fig. 2), these solids manifest abnormally large ideal shear strains s_m^u and stresses σ_m^u, which are attributed to the bare Coulomb repulsion between like-charge ions, as in a simple Madelung sum model. In an atomic environment such as a crack tip, the surrounding medium would not allow for either fully relaxed or fully unrelaxed local shear. This result implies that ionic materials could be either less or much more brittle than covalent materials, depending on the subsidiary deformation constraints; this situation is analogous to the distinction of plane-stress vs. plane-strain loading conditions in the fracture of metals. Another noteworthy feature of Figs. 1 and 2 is the approximately universal linear scaling between s_m and σ_m/G across a range of crystal structures, bond types, and slip systems. The original Frenkel model (Frenkel 1926), which contains a single parameter G, is well known and widely used (Peierls 1940; Nabarro 1947; Rice 1992; Kysar 2003) in an empirical fashion. Various researchers have noted that, on the basis of physical intuition, a more realistic description is to treat the peak position of $\sigma(s)$ as an adjustable parameter (Foreman et al. 1951; Xu et al. 1995) rather than as a fixed value at $b/4d_0$. As shown here, on the basis of ab initio first-principles computation results, a two-parameter representation

$$\sigma = \frac{2Gs_m}{\pi} \sin\left(\frac{\pi s}{2s_m}\right), 0 < s < s_m, \quad \sigma_m = \frac{2Gs_m}{\pi} \tag{3}$$
Fig. 2 Shearability (unrelaxed) (Ogata et al. 2004). The solid line indicates a unit slope, whereas the dashed line corresponds to a slope of $2/\pi$

with the shear modulus G and the shearability s_m as fundamental materials parameters provides an accurate description of simple metals and ceramics. As shown in Figs. 1 and 2, the slope of $2/\pi$ implied by our proposed extension of the Frenkel model (Eq. 3) indeed represents the data well. In addition, the fundamental constitutive behavior for shear deformation can be captured in a master curve in terms of normalized stress $\tilde{\sigma} \equiv \sigma/Gs_m$ and strain $\tilde{s} \equiv s/s_m$, as shown in Fig. 4. In this rescaling, all curves have an initial unit slope and reach a maximum at $\tilde{s} = 1$. The behavior labeled as "Frenkel (renormalized)" reflects a universal shear-softening response for $s < s_m$. Notably, this new, "renormalized Frenkel" model is the shear counterpart to the universal binding energy relation (Rose et al. 1983), which also has two parameters and has been quantitatively checked against ab initio computation results. Taken together, the renormalized Frenkel model and the universal binding energy relation enable the formulation of materials design and performance criteria in which tensile and shear dissipation modes compete (Rice 1992; Xu et al. 1995; Li et al. 2002; Vitos et al. 2003; Kysar 2003). For example, the "brittleness parameter" of Rice (1992), which compares the unstable stacking energy γ_{us} to the surface energy γ_s, can be very crudely estimated as

$$\beta \equiv \frac{\gamma_{us}}{\gamma_s} \propto \frac{Gs_m^2}{Bt_m^2} = \left(\frac{G}{B}\right) \cdot \left(s_m^2\right) / \left(t_m^2\right) \tag{4}$$

by scaling arguments (Ogata et al. 2004; Ogata and Li 2009). Parameter G/B is accessible experimentally and has been used as a brittleness predictor. However, s_m and t_m, although easy to obtain in ab initio first-principles computations (Černy et al. 2003), are unavailable experimentally despite having been theoretically established
Fig. 3 Isosurface plot of valence charge density of elements at their stress-free states (Ogata et al. 2004): (**a**) FCC Ag, (**b**) FCC Al, (**c**) BCC Mo, and (**d**) diamond cubic Si. Ω_0 is the atomic volume

to be important (Foreman et al. 1951; Xu et al. 1995). The results indicate that a wide gap in β exists between metals and ceramics because G/B and s_m are governed not only by the crystal structure but also by the nature of chemical bonding (e.g., $s_m^r = 0.105$ in FCC Au vs. $s_m^r = 0.200$ in FCC Al) and by the loading condition (e.g., $s_m^r = 0.221$ vs. $s_m^u = 0.658$ in B1 NaCl). By contrast, the relative variation of t_m is less sensitive than that of s_m, and it has no spectral gap (see Fig. 5). The results suggest that the brittleness is governed by the shearability (Ogata and Li 2009).

3 Intrinsic Strength of Crystal Lattice

In the previous section, lattice strain, such as the shear in a common slip system, and triaxial tension were applied to primitive cells to examine the shearability and tensibility of chemical bonding. Here, we more generally consider the intrinsic
Fig. 4 Relaxed shear stress-strain curves for 22 materials and a renormalized Frenken model (Ogata et al. 2004)
Fig. 5 Tensibility (Ogata et al. 2004)

strength of the crystal lattice, which is defined as the critical stress that induces lattice instability on a minimum deformation unit. Lattice instability sometimes leads to shear deformation (e.g., dislocation or deformation twinning), sometimes to decohesion (e.g., cracks), and sometimes to a solid-solid transformation (e.g., martensitic or Bainitic transformation). Because the deformation, decohesion, and

transformation instability modes, hereafter referred to simply as "deformation," have different critical stresses, a first-principles prediction of the critical stress enables the construction of a deformation mechanism map of the crystal lattice as a function of stress. Unlike the analysis of strength of chemical bonding, we cannot always use a primitive cell because the deformation has different minimum deformation units (irreducible lattice correspondence pattern), such as in the case of deformation twinning of HCP Mg, which is discussed later. Thus, generally, the minimum deformation unit differs from and is larger than the primitive cell. That is, the deformation unit may have more internal degrees of freedom independent of lattice strain. To compute the critical stress at zero temperature from first principles, one can actually apply various stresses to the supercell of the minimum deformation unit and detect the lattice instability using, for example, soft mode analysis (Qi and Chrzan 2014). In this case, the task is no longer technically difficult. Importantly, the internal degrees of freedom, so-called non-affine atomic "shuffling," cannot be controlled independently from the lattice strain induced by stress because the internal degrees of freedom are "slaves" of the affine lattice strain. However, in the meantime, actual deformation occurs at finite temperatures. The thermal energy induces thermal fluctuations that can independently disturb the internal degrees of freedom from the lattice strain, that is, free from slavery and excite the internal degrees of freedom. Moreover, the thermal energy paves the way for untouched instability points (saddle points) on the Gibbs free energy landscape that cannot be taken only by stress, where the soft mode is mostly related to corresponding non-affine atomic shuffling. The usual method of applying stress to the lattice at zero temperature may overlook these instability points. Drawing the Gibbs free energy landscape in a space spanned by lattice strain and shuffling degrees of freedom under different stresses is the best approach for observing all of the saddle points without omission. After the Gibbs free energy landscape has been computed, one can obtain not only the critical stress at zero temperature (ideal strength of lattice) but also the minimum energy pathway (MEP) and the activation Gibbs free energy of each deformation mode. Note that the critical stress is generally a temperature- and strain-rate-dependent quantity.

To determine the Gibbs free energy landscape with the non-affine atomic shuffling, one can separate the non-affine atomic shuffling with the instantaneous affine strain at the smallest lattice correspondence pattern level as the "shuffling" and "strain" variables and compute the Gibbs free energy landscape and MEP (Jónsson et al. 1998) of possible strain modes in this joint "shuffling"-"strain" space (Ishii et al. 2016). Let us define a scalar to represent the shuffling degree of freedom (Ishii et al. 2016):

$$I \equiv (s - s^{\text{ini}})^T \mathbf{H}_0^T \mathbf{H}_0 (s^{\text{fin}} - s^{\text{ini}})/M \qquad (5)$$

where s^{ini} is the internal coordinates of labeled atoms before deformation ($\lambda = 0$) and s^{fin} is the internal coordinates of labeled atoms after deformation ($\lambda = 1$) for a given σ. Notably, the s differences in (5) are the changes in internal coordinates without periodic boundary condition (PBC) wraparound. I has the unit of Å^2 and

takes the meaning of the mean-square non-affine displacements (MSDs) when the deformation is complete. The deformation transforms the crystal from a reference configuration to another configuration with strain $\boldsymbol{\varepsilon}_{\text{final}}$. The supercell describing the deformation can be taken as the irreducible lattice correspondence pattern, which can be larger than the primitive cell of the host lattice. The deformation can be represented atomistically by

$$\mathbf{x}_m(\lambda) = \mathbf{H}(\lambda)\mathbf{s}_m(\lambda), \quad \mathbf{H}(\lambda) = \mathbf{R}(\lambda)(\mathbf{I} + 2\boldsymbol{\varepsilon}(\lambda))^{1/2}\mathbf{H}_0, \tag{6}$$

where λ is the reaction progress variable (scalar), $\mathbf{x}_m$ is the Cartesian position, and $\mathbf{s}_m = [s_{m1}; s_{m2}; s_{m3}] \in [0, 1)$ is the reduced coordinate vector of atom m under PBC; $\mathbf{H} = [\mathbf{h}_1\mathbf{h}_2\mathbf{h}_3]$ is a 3×3 matrix, where $\mathbf{h}_1$, $\mathbf{h}_2$, and $\mathbf{h}_3$ are three edge vectors of the supercell; and $m = 1..M$ is the index of atoms in the supercell. Equation components $(\mathbf{I} + 2\boldsymbol{\varepsilon}(\lambda))^{1/2}$ and $\mathbf{R}(\lambda)$ are the irrotational and rotational parts of the deformation gradient, respectively, where $\boldsymbol{\varepsilon}(\lambda)$ is the Lagrangian strain with respect to the initial configuration. The representation (6) is general in the sense that it can be used to represent liquid or solid geometries in molecular dynamics simulations that have general displacive and diffusive motions. Here, however, the integer M would be taken to be as small as possible. Although deformation in reality must be a heterogeneous and asynchronous transformation, the supercell of the irreducible M should still provide essential and key physics about the process (Ogata et al. 2005) and the strength of the lattice. We can then compute the MEP with the least M using parameter-free ab initio first-principles computation at a constant external stress $\boldsymbol{\sigma}$, which gives the activation Gibbs energy $G(\lambda, \boldsymbol{\sigma})$ vs. reaction coordinate λ, parametrized by $\boldsymbol{\sigma}$. An algorithm is applied to compute the MEP and to find the saddle point of deformation:

$$Q(\boldsymbol{\sigma}) \equiv G(\lambda^*, \boldsymbol{\sigma}) - G(0, \boldsymbol{\sigma}) \tag{7}$$

on the joint $\boldsymbol{\varepsilon} \otimes \mathbf{s}$ space (Sheppard et al. 2012), where $\lambda = 0$ is used to denote the state before deformation, $\lambda = 1$ to denote the state after deformation, and λ^* for a saddle point, at constant external stress $\boldsymbol{\sigma}$.

3.1 Strain-Controlled vs. Shuffling-Controlled

An interesting but very important question is whether the MEP or reaction coordinate is dominated by $\Delta\mathbf{s}$ or $\Delta\boldsymbol{\varepsilon}$. Two opposite physical transformation limits can be identified. In the diffusive limit (annealing transformation), $\boldsymbol{\varepsilon}_{\text{final}} \approx 0$; in addition, because of the randomized short-range diffusion that destroys labeled-atom registry (if identical atoms have labels), the lattice correspondence pattern is random, and M can be taken to be infinity. Thus, this deformation would be a pure "shuffling-dominated" deformation with a huge but unchanged (fixed-shaped) supercell. By contrast, many simple metals have one-atom primitive cells (e.g., FCC Cu, Au, and Al and BCC Mo and Fe) that deform at low temperatures with $M = 1$,

where the irreducible lattice correspondence pattern (before and after deformation) involves merely one atom, as evidenced by direct molecular dynamics simulations; thus, there is no shuffling degree of freedom, and the metal is purely strain-dominated. The former case is classified as civilian/diffusive transformation, the latter case is classified as military/displacive transformation (Christian 2002), and the two cases tend to manifest different sensitivities to temperature and strain rate (Suresh and Li 2008; Li 2007; Zhu and Li 2010). The civilian/diffusive deformation tends to be more temperature and strain-rate sensitive but less stress sensitive (less nonlinear-thresholding behavior) than military/displacive transformation because of the smaller activation volume (Li 2007; Zhu and Li 2010). The origin of this can, in turn, be traced to the lack of long-range elastic interactions, which tends to reduce the activation volume. Activation processes with long-range elastic interactions (Shen et al. 2008) tend to have much larger activation volume, reflecting greater collective coordination. If the same MEP and saddle-point energy can be obtained by continuously increasing just the shuffling and instantaneously relaxing the strain by steepest descent, we refer to the path as being "shuffling-controlled." Vice versa, if the same MEP and saddle-point energy can be obtained by continuously increasing the strain and relaxing the internal non-affine displacement by steepest descent, we refer to the path as being "strain-controlled."

Let us give a precise and general mathematical definition of the *strain-controlled* vs. *shuffling-controlled* concept for deformation as follows (Ishii et al. 2016). One can choose dominant strain components $\boldsymbol{\varepsilon} = \{\varepsilon_1, \cdots, \varepsilon_n; n \leq 6\}$, which can be taken to be strain components induced by the deformation. One can then increase $\boldsymbol{\varepsilon}$ slightly, fix it as a constraint, and then relax the remaining $3M + 6 - n$ degrees of freedom in ab initio first-principles supercell computation by the steepest descent method. The process is then repeated. If one can reach the same activation energy $G(\lambda^*)$ as the full-$\boldsymbol{\varepsilon} \otimes \mathbf{s}$ MEP search by trotting along $\boldsymbol{\varepsilon}$, this activation path can be called strain-controlled in the sense that the reaction coordinate can be well represented by $\boldsymbol{\varepsilon}$. By definition, $I = 0$ when $\boldsymbol{\varepsilon} = \mathbf{0}$. In an alternative calculation, one increases I slightly, fixes it as a constraint variable, relaxes the remaining $3M + 6 - n$ degrees of freedom by steepest descent, and then repeats trotting along I. In this case, all six strain tensor components become slaved variables of I: the supercell shape and size respond instantaneously to the tweaking of this internal shuffling motion. If one can reach the same saddle point $G(\lambda^*)$ as the full-$\boldsymbol{\varepsilon} \otimes \mathbf{s}$ path search, this activation path can be called shuffling-controlled in the sense that the reaction coordinate can be well represented by I. If neither $\boldsymbol{\varepsilon}$-control or I-control give the correct saddle energy, or if both do, we refer to such a transformation path as being under *mixed*-control.

3.2 A Case of Non-basal $\{10\bar{1}2\}\langle10\bar{1}\bar{1}\rangle$ Deformation Twinning in HCP Magnesium (Ishii et al. 2016)

Deformation twinning (DT) (Christian and Mahajan 1995) transforms a crystal into a mirrored configuration with transformation strain $\boldsymbol{\varepsilon}_{\text{final}}$. Numerous experimental
Fig. 6 Atomic arrangements and four-atom supercell shape of perfect HCP and twinned HCP configurations viewed from $[1\bar{2}10]$ (Ishii et al. 2016)

studies and theoretical analyses on the HCP $\{10\bar{1}2\}\langle10\bar{1}\bar{1}\rangle$ twinning system have been reported. Nevertheless, information relating to the required mechanical conditions and atomistic twinning processes remains controversial; in addition, certain aspects of and mechanisms involved have not been fully clarified, especially the issue of whether the twinning processes are atomic-shuffling dominant (Li and Ma 2009; Li and Zhang 2014) or shear-strain induced. The reason for this controversy appears to be a lack of fundamental energetics. The idea discussed in the previous section can be naturally applied to this issue, thus shedding light on a DFT-based Gibbs free energy landscape that can clarify the deformation mechanism. Figure 6 shows perfect ($\lambda = 0$) and twinned ($\lambda = 1$) HCP atomic structures viewed from $\langle1\bar{2}10\rangle$, at $\sigma = 0$. The four-atom parallelepiped supercell used in this study, which includes atoms A, B, C, and D, is indicated as a broken red line. The four-atom supercell ($M = 4$) is the minimum lattice correspondence pattern unit necessary to render the atomic arrangements during $\{10\bar{1}2\}\langle10\bar{1}\bar{1}\rangle$ twinning shear deformation (Li and Ma 2009; Wang et al. 2013). Notably, even though the Bravais primitive cell of HCP metals contains only $N = 1$ atom, because of the anisotropy (a_0 and c_0 are required to specify an HCP lattice, in contrast just a_0 for cubic metals) and low symmetry of the twinning system, M can be greater than 2. The internal energy U and Cauchy shear stress of the supercell with respect to the uniform twinning shear deformation $\gamma = \gamma_{yz} = 2\varepsilon_{yz}$;

$$U(\gamma) = \min_{s, \varepsilon \in \gamma} U(\varepsilon, s) \qquad (8)$$

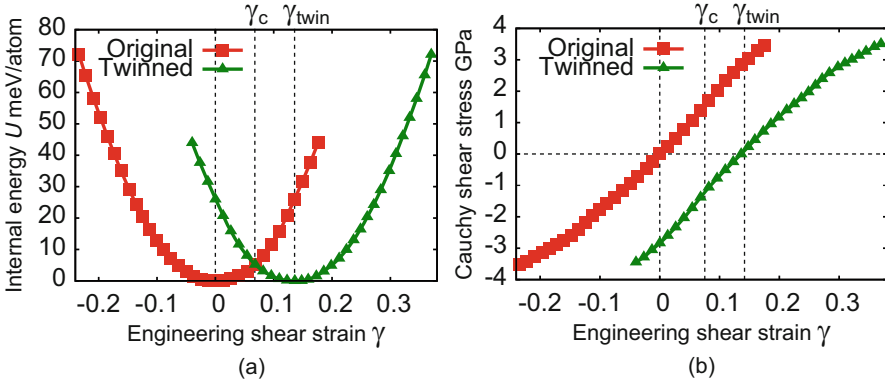
is shown in Fig. 7a, b. The shear deformation has been applied to two different fully relaxed HCP supercells with HCP and twinned HCP configurations; these supercells are labeled as "original" (red plots in Fig. 7a, b) and "twinned" (green


Fig. 7 Supercell internal energy (**a**) and Cauchy shear stress (**b**) with respect to engineering shear strain γ. The shear deformation is applied to two different initial supercell atomic configurations: "original" (red plots) and "twinned" (green plots). An energy crossover occurs at $\gamma = \gamma_c (= 0.068)$ (Ishii et al. 2016)

plots in Fig. 7a, b), respectively. Both of these supercells have the same perfect HCP lattice structure; however, the twinned supercell has the sheared supercell frame from the original supercell of $\gamma = \gamma_{yz} = 0.136$ engineering shear strain. Note that the internal atomic configurations in these supercells can be different even though they have the same supercell shape. The internal atomic configuration **s** at a certain engineering shear strain is dependent upon whether it has been sheared from the "original" or the "twinned" supercell. This dependence causes internal energy and stress differences at each engineering strain γ, shown as the red and green plots in Fig. 7a, b. In Fig. 7a, an energy crossover occurs at a critical $\gamma = \gamma_c (= 0.068)$ between these plots. At strains above the critical strain, an atomic configuration sheared from a twinned supercell becomes energetically favorable compared with that of the original supercell with the same cell shape, and thermodynamics would start to allow DT to occur at $T = 0$ K. However, even at a strain only slightly above the critical strain, a transition from the red to the green curve in Fig. 7a, b still appears to involve an energy barrier. That is, spontaneous twinning in the absence of thermal fluctuations and waiting times is not observed in the DFT calculation. This observation already hints that the twinning shear strain γ may not be the dominant reaction coordinate. Something internal "got stuck," preventing the red→green transition from occurring spontaneously, even at strains substantially greater than the equi-energy strain γ_c.

To examine this interesting behavior, we evaluated the Gibbs free energy landscape numerically using ab initio first-principles supercell energetics.

$$G(\boldsymbol{\varepsilon}, \mathbf{s}, \boldsymbol{\sigma}) \equiv U(\boldsymbol{\varepsilon}, \mathbf{s}) - W(\boldsymbol{\varepsilon}, \boldsymbol{\sigma}), \tag{9}$$

where $W(\boldsymbol{\varepsilon}, \boldsymbol{\sigma})$ is the work done by constant external Cauchy stress $\boldsymbol{\sigma}$ (Wang et al. 1995):

$$W(\boldsymbol{\varepsilon}, \boldsymbol{\sigma}) \equiv \int_0^1 dl \, \det |\mathbf{J}(\boldsymbol{\eta} = l\boldsymbol{\varepsilon})\mathbf{H}_0| \times \mathrm{Tr}\left[\mathbf{J}^{-1}(\boldsymbol{\eta} = l\boldsymbol{\varepsilon})\boldsymbol{\sigma}\mathbf{J}^{-T}(\boldsymbol{\eta} = l\boldsymbol{\varepsilon})\boldsymbol{\varepsilon}\right], \quad (10)$$

where $\boldsymbol{\eta} = l\boldsymbol{\varepsilon} = 1/2(\mathbf{J}^T\mathbf{J} - \mathbf{I})$ is the Lagrangian strain tensor, $\mathbf{J}$ is the corresponding deformation gradient tensor,

$$\mathbf{J} = \mathbf{R}(\mathbf{I} + 2\boldsymbol{\eta})^{1/2} \quad (11)$$

and $\mathbf{R}$ is an additional rotation matrix $\mathbf{R}^T\mathbf{R} = \mathbf{I}$ that is completely defined when the transformation coordinate frame convention is chosen. Even though $G(\boldsymbol{\varepsilon}, s, \boldsymbol{\sigma})$ is now defined by (9), it is difficult to visualize directly because $\boldsymbol{\varepsilon} \otimes s$ space is $3M + 6$ dimensional. Thus, (5) can be used to aid visualization. By applying energy minimization to all degrees of freedom of the supercell system other than γ and I, we can uniquely compute $G(\gamma, I, \boldsymbol{\sigma})$:

$$G(\gamma, I, \boldsymbol{\sigma}) \equiv \min_{\boldsymbol{\varepsilon} \in \gamma, s \in I} G(\boldsymbol{\varepsilon}, s, \boldsymbol{\sigma}) \quad (12)$$

The computed Gibbs free energy landscapes $\Delta G(\gamma, I)$ at different external Cauchy shear stresses ($\sigma_{yz} = \sigma_{zy} = 0, 1$ and 2 GPa along the twinning direction) are shown in Fig. 8. The other Cauchy stress components were set to zero. The red curves on the Gibbs free energy landscapes represent the MEPs from the original to the twinned configuration under these external shear stresses, which were estimated by applying the nudged elastic band (NEB) method (Jónsson et al. 1998) to obtain the two-dimensional Gibbs free energy landscapes. The Gibbs free energy change along the MEP under different external shear stresses is shown in Fig. 10a, b shows the change in the Gibbs free energy barrier with respect to the external shear stress. The following two NEB calculations were independently performed: (1) an NEB calculation with respect to the internal atomic configuration I, in which the supercell frame is relaxed under the predefined external stress (I-control NEB), and (2) an NEB calculation with respect to γ, in which internal atomic configuration s is relaxed for each supercell frame shape (γ-control NEB). A comparison between their Gibbs free energy barriers is presented in Fig. 10b; the Gibbs free energy barrier determined by I-control NEB agrees well with the Gibbs free energy barrier based on the two-dimensional Gibbs free energy landscape, whereas the Gibbs free energy barrier obtained by the γ-control NEB is substantially higher. This result indicates that the DT is an I-dominant (non-affine displacement dominant) deformation. Thus, if an assist of thermal energy were to exist, the twinned structure could be generated without generating local shear strain because the phonons could toggle the "internal cog." After the "internal cog" is flipped, the voxel γ will later spontaneously relax toward the twinned configuration. The MEP analysis based on the Gibbs free energy landscape also clearly indicates that a uniform supercell shape change and an atomic position change simultaneously occur during the DT process. Figure 9 represents the change in atomic position along the MEP at a shear stress of 0 GPa. A "dumbbell flipping" or "shuffling" behavior – that is, staggered rotations of
Fig. 8 Gibbs free energy distribution $\Delta G(\gamma, I)$ at different levels of external shear stress $\sigma_{yz} = \sigma_{zy} = 0$ GPa (**a**), 1 GPa (**b**), and 2 GPa (**c**). The red curves represent the MEPs of the deformation twinning processes (Ishii et al. 2016)
Fig. 9 Atomic configuration change along the MEP (Ishii et al. 2016)
Fig. 10 Gibbs free energy variation along the MEP (**a**) and the energy-barrier change with respect to external shear stress (**b**). In (**a**), the solid curves and dots represent results obtained from the Gibbs free energy landscape and direct NEB analysis, respectively. In (**b**), the square, triangular, and circular symbols represent the Gibbs free energy barriers obtained from the two-dimensional Gibbs free energy landscape (2D land), I-control NEB, and γ-control NEB, respectively (Ishii et al. 2016)

the A-B and C-D atomic bonds – is observed together with uniform supercell shear deformation. Figure 10b also shows that the Gibbs free energy barrier decreases with increasing applied external shear stress and that an athermal condition is eventually achieved at a critical external shear stress of $\sim$3.0 GPa. Thus, applying an external shear stress of 3.0 GPa can induce the DT regardless of the internal atomic configuration I. Thus, the DT becomes γ-dominant (shear-strain induced) under such an extremely high shear stress.

4   Conclusions

The first-principles computations of primitive crystal lattices revealed the fundamental mechanical properties of chemical bonding in crystals from the standpoint of shearability and tensibility. The simplified computational framework enabled us to perform vast numbers of computations for different crystal lattices. Thus, the computational approach may lead to a base of high-throughput ultra-strength and ultra-toughness structural alloys designed from first-principles, although extrinsic factors will need to be considered for a more accurate quantitative analysis. The first-principles computation of intrinsic strength of crystal lattice based on Gibbs free energy landscape in the shuffling-strain joint space redefines the strength of a crystal lattice, which is not only stress but also temperature dependent; moreover, it depicts untouched saddle points that cannot be accessed only by applying stress or strain. The computation framework judges whether the lattice deformation is shuffling-controlled or strain-controlled. The former is more temperature sensitive, and the latter is more stress sensitive. This computational approach may be very useful for

lattice deformations with a more shuffling-contorted aspect, such as deformation twinning in HCP and solid-solid transformations. Although these studies provide valuable fundamental information about the strength of materials, which could be useful in high-throughput materials design, numerous tasks remain to enable the consideration of extrinsic factors for more precise predictions of the mechanical properties of actual structural materials. A sophisticated spatial- and temporal-scale coarse-grained framework (Zhao et al. 2013) based on the given first-principles intrinsic mechanical properties is desired because, in reality, deformation must be heterogeneous and asynchronous.

Contents

Abstract

Atomistic simulation has been recognized as a powerful tool to investigate and predict the mechanical properties and behaviors of nanostructured and amorphous materials. In this chapter, we first introduce some basic methodologies, including the setups for simulations of fracture and fatigue, and how to characterize the resistance to fracture and fatigue based on the information from atomistic simulations. Then we highlight some recent studies about large-scale atomistic simulations for fracture and fatigue of nanotwinned and amorphous

materials (such as metallic glasses and lithiated silicon). At the same time, we further address the mechanistic insights to damage initiation around crack tip, interaction between crack and various defects, and origins of brittle and ductile behaviors. These results from atomistic simulations help provide a fundamental understanding of fracture and fatigue behaviors of nanotwinned and amorphous materials, which facilitates the design and fabrication of new materials with excellent mechanical properties and performance.

1   Introduction

Fracture is one of the most common failure modes of materials with or without pre-existing cracks under static and dynamic strain, and fatigue usually refers to the deformation and failure of materials under cyclic loads. Investigating the fracture and fatigue behaviors of materials is crucial for the reliability and safety of materials and structures in many practical applications.

Over the past decades, a number of novel nanostructured and amorphous materials (such as nanocrystalline and nanotwinned materials, metallic glasses, and lithiated silicon) have emerged as a result of rapid advances in fabrication and processing technologies. In contrast to conventional crystalline materials with characteristic sizes above tens of micrometers, nanostructured and amorphous materials can often achieve extraordinary mechanical properties owing to their unique microstructures, including higher strength, better ductility, higher fracture toughness, and more remarkable resistance to fatigue, corrosion, and wear. Several comprehensive reviews of experimental studies on the fracture and fatigue behaviors of these new materials can be found in the literature (Kumar et al. 2003; Ovid'ko 2007; Sun and Wang 2015; Zhu and Li 2010; Li et al. 2016; Pineau et al. 2016a, b, c; McDowell et al. 2016). However, due to various limitations in testing and visualization techniques, it is still difficult or even impossible to determine the deformation processes or mechanisms of materials at the smallest characteristic scales (usually the nanoscale) through experiments alone.

In recent years, atomistic simulations have become increasingly recognized as a powerful tool to investigate the deformation and failure of materials (Yip 2005; Li and Gao 2015), including both crystalline and amorphous materials. Due to their intrinsic atomic-scale resolution, atomistic simulations are often used to complement experiments in probing the prevailing deformation and failure mechanisms in nanostructured and amorphous materials. On the other hand, an amount of caution is needed to interpret the simulation results in view of the large disparities in sample sizes and loading rates between simulations and experiments, even though continuous advances in supercomputers and the development of efficient algorithms (multiscale modeling, machine learning methods, etc.) have to some extent reduced such gaps in recent years. Inspiringly, the deformation and failure mechanisms revealed by atomistic simulations can be validated at overlapping length scales through direct in situ observations using a scanning/transmission electron microscope (SEM/TEM) (Li and Gao 2015). Currently, atomistic

simulations are broadly applied to explore deformation and failure behaviors and the associated mechanisms of nanostructured and amorphous materials (Li and Gao 2015). Atomistic simulations not only provide new mechanistic insights into the microstructural evolution and interaction between various defects but also shed light on the structure-property-processing relationships of new materials. The results and insights from atomistic simulations have profound implications on the design and fabrication of new materials with excellent mechanical properties and performance.

In this section, we first introduce some fundamental methodologies for simulations of fracture and fatigue and for the extraction of mechanical information or quantities (characterizing the resistance to fracture and fatigue) from atomistic simulations. We highlight some recent studies using atomistic simulations to examine the fracture and fatigue of nanotwinned and amorphous materials (such as metallic glasses and lithiated silicon) with a number of illustrative examples. These atomistic simulations can offer an atomically resolved view of complex fracture and fatigue processes, as well as the underlying failure mechanisms. Moreover, we offer some mechanistic insight into damage initiated around the tip of a crack, the interaction between a crack and various defects, and the origins of brittle and ductile behaviors, which improves the fundamental understanding of the fracture and fatigue of new nanostructured and amorphous materials.

2   Methodology

Studies on the fracture of materials have mainly focused on crack propagation or growth under an applied mechanical loading. Therefore, when one constructs fracture simulations, a pre-existing crack should be first introduced in the simulated samples. Appropriate loading and boundary conditions are then applied. As the applied loading varies, mechanical information (such as atomic stress, atomic strain, crack advance, and applied stress intensity factor) related to crack propagation is recorded and used to quantify the relationships among crack propagation, microstructure, and applied load. At the same time, some mechanistic details (such as the interaction between the crack and other defects) of crack propagation are also captured. In this part, we briefly introduce the basic procedure and setup for simulations of fracture and fatigue. For fracture simulations, we also introduce several methods to calculate the fracture energy or toughness of materials according to information extracted from atomistic simulations.

Based on the relaxation method, atomistic simulations can be generally classified into two groups: molecular statics (MS) simulations and molecular dynamics (MD) simulations. During MS simulations, the system is relaxed based on an energy minimization algorithm (such as conjugate gradient or second-order Newton-Raphson). MS simulations can reflect the quasi-static evolution of the system under a slowly varying strain but are not able to account for the effects of finite temperature. In contrast, during MD simulations, the system is relaxed by involving the actual motion of the atoms, which is determined by numerically solving Newton's equations of motion within a given time step. This allows MD simulations

to study the evolution of the dynamics and thermodynamics and the response of the system at finite temperatures. However, MD simulations have the disadvantage that the time step is around one femtosecond; thus, the total simulation time is generally limited to several nanoseconds, leading to an extremely high strain rate which is 7–11 orders of magnitude higher than those used in typical experiments. Fortunately, in many cases such high strain rate does not have a significant effect on the underlying deformation and failure mechanisms of materials. In parts 3 and 4, we introduce some recent MD simulations on the fracture and fatigue of nanotwinned and amorphous materials to highlight the success of atomistic simulations. When introducing fatigue in nanotwinned metals, we will also compare the simulation results between the MS and MD techniques.

2.1   Simulation Setup for Fracture

During fracture simulations, we are mainly interested in the failure and damage from crack propagation and advancement. Therefore, a pre-existing crack is introduced in the initial configurations of the simulated samples. Generally, there are two methods to introduce a pre-existing crack. The first method is to create a crack or notch by removing a wedge of atoms, while the second method is to generate a crack by preventing interatomic interaction across the crack surface. The crack generated by the second method has an atomically sharp tip. The initial crack is generally located at the center or edge of a simulated sample to achieve the center or edge cracked configuration.

   During fracture simulations, applying a loading on the crack is a crucial step for the overall simulation. Mode I is the dominant fracture mode in practical fracture cases; thus, most simulations primarily model mode I crack propagation, where the applied tensile loading is normal to the crack surface. There are three methods to achieve mode I loading. The first method is that during each loading step, a uniform tensile strain is applied, and then the overall system is relaxed with a fixed boundary along a direction normal to the tensile direction. Such loading step is repeated until the simulation is terminated. In the second method, one edge along the tensile direction of the sample is fixed, while another edge is stretched at a given constant velocity. To avoid stress waves induced at the onset of the constant velocity loading at one edge, a linear velocity profile is imposed on all atoms at the beginning of the simulation. Throughout the simulation, atoms on both edges are subjected to a controlled velocity, while all other atoms are free to move according to Newton's equations of motion. The third method is to apply a K-field to the simulated sample (hence often referred to as the K-controlled method). Figure 1 shows the schematic illustration of mode I loading on a simulated sample with a pre-existing crack. During the simulation, mode I loading is accomplished by increasing the stress intensity factor K in a very small increment ΔK. Such increment is usually $K_{IC}/100$ or less to ensure the iteration accuracy and convergence, where K_{IC} is the critical stress intensity factor for crack initiation. During each loading step, all the atoms in the fixed region in Fig. 1 are first positioned according to the continuum
elasticity solution (i.e., asymptotic solution) of the crack tip displacement field with
the specified K, while all interior atoms in the free region are relaxed via the MS or
MD technique. The applied K-field thus serves as the boundary conditions for the
free region. To avoid the influence of the K-field on the crack tip plastic behavior,
the fixed region is required to be far from the crack tip, which indicates small-scale
yielding conditions, i.e., the size of the simulated sample in Fig. 1 is large enough
to accommodate the plastic zone around the crack tip. If the simulated sample is
relatively small, a buffer region needs to be introduced between the fixed and free
regions (Yip 2005), as shown in Fig. 1. Atoms in the buffer region are controlled
according to the forces from atoms in the free region (Yip 2005), which to some
extent avoid the influence of the fixed region of the crack tip (Yip 2005). The first
and second methods are simple and can be realized easily during fracture simulation.
In contrast to the first and second methods, the third method is more complex but
could be more effective in determining the fracture resistance curve and the fracture
toughness K_{IC}.

Atomistic simulations not only provide mechanistic details of the fracture
process but can also be used to estimate the fracture toughness. Here, we introduce
four methods to calculate the fracture toughness based on the results of atomistic
simulations. The first method is to calculate the energy release rate and is usually
used for the brittle materials. The critical energy release rate G_c can be calculated
by comparing the initial and final cracked configurations as follows:

$$G_c = -\frac{\Delta U - \Delta W}{t \Delta a} \tag{1}$$

where ΔU is the change in the strain energy and ΔW the change in the external
work associated with crack extension Δa, and t is the thickness of the simulated
sample; ΔU can be estimated based on the elastic stress and strain states of

the initial and final configurations, while ΔW can be calculated by integrating the force-displacement curves obtained from simulations. This method has been used to calculate the G_c of nanocrystalline graphene, with result consistent with experimental measurements (Jung et al. 2015).

The second method is to estimate the fracture energy by integrating the stress-strain curves for crack propagation. For a strip with an edge crack, the fracture energy for crack propagation can be calculated by the following expression (Freund 1990):

$$G = 2H \int_0^{\varepsilon_c} \sigma \, d\varepsilon \tag{2}$$

where H is the half width of the strip and ε_c is the critical strain at which the crack starts to propagate. The integration in Eq. (2) represents the area under the stress-strain curve, which can be obtained from the simulations. For brittle materials, Eq. (2) can be reduced to a linear elastic stress-strain relationship,

$$G = HE\varepsilon_c^2 \tag{3}$$

where E is the Young's modulus.

The third method is to obtain the critical stress intensity factor K_{IC}. During the fracture simulation, if the applied loading is achieved by imposing a K-field, K_{IC} can be easily taken as the stress intensity factor at crack initiation. This method has been used to predict the fracture toughness of lithiated silicon (Khosrownejad and Curtin 2017). The predictions for amorphous $Li_{0.5}Si$ and $LiSi$ from atomistic simulations are comparable to experimental measurements (Khosrownejad and Curtin 2017).

The fourth method is to extract the interfacial fracture energy based on a cohesive-zone-volume-element (CZVE) model (Yamakov et al. 2006). This method is only for interfacial cracks. The CZVE model is very similar to the continuum cohesive zone model and can provide the traction-separation relationship through a statistical average of the atomic information (such as atomic stress and displacement) around the interfacial crack. Before the simulations, the regions on both sides of the interface need to be sliced into a large number of square CZVEs. The dimension of each CZVE is usually set to 1 nm. During the simulations, the traction of each element is the average of the atomic stress of all atoms in the element, while the separation (i.e., opening displacement of the crack) is estimated by calculating the displacement of the mass point of the element. In the process of crack opening and propagation, the traction and separation of each CZVE are averaged at each given time interval to avoid thermal fluctuations. A traction-separation curve is obtained through the statistics of all data on the traction and separation of each CZVE. Finally, the interfacial energy is calculated by integrating over the traction-separation curve. This method has been used to capture the brittle and ductile fracture of an interfacial crack along a high-angle grain boundary in aluminum (Yamakov et al. 2006), as well as to calculate the interfacial fracture energy between lithiated silicon and amorphous silicon (Lang et al. 2017). These results

from atomistic simulations are consistent with those from the relevant continuum cohesive zone modeling (Yamakov et al. 2006) and experiments (Lang et al. 2017).

To calculate the fracture toughness through atomistic simulations for three-dimensional block samples, the plane strain condition must be imposed in the direction parallel to the crack front to ensure the validity of the calculated fracture toughness. Currently, there is still a gap in quantitative predictions of fracture toughness between atomistic simulations and experimental measurements, which may be attributed to distinct differences in the length scale and microstructure of the samples.

2.2   Simulation Setup for Fatigue

For fatigue simulations, the focus of the study is to assess the damage evolution of samples with or without pre-existing cracks under cyclic loading. For samples without an initial crack, cyclic loading is generally achieved by applying periodic alternating strain within a given timeframe. In each strain-controlled cycle, the maximum applied strain is generally smaller than the yielding strain of the simulated samples. This type of simulation is used to study damage initiation and development as well as the associated microstructural evolution of simulated samples with the accumulation of plastic strain.

For samples with a pre-existing crack, cyclic loading is accomplished by imposing a triangle-shaped alternating stress intensity factor. In each loading/unloading step, a specific K-field is imposed around the crack tip according to the K-controlled method mentioned above. The stress intensity factor range $\Delta K = K_{\max} - K_{\min}$, where $K_{\max}$ and $K_{\min}$ are the maximum and minimum stress intensity factors, respectively, should be smaller than the fracture toughness (i.e., K_{IC}) of the simulation samples. This type of simulation is used to investigate fatigue crack growth behaviors and the associated mechanisms. Furthermore, when the applied stress intensity factor range ΔK varies, the relationship between the fatigue crack growth rate da/dN and ΔK can be obtained and compared with the experimental results and relevant analytical models.

During fatigue simulations of samples with a pre-existing crack, tracking the fatigue crack growth (or determining the crack extension) is crucial for calculating the crack growth rate da/dN. Figure 2 shows two typical methods to determine the crack extension: one is by locating the maximum coordinate of the crack tip, referred to as the maximum coordinate method (Fig. 2a), while the other is by taking the average value over a characteristic point distributed on the crack front profile, referred to as the average coordinate method (Fig. 2b). In real experiments, the position of the crack tip is usually indirectly estimated from the measurement of the crack tip stress and/or displacement fields. In atomistic simulations, it is relatively easy to locate the exact position of the crack tip. However, such atomic-level resolution may induce a large error in the fatigue crack growth rate if one uses the maximum coordinate method to locate the position of the crack tip. For fatigue crack growth in ductile materials, the error can reach 10% (Zhou et al. 2015).

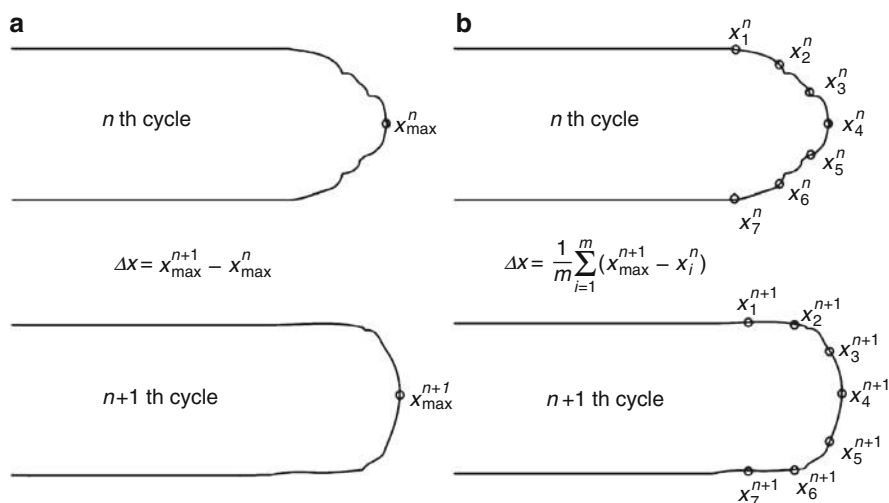

Fig. 2 Schematic illustrations for determining the fatigue crack growth during atomistic simulations (Zhou et al. 2015). (**a**) The maximum coordinate method and (**b**) the average coordinate method. (Reproduced with permission)

As indicated in Fig. 2b, the average coordinate method to some extent reflects the blunting effect of cracks. Therefore, the average coordinate method can be more suitable for estimating fatigue crack growth in ductile materials.

Since MD simulations have inherent limitations in terms of the time scale, fatigue simulations based on the MD technique only last for several hundred cycles, leading to low-cycle fatigue. Based on current computational power, it is possible to use the MS technique to study the high-cycle fatigue (i.e., cycle numbers above 10^4) of materials. However, the related computational cost is extremely high, and the length scale of the simulated sample is very limited.

3 MD Simulations for the Fracture of Nanotwinned and Amorphous Materials

In this section, we review recent atomistic simulations into the fracture behaviors of nanotwinned metals and ceramics and two representative amorphous materials (including metallic glasses and lithiated silicon). For nanotwinned metals and ceramics, the atomistic simulations reveal the complex interactions between a crack and various defects (such as dislocations and twin boundaries (TBs)). For the metallic glasses and lithiated silicon, atomistic simulations are used to investigate the microstructural evolution and deformation behaviors ahead of the crack tip.

3.1   Fracture of Nanotwinned Metals and Ceramics

Nanotwinned materials have a hierarchical microstructure, with a high density of nanoscale twins embedded in the micro- or submicron-sized grains. Therefore, nanotwinned materials exhibit higher strength and larger fracture toughness than their twin-free counterparts. So far, a large number of experimental and computational studies have investigated the plastic deformation of nanotwinned materials and revealed various strengthening mechanisms. There have also been an increasing number of studies on the fracture and fatigue behaviors of nanotwinned materials (Li et al. 2016). However, in contrast to plastic deformation mechanisms, the underlying fracture and fatigue mechanisms of nanotwinned materials are much less understood.

To reveal the underlying fracture mechanisms, we performed large-scale MD simulations of crack propagation in nanotwinned metals and ceramics. We simulated crack propagation in nanotwinned copper thin films with thicknesses varying from several nanometers to approximately 100 nm. Under mode I loading, an edge crack tip in a 100-nm-thick film emits numerous dislocations, which impact the TB ahead of the crack tip, as shown in Fig. 3a. These dislocations react with the TB, leading to the formation of a domain with a high density of dislocations on both sides of the TB, as shown in Fig. 3b. Such domain corresponds to the TB-affected dislocation zones observed experimentally and spans over approximately 5–7 nm, which is consistent with experimental observations (Kim et al. 2012). Such domain serves as a dislocation wall, which blocks further dislocation activities, resists crack propagation, and provides a reasonable explanation for the experimental observation of crack arrest and bridging by nanoscale twins (Kim et al. 2012). When the thickness of the nanotwinned film is only several nanometers, dislocations emitted from the crack tip easily slip across the TB, so that no dislocation wall forms (Kim et al. 2012). Figure 3c shows the typical crack propagation route along a zigzag path in the 1.7-nm-thick film (Zeng et al. 2015). Such zigzag cracking is induced by the persistent slip of dislocations and screw dislocation-mediated local thinning ahead of the crack (Zeng et al. 2015). The zigzag crack path corresponds to the cross-slip direction (i.e., <110> direction) of dislocations in the alternating matrix and twin domains (Zeng et al. 2015). These results (formation of dislocation wall and zigzag cracking) from MD simulations are consistent with previous experimental observations from in situ TEM (Kim et al. 2012; Zeng et al. 2015). Our MD simulations not only reveal the toughening mechanisms (i.e., the interaction between the crack and TBs) but also indicate the influence of film thickness on the fracture mechanisms of nanotwinned metallic thin films. These results have significant implications for understanding the mechanical failure of nanotwinned metallic thin films.

Due to the presence of hierarchical structures, conch shells possess remarkable strength and fracture toughness. Notably, as a basic structural building block, the third-order aragonite lamellae of a conch shell contain a large number of nanoscale {110} growth twins with an average TB spacing of 8 nm (Shin et al. 2016). However, the roles and functions of nanoscale growth twins in the mechanical behaviors of
Fig. 3 Fracture mechanisms in nanotwinned copper thin films (Kim et al. 2012; Zeng et al. 2015). (**a**) Interaction between a TB and dislocations emitted from a crack tip ahead of the TB in the 100-nm-thick film (Kim et al. 2012). This leads to the TB transforming into a dislocation wall, which further blocks crack propagation. (**b**) Patterns of the dislocation structures along the TB (Kim et al. 2012). (**c**) Snapshots from the MD simulation showing crack growth along a zigzag path (Zeng et al. 2015). the conch shell remain mysterious. We performed large-scale MD simulations of crack propagation in nanotwinned aragonite to explore the influence of nanoscale twins on the fracture properties and behaviors (Shin et al. 2016). Twin-free aragonite acts as the reference material for comparison. Figure 4a, b show snapshots of crack propagation in the twin-free aragonite single crystal with twin or matrix orientations, respectively. In the twin-free aragonite, the crack propagates fast and smoothly by cleavage, indicating brittle fracture. However, in nanotwinned aragonite, the crack tip is trapped by the TB and becomes blunt from sliding along the TB, as evidenced by Fig. 4c, d. It is noted that in twin-free aragonite, the stress/strain is

severely localized around the crack tip (Fig. 4a, b), while there exists an apparent stress/strain delocalization in nanotwinned aragonite (Fig. 4a, b). Such deformation delocalization is attributed to substantial irreversible phase transformation ahead of the crack tip. When the crack is trapped by the TB, a phase transformation occurs and spreads through the nanoscale twin domains ahead of the crack tip. Such phase transformation is driven by high crack tip stress (Shin et al. 2016). In twin-free aragonite, a phase transformation is also observed, but the transformed region is highly limited (Fig. 4e). In contrast, the transformed region in nanotwinned aragonite spans over the nanoscale twin lamella (Fig. 4f) and is much larger than that in the twin-free sample. The phase transformation involves a coordinated rotation of carbonate groups (Fig. 4g–i) and cannot spontaneously recover upon unloading. Figure 4g–i show the relevant details for the change in atomic configuration during the phase transformation. Our MD simulations reveal the underlying fracture mechanisms in nanotwinned aragonite, including the TB blocking crack propagation, phase transformation ahead of the crack tip, and crack tip blunting. These mechanisms facilitate energy dissipation and further delay catastrophic crack propagation, leading to an enhance fracture energy of the nanotwinned sample. This result is further evidenced by the calculation of the fracture energy based on our MD simulations. From the simulated stress-strain curves for crack propagation in the twin-free and nanotwinned samples, according to the second method mentioned in part 2, we calculated the fracture energy by integrating the stress-strain curve. It was found that the fracture energy of nanotwinned aragonite is one order of magnitude higher than that of twin-free aragonite. This prediction is in good agreement with experiment measurements (Shin et al. 2016).

3.2   Fracture of Metallic Glasses and Lithiated Silicon

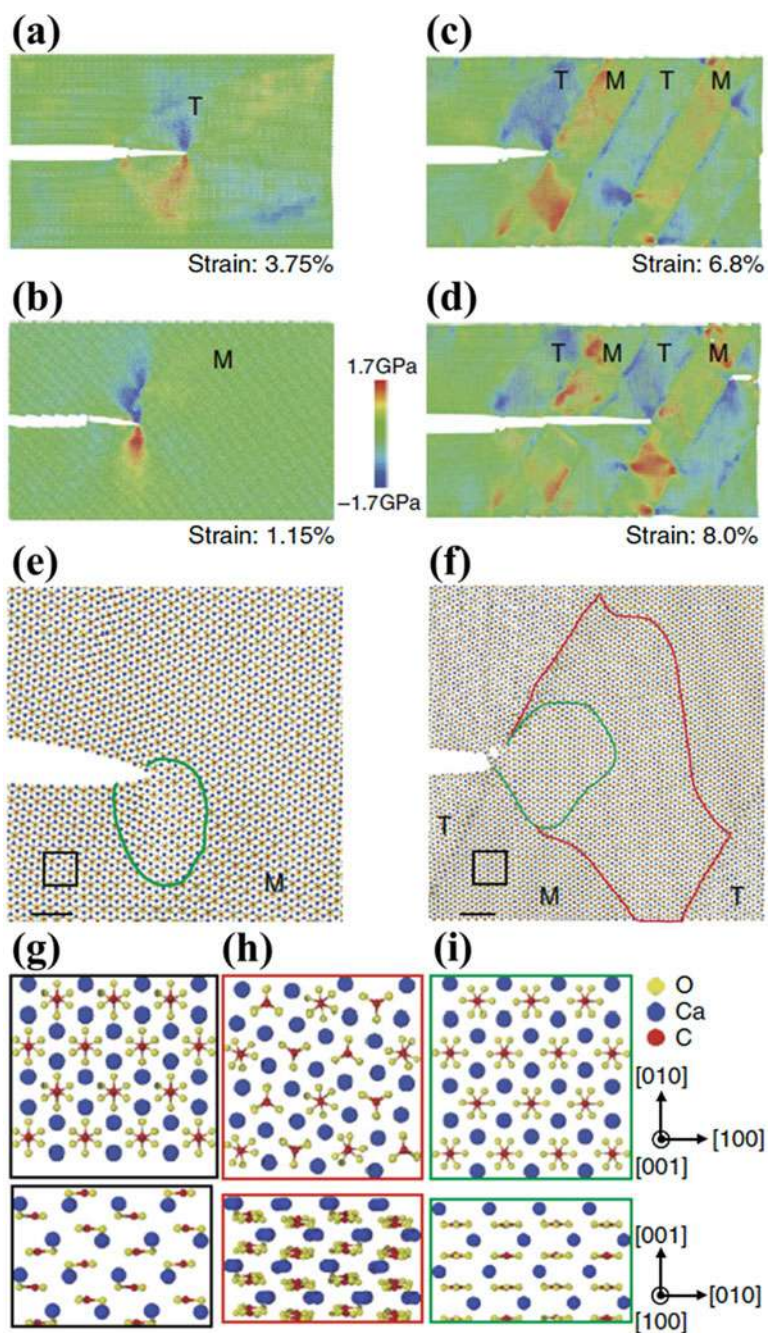
Metallic glasses are a novel type of engineering alloy with metastable glassy states and are usually fabricated through rapid cooling of melting alloys. Due to their amorphous atomic structures, metallic glasses exhibit unique mechanical properties, such as high strength and high resistance to corrosion and oxidation. Notably, the fracture toughness of metallic glasses has a pronounced variation from 1 to 80 MPa·m$^{1/2}$ (Murali et al. 2011). Thus, metallic glasses are generally classified into brittle and ductile types. To reveal the fracture behaviors and associated mechanisms of these two types of metallic glasses, we performed MD simulations of crack propagation in FeP (brittle) and CuZr (ductile) samples (Murali et al. 2011). During the simulations for the FeP sample, some nanoscale voids nucleated and coalesced ahead of the crack tip, and subsequently, the crack merged with the nanoscale voids, leading to rapid growth of an atomically sharp crack, as shown in Fig. 5a. In contrast, in the CuZr sample, the crack tip becomes blunted through extensive shear banding ahead of the crack tip, as shown in Fig. 5b. These two distinct fracture mechanisms reflect the intrinsic features of brittle and ductile fracture, respectively. Further detailed analyses based on atomic stress ahead of the crack tip and critical hydrostatic stress for cavitation show that the observed nanoscale


Fig. 4 (continued)

cavitation in the FeP sample can be attributed to pronounce spatial fluctuations in the local cavitation stress (Murali et al. 2011). Moreover, our MD simulations show that for samples with an initial nanoscale void under equi-biaxial plane strain loading, a single, isolated void grows in the CuZr sample during deformation, while multiple voids nucleate near the initial void and then merge with the initial void in the FeP sample. The critical stress for void growth is insensitive to the void size in the FeP sample but decreases with increasing void size in the CuZr sample.

A recent experimental study (Pan et al. 2015) reported an abnormal inverse notch effect in Zr-based metallic glasses, i.e., when a notch is introduced into the material, its tensile fracture strength is dramatically enhanced rather than decreased. To reveal the underlying mechanisms behind such inverse notch effect, we carried out large-scale MD simulations to investigate the fracture behaviors of notched CuZr samples. Similar to the experimental samples, we constructed two notched samples (ND1 and ND6), as shown in the inset in Fig. 5c. The ND6 sample has a narrower and sharper notch than the ND1 sample. Thus, based on the stress concentration, the ND6 sample is expected to have a lower fracture strength than the ND1 sample. The MD simulations show that the ND1 sample exhibits a higher fracture strength than the ND6 sample, which is consistent with the experimental results, as shown in Fig. 5c. Our MD simulations further reveal that this abnormal phenomenon is related to a transition in the fracture mechanism from shear banding to cavitation. In the notched ND1 sample, a large number of shear transformation zones (STZ) are activated and merge with one another, leading to the formation of an inclined shear band through the sample (Fig. 5d). However, in the notched ND6 sample, due to the sharper notch, there exists a triaxial stress state ahead of notch tip which is large enough to drive the nucleation and growth of nanoscale voids rather than shear banding (Fig. 5e). These fracture simulations provide a fundamental understanding of failure mechanisms in brittle and ductile metallic glasses, as well as mechanistic insights into the design of the macrostructure of metallic glasses to achieve enhanced capability.

Due to its high theoretical charge capacity, silicon has been identified as a promising cathode material for lithium-ion batteries. During the cyclic charging and discharging of batteries, crystalline silicon gradually becomes amorphous. In particular, during charging, numerous lithium ions are inserted into the silicon cathode, leading to a large volume change and the formation of amorphous lithiated

Fig. 4 Fracture mechanisms in nanotwinned aragonite (Shin et al. 2016). (Reproduced with permission)

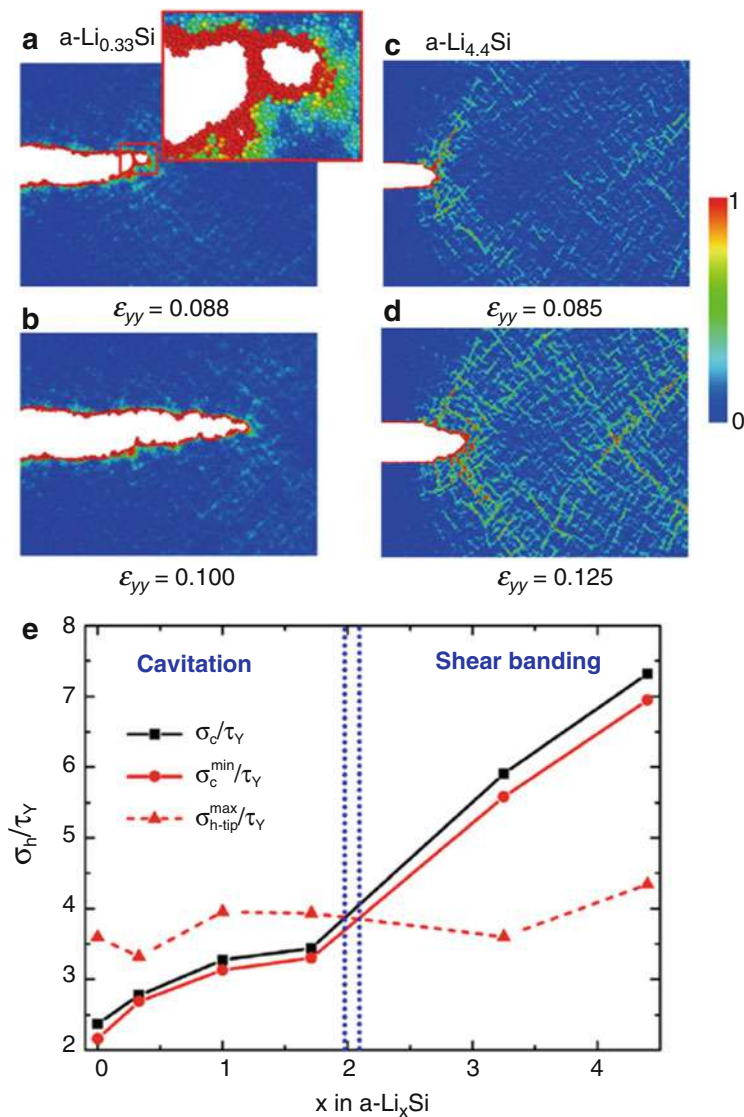
silicon (a-Li_xSi, where x represents the lithium concentration). Fracture of lithiated silicon is believed to be a major cause of capacity fading in the battery. Therefore, it is essential for the design and development of high-capacity batteries to study the fracture behaviors and mechanisms of lithiated silicon. Recent experimental studies show that as the lithium concentration increases, a brittle-to-ductile transition occurs in lithiated silicon (Wang et al. 2015). This implies that the fracture toughness of lithiated silicon is dependent on the lithium concentration. To explain the experimentally observed brittle-to-ductile transition, we performed a series of large-scale MD simulations to mimic crack propagation in a-Li_xSi with x varying from 0 to 4.4. During the simulations, a modified embedded-atom method (MEAM) potential was used to describe the interatomic interactions. Figure 6a–d show typical snapshots of crack propagation in a-$Li_{0.33}Si$ and a-$Li_{4.4}Si$ obtained from


Fig. 6 Brittle-to-ductile fracture transition in lithiated silicon (Ding et al. 2015). (**a, b**) Snapshots of crack propagation in a-Li$_{0.33}$Si, showing a brittle fracture mode, i.e., rapid propagation of an atomically sharp crack through the nucleation and coalescence of nanovoids ahead of the crack tip. (**c, d**) Snapshots of crack propagation in a-Li$_{4.4}$Si, showing a ductile fracture mode, i.e., crack blunting through extensive shear banding. our MD simulations. In the samples with relatively low lithium concentrations (i.e., x ≤ 1.71), nanoscale voids nucleate ahead of the crack tip and then coalesce with the main crack, leading to rapid propagation of an atomically sharp crack, similar to the mechanism of brittle fracture in metallic glasses, as discussed in part 3.2. In contrast, in the samples with high lithium concentrations (i.e., x ≥ 3.25), shear bands form ahead of the crack tip. As the applied strain increases, the crack tip becomes blunted, which is similar to the fracture response of ductile metallic glasses discussed in part 3.2. Our simulation results are consistent with those from recent MD simulations for crack propagation in a-Li$_{0.5}$Si and a-Li$_{2.5}$Si (Wang et al. 2015), where the reactive force field (ReaxFF) was used. Most recently, the K-controlled loading method (introduced in part 2.1) and MEAM potential were used to simulate edge crack propagation in as-quenched a-Li$_x$Si with $x = 0.5, 1.0, 1.5$ and discharged samples with $x = 0.5, 1.5$ (Khosrownejad and Curtin 2017). During crack propagation, void nucleation occurs in these samples, which is consistent with our simulations. In these MD simulations, the fracture toughnesses were estimated by determining the critical K at crack initiation. The results indicated that the fracture toughness of lithiated silicon depends not only on the lithium concentration but also on the lithiation/delithiation history (Khosrownejad and Curtin 2017).

Our MD simulations provide important insight into the fracture mechanisms of lithiated silicon. According to the elastic-plastic fracture theory, we established the following criterion (Ding et al. 2015) for cavitation ahead of the crack tip:

$$\frac{\sigma_c}{\tau_y} \leq \alpha \left(\nu, \varepsilon_y, N \right) \tag{4}$$

where σ_c is the critical cavitation stress, τ_y is the shear yield stress, and α is a dimensionless ratio $\sigma_{h\text{-tip}}^{\max}/\tau_y$ dependent on Poisson's ratio ν, tensile yield strain ε_y, and hardening index N. To validate the above criterion, we determined the critical cavitation stresses σ_c and the shear yield stresses τ_y of lithiated silicon and computed the maximum hydrostatic stress $\sigma_{h\text{-tip}}^{\max}$ ahead of the crack tip and the minimum cavitation stress $\sigma_c^{\min}$ arising from atomic-scale fluctuations through MD simulations. Figure 6e shows the variations in σ_c/τ_y, $\sigma_c^{\min}/\tau_y$, and $\sigma_{h\text{-tip}}^{\max}/\tau_y$ with the lithium concentration x. As shown in Fig. 6e, $\sigma_{h\text{-tip}}^{\max}/\tau_y$ is nearly constant close to the predicted value of $1 + \pi$ from the Prandtl slip-line theory (Ding et al. 2015). For x ≤ ~2, σ_c/τ_y is less than $\sigma_{h\text{-tip}}^{\max}/\tau_y$, while for x ≥ ~2, σ_c/τ_y is greater than $\sigma_{h\text{-tip}}^{\max}/\tau_y$. According to the criterion in Eq. (4), it is predicted that nanoscale cavitation occurs in samples with x ≤ ~2, while shear banding dominates in samples with x ≥ ~2. Such prediction is in good agreement with our MD simulations, confirming a brittle-to-ductile transition in the fracture mechanism from intrinsic nanoscale cavitation to extensive shear banding ahead of the crack tip. Our MD simulations address a crucial effect of lithium concentration on the fracture properties of lithiated silicon, which may have profound implications for the design of damage-tolerant electrodes.

4   MD Simulations of the Fatigue of Nanotwinned and Amorphous Materials

As introduced in part 3, the fracture behaviors of nanotwinned and amorphous materials under monotonic loading were studied. However, their failure behaviors (i.e., fatigue) under cyclic loading and the associated microscopic mechanisms are much less known. In this part, we introduce some recent studies on low-cycle fatigue of nanotwinned metals and metallic glasses through large-scale atomistic simulations, with an emphasis on the underlying fatigue mechanisms as well as the relationship between the fatigue properties and microstructures.

4.1   Fatigue of Nanotwinned Metals

A few experimental studies have shown that nanotwinned metals have a noticeably improved resistance to fatigue crack growth compared with their twin-free counterparts (Li et al. 2016). However, the underlying mechanism responsible for the enhanced fatigue resistance is still poorly understood. We therefore conducted a series of large-scale MS and MD simulations to investigate the fatigue behaviors and mechanisms of nanotwinned copper with a mean grain size d from 10 nm to 20 nm and TB spacing λ from 0.83 nm to 5.01 nm. The ratios of d/λ in the simulated samples are between 5 and 18, close to those of experimental samples. During the simulations, the simulated samples are subject to a cyclic loading through the K-controlled method. The applied stress intensity factor amplitude ΔK varies from 2.40 MPa m$^{1/2}$ to 4.32 MPa m$^{1/2}$. All simulated samples are loaded for 30 cycles under a given ΔK. Figure 7a, b show snapshots of the crack tip configurations under maximum and minimum loading in a typical cycle, respectively. Many preexisting TBs ahead of the crack tip disappear during fatigue (Fig. 7a), indicating that detwinning is activated by TB migration through consecutive slip of partial dislocations along the TBs (Zhou et al. 2015). The crack tip is blunted due to dislocation emission and slip. Notably, double striations form at the crack tip (Fig. 7b), which are attributed to alternating crack tip blunting and sharpening during loading and unloading cycles (Zhou et al. 2015). Such double striation is commonly observed during the fatigue of ductile coarse-grained metals and alloys and is essentially distinct from the nucleation of nanoscale voids ahead of the crack tip during fatiguing of twin-free nanocrystalline metals (Zhou et al. 2015). For nanotwinned metals, detwinning and crack tip blunting are two dominant mechanisms during fatigue, which induces large energy dissipation and enhanced fatigue resistance. During the fatigue simulations, we obtained the crack growth curve by tracking the crack tip via the average coordinate method (introduced in part 2.2). We then characterized the fatigue crack growth rate da/dN by fitting the linear slope of the crack growth curve (Fig. 7c). Figure 7d shows a linear relationship between da/dN and ΔK on the log-log scale, indicating that the fatigue crack growth from atomistic simulations conforms to Paris' law (Zhou et al. 2015). It is noted

that as the ratio of d/λ increases, the da/dN-ΔK curve moves down in the log-log diagram, suggesting that the fatigue resistance increases with increasing d/λ (Zhou et al. 2015). This result is consistent with experimental measurements. By fitting the simulation data in Fig. 7d, the exponent m in Paris' law is obtained as $\sim$3.5, which is close to that ($\sim$3.9) obtained from experimental studies (Zhou et al. 2015). Based on the damage accumulation model, we derived the following da/dN-ΔK relationship in the form of Paris' law (Zhou et al. 2015),

$$\frac{da}{dN} = \frac{5\pi}{96\alpha K_{IC}^2 \sigma_y^2}(\Delta K)^4 \tag{5}$$

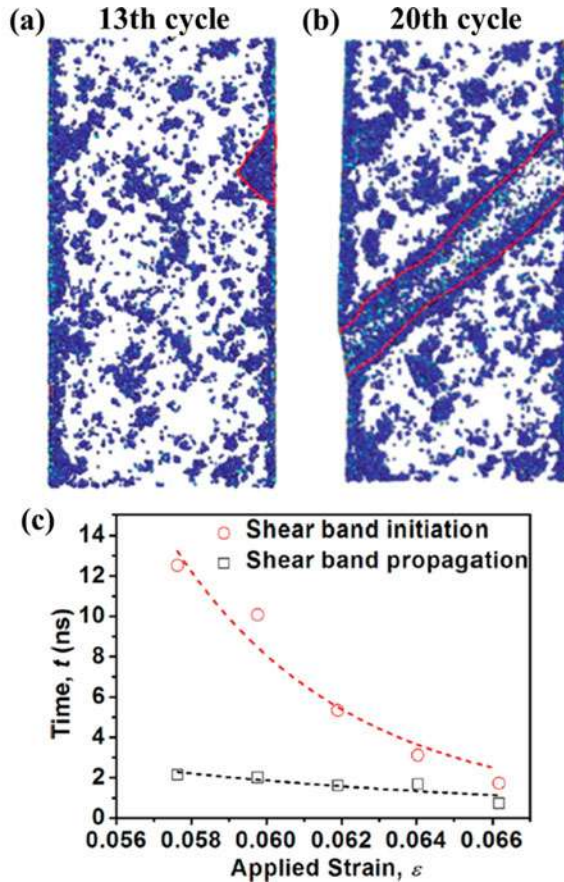
where K_{IC} is the fracture toughness, σ_y is the yield strength, and α is a material constant (approximately 3000 for nanotwinned copper). The predictions from Eq. (5) agree well with the results from both atomistic simulations and experiments (Zhou et al. 2015).

During fatigue, the cyclic stress responses of many metals and alloys are unstable (hardening or softening) due to the accumulation of irreversible damage to the microstructures and exhibit an apparent dependence on the loading history (Pan et al. 2017). Remarkably, a recent fatigue experiment on nanotwinned copper

with columnar grains showed that when the cyclic loading axis is approximately parallel to the majority of the twin planes, the cyclic response becomes stable and history independent, irrespective of the imposed plastic strain amplitudes and cycle numbers (Pan et al. 2017). To explore the underlying mechanisms behind the history-independent and stable cyclic response, we carried out a series of MD simulations for the cyclic deformation of nanotwinned copper with $d = 40$ nm and $\lambda = 2$ nm, 3 nm, 5 nm, and 12 nm. The simulated samples contain columnar grains with <111> texture and have an initial dislocation density of 1.2×10^{17} m^{-2}, similar to the experimental samples. During the simulations, the simulated samples were subjected to uniaxial symmetric tension-compression cyclic loading through a strain-controlled method. All simulated samples were loaded for 20 cycles. Our MD simulations showed similar history-independent cyclic behaviors as the experimental observations. More importantly, a new type of dislocation structure, referred to as a correlated necklace dislocation (CND) (Fig. 7e), was discovered. Such CND is completely distinct from the typical dislocations observed in conventional metals and alloys during fatigue, as well as various dislocations found in nanotwinned metals under monotonic loading (Pan et al. 2017). A CND consists of a series of threading dislocation segments on inclined slip planes between neighboring TBs and stair-rod dislocations at the intersection between the inclined slip planes and TBs (Pan et al. 2017), as illustrated in Fig. 7f–h. The CND structures were verified by TEM observations (Pan et al. 2017). They are formed by linking neighboring threading dislocation tails on the TBs, and collectively they move back and forth along the TBs under cyclic deformation (Fig. 7e), which not only carries relatively homogeneous plastic strain in the neighboring twin/matrix lamellae but also preserves the coherency and stability of the TBs. Throughout the simulations, the collective motion of CNDs is identified as a dominant deformation mechanism responsible for the observed stable and history-independent cyclic behaviors. Our MD simulations also indicated that as long as the highly oriented twins are titled within approximately 15° of the loading axis, CNDs are formed during cyclic deformation, thereby leading to a history-independent cyclic response. Our MD simulations thus revealed a novel fatigue mechanism at the atomic scale, which can be used to account for the observed history-independent behavior and may benefit the fabrication and design of structured materials with enhanced fatigue resistance.

4.2 Fatigue of Metallic Glasses

Fatigue experiments on various metallic glasses have revealed some characteristic deformation behaviors under cyclic loading (Sun and Wang 2015), e.g., shear banding significantly affects the fatigue of metallic glasses. The experimental results also indicated that the fatigue properties of metallic glasses are sensitive to defects (such as micro-cracks, pores, and surface flaws) as well as environmental and geometrical effects. Currently, there is little or no atomic-level understanding of the formation of shear bands in metallic glasses during fatigue. Thus, we conducted a series of MD simulations on the cyclic deformation of a CuZr slab. During the

Fig. 8 Fatigue mechanisms in metallic glasses (Sha et al. 2015). (**a**) Aggregation of STZs marked by the red line in the 13th cycle, indicating the formation of a shear band. (**b**) Penetration of the shear band through the entire sample occurred at the 20th cycle. (**c**) Times for shear band initiation propagation as functions of applied strain amplitude. (Reproduced with permission)


simulations, the simulated samples were subjected to tension-compression loading through a strain-controlled method. The maximum applied strain varied from 1.71% to 6.40%, which ranges over the elastic and plastic regimes of the simulated sample under monotonic loading (Sha et al. 2015). The simulated samples were loaded for 175 cycles. Figure 8a, b show two typical snapshots of the simulated sample during fatigue with an applied strain of 6.40%. In the initial cycles, a large number of STZs formed at the surface or inside of the sample. With increasing cycle number, some STZs near the surface aggregated in an embryonic region of the shear band (Fig. 8a). When the region size exceeded a critical value, the shear band initiated and then quickly propagated across the entire sample (Fig. 8b). Figure 8c shows the time instants for shear band initiation and propagation as functions of applied strain. It is seen that as the applied strain increases, the time needed for shear band initiation slowly decreases, whereas the time for shear band propagation quickly decreases (Sha et al. 2015). Notably, shear band initiation dominates most of the fatigue life of metallic glasses. This phenomenon is somewhat similar to

that in crystalline materials, where the fatigue life is also dominated by the damage initiation stage (Sha et al. 2015). Moreover, during the MD simulations, we changed the cycling frequency to investigate its influence in the fatigue life of metallic glasses. It was found that increasing the cycling frequency prolonged the fatigue life of metallic glasses (Sha et al. 2015). This phenomenon is attributed to the fact that the accumulation rate of STZs decreases with increasing cycling frequency (Sha et al. 2015). Our MD simulations not only provide some atomistic insights into the fatigue process of metallic glasses but may also suggest a strategy to enhance the fatigue life of metallic glasses by suppressing shear band initiation.

5   Summary

Atomistic simulations were applied to explore the fracture and fatigue behaviors and associated mechanisms of nanotwinned and amorphous materials. The results from atomistic simulations shed light on the fundamental failure mechanisms of these materials and have been used to explain or interpret experimental results. The phenomena observed in the atomistic simulations are consistent with those from related experiments, especially those involving in situ TEM observations. Furthermore, atomistic simulations can supply some quantitative predictions, such as the fracture toughness, the fatigue crack growth rate, and the da/dN-ΔK diagram, which are found to be comparable to experimental measurements.

Despite the rapid development of atomistic simulations, there still exists an apparent gap between atomistic simulations and experiments due to the inherent limitations in the length scales and time scales of atomistic simulations, as well as the limited accuracy of interatomic potentials. For example, the strain rate of MD simulations is several orders of magnitude higher than the loading rate used in experiments, and atomistic simulations have been limited to modeling low-cycle fatigue. Such gap can be reduced with the emergence of increasingly accurate interatomic potentials and multiscale modeling techniques, as well as the continuous improvement of supercomputing capacity. More powerful supercomputers allow atomistic simulations to mimic the failure of materials at slower and more realistic strain rates and at larger length scales. In recent years, some multiscale methods have been proposed by coupling quantum calculations, atomistic simulations, and continuum-level modeling. These multiscale methods bridge different length scales and allow us to comprehensively capture complex fracture processes of materials, from bond breakage, to crack growth, to the interplay of crack tip elastic and plastic fields. The interatomic potentials used for atomistic simulations are becoming increasingly more accurate, reliable, and sophisticated. In particular, reactive fore fields based on the bond order have been developed to describe bond formation and breakage (Li and Gao 2015). Such force fields should be more accurate than empirical interatomic potentials. Atomistic simulations with reactive force fields can treat systems with length scales on the order of tens of nanometers. Most recently, with the advances of artificial intelligence, machine learning methods (including artificial neural networks, Gaussian processes, and support vector machines) have

been used to develop interatomic potentials (Behler 2016). Such machine learning potentials can provide very accurate energies close to those of quantum methods but are much more efficient than quantum methods (Behler 2016). Currently, atomistic simulations with machine learning potentials can address systems with length scales of approximately 10 nm. The rapid development of supercomputers, multiscale methods, and interatomic potentials will undoubtedly make atomistic simulations more realistic, predictive, and useful for research into the processing, properties, microstructure, deformation, and failure of next generations of advanced materials systems.

can be hosted unintentionally or intentionally into two-dimensional materials to modify their mechanical properties. In general, there are two types of intrinsic defects in two-dimensional materials: point defects (vacancies, self-interstitials, dislocations, and topological defects) and line defects (grain boundaries). Due to the difference in lattice structures and bonding energies, the configurations of these defects may take difference forms. Here we outline the main computational techniques (ab initio, density functional-based tight binding and molecular dynamics) most commonly used to study defects in two-dimensional materials. The basic modelling approaches to simulate the defect forms and their effects on the mechanical properties of 2D materials are reviewed. Although the family of two-dimensional materials is expanding fast, we mostly focus on four members of this family: graphene, boronitrene, MoS_2, and phosphorene, with emphasis on typical types of defects: vacancies, Stone-Wales defects, dislocations, and grain boundaries.

1   Introduction

The family of two-dimensional (2D) materials is expanding rapidly. Due to the difference in chemical compositions, the lattice structure and bonding energy for each family member are different. As a result, they exhibit various distinctive mechanical, physical, and chemical properties. Here, we briefly discuss four prime representative 2D materials: graphene, boronitrene or hexagonal boron nitride (h-BN), molybdenum disulfide (MoS_2), and phosphorene. Graphene, a single layer of carbon atoms in a hexagonal honeycomb lattice, is one of the most prominent examples of 2D materials. It has attracted considerable attention due to its unique electronic structure, outstanding electrical conductivity, and exceptional strength. Boronitrene is a 2D insulator with noteworthy mechanical properties. Structurally, boronitrene, also called "white graphene," is similar to graphene with comparable bond lengths and layer thicknesses. However, these two materials display different mechanical behavior, predominantly due to the different type of bonding (covalent bonding between C-C atoms vs. mixed ionic-covalent bonding between B-N atoms) (Pakdel et al. 2012). Semiconducting MoS_2 has a triple-layer structure with the central hexagonal plane of molybdenum sandwiched between two hexagonal sulfur planes. Its crystal structure is effectively a 2D honeycomb lattice with the two sub-lattices populated by Mo- and S-atoms, where each Mo-atom is sixfold coordinated, while each S-atom is threefold coordinated. Its unusual mechanical properties arise from the significant ionic character of Mo-S bonds (Sorkin et al. 2014). Semiconducting phosphorene, a monolayer of black phosphorus, has provoked a significant interest due to its unusual puckered structure, direct bandgap, and strong anisotropy of the mechanical properties (Sorkin et al. 2016).

Defects in 2D materials can have profound effects on their mechanical properties. In thermodynamic equilibrium, the second law of thermodynamics predicts the inevitable existence of defects. In non-equilibrium state, defects can be intentionally

introduced into 2D materials during fabrication to realize certain functionalities that are absent in the defect-free ones. In general, there are two classes of intrinsic defects in 2D materials: point defects (vacancies, self-interstitials, topological defects, and dislocations) and line defects (grain boundaries). Due to the difference in lattice structures and bonding energies, the configurations of these defects may take different forms in different 2D materials.

In this book chapter, we will first briefly discuss several major computational techniques (density functional theory, tight binding, and molecular dynamics) that have been widely used in the study of defects in 2D materials, and also basic modelling methods that are often used to examine the defect geometries, the formation energies, and their effects on the mechanical properties. We next discuss in detail the specific structural features and properties of vacancies, topological defects, dislocations, and grain boundaries in the four selected 2D materials, mainly focusing on their effects on the ultimate strength, fracture strain, and failure mechanism. Finally, we will discuss the opportunities and challenges of defect engineering in 2D materials.

2   Computational Methods and Techniques

2.1   Computational Methods

Three main computational techniques: density functional theory, tight binding, and molecular dynamics, are commonly used to investigate defects in 2D materials. Among them, density functional theory (DFT) is one of the most efficient and accurate first-principles computational techniques in 2D materials research. Since DFT is a quantum mechanical method, it does not require any specific prior knowledge of system under the examination. Given that DFT calculations are generally rather computationally expensive, only relatively small samples (reaching a few hundred atoms) can be studied by this technique. In dealing with 2D materials, plane-wave DFT calculations are usually carried out with the exchange correlation potential, approximated by generalized gradient approximation (GGA) or a variety of other functionals. In these calculations, all the structures are treated by using the periodic boundary conditions. Commonly used DFT calculation software packages are VASP or CASTEP.

The behavior of larger systems with thousands to billions of atoms can be studied using classical molecular dynamics (MD) simulations. In MD simulations, the atoms in 2D materials obey Newton's law of motion driven by interatomic forces derived from semiempirical interatomic potentials. These interatomic potentials are constructed and fitted to model the particular behavior of the system obtained by first-principles calculations and/or experimental measurements. For example, in order to simulate graphene, adaptive intermolecular reactive empirical bond order (AIREBO) or Tersoff potential is often employed. It is now known that AIREBO potential is capable to capture accurately the interaction between carbon

atoms, as well as bond breaking and making, while Tersoff potential is the most suitable to examine the mechanical properties. In addition, Tersoff potential was parametrized to describe the interaction between boron and nitrogen atoms in boronitrene (Sorkin et al. 2014). Stillinger-Weber and reactive empirical bond order (REBO) potentials are used to model interactions between molybdenum and sulfur atoms in MoS2 (Li et al. 2016a) and between phosphorus atoms in phosphorene (Sha et al. 2016).

Tight-binding (TB) technique is another method that has often been applied to study the structure, large deformation, and failure of 2D materials with defects. The TB technique has a very special place among the computational methods. On one hand, as discussed above, the DFT method is very precise but computationally demanding. As a result, the DFT calculations are not feasible for large or even moderate scale systems. On the other hand, applying molecular dynamics (MD) method for large systems is rather restricted as reliable and commonly accepted interatomic potentials for many 2D materials are not yet available. Consequently, empirical TB technique, placed in between DFT and MD in terms of computational cost and accuracy, is an appropriate method in dealing with the size problem. Thus, TB methods can be considered as a bridge between classical atomistic methods and quantum mechanical methods. TB simulations are usually performed by using DFTB+ package.

In the following, we briefly discuss computational models and methods that are commonly used to determine the mechanical properties of 2D materials, that is, defect mobility, elastic modulus, and failure behavior.

2.2   Determine Defect Mobility

One of the important characteristics of a defect is its mobility. In general, the mobility of a vacancy is determined by its diffusion (activation) barrier, which the defect must overcome while moving in the sample. Diffusion barriers and migration paths of vacancies are commonly explored by using the nudged elastic band (NEB) method in combination with DFT-based or TB-based techniques (Zobelli et al. 2007). The NEB method is constructed using the optimization of the total energy of a string of system images linking the initial and the final states, and no a priori assumption for the migration path is required. Thus, the NEB method is suitable for examining large regions of configuration space to obtain the set of minimum-energy transition paths. However, due to the slow convergence of the NEB method, the use of standard DFT techniques can be computationally expensive. A good substitute for DFT is density-functional tight-binding (DFTB) or MD method, which is able to reduce computational cost by orders of magnitude while still remaining a reasonable accuracy. It has already been demonstrated that combining DFTB and NEB gives results that are comparable to other higher-end techniques (Zobelli et al. 2007).

2.3   Determine Elastic Moduli

The presence of defects may significantly change the mechanical properties of 2D materials. A special interest is the modification of elastic moduli by defects. The most studied elastic quantity is the change of Young's modulus due to vacancies. By hosting a sample with vacancies (or other types of defects) at different concentrations, one is able to calculate the stress vs. strain curve by subjecting the constructed sample to small uniaxial tensile and compressive strain ($\varepsilon \leq 5\%$). The slope of the calculated stress-strain curve or the second derivative of the strain energy with respect to strain at $\varepsilon = 0$ can be used to find the Young's modulus (Jing et al. 2012). Other elastic moduli can be obtained in a similar way.

2.4   Determine Failure Behavior

In general, the failure behavior of 2D materials is dictated by defects. Due to the presence of defects, 2D materials can fail at much lower failure stress than their defect-free counterparts. In order to investigate the failure mechanism, 2D samples with defects are subjected to uniaxial tensile straining (Jing et al. 2012; Sorkin and Zhang 2016; Sorkin and Zhang 2015). Under uniaxial tensile straining, the strain is defined as the change in length, L, relative to the initial (reference) length, L_0: $\varepsilon = L/L_0 - 1$. In simulations, the sample can be stretched quasi-statically or at a specific strain rate. When a uniaxial tensile strain is applied quasi-statically, the 2D sample is strained along the specific direction by changing the length of the computational box and rescaling the atom positions in that direction. Subsequently, the sample geometry is optimized, and stress is relaxed in the direction perpendicular to the applied strain by minimizing the total energy of the sample. Conjugate gradient or quasi-Newton minimization techniques are commonly used for energy minimization. The defected sample is quasi-statically strained until it fails via bond fracture. Thus one can obtain the fracture strength and fracture strain and examine the fracture mechanism in details. Fracture strength and fracture strain are determined at the point on the stress-strain curve where the maximum stress is reached. The tensile stress, σ, is defined as $\sigma = F/A$, where F is the tensile force and $A = wt$ is the cross-sectional area (assuming thickness of $t = 0.335$ nm for graphene, $t = 0.61$ nm for MoS_2, $t = 0.34$ nm for boronitrene, and $t = 0.53$ nm for phosphorene).

The quasi-static calculations are performed at zero temperature using first-principle methods (Sorkin and Zhang 2015, 2016; Dettori et al. 2012; Rodrigo et al. 2016; Sensoy et al. 2017; Gan and Zhao 2014; Akinwande et al. 2016; Zhang et al. 2012). A 2D sample with defects can be stretched at finite temperature and specific strain rate using MD simulations (Akinwande et al. 2016; Zhang et al. 2012; Xiong et al. 2015; Sha et al. 2014, 2015; Guo et al. 2016). Initially, the sample is thermally equilibrated at the selected temperature using an NPT ensemble (constant number of atoms, pressure, and temperature). The internal residual stresses in the sample are relaxed to zero since during the thermal equilibration, the computational box is

allowed to change its shape and volume. Subsequently, a uniaxial tensile strain is applied by increasing the computational box length in a specific direction at a given strain rate ($\dot{\varepsilon} = 10^8$–10^{10} s^{-1}). At each time step of MD simulations, all the atomic positions are rescaled following the changes in the length of the computational box. Alternatively, a uniaxial tensile strain can be applied in a step-by-step manner. In each strain increment, the thermal equilibration of the strained sample is performed for a short period of time. During atomistic simulations, the 2D sample is kept at a specific temperature using a thermostat (Nose-Hoover thermostat or simple velocity rescaling method). The strain rate is chosen to be as slow as possible to reduce the potential strain rate-dependent effects. The typical engineering strain rate in atomistic simulations is within 10^8–10^{10} s^{-1}; this strain rate is by several orders of magnitude higher than those applied in experimental tensile tests. The prohibitive computational cost limits the ability to simulate the tensile deformation at a much lower strain rate. Like in the case of straining at zero temperature, the defected sample at finite temperatures is stretched until the ultimate failure strain is reached, from which the fracture strength and fracture mechanism can be determined.

In the following, we will discuss structures of four types of defects (vacancy, Stone-Wales defect, dislocation, and grain boundary) and their effects on the mechanical properties of four different 2D materials, that is, graphene, boronitrene, MoS$_2$, and phosphorene.

3 Vacancies

Vacancies are the most commonly studied point defects in 2D materials. Vacancies can be formed during the fabrication processes or can be intentionally introduced by ion (electron) irradiation. In simulations, vacancies are introduced by removing atoms from 2D materials. A single vacancy (monovacancy) requires a removal of a single atom, a double vacancy (divacancy) requires a removal of a couple adjacent atoms, and so on. Subsequently, geometry optimization is followed, through which the atomic structure around the vacancy is relaxed. The sample geometry is optimized by minimizing its total energy (usually at zero temperature using conjugate gradient method). Atomic structure around the vacancy can be obtained using a variety of modelling techniques, ranging from first-principles to atomistic simulations. The technique is selected as required by the preferred accuracy.

3.1 Structure and Formation Energy

The most important characteristic of a vacancy is its formation energy (E_f), which determines its concentration at thermodynamic equilibrium. The formation energy can be obtained by calculating the difference between the total energy of a sample with vacancy and the energy of the corresponding defect-free sample with the same number of atoms. The vacancy formation energy can be calculated by DFT with a high accuracy and precision.
Fig. 1 Vacancies in 2D materials: (**a**) Monovacancy (5|9) in graphene (Adapted with permission from Rajasekaran et al. 2015: copyright 2015 Taylor & Francis). (**b**) Single Mo-vacancy in MoS_2 (Adapted from Yu et al. 2015a with permission of the PCCP Owner Societies). (**c**) Monovacancy (5|9) in phosphorene. (**d**) Double (5|8|5) vacancy in graphene (Reprinted with permission from Rajasekaran et al. 2015: Copyright 2015 Taylor & Francis). (**e**) Double (5|8|5) vacancy in MoS_2 (Adapted from Yu et al. 2015a with permission of the PCCP Owner Societies). (**f**) Double (5|8|5) vacancy in phosphorene

The atomic configurations around single and double vacancies in different 2D materials are illustrated in Fig. 1. The removal of a single atom in graphene produces a monovacancy with three under-coordinated neighboring atoms around it (each atom possesses a single dangling bond at the vacancy edge). The rearrangement of the under-coordinated atoms around the monovacancy leads to the formation of covalent bonds between them (El-Barbary et al. 2003). As a result, a single (5|9) configuration appears in graphene by forming five- and ninefold rings and leaving only one dangling bond (see Fig. 1a). In this process, small out-of-plane displacements of the under-coordinated atoms also occur. In contrast, rearrangement of under-coordinated atoms around a double vacancy in graphene eliminates all the dangling bonds and can lead to a pentagon-octagon-pentagon (5|8|5) structure (see Fig. 1d). A fully reconstructed divacancy actually has several structure variants, including (5|8|5), (555|777), and (5555|6|7777) "flower" defects (see Fig. 2d). Although these divacancies have a similar level of formation energy (of which the (555|777) divacancy has the lowest E_f), they are separated by high energy barriers ($\Delta E_b \approx 5$ eV), which effectively impede any transformation between them (via thermally activated bond rotation) at room temperature.

A double vacancy is more stable than two single vacancies (see Table 1). The formation energy of a double vacancy is lower since it does not contain

Table 1 Vacancy formation energy of single and double vacancies in 2D materials: graphene (Banhart et al. 2011; Faccio and Mombrú 2012), phosphorene (Liu et al. 2014), MoS_2 (Ataca and Ciraci 2011; Yu et al. 2015b; Hong et al. 2015), and boronitrene (Yu et al. 2015a; Zobelli et al. 2006; Okada 2009; Alem et al. 2009)

2D material	Vacancy formation energy	
	Single vacancy (eV)	Double vacancy (eV)
Graphene	7.57	6.37
Phosphorene	1.56	1.36
MoS_2 (Mo-vacancy)	5.59–6.2

under-coordinated carbon atoms with dangling bonds. Thus, single vacancies have a tendency to migrate via thermally activated diffusion and coalesce to form divacancies by releasing energy (Do et al. 2005). In the same way, triple vacancies have a lower energy than separated monovacancy and divacancy and so forth. It is expected that the coalescence of large numbers of vacancies at elevated temperatures may lead to the formation of amorphous graphene structure (Skowron et al. 2015).

Typical configurations of atoms around monovacancies and divacancies in MoS_2 are shown in Fig. 1b, e, respectively. Since MoS_2 is composed of two atomic species, there are two types of monovacancies: S-vacancy and Mo-vacancy (see Fig. 1b). In contrast to graphene, covalent bond formation is not observed between the under-coordinated atoms around a single Mo-vacancy. The S-atoms surrounding Mo-vacancy show an outward relaxation, while the Mo- and S-atoms surrounding S-vacancy exhibit slightly inward relaxation (Feng et al. 2014a). First-principles calculations show that the formation energy for Mo-vacancy is significantly larger than that of S-vacancy (Ataca and Ciraci 2011) (see Table 1). Experimentally, S-vacancies (with a concentration of $c_v \approx 1\%$) are predominantly observed during CVD growth and mechanical exfoliation (Yu et al. 2015b). The type of observed S-vacancies depends on the nature of MoS_2 fabrication: single S-vacancies are found in exfoliated samples while double S-vacancies in CVD samples (Yu et al. 2015b). DFT calculations and experimental observations (Zhou et al. 2013) showed that the formation energy of double S-vacancies is roughly twice of that single vacancy (see Table 1). In sharp contrast to graphene (where the formation of double vacancies by combination of monovacancies is energetically favorable), in MoS_2, single S-vacancies do not have a strong propensity to combine to form double vacancies. The single S-vacancy is the most common point defect repeatedly observed in experiments because it has the lowest formation energy. This explains why S-vacancies are mainly found in exfoliated samples but fails to explain why double S-vacancies are mostly observed in CVD samples. This peculiarity of the double S-vacancy formation was explained by Yu et al. (2015b). Using DFT calculations, they revealed an intricate pathway for preferable formation of S-divacancies in MoS_2, which involves dislocations and grain boundaries abundant

in CVD samples. Formation energy for vacancies in MoS_2 (see Table 1) also strongly depends on the ambient conditions, i.e., S-rich or S-poor environment during CVD growth. The formation energies of Mo-monovacancies can be lower than those of S-monovacancies under S-rich condition. However, single Mo-vacancies are never observed experimentally. Instead Mo-vacancy complexes, which include a group of missing atoms (a Mo-atom and its three S-neighbors), are mainly found since once the Mo-vacancy is generated, the neighboring S-atoms become unstable and predisposed to be lost even under S-rich condition (Zhou et al. 2013).

Vacancies in boronitrene can be formed under electron beam exposure, with B-atoms being much more likely to be ejected than N-atoms. In boronitrene, like in MoS_2, formation of covalent homoelemental B-B (N-N) bonds between the under-coordinated neighboring B-atoms of N-monovacancy (N-atoms of B-monovacancy) is rarely observed (Zobelli et al. 2006) since it is energetically unfavorable. Both single B- and N-vacancies conserve the threefold symmetry around the missing atom without local reconstruction of dangling bonds. Only small local in- and out-of-plane atom relaxations around single vacancies are found (Zobelli et al. 2006). However, deletion of a couple of the adjacent B-N atoms leads to the formation of a double (5|8|5) B-N vacancy and results in the creation of homoelemental bonds (Okada 2009). Akin to MoS_2, the formation energy of boronitrene also depends on the ambient condition, i.e., chemical potentials of B- and N-atoms.

Atomic configurations around single (5|9) and double (5|8|5) vacancies in phosphorene are shown in Fig. 1c, f, correspondingly. Atoms around the single vacancy undergo reconstruction by forming a stable (5|9) pentagon-nonagon defect (see Fig. 1c), similar to that of graphene. Since the formation energy of mono-vacancy ($E_f = 1.56$ eV) is larger than that of divacancy ($E_f = 1.36$ eV), it is energetically favorable for two monovacancies to combine into a divacancy. First-principles calculations predict at least 14 variants of divacancies in phosphorene (Liu et al. 2014) (see Fig. 2b, c, e, f), while in graphene, there are only 3 types of fully reconstructed divacancies (see Fig. 2a, d). This staggering variety of divacancies is due to the anisotropic puckered lattice structure of phosphorene. Among these different variants, the (5|8|5) divacancy (see Fig. 2c) has the lowest formation energy. The vacancy formation energy in phosphorene is the smallest one (see Table 1), indicating that equilibrium vacancy concentration in phosphorene should be abnormally large in comparison with other 2D materials at the same conditions (Liu et al. 2014). The low value of E_f in phosphorene is related to its intrinsically softer P-P bonds (compared to the much stronger C-C bonds in graphene and other 2D materials) and also to the curvature effects of its puckered structure.

3.2 Vacancy Diffusion

Defects in 2D materials are not necessarily stationary, and their migration is able to affect the properties of the hosting materials. For example, vacancies can be
Fig. 2 Atomistic structures of reconstructed divacancies in graphene: (**a**) (5|8|5) divacancy, (**d**) (5555|6|7777) "flower" divacancy. The transformation between the neighboring divacancies can be realized through 90° rotation of the highlighted bond (Adapted from Rajasekaran et al. 2015: copyright 2015 Taylor & Francis). Atomistic structures of various reconstructed divacancies in phosphorene: (**b**, **c**) two variants of (5|8|5) divacancy and (**e**, **f**) two variants of (5555|6|7777) "flower" divacancy

Table 2 Diffusion energy barrier of single and double vacancies in 2D materials: graphene (El-Barbary et al. 2003; Rajasekaran et al. 2015), phosphorene (Cai et al. 2016), MoS_2 (Komsa et al. 2013), and h-BN (Zobelli et al. 2007)

2D material	Diffusion energy barrier	
	Single vacancy (eV)	Double vacancy (eV)
Graphene	1.39	7.1
Phosphorene	0.3	0.44–1.83
MoS_2 (S-vacancy)	2.27	8.5
h-BN (B-vacancy)	2.6	
h-BN (N-vacancy)	5.8	4.5–6.0

fairly mobile at high temperatures. The mobility of vacancies is determined by activation (diffusion, migration) energy barriers (see Table 2), which they have to overcome in the process of diffusion. In graphene, migration of a single vacancy occurs through the displacement of one of the carbon atoms located near the vacancy into a vacant site. This diffusion can be directly observed even at room temperature (El-Barbary et al. 2003). In contrast to single vacancy, the activation barrier for divacancy is almost five times larger (Banhart et al. 2011; Faccio and Mombrú 2012) (see Table 2). This high activation barrier indicates that divacancies in graphene are

immobile at room temperature, and their thermally activated migration takes place only at extremely elevated temperatures of T $\geq$ 3000 K (El-Barbary et al. 2003).

In boronitrene, only thermally activated B-monovacancies can diffuse at high temperatures (T $\geq$ 840 K) according to DFT calculations (Zobelli et al. 2007). Thermal migration of a single B-vacancy is a complex process: it occurs as one of its *second* neighbor atoms jumps into a vacant site (a boron atom reaches the vacant site through a few intermediate configurations). This B-vacancy migration preserves the heteroelemental B-N bonding between atoms. The activation energy barrier for N-monovacancies is so high (see Table 2) that their migration is energetically unfavorable at any temperature below the melting point (Zobelli et al. 2007). Migration of single B-vacancies often leads to the coalescence with immobile N-vacancies by forming a more stable B-N divacancies; their diffusion can be thermally activated at even higher temperatures (T $\geq$ 1400 K). The single and double vacancies agglomerate further by forming extended rotational and line defects (Zobelli et al. 2007).

Single S-vacancies in MoS_2 are found to be only mobile under electron beam radiation since the diffusion energy barrier (see Table 2) is prohibitively high for thermally activated diffusion at room temperature. The diffusion energy barrier for Mo-vacancies is even higher (Komsa et al. 2013). The rate of single S-vacancy diffusion caused by the impacts of energetic electrons in irradiation experiments is fairly small (Komsa et al. 2013; Feng et al. 2014b). However, DFT calculations suggest that the diffusion barrier can be markedly lowered (from $E_b = 2.3$ eV down to $E_b = 0.8$ eV) if the vacancy concentration is increased (Komsa et al. 2013). Using DFT calculations, Sensoy et al. (2017) found that the lattice reorganization around single S-vacancies is extremely localized, and there is no elastic interaction between two neighboring defects. In view of this, there is no thermodynamic driving force for the formation of vacancy clusters in MoS_2 (Sensoy et al. 2017).

Vacancy diffusion in phosphorene was studied by Cai et al. (2016) using first-principles calculations. They found that the single vacancy in phosphorene has the lowest activation energy barrier among all discovered 2D materials ($E_b \approx 0.3$ eV along the ZZ direction). The monovacancy diffusion in phosphorene is very anisotropic, with predominant migration in the ZZ direction. At room temperature, the motion of single vacancy in phosphorene is by $\sim$16 orders of magnitude faster than in graphene. The itinerant features of phosphorene vacancies are rooted in the unique puckering structure of phosphorene (Cai et al. 2016). It was predicted that experimental observation of vacancies in phosphorene would only be possible at low temperatures (T $\leq$ 70 K), where their thermally activated diffusion is amply suppressed. Furthermore, in contrast to other 2D materials exhibiting an extremely low mobility of double vacancies even at high temperatures, the migration divacancies in phosphorene can be detected around T=600 K. This is because the migration of double vacancies in phosphorene can occur in a completely novel way – through repeated association and dissociation of the fast-moving single vacancies (Cai et al. 2016). The presence of the itinerant vacancies in phosphorene can explain its fast structure evolution in vacuum and its rapid degradation in air.

3.3   Elastic Modulus

The effect of vacancies on the mechanical properties of 2D materials depends on the type, concentration, distribution of vacancies, and the loading direction (for anisotropic 2D materials). First we discuss the effect of vacancies on the elastic moduli of 2D materials, in particular, Young's modulus, which is a measure of stiffness of a material, one of the most important properties in engineering design.

It is expected that the presence of vacancies in graphene should lead to the deterioration of its mechanical properties. Both first-principles (Rodrigo et al. 2016) and atomistic simulations (Mortazavi and Ahzi 2013) indicate significant softening of graphene containing vacancies. However, one of the most surprising experimental discoveries was the observation of an increase in the Young's modulus at sufficiently low vacancy concentration (López-Polín et al. 2014). The Young's modulus increases up to almost twice of its original defect-free value at $c_v \approx 0.2\%$. DFT calculations revealed that at very low concentration, monovacancies stretch graphene and induce the strain fields that quench the out-of-plane vibrations, making the defective graphene effectively stiffer than pristine one (Rodrigo et al. 2016). At a higher concentration of vacancies, the Young's modulus decreases almost linearly with increasing vacancy concentration (Mortazavi and Ahzi 2013): at vacancy concentration $c_v = 2\%$, it decreases by about 20% (see Fig. 3a).

In contrast to graphene, introduction of sulfur monovacancies and divacancies in MoS_2 has only a relatively minor effect on its Young's modulus. DFT calculations indicate a relatively minor reduction of the elastic modulus about 4% for both types of vacancies at $c_v \approx 5\%$ (Gan and Zhao 2014). However, removal of a pair of neighboring Mo- and S-atoms (Mo-S divacancy) has a more dramatic effect – the Young's modulus decreases by about 36% along the AC direction and about 63% along the ZZ direction (Gan and Zhao 2014). The effect of V_{MoS3} point defects (a vacancy complex created by removal of a Mo-atom and its three nearby S-atoms) on the elastic properties of MoS_2 was examined by Li et al. (2016a) using MD simulations. They found that an increase of V_{MoS3} vacancy concentration (from $c_{MoS3} = 1\%$ to $c_{MoS3} = 10\%$) leads to a significant decrease in the Young's modulus ($\Delta Y/Y_0 \approx -25\%$). In addition, they identified an anomalous stiffening effect (the Young's modulus increases at elevated temperature) in defected MoS_2 containing V_{MoS3} vacancies at $c_{MoS3} = 0.1\%$ (Li et al. 2016a).

The impact of vacancies on the elastic moduli of boronitrene is rather insignificant. MD simulations showed that the Young's modulus is nearly unchanged ($\Delta Y/Y_0 \approx -2\%$) at relatively low concentration of double B-N vacancies ($c_v \approx 1\%$) (Le and Nguyen 2014).

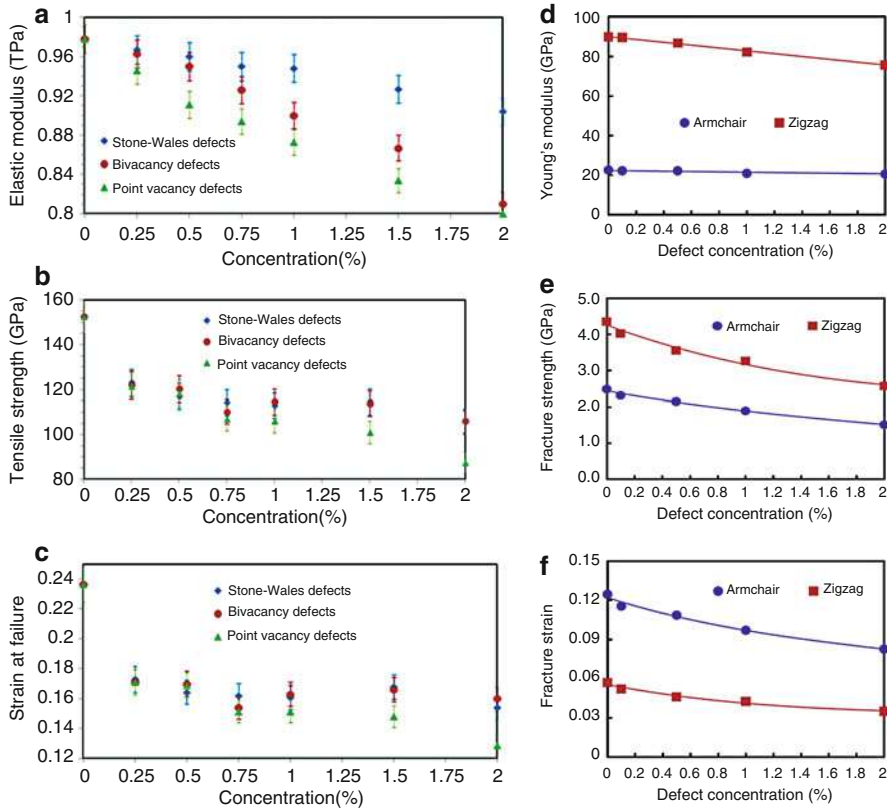
Phosphorene is known for its distinctly anisotropic mechanical properties. In particular, its Young's modulus along the ZZ direction is considerably larger than that along the AC direction. Correspondingly, the effect of vacancies on the Young's modulus is also remarkably anisotropic. The magnitude of this effect is still the subject of considerable discussion. Using MD simulations, Sha et al. (Sha et al.


Fig. 3 Effect of single (green triangles) and double (red circle) vacancies on the Young's modulus (**a**), fracture strength (**b**), and fracture strain (**c**) of graphene (Adapted from Mortazavi and Ahzi 2013 with permission of Elsevier Ltd). Effect of single vacancies on the Young's modulus (**d**), fracture strength (**e**), and fracture strain (**f**) of phosphorene calculated along the AC and the ZZ directions (Adapted from Sha et al. 2016 with permission of the IOP publishing)

2016) found that vacancies significantly reduce the Young's modulus along the AC direction ($\Delta Y/Y_0 \approx -10\%$ at $c_v = 2\%$) but have negligible effect along the ZZ direction ($\Delta Y/Y_0 \leq -1\%$) as shown in Fig. 3d. On the other hand, first-principles calculations (Hao and Chen 2016) demonstrate that the Young's modulus of phosphorene is affected by vacancies along the AC direction, but along the ZZ direction, it can be reduced up to $\Delta Y/Y_0 \approx -12\%$ by monovacancies and up to $\Delta Y/Y_0 \approx -7\%$ by divacancies at $c_v = 2\%$. While by using atomistic simulations, Chen et al. (2017) indicated that vacancies can reduce the Young's modulus almost to the same extent in both directions: $\Delta Y/Y_0 \approx -9\%$ in the AC direction and $\Delta Y/Y_0 \approx -7\%$ in the ZZ (at $c_v \approx 1.2\%$). They also found that the softening effect of double vacancies is markedly larger than that of single vacancies.

3.4   Fracture Strength, Strain, and Failure Mechanism

Understanding of the effect of vacancies on the fracture strain and strength and failure behavior of 2D materials is crucial for their applications. The fracture strength is much more sensitive to defects than the Young's modulus. This can be understood in terms of the "weakest link" model, which conjectures that one weak link may be sufficient to cause failure.

Fracture strength of graphene decreases significantly with increasing vacancy concentration. Atomistic simulations demonstrate a sharp decline ($\Delta\sigma/\sigma_0 \approx -20\%$ -40%) in the tensile fracture strength of graphene even at sufficiently low vacancy concentration $c_v \approx 0.3\%$ at room temperature (Mortazavi and Ahzi 2013; Wang et al. 2012) (see Fig. 3b, c). The hosted vacancies act as stress concentration centers, causing a significant out-of-plane wrapping. Moreover, they coalesce into sizeable holes in graphene; hence fracture strength is greatly reduced.

The dependence of the fracture strain on the vacancy concentration in graphene is more complicated: it decreases at low concentrations but increases again at higher ones. At very high vacancy concentration, the graphene deformation becomes plastic-like and exhibits superductility (Xu et al. 2013). Near the failure strain, multiple monoatomic carbon chains are formed along the AC direction. As the tensile strain increases, the elongation of these monoatomic carbon chains holds the graphene connected until the last connecting carbon chain ruptures (Mortazavi and Ahzi 2013).

MD simulations indicate that monovacancies reduce both the fracture strength and failure strain of graphene to a larger extent than divacancies (Mortazavi and Ahzi 2013). Mortazavi et al. (Mortazavi and Ahzi 2013) found that the failure strain decreases by $\Delta\varepsilon/\varepsilon_0 \approx -47\%$ due to monovacancies and only by $\Delta\varepsilon/\varepsilon_0 \approx -31\%$ due to divacancies at $c_v = 2\%$ (see Fig. 3b). The fracture strength is reduced by $\Delta\sigma/\sigma_0 \approx -43\%$ due to single vacancies and only by $\Delta\sigma/\sigma_0 \approx -30\%$ due to double vacancies as shown in Fig. 3c. This indicates that double vacancies are more stable since they undergo a series of configuration changes, allowing them to sustain a larger tensile strain (Mortazavi and Ahzi 2013).

The failure of defected graphene initiates when a few bonds in the vicinity of a vacancy rupture (see Fig. 4a). Consequently, a nano-size void is formed around the ruptured bonds. The void grows under applied tensile strain, while the C-C bonds along its edge rupture. This process ultimately leads to the failure of graphene (Degefe and Parashar 2016).

Likewise, the fracture strength and the ultimate strain of boronitrene are abruptly reduced by vacancies. N-monovacancies lessen the fracture strain along the ZZ direction by $\Delta\varepsilon/\varepsilon_0 \approx -36\%$ (at $c_v = 6\%$) while B-monovacancies only by $\Delta\varepsilon/\varepsilon_0 \approx -20\%$. Equally, the fracture strength of boronitrene is significantly reduced by N-monovacancies ($\Delta\sigma/\sigma_0 \approx -16\%$) in comparison with B-monovacancies ($\Delta\sigma/\sigma_0 \approx -8\%$) (Xiong et al. 2015). For boronitrene, the detrimental effect of N-monovacancies and BN divacancies on the fracture strain and the ultimate strain is practically the same (Le and Nguyen 2014).

The effect of single and double S-vacancies on the fracture strength of MoS_2 depends on the direction of applied strain. It is relatively weak along the ZZ
Fig. 4 (**a**) Tensile fracture of graphene containing double vacancies under applied strain along the AC direction (Adapted from Degefe and Parashar 2016 with permission of the IOP publishing). (**b**) Crack nucleation and fracture of phosphorene containing a single vacancy under applied tensile strain along the AC direction (Adapted from Sha et al. 2016 with permission of the IOP publishing)

direction: the fracture strength is reduced by less than $\Delta\sigma/\sigma_0 \approx -4\%$ by mono- and divacancies at vacancy concentration $c_v = 5\%$. However, along the AC direction, it is reduced by $\Delta\sigma/\sigma_0 \approx -48\%$ by monovacancies and $\Delta\sigma/\sigma_0 \approx -21\%$ by divacancies (Gan and Zhao 2014). Besides, the fracture strain of defected MoS_2 decreases by $\Delta\varepsilon/\varepsilon_0 \approx -42\%$ due to introduction of S-monovacancies along the ZZ direction and by $\Delta\varepsilon/\varepsilon_0 \approx -32\%$ due to S-divacancies. Along the AC direction, the fracture strain is reduced by $\Delta\varepsilon/\varepsilon_0 \approx -48\%$ due to the monovacancies and by $\Delta\varepsilon/\varepsilon_0 \approx -32\%$ due to the divacancies (Gao and Zhao 2016). However, the hosting of Mo-S divacancies has the most dramatic effect. The fracture strength is reduced by $\Delta\sigma/\sigma_0 \approx -80\%$ along the ZZ direction and by $\Delta\sigma/\sigma_0 \approx -17\%$ along the AC direction. The corresponding reduction in the fracture strain is $\Delta\varepsilon/\varepsilon_0 \approx -56\%$ along the ZZ direction and $\Delta\varepsilon/\varepsilon_0 \approx -34\%$ along the AC (Gan and Zhao 2014). The effect of the Mo-S divacancies is so strikingly detrimental that the stability of defected MoS_2 for fracture along the ZZ direction was questioned (Gan and Zhao 2014).

In phosphorene, the fracture strength and fracture strain are greatly reduced by vacancies (see Fig. 4). MD simulations indicate that due to its flexible puckered structure, the atomic stress distribution is nearly uniform in defected phosphorene, except for the region around the vacancy (the stress concentration is shown in Fig. 4b). The stress concentration causes the bond failure in this region, resulting in the crack nucleation. The emerged crack propagates along a groove of the puckered structure, forming atomically flat fracture surface (Sha et al. 2016).

Both the fracture strength and ultimate strain of phosphorene along the AC and the ZZ directions decrease with an increase in the vacancy concentration (Sha et al. 2016) (see Fig. 3e, f, respectively). At a vacancy concentration of $c_v = 2\%$, the fracture strength decreases by $\Delta\sigma/\sigma_0 \approx -39\%$ along the AC direction

Table 3 Effect of monovacancies on the mechanical properties of 2D materials. Reduction of the Young's modulus, fracture strength, and fracture strain of defected 2D materials: graphene (Mortazavi and Ahzi 2013), phosphorene (Sha et al. 2016; Hao and Chen 2016), boronitrene (Le and Nguyen 2014), and MoS_2 (Gao and Zhao 2016) relative to the defect-free ones. Only effects of N-vacancies in boronitrene and S-vacancies in MoS_2 are indicated

2D material	Chirality	Vacancy concentration	$\Delta Y/Y_0$	$\Delta\sigma/\sigma_0$	$\Delta\varepsilon/\varepsilon_0$
Graphene	AC/ZZ	2%	−20%	−43%	−36%
Phosphorene	AC	2%	−10%	−39%	−34%
	ZZ	2%	−6%	−43%	−47%
Boronitrene	AC	6%	−3%	−12%	−23%
	ZZ	6%		−15%	−35%
MoS_2	AC	5%	−4%	−25%	−48%
	ZZ	5%		−4%	−42%

and by $\Delta\sigma/\sigma_0 \approx -41\%$ along the ZZ direction. The ultimate strain reduces by $\Delta\varepsilon/\varepsilon_0 \approx -34\%$ and by $\Delta\varepsilon/\varepsilon_0 \approx -39\%$ along the AC and ZZ directions, correspondingly. First-principles calculations (Hao and Chen 2016) also indicate that the fracture strength ($\Delta\sigma/\sigma_0 \approx -45\%$) and fracture strain ($\Delta\varepsilon/\varepsilon_0 \approx -56\%$) of defected phosphorene ($c_v = 2\%$) are particularly reduced along the ZZ direction. Therefore, it is much easier to fracture the defected phosphorene along the ZZ direction than the defect-free phosphorene.

The type of vacancy also has influence on the failure mechanism of defected phosphorene: introduction of single vacancy has stronger effect than that of double vacancy. Due to the anisotropy of its mechanical properties, the effect of single and double vacancies differs along the AC and the ZZ directions. Effective reduction in the fracture strength due to double vacancies is much larger than that due to the single ones along the AC direction, while the reduction is similar along the ZZ direction (Sha et al. 2016).

The effects of single vacancies (at a similar vacancy concentration) on the mechanical properties of 2D materials are summarized in Table 3. It can be seen that the mechanical properties of graphene and phosphorene are most sensitive to vacancy defects among the listed 2D materials. In particular, the mechanical properties of graphene are modified to the largest extent by vacancies.

4 Stone-Wales Defects

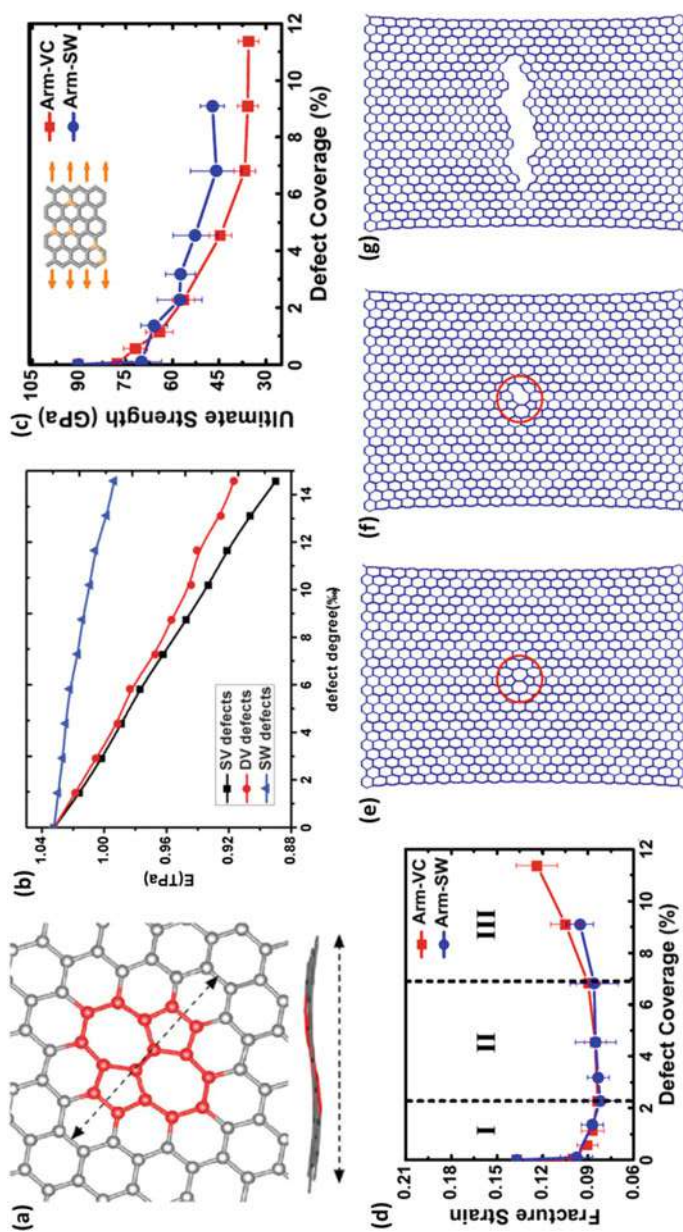
One of the exceptional properties of 2D materials with honeycomb lattice structure is their capacity to undergo local restructuring via bond rotations and form non-hexagonal rings. Hence a novel class of topological defects can be introduced in 2D materials without adding or removing atoms. The most extensively studied topological defects are the Stone-Wales defects in graphene (Ma et al. 2009; Stone and Wales 1986) (see Fig. 5a). A Stone-Wales (SW) defect in graphene can be


Fig. 5 (**a**) Structure of Stone-Wales (SW) defect in graphene: top (upper panel) and side (lower panel) views. The red atoms represent the SW defect. Arrows indicate the size of the buckled region (Adapted with permission from Ulman and Narasimhan 2014. Copyright 2014 American Physical Society). (**b**) The Young's modulus of graphene vs. the concentration of SW defect (triangles) and vacancies (squares, circles) (Adapted from Jing et al. 2012 with permission of The Royal Society of Chemistry). (**c, d**) The fracture strength and the ultimate strain as a function of defect concentration: SW defects (circles) and monovacancies (squares) (Adapted from Xu et al. 2013 with permission of IOP Publishing) (**e–g**). Failure mechanism of defected graphene containing a Stone-Wales defect under the strain applied along the AC direction: (**e**) initial structure, (**f**) bond rupture, and (**g**) crack propagation during the fracture (Adapted with permission from Ansari et al. 2012: Copyright 2012 Elsevier Ltd)

formed by the 90° rotation of two adjacent carbon atoms around the midpoint of the connecting bond (see Fig. 5a). This rotation transforms four neighboring hexagons into two pentagons and two heptagons, forming a (5|7|7|5) defect. The bonds between pentagon and nearby hexagons, as well as the central rotated bond (separating two adjacent heptagons), are compressed, while the bonds between heptagons and pentagons (and the nearby hexagons) are stretched. Besides, the out-of-plane buckling area ($\Delta z \approx 2$ Å, see Fig. 5a) containing the SW defect (the buckled region extends over several nanometers) lowers further the defect energy (Skowron et al. 2015; Ertekin et al. 2009).

According to the first-principles calculations, the formation energy of the SW defect in graphene is $E_f = 4.6$–5.8 eV (Skowron et al. 2015; Ertekin et al. 2009). The DFT value for the activation energy of SW transformation (90° bond rotation) is $\Delta E_b = 9.2$ eV (Ertekin et al. 2009; Li et al. 2005a), reflecting the fact that two carbon bonds must be simultaneously broken and two C-atoms must be concurrently rotated during the transformation, which is an energetically expensive process. The energy barrier for the reverse transformation is half of the direct SW transformation (~ 5 eV) (Banhart et al. 2011). The energy cost of SW transformation is prohibitively high; hence SW defects cannot form spontaneously in equilibrium conditions at room temperature. However, this high energy barrier can be significantly reduced (2–7 eV) by chemical functionalization (with transition metals (Meng et al. 2014), carbon adatoms (Wang and Ding 2013), hydrogen and hydroxyl groups (Nascimento and Nunes 2013)), applied tensile strain (Samsonidze et al. 2002), or electron irradiation (Kotakoski et al. 2011). For example, DFT calculations predict that formation of SW defects can be thermodynamically favorable at room temperature when the applied strain exceeds $\varepsilon \approx 0.2$ along the AC direction and $\varepsilon \approx 0.17$ along the ZZ direction (Skowron et al. 2015; Li et al. 2005b). In most cases, SW defects are introduced in graphene during the synthesis (rapid quench from high temperature) or under electronic irradiation (Stone and Wales 1986; Samsonidze et al. 2002). As soon as SW defects are formed under the non-equilibrium conditions, the high energy barrier for the reverse transformation ensures their presence at room temperature.

The effect of SW defects on the mechanical properties of graphene was studied by both first-principles and atomistic simulations. According to atomistic simulations, the effect of SW defects on the Young's modulus ranges from negligible $\Delta Y/Y_0 \approx -1\%$ (Jing et al. 2012; Ansari et al. 2012) to moderate $\Delta Y/Y_0 \approx -6\%$–13% (Mortazavi and Ahzi 2013; Hao et al. 2011), although the detrimental effect of SW defects becomes more prominent with increasing defect concentration (see Figs. 3a–c and 5b). Using DFT calculations, Ren et al. (Ren and Cao 2016) also found that the Young's modulus is only slightly affected by SW defects. As the SW defects prestress graphene by making it slightly anisotropic, the deformation along the AC direction is easier than along the ZZ (Ren and Cao 2016). In sharp contrast, Yanovsky et al. (2010) found a considerable reduction ($\Delta Y/Y_0 \approx -60\%$) in the Young's modulus (and failure strain) of graphene by using DFT method. This discrepancy may be partially explained by the significantly smaller size of graphene samples used in DFT calculations (Yanovsky et al. 2010).

The reduction of Young's modulus due to SW defects is noticeably smaller than that due to vacancies (see Figs. 3a and 5b). The SW defects preserve interatomic sp^2 bonding and do not contain dangling bonds; hence they weakly reduce the Young' modulus (Jing et al. 2012; Ansari et al. 2012). The Young's modulus decreases almost linearly with increasing vacancy concentration (Hao et al. 2011), while it deteriorates nonlinearly (and more gradually) with increasing SW concentration (see Figs. 3a and 5b). The hydrogenation of SW defects reduces the Young's modulus furthermore. Hydrogen atoms attached to the SW defects change their hybridization from sp^2 to sp^3, resulting in an additional reduction of Young's modulus. In contrast, hydrogenation of monovacancies eliminates dangling bonds and thus enhances the Young's modulus of defective graphene (Jing et al. 2012).

The effect of SW defects on the ultimate strain and intrinsic strength of graphene was studied by using atomistic simulations (Wang et al. 2012; Ansari et al. 2012). The SW defects can significantly reduce the failure strain and strength of graphene. Their effect on the mechanical properties is strongly anisotropic (even at very low defect concentration $c_{sw} \approx 1\%$). The failure strain reduction along the AC direction ($\Delta\varepsilon/\varepsilon_0 \approx -22\%$) is considerably larger than that along the ZZ direction ($\Delta\varepsilon/\varepsilon_0 \approx -3\%$) (Wang et al. 2012; Ansari et al. 2012). Similarly, the reduction in the intrinsic strength along the AC direction ($\Delta\sigma/\sigma_0 \approx -11\%$) is considerably larger than along the ZZ direction ($\Delta\sigma/\sigma_0 \approx -2\%$) (Ansari et al. 2012). Compared to single vacancies, SW defects lead to a smaller reduction in the failure strength and strain of graphene. Introduction of single vacancies ($c_v \approx 1\%$) decreases the intrinsic strength by $\Delta\sigma/\sigma_0 \approx -12.2\%$ along the AC direction and by $\Delta\sigma/\sigma_0 \approx -5\%$ along the ZZ direction (Ansari et al. 2012). DFT calculations predict the similar reduction in the intrinsic strength of defected graphene ($\Delta\sigma/\sigma_0 \approx -10\%$). But in contrast to MD simulations, they predict an extra sharp reduction in the failure strain ($\Delta\varepsilon/\varepsilon_0 \approx -60\%$) (Ren and Cao 2016; Yanovsky et al. 2010). This is because the stress field around the SW defects obtained by DFT calculations differs significantly from that calculated by MD simulations. The stress field causes a noticeable pre-straining of defected graphene. Due to the intricate coupling effects among the pre-strained graphene, tensile strain response, and highly nonlinear bond stretching behavior, DFT calculations predict a rather different failure strain (Ren and Cao 2016; Yanovsky et al. 2010).

The impact of SW defects on the failure behavior of graphene greatly amplifies with their accumulation. Using MD simulations, Xu et al. (2013) varied the concentration of SW defects and studied their effect on the failure characteristics of defected graphene. They found that at low concentration ($c_{sw} \approx 1\%$), the ultimate strength of graphene gradually decreases with increasing defect concentration, and it remains constant at the high concentration ($c_{sw} \approx 10\%$, see Figs. 3b and 5c). In contrast, the dependence of fracture strain on defect concentration is very unusual (see Figs. 3c and 5d): the fracture strain initially decreases at low defect concentration, reaches a plateau, and then increases at higher concentration. At higher concentration of SW defects, graphene becomes weaker but more ductile. This transition from brittle rupture to ductile fracture is caused by the specific

rearrangement of atoms around the SW defects. The rearranged atoms trap and blunt the propagating crack tips; hence the ductile fracture is observed. At high strain and elevated temperatures, SW defects participate in plastic deformation of graphene (Xu et al. 2013).

Using atomistic simulations, Ansari et al. (2012) examined the fracture of graphene containing randomly distributed SW defects (Fig. 5e). They found that SW defects are nucleation centers for fracture. Fracture initiates as a nano-crack appearing at a SW defect, where the C-C bond shared by the heptagon and nearby hexagon ruptures at the critical strain (see Fig. 5f). As the neighboring bonds break, the emerging crack propagates perpendicularly to the loading direction, as shown in Fig. 5g. The final rupture occurs when the last connecting carbon chain fails (Mortazavi and Ahzi 2013; Xu et al. 2013; Ansari et al. 2012).

Using first-principles calculations, Wang et al. (2016) investigated the energetics and the structural properties of SW defects in boronitrene. In boronitrene, a SW defect can be formed by the 90° rotation of two adjacent B- and N-atoms around the midpoint of the bond connecting them (see Fig. 6a). However, this rotation results in the formation of two homoelemental bonds (B-B and N-N), which are energetically unfavorable. The formation energy of SW defects in boronitrene $E_f = 6.5$ eV (Wang et al. 2016) is higher than that in graphene $E_f = 4.6$–5.8 eV (Skowron et al. 2015; Ertekin et al. 2009). In order to create a SW defect in boronitrene, one needs to overcome the energy barrier of $\Delta E_b = 10.4$ eV (Wang et al. 2016), which is greater than that of graphene $\Delta E_b = 9.2$ eV (Ertekin et al. 2009; Li et al. 2005a). This high energy barrier indicates that boronitrene with SW defects is stable. Though the formation energy of SW defects is rather high, they can be formed by rapid quenching from high temperature during the synthesis or under electronic irradiation (Wang et al. 2016).

The effect of SW defects on the mechanical properties and failure behavior of boronitrene was studied by Le et al. (Le and Nguyen 2014) using MD simulations coupled with finite element method (FEM). They found that uniaxial tensile stress-strain curves of pristine and defective boronitrene are nearly identical up to the fracture points (see Fig. 6b, c).

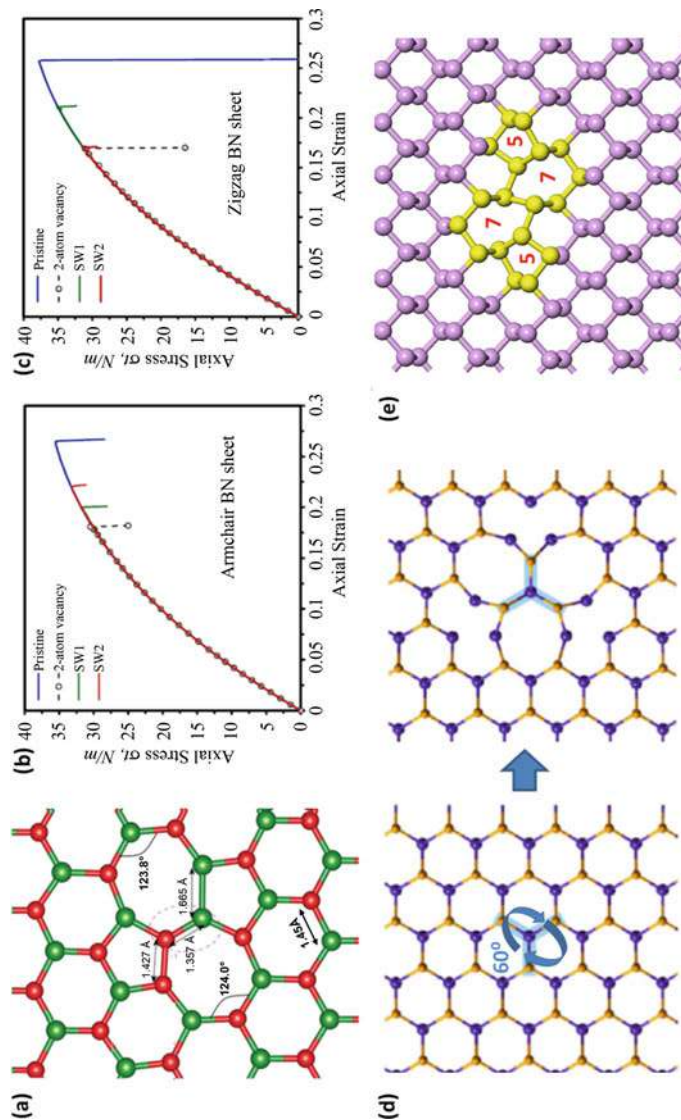
Similar to graphene, fracture of defected boronitrene is brittle, as shown in Fig. 6b, c. It indicates that the effects of SW defects on the mechanical properties of 2D materials exhibit certain universal features. Brittle fracture starts near the SW defects when boronitrene is stretched along the AC direction. But if it is strained along the ZZ direction, the fracture begins far away from the SW defects, because when the tensile strain is applied in parallel to the orientation of the most compressed central bond of the SW defect, the possibility of fracture onset at the defect is significantly reduced (Le and Nguyen 2014). The SW defects ($c_{sw} \sim 5\%$) decrease the fracture stress by $\Delta\sigma/\sigma_0 \approx -10\%$ along the AC direction (similar to graphene) and by $\Delta\sigma/\sigma_0 \approx -7\%$ along the ZZ direction (which is notably larger than that for graphene). The fracture strain is reduced by $\Delta\varepsilon/\varepsilon_0 \approx -25\%$ along the AC direction (similar to graphene) and by $\Delta\varepsilon/\varepsilon_0 \approx -18\%$ along the ZZ direction (which is considerably larger than that for graphene). Overall the effects of SW defects on the mechanical properties of boronitrene are the same as on those of


Fig. 6 (**a**) Atomistic structure of SW defects in boronitrene (N-atoms marked by red and B-atoms by green). (**e**) The atomic model of Stone–Wales defects in phosphorene

graphene: the SW defects significantly reduce the ultimate strain and fracture stress of boronitrene but do not affect the Young's modulus to the same extent (Le and Nguyen 2014).

The formation of SW defects through 90° rotation in transition metal dichalcogenides (like in boronitrene) results in the formation of two energetically unfavorable homoelemental bonds. To avoid the formation of homoelemental bonds, Lin et al. (2015) suggested that the simultaneous 60° rotation of three bonds centered on a metal atom can sustain both the heteroelemental nature of bonding and the trigonal lattice symmetry, leading to the formation of a "trefoil"-shaped SW-like defect (see Fig. 6d). Using transmission electron microscopy (TEM), they observed these rotational defects in WS_2, WSe_2, and $MoSe_2$ at elevated temperatures. According to the first-principles calculations, the formation energy of these defects is within $E_f \approx 3$–5 eV range (Lin et al. 2015). The trefoil defects are mobile at elevated temperatures, although their mobility is much lower than that of vacancies, apparently due to the cooperative readjustment of a larger number of bonds. The diffusion barrier for migration of these defects is $\Delta E_b \approx 2.3$ eV (Lin et al. 2015), which can be overcome under electron irradiation. In addition, Lin et al. (2015) found that these SW-like defects only weakly depreciate the mechanical properties of transition metal dichalcogenides: at moderate concentration of defects ($c_{sw} = 3\%$), the Young's modulus of WSe_2 is reduced only by $\Delta Y/Y_0 \approx -4\%$ (Lin et al. 2015).

SW defects in phosphorene (see Fig. 6e) were investigated by Hu et al. (Hu and Yang 2015) using first-principles calculations. The formation energy of SW defect in phosphorene is $E_f = 1.01$ eV (Hu and Yang 2015), which is the lowest formation energy among the discussed 2D materials. By using DFT calculations, Li et al. (2016b) found that SW defects can migrate along the ZZ direction and aggregate to form line defects near grain boundaries. This migration is markedly anisotropic, since the lowest migration energy barrier along the ZZ direction ($E_m = 1.39$ eV) is half of that along the AC direction ($E_m = 2.58$ eV).

5   Dislocations

Dislocations are another type of point defects in 2D materials. There are several routes leading to the formation of dislocations. For example, in graphene, they can be formed during the chemical vapor deposition (CVD) growth, electron beam sputtering of carbon dimers, or as a combination of other defects, i.e., monovacancies and Stone-Wales defects. The effect of dislocations on the mechanical properties can be substantial. In 2D materials, dislocations form grain boundaries and lead to the out-of-plane wrapping of 2D materials, which can significantly change the fracture strength (Grantab et al. 2010). They also can serve as carriers of plastic flow under electron beam irradiation.

5.1   Dislocation Structure and Energies

Dislocations in graphene (see Fig. 7a, b) can be represented by pentagon-heptagon (5|7) pairs. Since the strain energy of a dislocation is proportional to the square of its Burgers vector, a (0,1) edge dislocation with the smallest Burgers vector (Zou et al. 2013) is the most energetically favorable one (see Fig. 7a). In this context, a Stone-Wales defect can be considered as a dislocation dipole in which two (5|7) dislocations with opposite Burgers vectors are moved by one lattice unit (Zou et al. 2013). Dislocations in graphene create a long-ranged stress field with high strain energy. Since neighboring atomic planes inhibiting out-of-plane deformations are absent in graphene, this strain energy can be partially released by its buckling around the dislocations (Alem et al. 2011; Yazyev and Louie 2010) (see Fig. 7b). According to DFT calculations, the formation energy of an isolated (5|7) edge dislocation in graphene is $E_d \approx$ 5–7.5 eV (Alem et al. 2011; Yazyev and Louie 2010).

The presence of two atomic species in boronitrene leads to a new (4|8) type of dislocations (see Fig. 7c). In odd-membered (5|7) dislocations, the alternating order of the two atomic species is interrupted when the bond is formed between atoms of the same type and charge (see N-N bond of a (5|7) dislocation in Fig. 7c). The homoelemental bonds significantly increase the formation energies of (5|7) dislocations and lead to positively (or negatively) charged dislocations. In contrast, the (4|8) dislocations, containing only even-membered rings, preserve the alternating order of B- and N-atoms (see a (4|8) dislocation in Fig. 7c) and therefore have a lower electrostatic energy. But their strain energy is larger than that of (5|7) dislocations. Similar to graphene, this strain energy is lowered via buckling of free-standing boronitrene in the out-of-plane direction around the defects (see Fig. 7c, bottom panel). The available experimental data indicate the presence of both types of dislocations but with noticeable abundance of the (5|7) dislocations along grain boundaries in boronitrene (Gibb et al. 2013).

The triple-layered structure of MoS_2 (a triangular lattice of Mo-atoms located in between two triangularly packed planes of S-atoms) brings an extra complexity to the atomic structure of its dislocations. The two types of dislocations in MoS_2 are shown in Fig. 7d: DFT calculations revealed complex concave polyhedrons extending in the third dimension (Zhou et al. 2013). As in the case of boronitrene, the homoelemental bonds in the (5|7) dislocations connect a couple of charged atoms of the same type (Mo-Mo and S-S), thus forming a high energy charged defect, while the strain energy of the (4|8) dislocation is higher than that of the (5|7) one. The high in-plane stiffness of triple-layered lattice prevents the buckling around the dislocations in MoS_2 (Zhou et al. 2013). Experimentally, both the (5|7) and the (4|8) dislocations were observed at grain boundaries of MoS_2 (Azizi et al. 2014).

In phosphorene, due to its distinctive anisotropic puckered structure, both slightly distorted (5|7) and (4|8) dislocations can be introduced (see Fig. 7e). In contrast to the strong sp^2-hybridized C-C bonds of graphene, much softer sp^3-hybridized P-P bonds of phosphorene constitute a malleable lattice structure, which allows to host dislocations without the detectable out-of-plane buckling around them (Sorkin and Zhang 2017).

5.2   Dislocation Mobility

The edge dislocations in 2D materials can migrate either via bond rotations or sputtering of lattice atoms: gliding and climbing, respectively. The glide of edge (5|7) dislocations is possible through the 90° rotation of the bond between the heptagon and its neighboring hexagon. Besides gliding, dislocation climbing is also feasible when atoms are either added or removed near the dislocation core (Lehtinen et al. 2013; Ding et al. 2007). In graphene under electronic irradiation, removal of lattice atoms happens frequently, while addition of new carbon atoms into the lattice is a rarer event (Lehtinen et al. 2013; Ding et al. 2007).

Energy cost for dissociation of SW defects into (5|7) edge dislocation pairs and their consecutive migration is prohibitively high at room temperature. Energy cost

for separation of two (5|7) dislocation pairs with an intervening hexagon is $E_d \approx$ 4–6 eV (Warner et al. 2012), although this energy decreases with increasing distance between them. Hence, plastic deformation in graphene starts through the formation of additional defects. This plastic deformation leads in the end to the formation of isolated (5|7) pairs (Skowron et al. 2015). Dislocations are also created via reconstruction of vacancies and adatoms introduced by electron irradiation.

6 Grain Boundaries

Grain boundary (GB) is a line defect in 2D materials. Typically, large-scale films of graphene produced by CVD are polycrystalline – they are composed of single-crystalline domains (grains) with different lattice orientations. This variety in grain orientations unavoidably leads to the presence of grain boundaries – the interfaces between the grains.

GB can be regarded as an array dislocations arranged in a linear way. In general, GBs can be classified by the value of the tilt angle separating the adjacent grains: low-angle and high-angle grain boundaries. In low-angle GBs, dislocation cores are separated by sufficiently large distance, while in high-angle GBs, dislocation cores are very close, and they can even overlap. The tilt angle is set in the course of non-equilibrium growth processes, rather than by equilibrium energetics. GBs in 2D materials are non-thermodynamic objects since they do not emerge as a result of thermal fluctuations. They are considered as kinetically "frozen" during growth process.

6.1 Construction of GB

A few 2D samples with GB composed of linear arrays of dislocations are shown in Fig. 8. In order to construct a sample with GB, a group of atoms, forming "wedge"-like region, is removed. Subsequently, the two adjacent crystalline domains are pivoted around a selected origin in the clockwise and anti-clockwise directions, respectively, and welded seamlessly together (with a minor bond length adjustment). The created dislocation cores (see Fig. 8) form a vertically oriented linear array of dislocations. This is the preferred alignment of identical edge dislocations (Liu and Yakobson 2010). In order to implement periodic boundary conditions in the direction perpendicular to the created grain boundary, the constructed sample is duplicated. The duplicate is rotated by 180° and joined to the original one. Therefore, the periodic boundary conditions are implemented by constructing a sample with two grain boundaries formed by linear arrays of dislocations oriented in the opposite directions (Liu and Yakobson 2010).

The distance between the nearest dislocations along GBs is associated with the angular rotation of the adjacent grains, which is described by tilt (misalignment or misorientation) angle, α. Low-angle grain boundaries are those with the misorientation angle less than about $\alpha \leq 15°$, while high-angle GBs have the larger tilt angle
Fig. 8 Grain boundaries: (**a**) graphene (Taken from Grantab et al. 2010), (**b**) boronitrene (Adapted with permission from Liu et al. 2012. Copyright 2015 American Chemical Society), (**c**) MoS_2 (Adapted with permission from Yu et al. 2015b. Copyright 2012 American Chemical Society), (**d**) phosphorene. Arrays of (4|8) dislocations (left panel) and (5|7) dislocations (right panel) form GBs between AC-oriented and ZZ-oriented crystalline domains

$\alpha > 15°$ (Liu and Yakobson 2010). The constructed GB is often oriented either along the AC or the ZZ direction, and hence two primary types of GBs: AC-GB and ZZ-GB, are usually studied. In addition, introduction of GBs in graphene and boronitrene leads to out-of-plane warping and inflection near the GBs (Liu and Yakobson 2010), which effectively relieve the in-plane stress by "screening" the in-plane elastic fields of dislocations (Liu and Yakobson 2010). The degree of warping is characterized by inflection angle, which in some cases can reach up to $\sim 72°$ in graphene and $\sim 77°$ in boronitrene, thus significantly reducing their mechanical strength (Zhang et al. 2012).

In order to construct a polycrystalline sample with a large number of grains of various sizes and random crystal orientations, the Voronoi cell method (Voronoi tessellation) is often applied (Yazyev and Louie 2010). The Voronoi tessellation is an assembly of convex polygons separated by line segments (walls perpendicular to the lines connecting the grain centers). The grain centers are seeded randomly or uniformly inside the simulation box. Each convex polygon (Voronoi cell) represents a grain domain filled with atoms. Usually, the grain sizes are normally distributed around the specified average grain size. Each grain is given an arbitrary in-plane orientation in order to mimic the grain orientations observed in experiments. The constructed polycrystalline sample is usually annealed at a high temperature and

then rapidly quenched to room temperature to remove any abnormally low or high density regions at grain boundaries (defined as the atomically thick layers adjacent to the Voronoi cell walls).

6.2   Grain Boundaries: Structures and Energies

Grain boundaries in graphene are generally composed of linear arrays of aligned (5|7) edge dislocations (see Fig. 8a). The array of (5|7) dislocations bisects the tilt angle between the two adjacent graphene domains. This configuration is optimal and energetically favorable: departure from the bisect increases the interface energy (Liu and Yakobson 2010). Even so, experimentally observed GBs in graphene are not strictly symmetrical and occasionally have serpentine-like geometry (Huang et al. 2011). Note that graphene GBs are composed only of (5|7) dislocations since their formation energy is considerably lower than that of (4|8) dislocations. Introduction of GBs in free-standing graphene leads to out-of-plane warping near the low-angle GBs, which relieves the in-plane strain at GBs (Yazyev and Louie 2010; Liu and Yakobson 2010; Kurasch et al. 2012). The high-angle grain boundaries are practically flat, as confirmed by the experimental data (Yazyev and Louie 2010).

In polycrystalline graphene, adjacent grain domains are competing to add carbon atoms to their outer boundaries at each other's expense. This process results in GB migration (via gliding and climbing of (5|7) dislocations), which reduces the fraction occupied by GBs in the sample and decreases the free energy contributed by them. The GB migration is observed in experiments and simulations only in the presence of significant GB curvature (Kurasch et al. 2012).

GBs in boronitrene formed by linear arrays of (5|7) and (4|8) dislocations are shown in Fig. 8b. In boronitrene, both the strain energy (associated with defect structure) and the type of bonding (homo- or heteroelemental bonding between B- and N-atoms) define the formation energy of dislocations. Energetically unfavorable homoelemental B–B and N–N bonding in the (5|7) dislocations makes the (4|8) dislocations, with heteroelemental B-N bonding, equally preferable (Liu et al. 2012). The higher strain energy of the (4|8) dislocations is compensated by the out-of-plane buckling along GBs (Ding et al. 2014) observed experimentally (Gibb et al. 2013). Hence, boronitrene is capable to avoid the unfavorable homoelemental bonding at the cost of increasing lattice strain. First-principles calculations indicate that ZZ-GBs are composed of (4|8) dislocations, while AC-GBs consist of (5|7) dislocations (Liu et al. 2012).

An array of dislocations forming GBs between the tilted adjacent grains in MoS_2 is shown in Fig. 8c. In contrast to boronitrene, where the (4|8) dislocations with large Burgers vectors are feasible due to its high flexibility, GBs in MoS_2 are formed only by (5|7) dislocations with small Burgers vectors. The reason is that the high flexural rigidity of triple-layered MoS_2 excludes the possibility of the out-of-plane buckling along its GBs (Zou et al. 2013).

Similar to boronitrene, GBs in phosphorene are formed by (4|8) dislocations along the ZZ direction (see Fig. 8d, left panel) and (5|7) dislocations along the

AC direction (see Fig. 8d, right panel), where the dislocation rings are highlighted. Phosphorene with GBs maintains its original planar shape, without any kind of out-of-plane wrapping, wrinkles, or inflections due to its unique puckered structure (see Fig. 8d). Its lattice structure, defined by tetrahedral geometry of sp^3-hybridized P-P bonds, is very flexible and capable to accommodate arrays of (4|8) and (5|7) dislocations forming GBs between neighboring crystalline domains. The energy per unit length of grain boundary E_{gb} is calculated according to:

$$E_{gb} = \frac{E_{tot} - NE_b}{2L}$$

where E_{tot} is the total energy of the simulation cell containing two grain boundaries, N is the total number of atoms, $2L$ is the total length of the two grain boundaries, and E_b is the energy per atom in defect-free bulk 2D material. The general observation is that the GB energy increases in direct proportion to the tilt angle, i.e., it increases in proportion to the dislocation density at GBs.

Graphene GB energies were studied by using both first-principles and atomistic simulations. The energy as a function of tilt angle, α, for symmetric GBs formed by an array of evenly spaced dislocations (Liu and Yakobson 2010) is shown in Fig. 9a. The GB energy can be approximately fitted to sine function. At low-angle GBs, the energy increases proportionally with the tilt angle. The GB energy is proportional to the dislocation density, which increases with the tilt angle (the larger the tilt angle, the smaller the distance between the nearby (5|7) dislocations, hence the larger the dislocation density). When the distance between adjacent dislocations reaches the minimum (i.e., they separated only by a single hexagon forming an array of – (5|7)6(5|7)6(5|7)6(5|7)6 – see Fig. 9a), the GB energy reaches its maximum. Subsequently, the energy decreases since the spacing between the neighboring dislocations increases again as shown in Fig. 9a, which eventually leads to the wavy interface between the adjacent grains.

The presence of two types of atoms in boronitrene brings more complexity to the energetics of its GBs in comparison to graphene. Three classes of boronitrene GBs can be constructed: symmetric GBs, where the grains have mirror symmetry about the bisecting GB; asymmetric GBs, where a grain on one side is an inverse reflection of the grain on the other side (with every B-atom replaced by N-atom and vice versa); and nonsymmetric GBs. Moreover, the homoelemental B-B and/or N-N bonds may appear along the GBs, and the unequal numbers of B-B and N-N bonds along a GB line cause elemental polarity (B-rich or N-rich GBs). Even so, the GB energy of boronitrene with symmetric grain boundaries is similar to that of graphene (Ding et al. 2014) (see Fig. 9b): It increases with increasing tilt angle, reaches the maximum, and then decreases once the tilt angle exceeds $\alpha \approx 60°$. This change of the GB energy reflects the hexagonal periodicity of boronitrene lattice: when the tilt angle is larger than $60°$, the structure would come closer to its original configuration at $\alpha \approx 0°$ (or $\alpha \approx 120°$) due to the angular periodicity of a hexagonal ring.

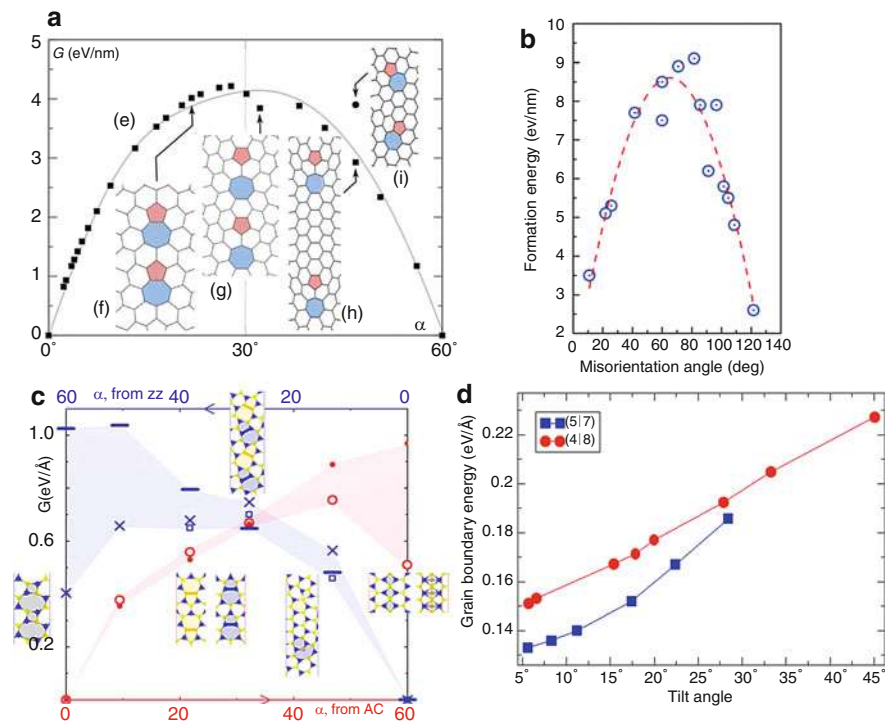
According to the first-principles calculations, the GB energy in MoS_2 is relatively low (see Fig. 9c), which signifies the easy formation of GBs and explains the relative


Fig. 9 Energy of grain boundary per unit length as a function of tilt angle: (**a**) graphene (Adapted with permission from Liu and Yakobson 2010. Copyright 2010 American Chemical Society), (**b**) boronitrene (Adapted from Ding et al. 2014 with permission of The Royal Society of Chemistry), (**c**) MoS$_2$ (Adapted with permission from Yu et al. 2015b. Copyright 2012 American Chemical Society), and (**d**) phosphorene formed by (4|8) defect pairs (red circles) and (5|7) defect pairs (blue squares) as a function of tilt angle (Reprinted from Sorkin and Zhang 2017 with permission of IOP Publishing)

abundance of GBs in MoS$_2$ observed experimentally (Yu et al. 2015b). The GB energies for both AC-GB and ZZ-GB are shown in Fig. 9c.

Grain boundary energy in phosphorene as a function of tilt angle is shown in Fig. 9d. The energy per unit length as a function of tilt angle is shown in Fig. 9c for the phosphorene samples containing grain boundaries composed of (4|8) dislocations (red circles) and (5|7) defect pairs (blue squares). The GB energies for the two types of grain boundaries are quite similar (Sorkin and Zhang 2017). Nonetheless, the grain boundaries formed by (5|7) defects have slightly lower energy, and therefore they are slightly more stable. Similar to graphene (Liu and Yakobson 2010) and boronitrene (Ding et al. 2014), GB energy in phosphorene increases with the increase in the tilt angle. The GB energies in phosphorene are lower than those in graphene (Yazyev and Louie 2010; Liu and Yakobson 2010), boronitrene (Hao and Chen 2016), and MoS$_2$ (Zou et al. 2013), implying a higher stability of GBs in phosphorene than in other 2D materials.

6.3   Failure Mechanism of Grain Boundary

Investigation on the effects of GBs on the mechanical properties of graphene has ended up with a few unexpected discoveries. It was at first predicted and then experimentally verified that contrary to standard reasoning, graphene with large-angle tilt boundaries (high GB defect density) is almost as strong as the pristine one and is much stronger than that with small-angle boundaries (see Fig. 10) (Grantab et al. 2010). These surprising results cannot be explained by Griffith-type fracture mechanics criterion since it does not take the details of bond stretching and breaking into account. It was observed that the failure always starts at GBs of graphene where the bonds shared by hexagon-heptagon rings of the (5|7) dislocations rupture (see Fig. 10a). Subsequently, nanovoids are generated around these broken bonds. The nanovoids gradually grow, leading to the fracture of graphene (Jhon et al. 2012). These broken bonds are more pre-strained at small-angle GBs than those at large-angle GBs, which can better accommodate the strained bonds (Grantab et al. 2010). The closer the (5|7) dislocations are to each other at large-angle GBs, the more significant the mutual cancellation of their overlapping compressive and tensile stress fields. Therefore, the tensile pre-strain of the critical bonds is reduced in large-angle GBs. The initial pre-strain of these critical bonds defines the intrinsic strength, which increases with the tilt angle (see Fig. 10b). But, this GB strengthening with tilt angle is valid only for symmetric GBs formed by linear array of evenly spaced (5|7) dislocations. It was later found that GB strength can decrease with the tilt angle for asymmetrical GB formed by irregularly spaced dislocations. This indicates that it is not just the density of dislocation defects that affects the mechanical properties but the detailed arrangements of defects are also important (Wei et al. 2012).

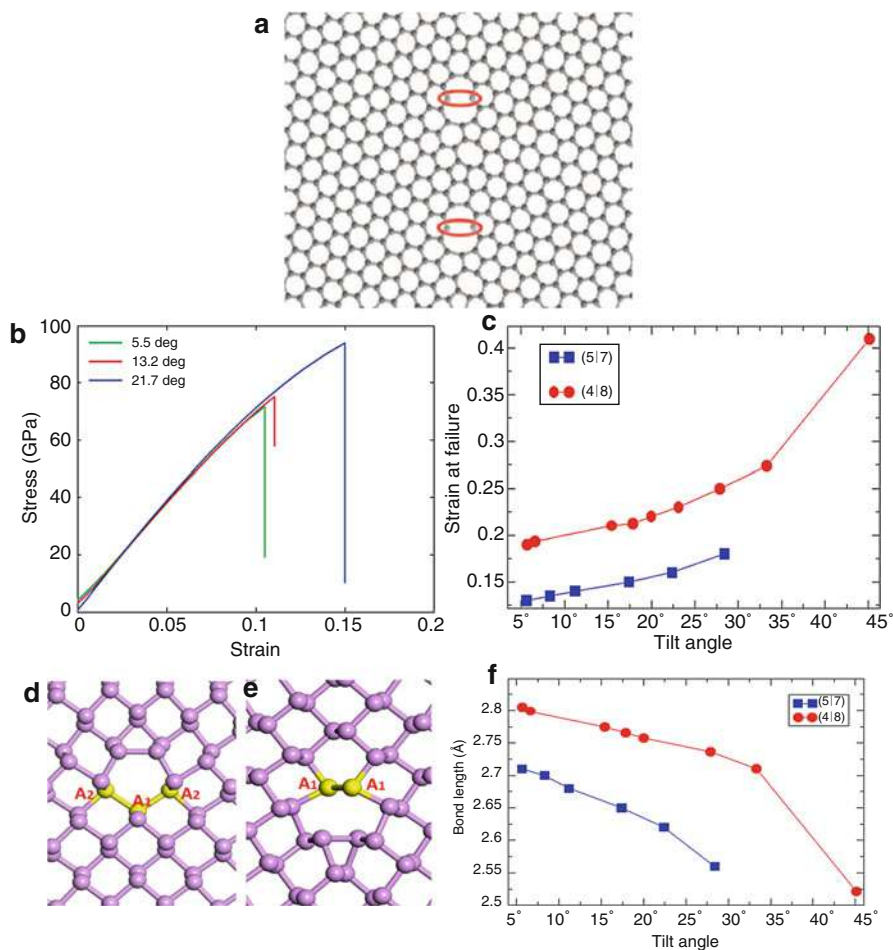
Similar to graphene, the high-angle symmetrical GBs of boronitrene with a larger dislocation density are stronger than the low-angle GBs (Ding et al. 2014). The atomistic simulations also demonstrated that failure of boronitrene is similar to that of graphene. At the failure strain, boronitrene with GBs undergoes a brittle fracture: the rupture occurs sharply without any noticeable preceding changes in the rate of tensile stretching (Ding et al. 2014). This sudden failure mainly stems from the rupture of overstretched homoelemental GB bonds. At grain boundaries formed by array of edge dislocations, homoelemental B-B and N-N bonds occasionally appear, which can be broken much easier than heteroelemental ones. Under applied tensile strain, they rupture first (Becton and Wang 2015). This fracture of homoelemental bonds leads to cumulative stress concentration in the remaining heteroelemental bonds. Since there are only few relatively highly stress-concentrated bond connections between the grains, if one part fails, the rest fails in a rapid fashion. The cracks in boronitrene propagate typically along the ZZ direction (Xiong et al. 2015; Ding et al. 2014). The fracture strength of boronitrene also drops rapidly with the increase in the inflection angle at its GBs. This is because the local sp^3 hybridization at the inflected GBs reduces the fracture strength (Ding et al. 2014).


Fig. 10 (**a**) Initial stage of failure in AC-oriented graphene with GBs. The broken critical hexagon-heptagon bonds of (5|7) defects are outlined (Grantab et al. 2010). (**b**) The stress-strain curves of ZZ-oriented graphene sheets strained perpendicular to the GBs (Grantab et al. 2010). (**c**) Failure strain as a function of tilt angle for phosphorene with linear grain boundaries formed by evenly spaced (4|8, red circles) and (5|7, blue squares) edge dislocations. (**d**) Critical bonds $|A_1A_2|$ in heptagon of a (5|7) defect pair. (**e**) Critical bonds $|A_1A_1|$ in octagon of a (4|8) defect pair rupture first at the onset of tensile failure. (**f**) Initial bond length of the critical $|A_1A_1|$ bonds in (4|8) defect pairs (red circles) and of the $|A_1A_2|$ bonds in (5|7) defect pairs (blue squares) as a function of tilt angle at zero strain. (**d–f**) (Reprinted from Sorkin and Zhang 2017 with permission of IOP Publishing)

Effects of grain boundaries on the mechanical behavior of MoS_2 subjected to uniaxial tensile were studied by Dang et al. (Dang and Spearot 2014) using MD simulations. They found that similar to other 2D materials, the failure initiates at GBs (Dang and Spearot 2014). Similar to graphene, the nucleated crack mainly propagates along the ZZ direction.

The unusual failure characteristics of tilt GBs in graphene and boronitrene are also shared by phosphorene (Sorkin and Zhang 2017) (see Fig. 10c), which signifies that it may be universal for all 2D materials. In phosphorene, large-angle GBs are stronger than low-angle ones. In analogy with graphene, the failure is due to the rupture of the most pre-strained bonds of the (5|7) and (4|8) dislocations forming GBs. The first bonds rupturing at the onset of brittle failure in phosphorene are the most stretched ones in (5|7) and (4|8) dislocations (see the highlighted bonds in Fig. 10d, e). These bonds connect the heptagons and the nearby hexagons in (5|7) defects (as well as the octagons and the adjacent hexagons in (4|8) defects) just as in graphene and boronitrene. Phosphorene with large-angle GBs formed by densely packed dislocations is much stronger than that with low-angle grain boundaries. Similar to graphene and boronitrene, the higher defect concentration at the grain boundaries does not inevitably lead to greater deterioration of its mechanical properties. The large-angle GBs are better able to accommodate the pre-strain and prevent failure that originates from the rupture of the critical bonds of the (4|8) and (5|7) edge dislocations (see Fig. 10f). The closer the (4|8) or (5|7) dislocations are to each other, the more significant the mutual cancellation of their overlapping compressive and tensile stress fields is. Therefore, the tensile pre-strain of the critical bonds is reduced in larger-angle GBs. The initial pre-strain of the critical bonds defines the intrinsic strength of defected phosphorene (Sorkin and Zhang 2017).

6.4   Failure Mechanism of Polycrystalline Materials

After examination of the effects of GB on the mechanical properties of 2D materials, the next logical step is to examine the effects of GBs in polycrystalline samples. The terminations of GBs or GB junctions (one-dimensional regions where three or more adjacent grain boundaries meet) in polycrystalline materials are crucial for failure: they generally serve as accumulators of pre-strain (stress concentrators), sites for crack nucleation, and therefore lower the fracture strength of 2D materials (see Fig. 11).

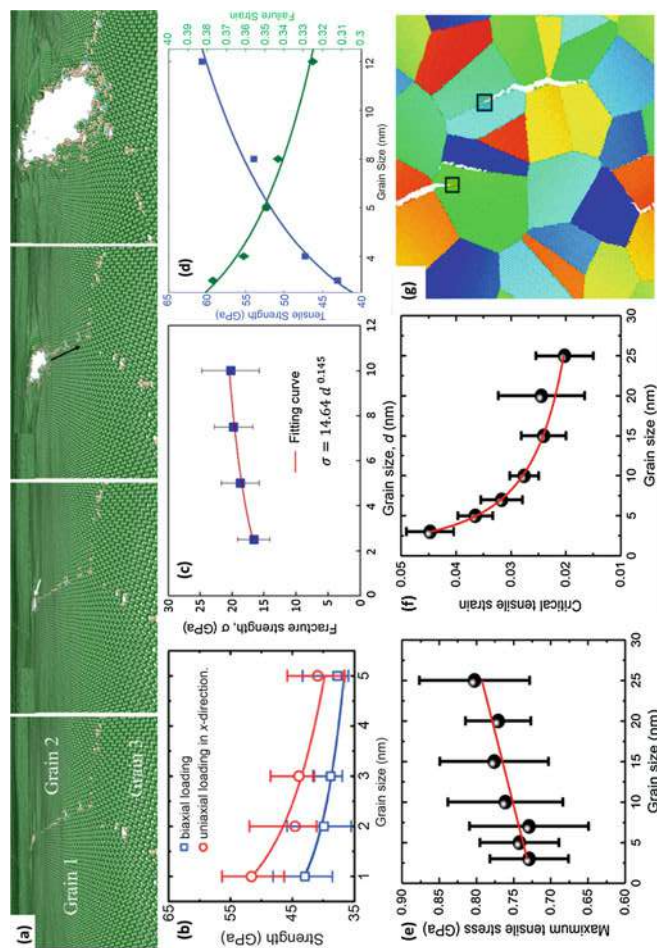
It was found that in polycrystalline graphene, the GB junctions are the "weakest links." In particular, triple junctions (TJs) of graphene or vacancy clusters at GBs are the nucleation centers for cracks (Li et al. 2015). Initial bond fracture at TJs or GBs leads to nano-size void formation, which in turn results in crack nucleation. Occasionally, a row of nano-size voids appear along GBs (see Fig. 11a), and when applied strain increases, these voids coalesce into cracks. The cracks in graphene propagate along GBs and traverse grain domains (see Fig. 11a), indicating that fracture strength of GBs is comparable to that of defect-free bulk (Li et al.


Fig. 11 (**a**) Snapshots of crack nucleation and unzipping mechanism leading to brittle intergranular fracture in graphene. The arrow indicates the unzipping direction (Adapted from Cao and Qu 2013 with permission of AIP Publishing). (**b**) Pseudo Hall-Petch: size-dependence of fracture strength for polycrystalline graphene monolayer with different grain sizes (Reprinted with permission from Song et al. 2013. (**d**) Size-dependence of tensile fracture strength (blue line) and failure strain (green) for polycrystalline boronitrene with different grain sizes (Adapted from Becton and Wang 2015 with permission of the PCCP Owner Societies). (**g**, **e**) Polycrystalline phosphorene: fracture strength (**g**) and tensile failure strain (**e**) as a function of grain size (Adapted from Cao et al. 2017). (**f**) Crack nucleation along grain boundaries in polycrystalline phosphorene (Adapted from Cao et al. 2017 with permission of IOP Publishing)

2015). The vacancies and dislocations seriously complicate crack propagation in polycrystalline graphene since they not only induce stress field but also lead to wrinkling deformation affecting its fracture mechanism (Liu and Yakobson 2010). Under the applied tensile strain, the deformation in polycrystalline graphene is completely elastic up to the brittle fracture since the (5|7) edge dislocations are immobile, and therefore plastic deformation is inhibited (Cao and Qu 2013). The predicted fracture strain ($\varepsilon_{cr} \approx 0.16$) in polycrystalline graphene, although lower than in monocrystalline graphene ($\varepsilon_{cr} \approx 0.23$), is still the highest ultimate strain in polycrystalline materials (Cao and Qu 2013). The transition to plastic deformation occurs only at elevated temperatures (T $\geq$ 1000 K). MD simulations (Yang et al. 2015) predict that the ductility of polycrystalline graphene can deteriorate unexpectedly due to accelerated bond breaking at high temperatures. Furthermore, if the applied strain rate is sufficiently fast at elevated temperatures, then polycrystalline graphene undergoes brittle fracture again. The reason is that the short relaxation time prevents the bond rotations and vacancy coalescence, resulting in simultaneous collective bond breaking (Yang et al. 2015).

A number of studies focusing on the strength of polycrystalline graphene show that there are two opposing trends in the dependence of the tensile fracture strength on the grain size: pseudo Hall-Petch, where the smaller the grain size, the larger the fracture strength (Song et al. 2013) (see Fig. 11b), and inverse Hall-Petch, where the smaller the average grain size, the lower the tensile failure strength (Li et al. 2014; Mortazavi and Cuniberti 2014) (see Fig. 11c). At the moment, the consensus is that the fracture strength of polycrystalline graphene is sensitive to the details of atomic structure (number, type, and distribution of various defects), which are dependent on the sample generating methods. The reduction in failure strength in polycrystalline graphene is up to $\Delta\sigma/\sigma_0 \approx -40\%$ for the smallest grains in the case of the inverse Hall-Petch dependence (Mortazavi and Cuniberti 2014).

The Young's modulus diminishes with the decrease in the average grain size. The Young's modulus of graphene with ultrafine grains (average grain size $\Delta \approx 1$ nm) can be reduced by $\Delta Y/Y_0 \approx -50\%$ in comparison with pristine monocrystalline graphene. However, this effect is negligible ($\Delta Y/Y_0 \approx -3\%$) when the average grain size exceeds $\Delta \approx 10$ nm (Mortazavi and Cuniberti 2014). The failure strain increases gradually when the average grain size decreases. This is because the smaller the average grain size, the more uniformly distributed the defective areas (containing GBs, TJs, and nano-sized voids) over the sample, making it more homogeneous. The more homogeneous the sample, the more uniformly it deforms under loading conditions and therefore fails at a higher failure strain. Besides that, the formation of monoatomic carbon chains between the adjacent GBs, separated by crack nucleation, also allows for polycrystalline graphene to withstand a higher strain and leads to the formation of irregular crack edges (Mortazavi and Cuniberti 2014).

The fracture strength of polycrystalline boronitrene is less studied. Atomistic simulations indicate the inverse Hall-Petch dependence of its failure strength on the grain size. There is a noticeable reduction in the fracture strength (and Young's modulus) when the average grain size decreases (Becton and Wang 2015) (see

Fig. 11d). The smaller the average grain size, the larger the percentage area (fraction) of GBs. These GBs are not as stable as in the pristine crystalline lattice and may serve as sources for crack nucleation. Thus a larger number of GBs reduce the fracture strength of polycrystalline boronitrene (Becton and Wang 2015). Like in graphene, the brittle failure of boronitrene is due to abrupt rupture of the bonds at TJs and GBs (Becton and Wang 2015).

Similar to graphene and boronitrene, fracture in MoS_2 is brittle: as soon as one bond ruptures near TJs or GBs, the released stress from the broken bond raises the stress on the nearby bonds, which consequently rupture. This process proliferates, causing a cascade of bond breaking and resulting in the brittle fracture of polycrystalline MoS_2 (Wang et al. 2015). The underlying reason for the brittleness is that the bond breaking is a localized event since the stress concentration near the ruptured bonds cannot be redistributed due to immobile dislocations in MoS_2. Thus, the cascade of bond failure results in crack propagation, which preferably takes place along the ZZ direction of MoS_2 (Wang et al. 2015).

The mechanical properties and the failure mechanism of polycrystalline phosphorene were studied by Cao et al. (2017) using atomistic simulations. They found that the Young's modulus of polycrystalline phosphorene decreases when the average grain size is reduced. Polycrystalline phosphorene also exhibits an inverse Hall-Petch dependence: its tensile fracture strength decreases with decreasing grain size (see Fig. 11e). The fracture strength of polycrystalline phosphorene is reduced by $\Delta\sigma/\sigma_0 \approx -20\%$ relative to monocrystalline defect-free phosphorene (Cao et al. 2017). In contrast, the fracture strain increases with reduced grain size (see Fig. 11f). The failure mechanism of polycrystalline phosphorene is also similar to that of graphene and boronitrene: the initial bond breaking and subsequent crack nucleation occur mainly at triple junctions and grain boundaries (nearly perpendicular to the stretching direction). The initiated cracks rapidly propagate along the GBs and occasionally across the grain interior (see Fig. 11g). In the grain interior, the cracks in phosphorene typically move along the ZZ direction.

7 Conclusions

Defects in 2D materials have a profound impact on their mechanical properties and failure behavior. In this chapter, we discussed the effect of four fundamental defects: vacancies, Stone-Wales defects, dislocations, and grain boundaries. Four representatives of 2D materials: graphene, boronitrene, molybdenum disulfide, and phosphorene, were considered. The intrinsic defects in these 2D materials have diverse atomic structures and energetics, and their effects on the mechanical properties also vary. Nevertheless, many of the discussed effects of defects on the mechanical properties of 2D materials such as softening of elastic moduli, deterioration in fracture strength, and reduction of ultimate strain are manifestly universal. Besides these effects, there are a few novel effects shared by 2D materials like the unexpected strengthening of high-angle grain boundaries and inverse Hall-Petch dependence of fracture strength on grain size in polycrystalline samples.

Despite the evident progress in studying defected 2D materials, many challenging questions still remain open. Here we mention just a few of them: How can one deliberately engineer defects in a controllable way? Can one control the fracture behavior of 2D materials by manipulating defects, chemical functionalization, and strain engineering? How do the out-of-plane effects induced by defects influence their properties? Can we enhance the toughness of 2D materials by defect engineering?

The family of 2D materials is rapidly expanding. Here, we only discussed four representative 2D materials. Certainly, defects in other 2D materials, such as silicene, germanene, borophene, and metal-organic frameworks, which are not included in the present review, are equally interesting. In addition, defect structures, defect interactions, and their impact on the mechanical properties of newly emerging 2D materials need also great research attention.

Finally, the grand challenge is to develop new models and computational methods for multiscale simulations of defects in 2D materials. Understanding the interactions between a variety of defects across length and time scales will continue to motivate further research.

Contents

Abstract

Two-dimensional (2D) materials have, over the past decade, attracted significant amounts of research interest due to their exceptional and unique physical properties. Here, two areas of graphene mechanics are overviewed where computational techniques, both existing (classical molecular dynamics) and new (electromechanical coupling techniques), have enabled new insights. First, we discuss the prediction of and insights gained with regard to atomistic simulations of auxetic behavior in 2D materials. Second, new computational techniques are discussed that couple molecular dynamics, tight-binding, and quantum transport to examine how mechanical strain can impact, in interesting and often unanticipated fashion, the electronic properties of graphene kirigami.

1   Introduction

Since the discovery of a facile method for its isolation, graphene (Novoselov et al. 2005), the simplest two-dimensional crystal, has attracted intense attention not only for its unusual physical properties (Geim et al. 2007; Castro Neto et al. 2009; Han et al. 2007; Seol et al. 2010; Akinwande et al. 2017) but also for its potential as the basic building block for a wealth of device applications (Portions of the introduction are reprinted with permission from Qi et al. (2014). Copyright 2014 by the American Physical Society.).

There exist key limitations that appear to restrict the application of graphene for all-carbon electronic circuits: one such limitation is that graphene, in its pristine form, is well known to be a semimetal with no bandgap (Castro Neto et al. 2009). A highly active field of study has recently emerged based on the idea of applying mechanical strain to modify the intrinsic response of electrons to external fields in graphene (Guinea et al. 2010a; Qi et al. 2013; Tomori et al. 2011). This includes the strain-induced generation of spectral (band) gaps and transport gaps, which suppress conduction at small densities. In this context, several groups (Guinea et al. 2008, 2010a, b; Pereira and Castro Neto 2009; Guinea and Low 2010; Abedpour et al. 2011; Kim et al. 2011; Yeh et al. 2011; Yang 2011; Kitt et al. 2012, 2013; Yue et al. 2012) have employed continuum mechanics coupled with effective models of the electronic dynamics to study the generation of pseudomagnetic fields (PMFs) in different graphene geometries and subject to different deformations. The potential impact of strain engineering beyond the generation of bandgaps has also attracted tremendous interest (Pereira and Castro Neto 2009; Pereira et al. 2010; Abanin and Pesin 2012; Wang et al. 2011).

Pereira and Castro Neto (Pereira et al. 2009) showed that a bandgap will not emerge under simple uniaxial strain unless the strain is larger than roughly 20%. This theoretical prediction, based on an effective tight-binding model for the electronic structure, has been subsequently confirmed by various more elaborate ab initio calculations (Ni et al. 2009; Farjam and Tabar 2009; Choi et al. 2010). The robustness of the gapless state arises because simple deformations of the lattice lead only to local changes of the *position* of the Dirac point with respect to the undeformed lattice configuration (Kane et al. 1997; Suzuura and Ando 2002) and to anisotropies in the Fermi surface and Fermi velocity (Pereira et al. 2010). The shift in the position of the Dirac point is captured, in the low-energy, two-valley, Dirac approximation, by a so-called pseudomagnetic vector potential and resulting pseudomagnetic field (PMF) that arises from the strain-induced perturbation of the tight-binding hoppings (Suzuura and Ando 2002). As a result, electrons react to mechanical deformations in a way that is analogous to their behavior under a real external magnetic field, except that overall time-reversal symmetry is preserved, since the PMF has opposite signs in the two time-reversal related valleys (Castro Neto et al. 2009). Guinea et al. (2010a) found that nearly homogeneous PMFs could be generated in graphene through triaxial stretching, but the resulting fields were found to be moderate, unless relatively large (i.e., >10%) tensile strains could be applied. Unfortunately, such large planar tensile strains have not been

experimentally realized in graphene to date. This is arguably attributed to the record-high tensile modulus of graphene and the unavoidable difficulty in effectively transferring the required stresses from substrates to this monolayer crystal (Gong et al. 2010).

An interesting and different direction has recently been pursued by employing lithography to extend the range of elastic deformation that can be sustained by a graphene by patterning nanomeshes out of large graphene sheets (Zhu et al. 2014) (Portions of the introduction are reprinted with permission from Bahamon et al. (2016). Copyright 2016 by the American Physical Society.). Such structures, inspired by the Japanese art of cutting paper called kirigami, have been designed and tested in recent experiments (Blees et al. 2015) that establish their mechanical robustness and extremely high elongation limits ($\sim$240%) compared to uncut graphene. In a previous study of the elastic and mechanical characteristics of graphene kirigami, some of us showed that their stretchability limit and effective Young's modulus can be characterized (and customized) in terms of two geometric parameters (Qi et al. 2014): α, the ratio of the overlapping cut length to the kirigami length, and β, the ratio of the overlapping width to the kirigami length.

The ability currently demonstrated to experimentally design graphene kirigami capable of ultrahigh elastic deformations raises the question of how the electronic states and the flow of current within the kirigami are, or can be, modified under deformation. In particular, since any kirigami always involves a number of bends, indentations, and narrow regions (henceforth, "constrictions"), it can naturally harbor a number of localized states at low energies (below the threshold for electronic transmission) as a result of either the geometry alone (González et al. 2011) or geometry combined with disorder (Ihnatsenka et al. 2009) and/or Coulomb interactions (Todd et al. 2008; Han et al. 2010). The experimental observation of Coulomb blockade in graphene nanoribbons and constrictions (Sols et al. 2007; Todd et al. 2008; Stampfer et al. 2009; Gallagher et al. 2010) indicates that such states are expected to be prevalent at low energies in "papercut" graphene devices and that disorder can promote or further stabilize them.

A segment of suitably patterned graphene hosting such states defines a quantum dot, and its periodic repetition would define an array of coupled quantum dots, analogously to what has been achieved in semiconductor structures through comb-shaped arrays of side gates (Kouwenhoven et al. 1990; Brum 1991; Ji et al. 1992). The fact that graphene kirigami of possibly any desired shape can sustain repeated stretching cycles (Blees et al. 2015) suggests that one might be able to design kirigami suitable for the study of coupled quantum dots, with the advantage that the inter-dot coupling responds directly to the deformed state of the structure. The vast range of stretchability limits and effective Young moduli that these structures can be designed with, combined with the proven mechanical resilience of graphene at the nanoscale, hint at the possibility of designing versatile electromechanical devices based on this concept of stretchable graphene quantum dot arrays whose current response can be strongly sensitive to the inter-dot coupling.

This is the first problem we address in this chapter, through a novel coupling of classical molecular dynamics, tight-binding, and quantum transport. We concentrate

only in the geometric aspects that contribute to localization of electronic states at certain portions of the kirigami. We confirm that such states define effective quantum dots, which result in a characteristic profile of the conductance at low energies defined by a sequence of resonant minibands and stop-gaps. This is analogous to the conductance of periodic split-gate semiconductor heterostructures (Kouwenhoven et al. 1990; Ulloa et al. 1990; Brum 1991), where each miniband consists of a set of resonant tunneling peaks. At low energies, the conductance profile is seen to be very sensitive to the deformation, and we analyze this response in terms of the interplay between variations in inter-dot coupling and strain barriers that develop under stretching.

The second problem we address in this chapter deals with recently discovered auxetic behavior in 2D materials (Jiang et al. 2016) (Portions of the introduction are reprinted with permission from Jiang et al. (2016). Copyright 2016 by the American Physical Society.). The Poisson's ratio, $\nu_{xy} = -\varepsilon_y/\varepsilon_x$, characterizes the resultant strain in the y-direction for a material under longitudinal deformation in the x-direction. The Poisson's ratio is typically a positive number and has a value around 0.3 for many engineering materials (i.e., steels). The value is positive when a material contracts in the transverse directions when stretched uniaxially. The Poisson's ratio in classical elasticity theory depends on the ratio between the bulk modulus and the shear modulus, e.g., $\nu = \frac{1}{2}\left(1 - 1/\left(\frac{K}{\mu} + \frac{1}{3}\right)\right)$ for three-dimensional isotropic materials. The Poisson's ratio is thus limited to the range $-1 < \nu < 0.5$ for three-dimensional isotropic materials within classical elasticity theory.

Materials are thus allowed to exhibit a negative Poisson's ratio (NPR) within classical elasticity theory. Materials with NPR were termed auxetic materials by Evans (1991). One way in which the impact of NPR can be gleaned is to note that there exist certain physical properties that are inversely proportional to $1 + \nu$ or $1 - \nu^2$, which implies that these properties become infinitely large in the limit of the Poisson's ratio $\nu \to -1$. For example, the sound of speed is proportional to $(1 + \nu)^{-1/2}$, and the material hardness is related to $(1 - \nu^2)^\gamma$, with γ as a constant. Hence, materials with NPR typically have novel properties such as enhanced toughness and enhanced sound and vibration absorption.

In 1987, Lakes performed seminal experiments to illustrate the NPR in a foam structure (Lakes 1987). Since then, many researchers have demonstrated that the NPR phenomenon is actually quite common both as an intrinsic material property and also in engineered structures (Rothenburg et al. 1991; Lakes 1993; Baughman and Galvao 1993; Evans and Alderson 2000; Yang et al. 2004; Ravirala et al. 2007; Lethbridge et al. 2010; Bertoldi et al. 2010; Alderson et al. 2012; Clausen et al. 2015). For example, 69% of the cubic elemental metals have intrinsic NPR along a non-axial direction, (Milstein and Huang 1979; Baughman et al. 1998) and the Poisson's ratio for FCC metals can be negative along some principal directions by proper control over the transverse loading (Ho et al. 2016).

Concurrently, nanomaterials, encompassing such well-known materials like buckyballs, carbon nanotubes, graphene, nanowires, black phosphorus, MoS_2, and others, have drawn significant interest within the past two decades. Within the last

3 years, the auxetic property has been found in some of these nanomaterials (Jiang and Park 2014), with the mechanisms underlying the auxetic properties often being due to specific nanoscale physical properties. In the present chapter, we discuss auxetic behavior in two forms of monolayer graphene, graphene nanoribbons (Jiang and Park 2016) and bulk graphene (Jiang et al. 2016), while discussing the distinct mechanics principles enabling the auxetic response in both of those forms.

2 Auxeticity in 2D Nanomaterials

2.1 Single-Layer Graphene

We begin our discussion of negative Poisson's ratio (NPR) in single-layer graphene (Jiang et al. 2016) (Section 2.1 reprinted (adapted) with permission from Jiang et al. (2016). Copyright (2016) American Chemical Society.). The crystal structure for single-layer graphene is shown in the inset of Fig. 1b. Periodic boundary conditions are applied in both x- and y-directions such that our studies,

Fig. 1 (Color online) Negative Poisson's ratio in graphene. (**a**) The resultant strain ε_y versus the applied strain ε_x. A robust valley point exists at $\varepsilon_x = 0.06$ in all curves for varying simulation parameters using both MD and MS approaches. (**b**) The Poisson's ratio extracted from the MS results in (a) through $\nu = -\partial \varepsilon_y / \partial \varepsilon_x$, which is negative for $\varepsilon_x > 0.06$. Image reprinted with permission from Jiang et al. (2016)
and the properties we report, represent those of bulk graphene without edge effects. The carbon-carbon interactions are described by the Brenner potential (Brenner et al. 2002), which has been widely used to study the mechanical response of graphene (Mo et al. 2009). The structure is stretched in the x (armchair)-direction, while graphene is allowed to be fully relaxed in the y (zigzag)-direction, using both molecular dynamics (MD) and molecular statics (MS) simulations. For the MD simulations, the standard Newton equations of motion are integrated in time using the velocity Verlet algorithm with a time step of 1 fs, which is small enough to maintain energy conservation during the MD simulations. This time step is also small enough to accurately discretize the atomic trajectory corresponding to the highest-frequency vibration modes in graphene (with frequency around (Jiang et al. 2008) 4.8×10^{13} Hz). For the MS simulations, the conjugate gradient algorithm is used for energy minimization. Simulations are performed using the publicly available simulation code LAMMPS (Plimpton 1995), while the OVITO package is used for visualization (Stukowski 2010).

Figure 1a shows the resultant strain ε_y in the y-direction in graphene that is stretched by ε_x in the x-direction. The x-axis is along the horizontal direction, while the y-axis is in the vertical direction as shown in the inset of Fig. 1b. The resultant strain in the y-direction is computed by $\varepsilon_y = \frac{L_y - L_{y0}}{L_{y0}}$ with L_{y0} and L_y as the initial and deformed lengths in the y-direction. We simulate the tensile deformation of graphene using both MD and MS simulations. MD simulations are carried out for square graphene of size $L = 200$ and 300 Å at 4.2 and 300 K. MS simulations are performed for graphene of dimension $L = 20$ and 50 Å.

As shown in Fig. 1a, there is a robust valley point around $\varepsilon_x = 0.06$ (6%) in all of these curves. This valley point indicates that the Poisson's ratio, calculated by (Ho et al. 2014) $\nu = -\partial \varepsilon_y / \partial \varepsilon_x$, is positive for $\varepsilon_x < 0.06$ but becomes negative for $\varepsilon_x > 0.06$. These results demonstrate that the NPR is robust, as it is observed for both low and room temperature conditions, as well as for all structural sizes we have considered. We note that graphene is highly stretchable and has been stretched in a wide strain range experimentally. A strain up to 0.15 has been applied on graphene to measure the nonlinear stiffness (Lee et al. 2008) or manipulate its rippled structure (Bao et al. 2009). Furthermore, recent experiments reported a uniaxial strain up to 0.1, which can be controlled in a reversible and nondestructive manner in graphene (Garza et al. 2014). Thus, the critical strain of $\varepsilon_x = 0.06$ we find has been achieved in contemporary experiments on graphene, so that theoretical results in the present work are experimentally verifiable. The Poisson's ratio is about 0.3 at $\varepsilon_x \approx 0$, which agrees with a recent numerical result with the realistic interatomic potential LCBOPII (Los et al. 2006).

Figure 1a shows that results from MD simulations at 4.2 K coincide with the results from MS simulations, so we will concentrate on the MS simulation results for the rest of this chapter. Figure 1b shows the strain dependence for the Poisson's ratio extracted from these two curves from MS simulations in panel (a). It explicitly shows that the Poisson's ratio is negative for $\varepsilon_x > 0.06$.

We note that there have been previous reports of NPR in graphene. Specifically, large numbers of vacancy defects (Grima et al. 2015) or patterning periodic porous structures (Ho et al. 2016) for bulk graphene or compressive edge stress-induced warping in graphene ribbons are three different mechanisms to achieve the NPR in graphene (Jiang et al. 2016). The Poisson's ratio for graphene can also be driven into the negative regime by thermally induced ripples at high temperatures above 1700 K (Zakharchenko et al. 2009). In contrast, the NPR revealed in the present work represents an intrinsic material property for single-layer graphene.

Discussion To explore the underlying mechanism for the intrinsic NPR, we first illustrate two major deformation modes for the tensile deformation of graphene in Fig. 2. These two deformation modes are fundamental deformation modes corresponding to the bond stretching and angle bending interactions (Chang et al. 2003); i.e., $V_b = \frac{K_b}{2} (b - b_0)^2$ and $V_\theta = \frac{K_\theta}{2} (\theta - \theta_0)^2$, where b is the bond length and θ is the angle in the deformed graphene and $\theta_0 = 120°$ and $b_0 = 1.42\,\text{Å}$ are material constants related to undeformed graphene. K_b is the force constant that characterizes the resistance to bond stretching, and so a larger value of K_b indicates a stiffer bond. K_θ characterizes the resistance to angle bending, and so a larger value of K_θ means a larger resistance to angle bending deformations. The values of these force constants can be obtained by using the value of the Young's modulus and the Poisson's ratio of graphene (Chang et al. 2003). The bond stretching and angle bending are two major interaction terms in graphene,
Fig. 2 (Color online) Two typical ideal deformation pathways during the tensile deformation of graphene. The left atom cluster (black online) is stretched along the horizontal x-direction. The parallelogram gray area indicates the unit cell. PW-I (blue online): carbon-carbon bond lengths remain constant ($\Delta b = 0$), while angles are altered to accommodate the external strain, which results in a Poisson's ratio of $\nu = 1$. PW-II (red online): angles are unchanged, and bond lengths are elongated to accommodate the external tension, resulting in a NPR of $\nu = -1/3$. The lighter shades show the undeformed structure. Image reprinted with permission from Jiang et al. (2016)

especially in graphene without out-of-plane deformation. We note that the bond stretching and angle bending interactions were used to derived analytic expressions for the Poisson's ratio in carbon nanotubes (Chang et al. 2003, 2005; Shen et al. 2004; Yao et al. 2008). The analytic expressions illustrate the dependence of the Poisson's ratio on geometrical parameters and force constants. For example, Yao et al. performed a speculative investigation on the possibility of NPR for carbon nanotubes by varying one parameter (or ratio of parameters) while holding all other parameters unchanged (Yao et al. 2008). However, it was determined that significant, and likely nonphysical changes to the geometry or material constants would be necessary for the NPR to appear in CNTs.

The overall deformation process for graphene depends on the competition between the bond stretching and angle bending interactions. For $V_b \gg V_\theta$, the bonds are too stiff to be stretched ($\Delta b \approx 0$), so only the bond angles will change during the tension of graphene. This type of deformation will be referred to as the PW-I deformation mode, as shown in the top (blue online) of Fig. 2. For $V_b \ll V_\theta$, the bond angles cannot be changed ($\Delta \theta \approx 0$), so the bond lengths will be stretched to accommodate the applied tension. This type of deformation will be referred to as the PW-II deformation mode, as shown in the bottom (red online) of Fig. 2.

The Poisson's ratio corresponding to the PW-I and PW-II deformation modes can be derived by simple algebra. The unit cell is displayed by the parallelogram gray area in the left configuration in Fig. 2. The size of the cell in Fig. 2 in the x- and y-directions are

$$L_x = 2 \left(b_1 + b_2 \cos \frac{\theta_1}{2} \right) \tag{1}$$

$$L_y = 2 b_2 \sin \frac{\theta_1}{2}, \tag{2}$$

which yields

$$dL_x = 2 \left(db_1 + db_2 \cos \frac{\theta_1}{2} - \frac{b_2}{2} \sin \frac{\theta_1}{2} d\theta_1 \right) \tag{3}$$

$$dL_y = 2 \left(db_2 \sin \frac{\theta_1}{2} + \frac{b_2}{2} \cos \frac{\theta_1}{2} d\theta_1 \right). \tag{4}$$

As a result, the Poisson's ratio is

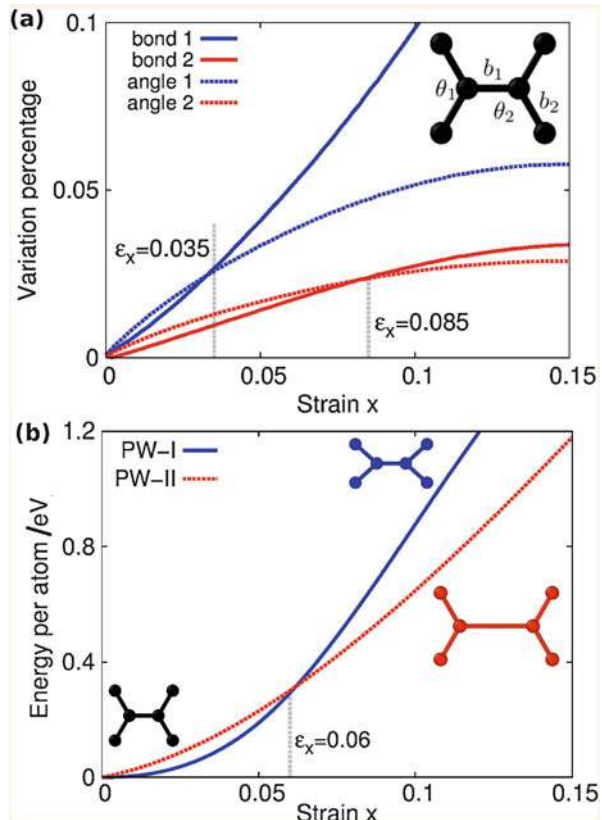
$$
\begin{aligned}
\nu &= -\frac{\varepsilon_y}{\varepsilon_x} = -\frac{dL_y/L_y}{dL_x/L_x} \\
&= -\frac{b_1 + b_2 \cos \frac{\theta_1}{2}}{b_2 \sin \frac{\theta_1}{2}} \times \frac{db_2 \sin \frac{\theta_1}{2} + \frac{b_2}{2} \cos \frac{\theta_1}{2} d\theta_1}{db_1 + db_2 \cos \frac{\theta_1}{2} - \frac{b_2}{2} \sin \frac{\theta_1}{2} d\theta_1},
\end{aligned}
\tag{5}
$$

where $b_1 = b_2 = b_0$ and $\theta_1 = \theta_2 = \theta_0$ for undeformed graphene. We note that, for small strains, the definition of the Poisson's ratio in Eq. (5) is consistent with the

numerical formula used in the above to extract the Poisson's ratio in Fig. 1b, because ε_y and ε_x have a linear relationship for small strains.

For the PW-I mode, we have $\Delta b_1 \approx 0$, $\Delta b_2 \approx 0$, and $\Delta \theta_1 \neq 0$. As a result, we obtain the Poisson's ratio for PW-I mode as $\nu = 1$ from Eq. (5). For the PW-II mode, we have $\Delta \theta_1 \approx 0$, and the force equilibrium condition leads to Chang et al. (2003) $db_2 = \frac{1}{2} db_1 \cos \frac{\theta_1}{2}$. Hence, the Poisson's ratio for the PW-II mode is $\nu = -1/3$ from Eq. (5). It is interesting to note that the Poisson's ratio ($\nu = -1/3$) for the PW-II mode coincides with the expectations of the self-consistent screening approximation (Los et al. 2006).

Figure 3a illustrates the interplay between the PW-I and PW-II deformation modes during the tensile deformation of graphene. Specifically, it shows the absolute value of the relative variation of the angles θ_1 and θ_2 and bond lengths b_1 and b_2; we note that the change in angle θ_1 is negative in stretched graphene. For $\varepsilon_x < 0.035$, the variations of angles θ_1 and θ_2 are larger than the variations of bonds b_1 and b_2, respectively, which indicates PW-I to be the dominant deformation mode for graphene subject to small uniaxial tensile strains. For $0.035 < \varepsilon_x < 0.085$, the variation of angle θ_1 becomes less than the variation of bond b_1, while the

Fig. 3 (Color online) Pathway energy criteria for PW-I and PW-II deformation modes. (**a**) The variation of key geometrical parameters (angles θ and bond lengths b) in graphene. The y-axis shows the relative variation, i.e., $\Delta b / b_0$ or $\Delta \theta / \theta_0$. (**b**) Pathway energy curve for PW-I and PW-II deformation modes. The curves show a crossover at $\varepsilon_x = 0.06$, which predicts a transition from PW-I mode (positive Poisson's ratio) to PW-II mode (negative Poisson's ratio) during the tensile deformation of graphene. Left bottom inset (black online) shows the undeformed structure. Top inset (blue online) displays the PW-I deformed structure. Right inset (red online) is the PW-II deformed structure. Image reprinted with permission from Jiang et al. (2016)


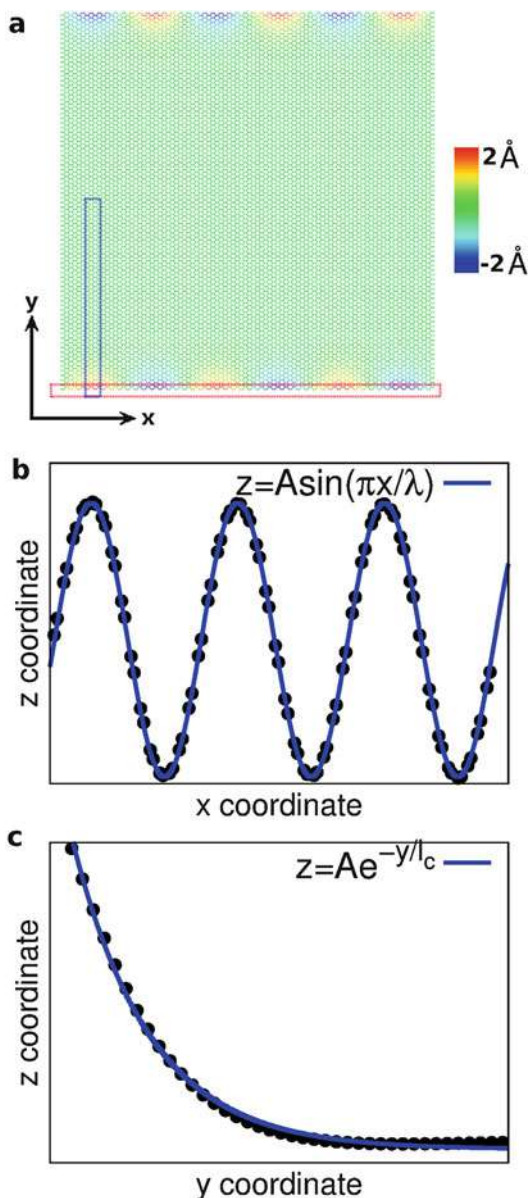
variation of angle θ_2 is still larger than the variation of bond b_2, which implies a competition between the PW-I and PW-II deformation modes for moderate strains. For $\varepsilon_x > 0.085$, variations for both bonds are larger than the variations of angles, so PW-II overcomes PW-I to be the dominant deformation mode for large tensile strains. Hence, the value of the Poisson's ratio will decrease with increasing strain and will become negative at some critical strain between [0.035, 0.085] when PW-II dominates the deformation process. The critical strain of 0.06 for the NPR in Fig. 1 falls in this strain range.

We perform an energy-based analysis, shown in Fig. 3b, of the PW-I and PW-II deformation modes to gain further insight into the interplay between these two deformation modes governing the transition from positive to negative Poisson's ratio at $\varepsilon_x = 0.06$. The energy curve is computed as follows. For PW-I, the structure is manually deformed corresponding to the PW-I mode shown in the top of Fig. 2. We then calculate the potential energy of this deformed structure, which is higher than the potential energy of undeformed graphene. The energy curve shown in Fig. 3b is the difference between the potential energy per atom of the deformed and undeformed graphene structures. The energy curve for PW-II is computed similarly, where angular distortions are allowed while the bond lengths are kept constant. Figure 3b clearly shows a crossover around $\varepsilon_x = 0.06$ between the energy curves for PW-I and PW-II modes.

We thus propose a pathway energy-based criteria: the tensile deformation process for graphene is governed by the deformation mode with lower pathway energy. According to this criteria, PW-I mode will be the major deformation mode for $\varepsilon_x < 0.06$, in which the pathway energy for PW-I mode is lower than the pathway energy for PW-II mode. Similarly, the pathway energy criteria predicts the PW-II to be the major deformation mode for $\varepsilon_x > 0.06$, in which PW-II has lower pathway energy. We showed in Fig. 2 that the PW-I mode has a positive Poisson's ratio, while the PW-II mode has a NPR. As a consequence, the Poisson's ratio is positive for $\varepsilon_x < 0.06$ and will turn negative for $\varepsilon_x > 0.06$. This prediction is in excellent agreement with the numerical results in Fig. 1, where the Poisson's ratio changes from positive to negative at $\varepsilon_x = 0.06$. We note that, to our knowledge, it is the first time the pathway energy criteria is proposed, which is based on the energetic competition for the two major in-plane deformation pathways. This criteria may be useful for future investigations into the mechanical properties of nanomaterials similar as graphene.

2.2   Single-Layer Graphene Ribbons

While the previous section discussed auxetic behavior in bulk, monolayer graphene, we now demonstrate that graphene ribbons can also exhibit NPR (Jiang and Park 2016) (Section 2.2 reprinted (adapted) with permission from Jiang and Park (2014). Copyright (2016) American Chemical Society.). A characteristic feature for free edges in graphene is the warped configuration that is induced by the compressive edge stress as shown in Fig. 4a. The warped structure can be described by the surface

Fig. 4 (Color online) Warped free edges in graphene. Warping surface is described by $z(x, y) = Ae^{-y/l_c}\sin(\pi x/\lambda)$, with $A = 2.26\,\text{Å}$, $l_c = 8.55\,\text{Å}$, and $\lambda = 32.01\,\text{Å}$. (**a**) Top view of graphene with free boundary conditions in the y-direction, while periodic boundary conditions are applied in the x-direction. Color is with respect to the atomic z-coordinate. (**b**) The z-coordinates for atoms in the horizontal red box. (**c**) The z-coordinates for atoms in the vertical blue box. Image reprinted with permission from Jiang and Park (2016)


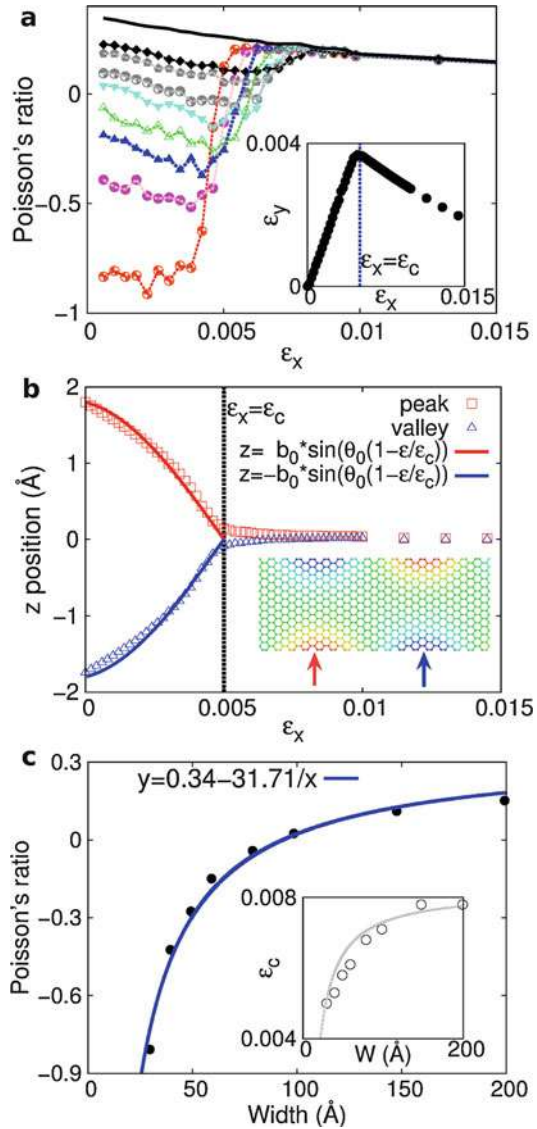
function (Shenoy and Reddy 2008) $z(x, y) = Ae^{-y/l_c}\sin(\pi x/\lambda)$, where $\lambda = L/n$, with L being the length of the graphene ribbon and n being the warping number. The graphene ribbon shown in Fig. 4a has dimensions of $195.96 \times 199.22\,\text{Å}$, resulting in the fitting parameters for the warped free edges as the warping amplitude $A = 2.26\,\text{Å}$, penetration depth $l_c = 8.55\,\text{Å}$, and half wave length $\lambda = 32.01\,\text{Å}$. We note that λ is about one sixth of the length L, i.e., $\lambda = L/6$.

We study five sets of graphene structures with free boundary conditions in the y-direction. Set I: graphene is 195.96 Å in length, and the warped edge has a warping number $n = 6$. Set II: graphene is 195.96 Å in length, and the warped edge has a warping number $n = 8$. Set III: graphene is 195.96 Å in length, and the warped edge has a warping number $n = 10$. Set IV: graphene is 195.96 Å in length, and the warped edge has a warping number $n = 12$. Set V: graphene is 97.98 Å in length, and the warped edge has a warping number $n = 2$. For each simulation set, we consider eight different widths of 29.51, 39.35, 49.19, 59.03, 78.70, 98.38, 147.57, and 199.22 Å. We will demonstrate that the NPR phenomena we report is robust and is observed for different warping periodicities.

Figure 5a shows the strain dependence for the Poisson's ratio of Set I, where the width of the graphene ribbon increases for data from the bottom to the top in the figure. The occurrence of a NPR is clearly observed for small strains and for the narrower width ribbons. Furthermore, the Poisson's ratio changes from negative to positive at some critical strain ε_c. This critical strain is more clearly illustrated in the inset, which shows a critical strain of $\varepsilon_c = 0.005$ in the ε_y-ε_x relation for graphene with width 29.51 Å. For $\varepsilon_x < \varepsilon_c$, graphene expands in the y-direction when it is stretched in the x-direction; i.e., the NPR phenomenon occurs.

The critical strain ε_c represents a structural transition for the warped edge. To reveal this structural transition, we show in Fig. 5b the z position of two atoms from different warped edge regions. One atom is at the peak of the warped edge (shown by the red arrow in the inset), while the other atom is at the valley of the warped edge (shown by blue arrow). Figure 5b clearly shows that both atoms fall into the xy plane at the critical strain $\varepsilon_x = \varepsilon_c$. In other words, the warped edge transitions at the critical point from a three-dimensional, out-of-plane warping configuration into a two-dimensional planar configuration due to the externally applied tensile strain. The connection of the critical strain in the disappearance of the NPR in Fig. 5a and the transition to the two-dimensional planar configuration in Fig. 5b implies that the NPR is connected to the flattening of the warped edges, as the Poisson's ratio becomes positive after the structural transition of the warped edge. We note that the z-coordinates of the atoms in the warped edges in Fig. 5b can be well fitted to the functions $z = \pm b_0 \sin(\theta_0(1 - \varepsilon/\varepsilon_c))$ for $\varepsilon < \varepsilon_c$.

The width dependence for the Poisson's ratio is displayed in Fig. 5c. The Poisson's ratio is strain dependent as shown in Fig. 5a, so we compute an averaged Poisson's ratio using data in the strain range $[0, \varepsilon_c]$, which is equivalent to extracting the Poisson's ratio value by a linear fitting for the ε_y-ε_x relation in $[0, \varepsilon_c]$. Figure 5c shows this averaged Poisson's ratio value for graphene with different widths. We note that the critical strain varies for graphene with different width as indicated by the inset in Fig. 5c, where the critical strain is fitted to the function $\varepsilon_c = 0.0082 - 0.092/W$. The critical strain is smaller in narrower graphene, because some interactions occur between the free ($\pm$y) edges for narrower widths. These edge interactions enable the tension-induced structural transition of the warped edges for narrower ribbons to occur at lower values of tensile strains, because the warping directions for the free ($\pm$y) edges are different, forming a seesaw-like configuration. The saturation value $\varepsilon_c = 0.0082$ at $W \to \infty$ can

Fig. 5 (Color online) Poisson's ratio for graphene from Set I. (**a**) Strain dependence for Poisson's ratio. Inset displays the strain-strain relation for graphene with width 29.51 Å, in which graphene expands in the y-direction when it is stretched in the x-direction by strain smaller than $\varepsilon_c = 0.005$, indicating the NPR effect. (**b**) The strain dependence for the z positions of two atoms in the peak (valley) of the warped edge in graphene. Data are fitted to functions $z = \pm b_0 \sin(\theta_0(1 - \varepsilon/\varepsilon_c))$ with constraint $b_0 = z_0/\sin\theta_0$. Inset displays these two atoms; i.e., the atom on the peak (red arrow) and valley (blue arrow) of the warped edge. Both atoms fall into the graphene plane for strain larger than ε_c. (**c**) Width dependence for the Poisson's ratio. Inset shows the critical strain in graphene ribbons of different width. Image reprinted with permission from Jiang and Park (2016)


be regarded as the actual value of the critical strain for an isolated warped free edge.

The Poisson's ratio in Fig. 5c increases with increasing width (W) and can be fitted to the function $\nu = 0.34 - 31.71/W$. According to this result, graphene can be regarded as the integration of one central region (with bulk Poisson's ratio ν_0) and two edge regions (with Poisson's ratio ν_e). The size of each edge region is l_c, which is the penetration depth of the warped configuration in Fig. 4. The size of the remaining central region is $W - 2l_c$. Simple algebra gives the effective Poisson's

ratio for the graphene ribbon as

$$\nu = \nu_0 - \frac{2l_c}{W}(\nu_0 - \nu_e).$$ (6)

Comparing Eq. (6) with the fitting function in Fig. 5c, we get $\nu_0 = 0.34$ and $\nu_e = -1.51$.

   This result shows that for the Set I ribbon geometries, in the limit of an ultra-narrow, edge-dominated graphene ribbon, the value of the NPR can be as large as -1.51. Perhaps more importantly, according to Eq. (6), the NPR phenomenon can be observed in graphene sheets with widths up to about 10 nm. Such width nanoribbons are not small and are regularly studied experimentally (Jiao et al. 2009). Furthermore, Fig. 5a shows that the NPR phenomenon is most significant for tensile strains smaller than about 0.5%. These strain values are important as they fall within the strain range of [0, 0.8%] that has already been achievable in many experimental strain engineering investigations (Ni et al. 2008; Mohiuddin et al. 2009). We thus expect that this NPR phenomenon can readily be observed experimentally in the near future.

Discussion   We have demonstrated in the above discussion the connection between the NPR phenomenon and the warped free edges in graphene. We now present an analytic model to describe the relationship between the NPR phenomenon and the warped free edges. In Fig. 6a, the warped edge is represented by an inclined plate (IP) (gray area). During the tensile deformation, the IP falls into the xy plane. The side view in the dashed ellipse illustrates the mechanism enabling the NPR clearly. Specifically, it shows that the projection (b_y) of the IP on the y-axis increases during the falling down of the IP, resulting in the NPR phenomenon.

   This IP model is inspired by the strain-dependent z (out-of-plane)-coordinates of atoms in the warped edges shown in Fig. 5b, where the z-coordinates are fitted to the functions $z = \pm b_0 \sin(\theta_0(1 - \varepsilon/\varepsilon_c))$, in which the parameters are restricted by $b_0 = z_0/\sin\theta_0$. This function describes exactly the trajectory of the tip of the IP (displayed by blue arrow in Fig. 6a) during its falling down process in Fig. 5b. This function also indicates that the IP's tilting angle θ is a linear function of the applied tensile strain ε:

$$\theta = \theta_0\left(1 - \frac{\varepsilon}{\varepsilon_c}\right),$$ (7)

where θ_0 is the initial tilting angle. This expression gives $\theta = 0$ at the critical strain $\varepsilon = \varepsilon_c$, as required by the definition of the critical strain in Fig. 5b. For the applied tensile strain ε in the x-direction, the resulting strain in the y-direction is

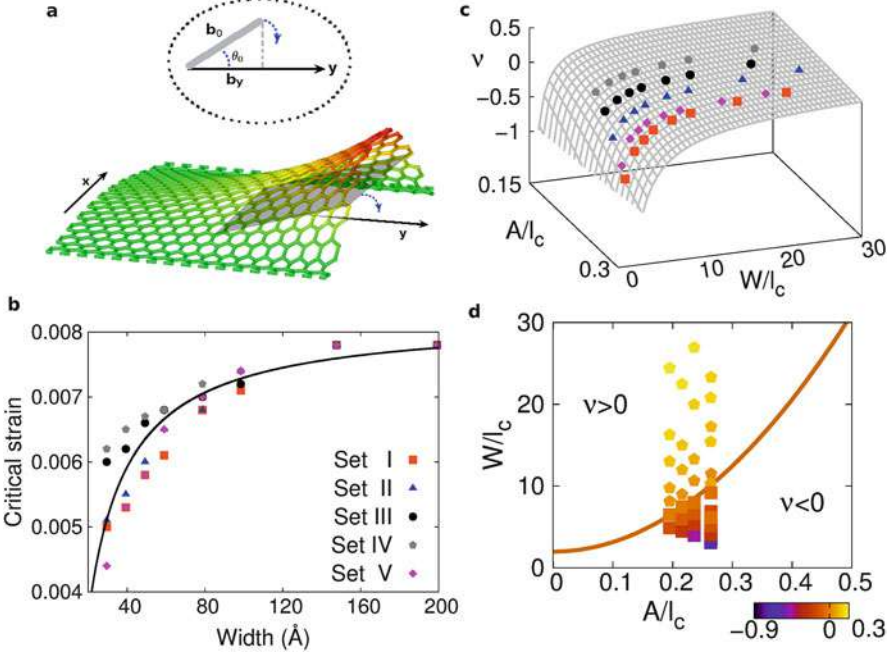
$$\varepsilon_y = \frac{\cos\theta - \cos\theta_0}{\cos\theta_0} \approx \frac{\theta_0^2}{\varepsilon_c}\varepsilon,$$


Fig. 6 (Color online) IP model for warped edge induced NPR. (**a**) The warped free edge is represented by the IP (in gray). During the tensile deformation of graphene, the IP falls down, which leads to the increase of its projection along the y-direction, resulting in the NPR effect. (**b**) Critical strain versus width for all of the five simulation Sets. The solid line is the fitting function $\varepsilon_c = 0.0082 - 0.092/W$. (**c**) Comparison of analytic IP model for Poisson's ratio as function of graphene width $\tilde{W} = W/l_c$ and warping amplitude $\tilde{A} = A/l_c$ according to Eq. (10) for simulation sets I, II, III, IV, and V. (**d**) Phase diagram for positive or negative Poisson's ratio in the $\tilde{W}$ and $\tilde{A}$ parameter space, according to Eq. (11), using all data from all of the five simulation Sets. Color bar is for the value of the Poisson's ratio. Image reprinted with permission from Jiang and Park (2016)

yielding the Poisson's ratio of the edge

$$\nu_e = -\frac{\varepsilon_y}{\varepsilon_x} = -\frac{\theta_0^2}{\varepsilon_c}. \qquad (8)$$

We now determine the initial tilting angle θ_0 for the IP. The tilting angle with respect to the y-axis for the tangent plane at point (x, y, z) on the warped surface is

$$\phi(x, y) = \tan^{-1}\left(\frac{\partial w}{\partial y}\right) \approx \frac{A}{l_c} e^{-y/l_c} \sin\frac{\pi x}{\lambda},$$

in which the tilting angle is assumed to be small. This assumption is reasonable as will be shown below. The average tilting angle for the warping area $x \in [0, \lambda]$ and $y \in [0, l_c]$ is

$$\bar{\phi} = \frac{1}{\lambda l_c} \int_0^\lambda dx \int_0^{l_c} dy \phi(x, y) = \frac{A}{l_c} \frac{2}{\pi} \left(1 - \frac{1}{e}\right). \tag{9}$$

Inserting the value of A and l_c from Fig. 4, we get an average tilting angle $\bar{\phi} = 0.106$. We use this average tilting angle as the initial tilting angle for the IP, i.e., $\theta_0 = \bar{\phi} = 0.106$. As a result, we obtain the Poisson's ratio for the warped edge:

$$\nu_e = -\frac{\theta_0^2}{\varepsilon_c} = -\left(\frac{A}{l_c} \frac{2}{\pi} \left(1 - \frac{1}{e}\right)\right)^2 / \varepsilon_c = -1.37$$

in which the critical strain $\varepsilon_c = 0.0082$ is the saturation value from the inset of Fig. 5c, which should be used here in the discussion of the Poisson's ratio for an isolated warped edge. The Poisson's ratio of -1.37 for the Set I geometries that is obtained in the limit of an ultra-narrow graphene ribbon using the IP model is very close to the value of -1.51 obtained via the molecular statics calculations in Fig. 5c.

We find in Fig. 6b that the critical strains for Sets I–V obey the same relation $\varepsilon_c = 0.0082 - 0.092/W$, where again we use the saturation value of $\varepsilon_c = 0.0082$ for the calculation of the effective Poisson's ratio of graphene ribbons with warped edges. The critical strain is directly related to the compressive edge stress, which generates compressive strain (ε_e) in the edge region and thus various warped configurations (with different local minimum potential energies). From Eq. (7), the magnitude of the compressive edge strains equals the critical strain ε_c when the warped edges have been completely flattened into a planar structure, i.e., $\varepsilon_e = \varepsilon_c = 0.0082$. Using the calculated values for the Young's modulus of the edge region as $E_e = 11.158 \text{ eVÅ}^{-2}$, while the compressive edge stress density is Shenoy and Reddy (2008) $\sigma_e = 1.05 \text{ eVÅ}^{-1}$, we can estimate the width (W_e) of the region that will be compressed by the edge strain according to $W_e = \sigma_e/(E_e \varepsilon_e) = 11.48 \text{ Å}$. Taking a representative value of the penetration depth $l_c = 8.55 \text{ Å}$ from simulation Set I, we find that the penetration depth of the resultant warped configuration is close to W_e. These analysis illustrate that the saturation value of the critical strain is an intrinsic property for the free edge, which should not depend on the detailed warping configuration.

From Eqs. (6), (8), and (9), we can thus obtain the following general formula for the Poisson's ratio in graphene ribbons of arbitrary width:

$$\nu = \nu_0 - \frac{2}{\tilde{W}} \left(\nu_0 + \frac{1}{\varepsilon_c} \tilde{A}^2 C_0^2\right), \tag{10}$$

where $C_0 = \frac{2}{\pi} \left(1 - \frac{1}{e}\right)$ is a universal constant and $\nu_0 = 0.34$ is the Poisson's ratio for bulk graphene. The dimensionless quantity $\tilde{W} = W/l_c$ is the width with reference to the penetration depth l_c. This is a bulk-related quantity, and a larger $\tilde{W}$ correlates with moving the Poisson's ratio in the positive direction. The other dimensionless quantity $\tilde{A} = A/l_c$ is the warping amplitude with reference to

the penetration depth. This quantity is an edge-related property, which tunes the Poisson's ratio in the negative direction. The sign and also the value of the Poisson's ratio are determined by the competition between these two effects, while the length of graphene has no effect. Figure 6c shows a three-dimensional plot for the Poisson's ratio predicted by the IP model based on Eq. (10). The numerical results for all of the five simulation Sets are also shown in the figure, which agree quite well with the IP model.

We note that the effective Poisson's ratio defined in Eq. (10) is intrinsically width-dependent, due to the width dependence of the warping amplitude A and the penetration depth l_c. Thus, by using the dimensionless quantities $\tilde{W}$ and $\tilde{A}$, the effect of the warping number is intrinsically included in the expression for the effective Poisson's ratio. Furthermore, the resultant Eq. (10) is a general expression for the Poisson's ratio, which is an explicit function of the ribbon geometry. Hence, Eq. (10) could be readily extended to describe the Poisson's ratio in other similar atomic-thick materials.

By equating Eq. (10) to be zero, we get

$$\tilde{W} = 2 + \frac{2}{v_0} \frac{C_0^2}{\varepsilon_c} \tilde{A}^2. \tag{11}$$

This function is plotted in Fig. 6d and serves to delineate the positive and negative Poisson's ratio regions. This figure serves as a phase diagram for NPR phenomenon in the parameter space of $\tilde{A}$ and $\tilde{W}$. The NPR phenomenon occurs for graphene with parameters in the region below the curve. In particular, if the width $\tilde{W} < 2$, then the Poisson's ratio is negative irrespective of the value for the other parameter $\tilde{A}$. The numerical results for all of the five simulation Sets can be correctly categorized into positive or negative regions in this phase diagram, further validating the analytical IP model we have presented.

3   Computational Electromechanical Coupling for Graphene Kirigami

Having discussed how MD simulations can be used to predict unique mechanical behavior in 2D materials, we now focus on the insights that can be gained through unique computational electromechanical coupling approaches (Portions of Section 3, including Figures 7–16, are reprinted with permission from Bahamon et al. (2016). Copyright 2016 by the American Physical Society.). We illustrate this through the study of graphene kirigami. Specifically, we combine information of the local atomic displacements obtained from MD simulations of deformed kirigami with quantum transport calculations to assess the conductance characteristics at different stages of deformation (Bahamon et al. 2015). At the structural level, the initial stage (stage 1 in Fig. 7) of the end-to-end longitudinal deformation is characterized by a very small effective Young's modulus and an essentially negligible average stretching of the interatomic bonds because, in this early stage, elongation occurs
Fig. 7 (**a**) Pattern schematics of the graphene kirigami indicating the most relevant geometric parameters. Snapshots of the actual kirigami used in the calculations for deformations of (**b**) 0%, (**c**) 15.5%, and (**d**) 34.7%. The figures were generated by VMD (Humphrey et al. 1996). Image reprinted with permission from Bahamon et al. (2016)

mostly through bending and twisting of the structure in three-dimensional space (Qi et al. 2014). Despite the low in-plane stretching that occurs during this stage, the conductance and the current are significantly reduced, and the resonant features disappear. However, further elongation into a second stage of deformation where there is substantial bond stretching leads to the revival of the resonant features and the restoration of the magnitudes of conductance to the same levels observed in the undistorted kirigami. These changes are consistently understood as a consequence of transport at low energies being dominated by resonant tunneling between states localized at specific portions of each periodic unit of the kirigami: elongation during stage 1 of deformation perturbs the coupling (overlap) between these states and considerably degrades the conductance as a result of hopping disorder that weakens the super-periodicity of the kirigami structure; further stretching into stage 2 results in strong and localized strain barriers that re-establish the super-periodicity, favor electron localization, and hence revive resonant transmission. The

terminology "strain barrier" is employed here deliberately to emphasize the direct impact that deformation hot-spots have in the electronic behavior of the system at high elongations: as discussed below, the development of localized and periodic regions with extreme bond stretching reinforces the geometry-induced confinement of electronic states within each repeating unit of the kirigami.

3.1   Methodology

Our representative kirigami is obtained by cutting out a graphene nanoribbon of width b according to the pattern shown in Fig. 7a. The rectangular interior holes are defined by the height w and width c, while the connecting necks have length c and a cut starting from the outer edge of length 0.5 w. The longitudinal period is d, and L defines the total length of the system. We shall concentrate our discussion in the kirigami shown schematically in Fig. 7b: our actual system contains 11408 atoms with the geometrical parameters $b \approx 10$ nm, $w \approx 6.8$ nm, $c \approx 0.7$ nm, $d = 4.8$ nm, and $L \approx 34$ nm. For definiteness, we base our discussion on this specific structure where the graphene lattice is oriented so that all horizontal edges are zigzag edges. We also do not include any disorder or edge roughness at this stage. The results, however, are general and should hold when these two restrictions are relaxed because *the only key physical ingredient is the existence of localized states defining a local quantum dot* at specific constrictions or bends, and these can be stabilized by different geometries, with or without disorder (Ihnatsenka et al. 2009). For illustration, we show that explicitly by analyzing a different lattice orientation in the discussion session.

   This study is divided in three stages that aim to determine the electronic transport properties of the kirigami under longitudinal tension. The deformed structures are first obtained with molecular dynamics (MD) simulations of the finite kirigami. We used the Sandia open-source code LAMMPS (Lammps 2018; Plimpton 1995) with the AIREBO (Zhao and Aluru 2010; Stuart et al. 2000; Qi et al. 2010) potential to describe the C-C interactions: the cutoff radii are 2 Å for the REBO term and 6.8 Å for the Lennard-Jones term in the AIREBO potential. The explicit position of each carbon atom in the deformed structure is then used to build a π-band tight-binding Hamiltonian, $H = \sum_{<i,j>} t_{ij}(c_i^\dagger c_j + c_j^\dagger c_i)$, for the distorted kirigami. In this Hamiltonian c_i denotes the annihilation operator on site i, and t_{ij} represents the hopping amplitude between nearest neighbor sites i and j. The stretching, the compression, and the rotation of the C-C bonds created by the tensile load are taken into account in this effective Hamiltonian by means of a position-dependent hopping parameter that reflects the overlap between two arbitrarily oriented p_z orbitals (Bahamon et al. 2015):

$$t_{ij}(d) = V_{pp\pi}(d_{ij})\,\hat{n}_i \cdot \hat{n}_j$$
$$+ \left[V_{pp\sigma}(d_{ij}) - V_{pp\pi}(d_{ij}) \right] \frac{(\hat{n}_i \cdot \mathbf{d}_{ij})(\hat{n}_j \cdot \mathbf{d}_{ij})}{d_{ij}^2}. \tag{12}$$

Here, $\hat{n}_i$ is the unit normal vector to the surface at site i, $\mathbf{d}_{ij}$ is the vector connecting sites i and j, and $V_{pp\sigma}(d)$ and $V_{pp\pi}(d)$ are the Slater-Koster integrals. The presence of the local normals accounts for the relative rotation of neighboring orbitals, whereas the effect of bond stretching is captured by the distance dependence of the Slater-Koster parameters, which we assumed to vary as (Pereira et al. 2009; Qi et al. 2014)

$$V_{pp\pi}(d_{ij}) = t_0\, e^{-\beta(d_{ij}/a-1)}, \tag{13}$$

$$V_{pp\sigma}(d_{ij}) = 1.7\, V_{pp\pi}(d_{ij}), \tag{14}$$

where $t_0 = 2.7\,\text{eV}$, $a \simeq 1.42\,\text{Å}$ is the equilibrium C-C bond length in graphene, and $\beta = 3.37$ captures the exponential decrease in the hopping with interatomic distance. All these quantities are easily calculated using the atomic positions provided by the MD simulations.

Subsequently, in order to inject charge into the system, we couple two undeformed semi-infinite graphene nanoribbons to the left and right edges of the kirigami, the "contacts" being of the same width as the kirigami. To guarantee that the properties observed are those of the kirigami and not of the deformed contact or the contact-kirigami interface, we keep the contacts undeformed during all stages of deformation. In terms of Green's functions, the conductance in the Landauer-Büttiker formalism can be written as Caroli et al. (1971), Datta (1995), Haug et al. (2008)

$$G = \frac{2e^2}{h} T(E) = \frac{2e^2}{h} \text{Tr}[\Gamma_R G^r \Gamma_L G^a], \tag{15}$$

where $G^r = [G^a]^\dagger = [E + i\eta - H - \Sigma_L - \Sigma_R]^{-1}$ is the retarded (advanced) Green's function, the coupling between the contacts and the central region is represented by $\Gamma_{L(R)} = i[\Sigma_{L(R)} - \Sigma_{L(R)}^\dagger]$, and $\Sigma_{L(R)}$ is the self-energy of left(right) contact. To correlate the conductance features with the real-space distribution of the electronic states, we map the local density of states (LDOS) at a given site i directly from the local Green's function according to the identity $\rho_{ii} = -\text{Im}[G^r(\mathbf{r}_i, \mathbf{r}_i, E)]/\pi$. The $I - V$ curves of the device, where I is the total current as a function of the applied bias voltage V, are calculated from the transmission function $T(E, V)$ as (Datta 1995)

$$I(V) = \frac{2e}{h} \int_{-\infty}^{+\infty} T(E, V)\,[f_L(E) - f_R(E)]\,dE, \tag{16}$$

where $f_{L(R)}(E)$ is the Fermi distribution of the left (right) contact.

3.2   Conductance Under Deformation

For a representative illustration showing the behavior in the two stages of deformation, we chose the kirigami structure shown in Fig. 7b that has a small number of cuts per repeating unit and a very high stretchability, up to 65 %. In order to facilitate the presence of localized states within each segment of the kirigami even in the absence of any deformation, we chose to orient the underlying graphene lattice so that the longitudinal cuts are along a zigzag direction, as the internal mini-zigzag edges so defined are expected to naturally support localized states (Fujita et al. 1996) (as pointed out above, this is not a limitation).

   A kirigami such as this one has four deformation stages (Qi et al. 2014): (i) elongation with bending and twisting, but very little in-plane stress, (ii) elongation with stress, (iii) yielding, and (iv) fracture. We restrict our analysis to the first two, where deformations are elastic and reversible and whose stress-strain characteristic is shown in Fig. 8. During the first stage (in this particular structure that corresponds to total deformations below $\approx$20%), horizontal and vertical segments twist and rotate, and, as a result of this excursion of the graphene sheet into the third dimension, the kirigami elongates without significant modification of the average C-C bond length, except for very localized strain hot-spots at the corners of the connecting elements (Qi et al. 2014). A representative sample of a kirigami in this stage is shown in Fig. 7c for a total deformation of 15.5%. With further increase in the tensile load, the kirigami is not capable of accommodating higher elongations
Fig. 8 Stress-strain curve for the kirigami, showing the first two stages corresponding to the elastic and reversible deformations. Image reprinted with permission from Bahamon et al. (2016)

only by twisting, and this triggers the onset of stage 2 (here in the range 20–40%), where further deformation occurs through stretching of the carbon bonds. One important consequence of the existence of these two regimes is that the effective Young's modulus is much lower in stage 1, $E \simeq 0.69$ N/m, (where it is essentially determined by the very small bending stiffness of monolayer graphene) than in stage 2 $E \simeq 15.08$ N/m. This makes mechanical manipulation of kirigami structures experimentally possible and easy in stage 1 (Blees et al. 2015).

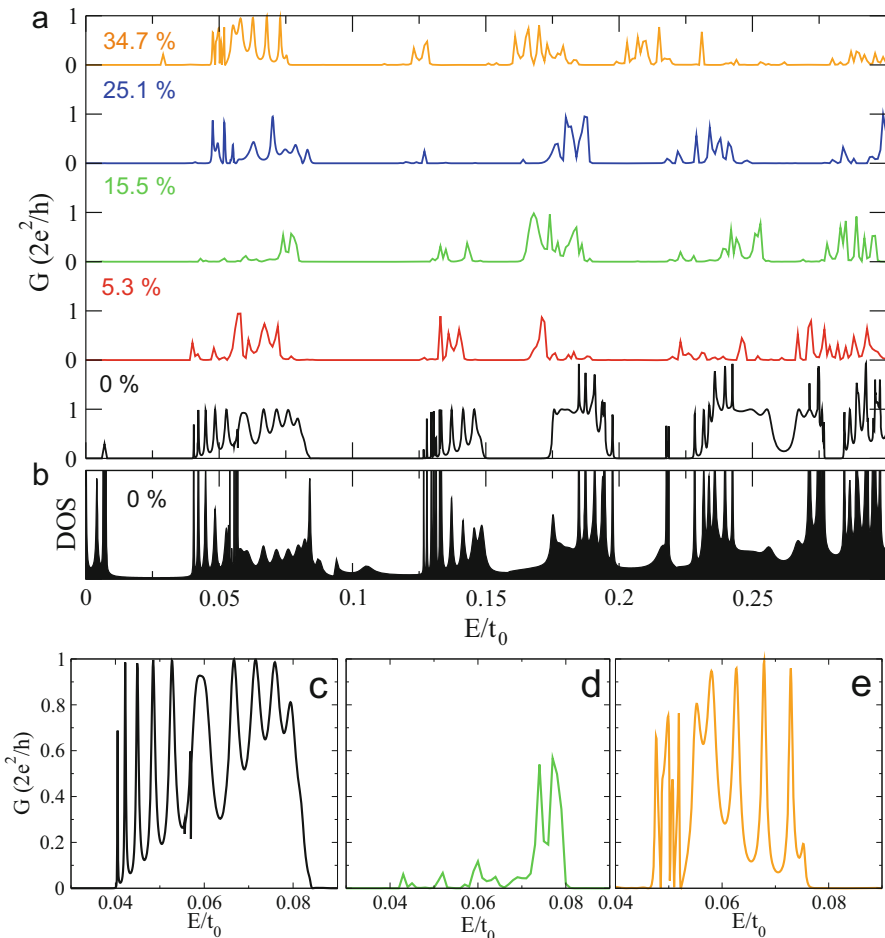
We followed the evolution of conductance at low energies for different strain values within the reversible and elastic region and summarize the results in Fig. 9a


Fig. 9 (**a**) Conductance of the kirigami for different values of deformation. (**b**) DOS of the undeformed structure. The lower row of panels contains a magnification of the energy range comprising the first group of resonances ($0.03 < E/t_0 < 0.09$) for the undeformed kirigami (**c**), kirigami deformed by 15.5% (**d**), and deformed by 34.7% (**e**). Image reprinted with permission from Bahamon et al. (2016)

for deformations of 0%, 5.3%, 15.5%, 25.1%, and 34.7%. The conductance profile of the reference (undeformed) structure displays resonant transmission within well-defined bands (minibands) of width $\approx 0.05\, t_0$. We can see in the DOS plotted in Fig. 9b for the undeformed structure that each miniband arises from the clustering of a finite number of states. At those energies transmission occurs through resonant tunneling and is entirely suppressed otherwise, strikingly different from the conductance profile expected for a graphene nanoribbon (Ulloa et al. 1990; González et al. 2011). In an infinite kirigami, the stop-gaps that separate the minibands arise from the folding of the 1D Brillouin zone of the ideal (pre-cut) graphene ribbon as a result of the new superlattice defined by the kirigami, with the expected opening of spectral gaps at the edge of the reduced zone. In our finite kirigami, Fig. 9b shows that the DOS is likewise strongly suppressed at the miniband edges but does not reach zero in the stop-gaps. This contrasts with the sharp changes in the conductance (Fig. 9a): finite (resonant) within a miniband and clearly zero in the stop-gaps. This is a clear sign that states contributing to the DOS in the stop-gap regions are spatially localized and unable to hybridize to form a tunneling pathway that spans the entire length of the system. Therefore, the robust stop-gap structure in the transmission is not a result of spectral characteristics of the kirigami alone.

To be specific, let us analyze the closeup plot shown in Fig. 9c that captures the energy interval $0.03 < E/t_0 < 0.09$. A mapping of the LDOS at any of the resonances shown in this panel confirms that the electronic density associated with a resonance is strongly localized around the internal longitudinal strips. Figure 10a shows a representative example of the "LDOS hot-spots" (in red) appearing at those regions and a good overlap/coupling with the external contacts. Another snapshot of the LDOS at a different transmission resonance is shown in Fig. 11. The existence of the minibands of resonant transmission is therefore due to the presence of localized states within each unit of the kirigami, which are localized both transversely and longitudinally by the combined effect of the internal zigzag edges and the finite extent of each segment of the kirigami (González et al. 2011; Zhang et al. 2008; Wu et al. 2010; Faria et al. 2015; Kouwenhoven et al. 1990; Ulloa et al. 1990; Brum 1991). At the lowest energies, transmission across the entire system is assisted by tunneling through these localized states that, hence, play a role similar to that of an array of coupled quantum dots that can enable resonant transmission across the entire system at (and only at) well-defined energies. The width of each miniband is determined by the overlap, γ, between localized states, and the number of resonant peaks in a miniband, N, counts the number of isolated quantum dots (Ulloa et al. 1990; Ji et al. 1992). Our geometry contains the 11 internal channels labeled 1–11 in Fig. 7b that define 11 effective quantum dots. Correspondingly, each transmission miniband has a fine structure consisting of 11 peaks as can be seen in Fig. 9c (the outermost two directly in contact with the metallic leads do not define quantum dots because backscattered electrons at these sections are completely absorbed by the contacts).

A quantitative estimate of the inter-dot overlap can be obtained assuming a one-dimensional tight-binding model, according to which the energy levels within one miniband should appear at positions

Fig. 10 Normalized LDOS for the kirigami (**a**) undeformed at $E = 0.067t_0$, (**b**) deformed by 15.5% at $E = 0.074t_0$, and (**c**) deformed by 34.7% at $E = 0.073t_0$. Image reprinted with permission from Bahamon et al. ([2016](#))
Fig. 11 LDOS at one of the transmission peaks ($E = 0.044t_0$) that contributes to the lowest transmission miniband of the undeformed kirigami, as discussed in the main text. The corresponding kirigami structure is shown underneath the density plot. Image reprinted with permission from Bahamon et al. (2016)
$$E_n = -2\gamma \, \cos\left(\frac{n\pi}{N+1}\right), \qquad n = 1, 2, \ldots, N, \qquad (17)$$

relative to the center of the miniband. The width of a miniband is given by $\Delta E = E_N - E_1$. The data in Fig. 9c allow us to estimate $\Delta E \approx 0.04t_0$ for the undeformed kirigami, which corresponds to $\gamma \approx 0.01\,t_0$. Recalling that t_0 is the hopping between nearest neighboring carbon atoms in undeformed graphene [13], this shows an interdot overlap two orders of magnitude smaller than the hopping in the underlying graphene lattice. Such a small value of γ is natural given the large spatial separation ($\sim d/2 = 2.4$ nm, cf. Fig. 7a) between each pair of hybridized localized states that we see in Fig. 11.

Under tensile load in stage 1, the kirigami elongates and becomes distorted, which significantly perturbs the overlap between the localized states. That is the conclusion that follows from the progressive disappearance of the resonant minibands under deformation that we can see in Fig. 9a for deformations of 5.3 and 15.5%. It is notable that, even though in stage 1 there is very little change in the *average* C-C bond length, the regions that are most affected by that, and which are more strongly bent, are those in the vicinity of the localized states of the undeformed kirigami. It is, therefore, not surprising that the conductance assisted by resonant tunneling through these states can be significantly modified in this stage since the perturbations to the hopping can be significant in precisely the regions more critical for the overlap between neighboring localized states. For an elongation of 15.5%, Fig. 9a shows that the miniband structure disappears and the system behaves largely as an insulator through most of the energy range shown. The LDOS associated with the few remaining weak conductance peaks reflects the less effective coupling between the localized states (see Fig. 10a). In the analogy introduced above, in this stage of deformation, we have the equivalent of a device consisting of distinct and asymmetrically coupled quantum dots, for which the energy of transmission resonances is predominantly determined by the energy levels and coupling of individual dots (Joe et al. 2000; Chen et al. 1994).

A simple extrapolation of this picture would forecast a progressively more substantial degradation of the conductance with further stretching. However, inspection of Fig. 9a reveals otherwise: resonant transmission is revived beyond a geometry-controllable threshold when the system enters stage 2 of deformation. At 25.1% strain, resonant transmission is recovered at particular energies within the lowest miniband, and further stretching to 34.7% strain, rather than degrading, further improves this situation with resonant peaks reappearing again throughout the entire lowest miniband as in the undeformed device. As expected, the width of each miniband is now smaller than in the undeformed state, a combined effect of the increase in inter-dot distance and the decrease of electronic hoppings in the carbon lattice. Figure 10c exhibits the LDOS for one of the revived conductance peaks of the same system that shows a strong similarity with the undeformed counterpart in Fig. 10a.

It is clear from both the conductance and the LDOS that deforming the system well inside stage 2 restores the coupling between the localized states trapped at the internal mini-edges that is strongly affected during stage 1. As pointed out earlier, the major difference between stages 1 and 2 is that, in the latter, further elongation proceeds through deformation of the C-C bonds and therein lies the mechanism that promotes the enhanced coupling and the revival of resonant transmission. As one intuitively anticipates, and can be explicitly seen in Fig. 12b, the deformations in question are borne almost entirely by the bonds along the segments that link neighboring units of the kirigami. A comparison of the bond length distribution in stage 1 (Fig. 12a) versus stage 2 (Fig. 12b) indeed shows that the first regime is characterized by small and seemingly random variations, whereas the latter features a clear and periodic pattern of deformation hot-spots where the C-C bond is stretched in excess of 20%.

Variations in bond length imply perturbations to the electronic hopping [t_{ij}, (12)], which is the quantity that directly affects the transport. However, it is important to mention that the C-C bond map excludes bending contributions that should dominate the hopping modifications in stage 1. To clarify this point, we plot in Fig. 13 the corresponding hopping distribution maps. The variations are of the order of $\sim \pm 10\%$ and $\sim \pm 20\%$ at 15.5% and 34.7% elongation, respectively. More than the magnitude, the key difference lies in the sign and spatial pattern of these hopping variations: in the first case, they appear randomly distributed and one sees places of both enhanced and reduced hopping compared to the undeformed structure; in the second, the pattern is clearly periodic and dominated by reduced hopping ($\sim 20\%$) spatially correlated with the strain hot-spots of Fig. 12b. These electronic "weak links" reinforce the super-periodicity of the structure, while simultaneously contributing to localize further the electronic states within each segment, thereby promoting the revival of the miniband and stop-gap structure in the conductance.

In summary, the profile of the conductance at low energies in these graphene structures is typical of a system of weakly coupled quantum dots: minibands of resonant transmission alternating with stop-gaps due to the superlattice periodicity along the longitudinal direction. Direct inspection of the LDOS at any of the
Fig. 12 Normalized C-C bond length for the kirigami deformed by 15.5% (panel a, stage 1) and 34.7% (panel b, stage 2), where the normalization is by the undeformed C-C bond length. Image reprinted with permission from Bahamon et al. (2016)

resonant energies provides a direct confirmation of this in real space. Analysis of the evolution of the conductance and the LDOS with deformation shows that the resonant tunneling assisted by localized states is strongly suppressed during stage 1 of deformation. The local perturbations to the electronic hopping in this regime are sufficient to disturb the overlap between the localized states. This effect is reversed in stage 2 by the appearance of strong strain barriers spanning the length of the system along the links between individual elements of the periodic structure. These have a confining nature from the electronic point of view, which consistently explains the reinforcement of overlap between localized states and the revival of resonant transmission, at the highest deformations.

3.3   I-V Characteristics and Negative Differential Resistance

In principle, to fully examine the current-voltage characteristics of these kirigami, we should calculate the transmission function for different bias and gate voltages, according to (16). However, similar to the experimental setup used in Blees et al. (2015) where the kirigami was immersed in an electrochemically controlled liquid gate with a fixed bias voltage $V_{SD} = 100$ meV, we restrict our analysis to the electric current as a function of gate voltage for a fixed bias. Figure 14 displays current for kirigami deformed by 0%, 15.5%, and 34.7% under a fixed $V_{SD} = 100$ meV and at $T = 300$ K.

One can see a clear oscillation of the current with increasing V_g, a behavior that traces back to the underlying miniband structure of the conductance discussed in the context of Fig. 9. The fact that below $V_g = 0.1\,t_0$ the current magnitude first decreases with deformation, but then increases again in stage 2, is a natural

et al. (2016)
consequence of the revival of resonant transmission at low energies promoted by
the localized strain that emerges in stage 2. The most interesting aspect of the
I-V characteristics shown in Fig. 14 is that the current oscillation immediately
implies that these kirigami have negative differential resistance over reasonably
large intervals of V_g, which is a much sought-after property for new classes of
nonlinear electronic devices (Esaki and Tsu 1970; Capasso et al. 1986).

3.4   Introducing Dephasing

So far, our electronic transport model considers coherent transport, including
only edges and mechanical deformations as source of scattering. To address the
robustness of the strain modulation of the conductance in a more realistic scenario,
we now turn to effects of random scatterers modeled within the dephasing Büttiker-
probe model (Büttiker 1986). To achieve that, we distribute voltage probes as
phase-breaking scatterers all over the kirigami (except the left and right edges) and
set the current at each probe to zero. Given that we are not interested in the particular
physical mechanism (impurities, phonons, or electrons) behind the destruction of
quantum coherence, we fix the self-energy of each Büttiker-probe to $\Sigma_\phi = -i\eta$
(Golizadeh-Mojarad and Datta 2007), which is related to the phase relaxation time
by $\tau_\phi = \hbar/2\Gamma_\phi = \hbar/4\eta$ (Datta 1995; Pastawski and Medina 2001). In Fig. 15, we
plot the effective conductance that obtains for weak ($\eta = 0.01t_0$, $\tau_\phi \approx 6.1 \times 10^{-15}$s)
and strong ($\eta = 0.5t_0$, $\tau_\phi \approx 1.2 \times 10^{-16}$s) phase-breaking under various
deformations. Inspecting Fig. 15a, we can see that weak dephasing is sufficient
to destroy the resonant transmission and miniband structure in the transmission,
irrespective of the amount (or absence) of deformation. Strong phase-breaking
processes (Fig. 15b) completely destroy any fine structure in the conductance
associated with the particular geometry of the device that are still visible in Fig. 15a.
In this case, there are no differences among the effective conductances of unstrained
and deformed kirigami, all of which display the step-wise behavior characteristic
Fig. 15 Effective conductance in the presence of (**a**) weak ($\eta = 0.01t_0$, $\tau_\phi \approx 6.1 \times 10^{-15}$s) and (**b**) strong ($\eta = 0.5t_0$, $\tau_\phi \approx 1.2 \times 10^{-16}$s) phase-breaking scatterers for different deformations. The dashed blue line corresponds to the conductance of a pristine zigzag nanoribbon with the same width of our contacts. Be aware of the different scales in the vertical axes. Image reprinted with permission from Bahamon et al. (2016)

of a pristine graphene nanoribbon, with the steps appearing at energies that are determined by the overall width of the device (parameter b in Fig. 7a).

To illustrate the distinction between the weak and strong dephasing regimes used in Fig. 15, it is instructive to compute the associated phase-relaxation lengths, $l_\phi = \sqrt{D\tau_\phi}$ (Datta 1995) using the representative carrier diffusion coefficient $D = 0.3$ m^2/s (Berger et al. 2006). In the case of weak dephasing discussed above, the phase-relaxation length is larger than the device size, $l_\phi \approx 42$ nm $> L$, whereas that value for strong dephasing is similar to the periodicity of the kirigami, $l_\phi \approx 6$ nm $\approx w$. Coherent effects in the conductance are observed when the typical device dimensions are smaller than the phase relaxation length (Datta 1995; Golizadeh-Mojarad and Datta 2007; Berger et al. 2006). In our case, the formation of gaps and minibands is a coherent effect created by destructive and constructive interference of electron waves at the periodically repeating segments of the kirigami (the localized states arise as the electron bounces back and forth without losing its phase within different sections of the kirigami). Figure 15b shows a conductance that has become insensitive to any effect associated with strain or even the geometry. This confirms that, in order to observe efficient mechanical control over the conductance, the phase-relaxation length must be larger than the segments of the kirigami that harbor the localized states that support the resonant tunneling at low energy. Measurements of the phase-relaxation length at low temperature in graphene have found $l_\phi \approx 1$ μm (Berger et al. 2006), which is much smaller than the size of the typical internal lengths used in the kirigami experimentally probed by Blees and collaborators

(Blees et al. 2015). This might partially explain why deformed kirigami used in that experiment did not show noticeable sensitivity of the conductance to the elongation.

3.5   Final Remarks

Our study shows that, when the typical feature sizes of a graphene-based kirigami are in the nanoscale, the electric conductance at low energies might be governed by resonant tunneling through states that are localized by the specific local geometry of each repeating element of the kirigami. The longitudinal periodicity of the structure results in an efficient coupling (strong overlap) between these states in the undeformed configuration. This state of affairs is, however, strongly sensitive to stage 1 deformations, and the conductance easily degrades in that regime where the overall elongation is a result of the structural twisting and bending, rather than extensive stretching of the C-C bonds. The electronic overlap is reinforced for stage 2 deformations as a result of the confining nature of the localized strain barriers that set in during this stage, and resonant transmission is hence revived at high overall elongations. The regime of resonant tunneling exists within well-defined energy minibands isolated from each other by sizable transmission stop-gaps. Their existence results in a strong oscillation of the I-V characteristic as a function of gate voltage, and opens the possibility of driving the system from a conventional resistive regime to one of negative differential resistance, by simple electrostatic gating.

To explain the evolution of the conductance profile with elongation, we analyzed directly the bond stretching and the perturbations to the nearest-neighbor hopping. It is customary in discussions of strained graphene to introduce the concept of pseudo-magnetic field (PMF) (Kane et al. 1997; Suzuura and Ando 2002; Vozmediano et al. 2010) and map strain fields to PMFs in order to, for example, obtain a semiclassical intuition about how certain strain patterns disturb the motion of electrons. In the present case, however, the characteristic dimensions of our device are small, and, in addition, the strain distribution displays sharp variations within these small scales. This restricts the usefulness of the PMF concept and any semiclassical picture to interpret the effects of strain. We therefore focused directly in the changes affecting the nearest-neighbor hopping amplitudes since these are the quantities that more direct and fundamentally determine the conductance.

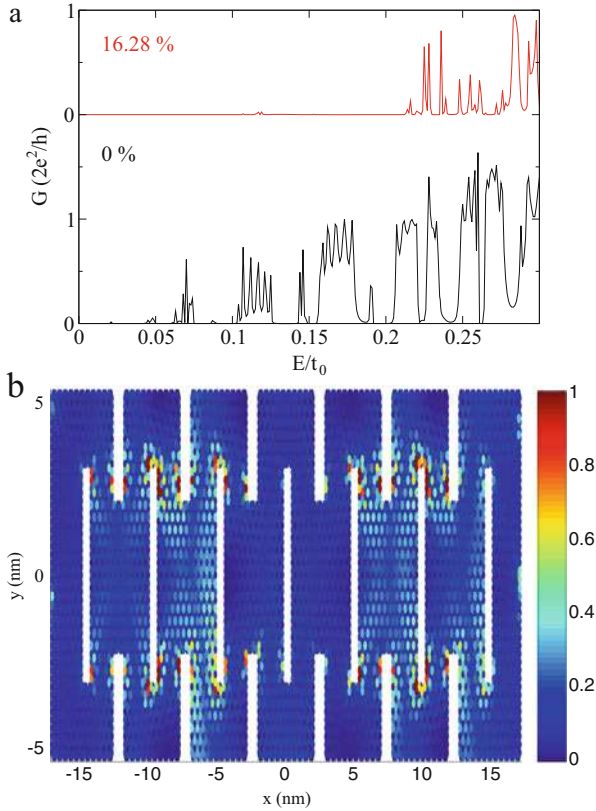
Finally, in our main discussion, we focused on a kirigami whose horizontal segments consisted of zigzag strips of graphene. Not surprisingly, the mini zigzag edges parallel to the transverse direction play an important role in stabilizing the localized states in the undeformed structure that are key for the conductance profile at low energy. It is important to reiterate that this is not a limitation, for *the key physical ingredient is the existence of localized states defining local quantum dots* and the interplay between the strain-induced changes of the C-C hopping and effective inter-dot coupling upon mechanical stretching. To be specific, in Fig. 16a we show that rotating the underlying lattice by 90 degrees in the same kirigami leads to a similar profile of miniband and stop-gap low-energy conductance and that it is equally sensitive to deformation: for example, at about 16% elongation, the mini-


Fig. 16 (**a**) Conductance of the armchair kirigami deformed by 0% and 16.28%. (**b**) LDOS for the undeformed armchair kirigami at $E = 0.121t_0$. Image reprinted with permission from Bahamon et al. (2016)

band structure is entirely suppressed. In a future study, we shall undertake the impact of edge roughness. We can, however, anticipate that edge roughness is expected to *improve* the scenario we describe here because this type of disorder promotes further localization of low-energy states in narrow graphene structures (Todd et al. 2008; Han et al. 2010), and that explains the experimentally observed gaps and Coulomb blockade in rough (lithographically patterned) graphene nanoribbons (Sols et al. 2007; Todd et al. 2008; Stampfer et al. 2009; Gallagher et al. 2010). We therefore predict that, in a realistic scenario, individual segments of a kirigami can behave as true quantum dots with a coupling (and, consequently, an overall transmission) amenable to modulation through the same type of deformation discussed here. The conditions for such behavior are expected to be very encompassing, depending only on choosing appropriate combinations of scales and geometries capable of hosting localized quantum dot states, supported either by the geometry, disorder, or interactions.

4   Conclusions

We have demonstrated that both existing computational techniques, like classical molecular dynamics, and new methodologies, such as combinations of molecular dynamics, and electronic structure tight-binding, and quantum transport, can both be used to develop new insights into the mechanics and electromechanics of graphene. There is significant potential for these computational tools to enable novel contributions to electromechanical coupling in 2D materials and also for 2D auxetics. For example, most reports of auxetic behavior in 2D materials have been for the out-of-plane direction, i.e. due to rippling of 2D materials. In contrast, very few examples of in-plane auxeticity have been reported. Similarly, other forms of electromechanical coupling in 2D materials, like piezoelectricity and flexoelectricity, have recently emerged – computational modeling will surely be needed to elucidate the behavior and properties of 2D piezo and flexoelectric materials (Akinwande et al. 2017). Finally, while we have focused on graphene in the present work, similar ideas and methodologies may be developed and used in the future to examine the physical properties of the other 2D materials families, like the transition metal dichalcogenides, black phosphorus, the monochalcogenides, boron nitride, and many others.

Surface Energy and Nanoscale Mechanics **79**

Kosar Mozaffari, Shengyou Yang, and Pradeep Sharma

Contents

Abstract

The mechanical response of nanostructures, or materials with characteristic features at the nanoscale, differs from their coarser counterparts. An important physical reason for this size-dependent phenomenology is that surface or interface properties are different than those of the bulk material and acquire significant prominence due to an increased surface-to-volume ratio at the nanoscale. In

this chapter, we provide an introductory tutorial on the continuum approach to incorporate the effect of surface energy, stress, and elasticity and address the size-dependent elastic response at the nanoscale. We present some simple illustrative examples that underscore both the physics underpinning the capillary phenomenon in solids as well as a guide to the use of the continuum theory of surface energy.

1   Introduction

In a manner of speaking, a free surface or an interface is a "defect." We will use the word "surface" to imply both a free surface as well as an interface separating two materials. It represents a drastic interruption in the symmetry of the material – much like the more conventionally known defects such as dislocations. Imagine the atoms on a free surface. They have a different coordination number, charge distribution, possible dangling bonds, and many other attributes that distinguish them from atoms further away in the bulk of the material (Ibach 1997; Cammarata 2009). It is therefore hardly surprising that the surface of a material should have mechanical (or in general other physical) properties that differ from the bulk of the material. In other words, as much as conventional defects (such as dislocations) impact the physical response of materials, so do surfaces. However, for coarse-sized structures, the surface-to-volume ratio is negligible, and so even though surfaces do have different properties, they hardly matter in terms of the overall response of the structure. This situation changes dramatically at the nanoscale. As a rather extreme example, 2 nm cube of Copper has nearly 50% of its atoms on the surface. What length scale is "small enough" for surface effects to become noticeable arguably depends on the strength of the surface properties. For hard crystalline materials, this length scale is certainly below 50 nm and often only of significant importance below 10 nm (Miller and Shenoy 2000). Ultra-soft materials (with elastic modulus in the 1–5 kPa range) are an interesting exception where even at micron scale, surface energy-related size effects may be observable (Style et al. 2013).

In a continuum field setting, the role of surfaces may be captured by assuming that they are zero-thickness entities and possess a nontrivial *excess* energy that is distinct from the bulk. The surface energy concept for solids encompasses the fact that surfaces appear to possess a residual "surface tension"-like effect known as surface stress and also an elastic response, termed "surface or superficial elasticity." In the context of fluids, "capillarity" has long been studied, and the concept of surface tension is well-known (see Fig. 1). The situation for solid surfaces is somewhat more subtle than fluids in many ways since deformation is a rather important contributor to surface energy – which is not the case for simple liquids. For a simple liquid, surface energy, the so-called surface stress and surface tension are the same concept. This is not the case for solid surfaces. For further details, see a recent review article by Style et al. (2017). Given the existence of an extensive body of work on this subject, we avoid a detailed literature review and simply point
Fig. 1 The ramifications of surface energy – in the form of surface tension – are well-known from our daily lives and are illustrated in this schematic. Surface tension forces, for instance, assist in overcoming gravity and enable the floatation of a ball. The ability of a water spider to walk on the water surface is another example. Also shown is a schematic of a capillary tube, frequently used by biologists and chemists, to highlight how surface tension causes water to be drawn up the tube

to the following overview articles that the reader may consult (and the references therein): (Javili et al. 2013; Duan et al. 2009; Wang et al. 2010, 2011; Li and Wang 2008; Cammarata 2009; Ibach 1997; Müller and Saúl 2004). We will primarily follow the approach pioneered by Gurtin, Murdoch, Fried, and Huang (Gurtin and Murdoch 1975b; Biria et al. 2013; Huang and Sun 2007) and attempt to present a simplified tutorial on the continuum theory for surface energy. For the sake of brevity and with the stipulation that this chapter is merely meant to be a first step to understand surface elasticity, we avoid several complexities and subtleties that exist on this topic such as choice of reference state in the development of the continuum theory (Huang and Wang 2013; Javili et al. 2018), consistent linearization from a nonlinear framework and differences in the various linearized theories (Javili et al. 2018; Liu et al. 2017), curvature dependence of surface energy (Steigmann and Ogden 1997, 1999; Chhapadia et al. 2011; Fried and Todres 2005), and generalized interface models that may allow greater degree of freedom than just a "no slip" surface c.f. (Gurtin et al. 1998; Chatzigeorgiou et al. 2017). We also present three simple case studies or illustrative examples that both highlight the use of the theory and the physical consequence of surface energy effects. While the focus of the chapter is primarily on mechanics and, specifically, elasticity, the framework used in this chapter can be used as a starting point for applications outside mechanics. Indeed, surface energy effects are of significant interest to a variety of disciplines and permeate topics as diverse as fluid mechanics (de Gennes et al. 2004), sensors and resonators (Park 2008), catalysis (Müller and Saúl 2004; Haiss 2001; Pala and Liu 2004), self-assembly (Suo and Lu 2000), phase transformations (Fischer et al. 2008), biology (Liu et al. 2017), and composites (Duan et al. 2005), among others.

2 Preliminary Concepts

2.1 The Need for Surface Tensors

In the study of mechanics of surfaces, we have to contend with tensor fields that "live" on a surface. For example, we will need to define the strain field experienced by a surface. The general machinery of curvilinear tensor calculus then becomes necessary to describe surface mechanics which (at least for our taste) becomes somewhat cumbersome. A direct notation was developed by Gurtin and Murdoch (1975b) which we (prefer and) briefly motivate in this section.

To establish the basic idea, for now, consider just a flat surface shown in Fig. 2 with outward unit normal $n = e_3$. On physical grounds, assuming that there is no "slip" between the surface and the underlying bulk material, the surface strain is simply the strain field of the bulk material *at the spatial position of the surface*. In addition, intuitively, the normal components of the strain tensor ought not to exist for the zero-thickness surface, i.e., $E_s(x) = E^{bulk}(x)$ projected on the tangent plane of the surface where x is on the surface. To make this idea more concrete, assume a body occupies a domain Ω_0 experiencing a strain $E : \Omega_0 \to \mathbb{R}^{3\times3}_{sym}$. We then expect the surface strain to be simply

$$E_s := \begin{bmatrix} E_{11} & E_{12} & 0 \\ E_{21} & E_{22} & 0 \\ 0 & 0 & 0 \end{bmatrix}. \tag{1}$$

Our intuition works well for flat surfaces, but we must generalize the mathematical framework to contend with general curved surfaces. This brings to fore the question of how we define surface tensors on arbitrarily curved surfaces. To understand this, we define next the surface projection tensor. More details on the mathematical preliminaries can be found in the work of Gurtin, Murdoch, and co-workers (Gurtin and Murdoch 1975b, 1978; Gurtin et al. 1998).
Fig. 2 Schematic of the deformation of a body that occupies the domain Ω_0. The upper surface is artificially separated from the underlying bulk to highlight the surface deformation $E(x)$. Cartesian coordinates with a positively oriented orthonormal basis $\{e_1, e_2, e_3\}$ are shown here and the outward unit normal to the upper surface is $n(x) = e_3$

2.1.1   Surface Projection Tensor

As discussed in the preceding section, we will often need to project second-order tensors on to a curved surface. To that end, the surface projection tensor for the tangent surface with outward unit normal $n(x)$ is defined as

$$\mathbb{P}(x) = \mathbf{I} - n(x) \otimes n(x). \tag{2}$$

Here $\mathbf{I}$ is the second-order identity tensor, and "$\otimes$" denotes the tensor product (or the dyadic product).

If we choose the flat upper surface shown in Fig. 2 as an example, the normal to the upper surface is $n = e_3$ in Cartesian coordinates with a positively oriented orthonormal basis $\{e_1, e_2, e_3\}$. With the definition in (2), the projection tensor on the flat upper surface admits the form

$$\mathbb{P}(x) = \mathbf{I} - e_3 \otimes e_3 = e_1 \otimes e_1 + e_2 \otimes e_2 := \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \end{bmatrix}_{\{e_1, e_2, e_3\}}. \tag{3a}$$

Another example is the projection tensor on a spherical surface with radius R that can be represented by $S = \{x \in \mathbb{R}^3 : x \cdot x - R^2 = 0\}$. The outward unit normal to this surface is $n = e_r$ in spherical coordinates $\{r, \theta, \phi\}$ with basis $\{e_r, e_\theta, e_\phi\}$. From the definition of the projection tensor in (2), we have

$$\mathbb{P}(x) = \mathbf{I} - e_r \otimes e_r = e_\theta \otimes e_\theta + e_\phi \otimes e_\phi := \begin{bmatrix} 0 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}_{\{e_r, e_\theta, e_\phi\}}. \tag{3b}$$

The projection tensor in (3b) can also be easily expressed in the Cartesian coordinates by using the identities $e_\theta = \cos\theta \cos\phi e_1 + \cos\theta \sin\phi e_2 - \sin\theta e_3$ and $e_\phi = -\sin\phi e_1 + \cos\phi e_2$ as well as the tensor product between two vectors.

2.1.2   Surface Vector and Tensor Fields

Let $v(x)$ be a smooth vector field and $T(x)$ be a smooth second-order tensor. Their projections $v_s(x)$ and $T_s(x)$ on a smooth surface with outward unit normal $n(x)$, respectively, are

$$v_s = \mathbb{P}v \quad \text{and} \quad T_s = \mathbb{P}T\mathbb{P}, \tag{4}$$

where the projection tensor $\mathbb{P}$ is defined in (2).

For example, consider a vector field $v = v_i e_i$ and a second-order tensor field $T = T_{ij} e_i \otimes e_j$ in Cartesian coordinates with a positively oriented orthonormal basis $\{e_1, e_2, e_3\}$. Take the upper surface with outward unit normal $n(x) = e_3$. The projection tensor in (2) becomes $\mathbb{P}(x) = \mathbf{I} - e_3 \otimes e_3 = e_1 \otimes e_1 + e_2 \otimes e_2$. Thus, with (4), the projected vector and tensor on the upper surface, respectively, are

$$\boldsymbol{v}_s = \mathbb{P}\boldsymbol{v} = (\boldsymbol{e}_1 \otimes \boldsymbol{e}_1 + \boldsymbol{e}_2 \otimes \boldsymbol{e}_2)v_i\boldsymbol{e}_i = v_1\boldsymbol{e}_1 + v_2\boldsymbol{e}_2 \tag{5a}$$

and

$$
\begin{aligned}
\boldsymbol{T}_s = \mathbb{P}\boldsymbol{T}\mathbb{P} &= (\boldsymbol{e}_1 \otimes \boldsymbol{e}_1 + \boldsymbol{e}_2 \otimes \boldsymbol{e}_2) \cdot T_{ij}\boldsymbol{e}_i \otimes \boldsymbol{e}_j \cdot (\boldsymbol{e}_1 \otimes \boldsymbol{e}_1 + \boldsymbol{e}_2 \otimes \boldsymbol{e}_2) \\
&= T_{11}\boldsymbol{e}_1 \otimes \boldsymbol{e}_1 + T_{12}\boldsymbol{e}_1 \otimes \boldsymbol{e}_2 + T_{21}\boldsymbol{e}_2 \otimes \boldsymbol{e}_1 + T_{22}\boldsymbol{e}_2 \otimes \boldsymbol{e}_2 \\
&:= \begin{bmatrix} T_{11} & T_{12} & 0 \\ T_{21} & T_{22} & 0 \\ 0 & 0 & 0 \end{bmatrix}.
\end{aligned}
\tag{5b}
$$

Equation (5b) makes it evident how the surface strain in (1), written earlier by intuition, may be formally derived from the bulk strain field.

By $(4)_2$, the projection of the identity tensor $\mathbf{I}$ on the surface with outward unit normal $\boldsymbol{n}(\boldsymbol{x})$ can be obtained as

$$\mathbb{I} = \mathbb{P}\mathbf{I}\mathbb{P}, \tag{6}$$

which is called the *surface identity tensor* on the surface and is often used in the context of second-order tensors.

2.2 Differentiation and Integration on a Surface

2.2.1 Surface Gradient, Normal Derivative, and Curvature Tensor

Consider a smooth scalar field $\phi(\boldsymbol{x}) : \Omega_0 \to \mathbb{R}$ and a smooth vector field $\boldsymbol{v}(\boldsymbol{x}) : \Omega_0 \to \mathbb{R}^3$ over the domain Ω_0. By using the gradient operator ∇, their (three-dimensional) gradients are represented by $\nabla\phi(\boldsymbol{x})$ and $\nabla\boldsymbol{v}(\boldsymbol{x})$, respectively. In contrast, the surface gradient operator on a surface with unit normal $\boldsymbol{n}$ is denoted by ∇_s, and together with the projection tensor $\mathbb{P}$ in (2), the *surface gradients* of the two fields can be represented by (Gurtin et al. 1998)

$$\nabla_s\phi = \mathbb{P}\nabla\phi \quad \text{and} \quad \nabla_s\boldsymbol{v} = (\nabla\boldsymbol{v})\mathbb{P}. \tag{7}$$

We now define the *normal derivative* of fields on a surface with outward unit normal $\boldsymbol{n}$. Following the scalar field ϕ and the vector field $\boldsymbol{v}$ in (7), we define their normal derivatives as

$$\frac{\partial\phi}{\partial n} = \boldsymbol{n} \cdot \nabla\phi \quad \text{and} \quad \frac{\partial\boldsymbol{v}}{\partial n} = (\nabla\boldsymbol{v})\boldsymbol{n}. \tag{8}$$

The normal derivative $\dfrac{\partial\phi}{\partial n}$ can be regarded as the rate of change of ϕ in the direction $\boldsymbol{n}$. By (2) and (8), the surface derivatives (7) can be recast as

$$\nabla_s\phi = \nabla\phi - \left(\frac{\partial\phi}{\partial n}\right)\boldsymbol{n} \quad \text{and} \quad \nabla_s\boldsymbol{v} = \nabla\boldsymbol{v} - \left(\frac{\partial\boldsymbol{v}}{\partial n}\right) \otimes \boldsymbol{n}. \tag{9}$$

Equation (9) represents the relation between the surface gradient, the gradient, and the normal derivative. We note that Eqs. (7) and (9) are two (alternative but equivalent) ways to represent the surface gradient.

The *curvature tensor* of a surface with outward unit normal $\boldsymbol{n}$ is then defined as (Gurtin et al. 1998)

$$\mathbb{L} = -\nabla_s \boldsymbol{n}, \tag{10}$$

which is symmetric and hence tangential, that is, $\mathbb{L} = \mathbb{L}^T$ and $\mathbb{L}^T \boldsymbol{n} = \boldsymbol{0}$.

In order to enhance the understanding of these definitions, we now consider some simple examples by referring to Fig. 2. In Cartesian coordinates, the gradients of the scalar and vector fields, respectively, are $\nabla \phi = \frac{\partial \phi}{\partial x_i} \boldsymbol{e}_i$ and $\nabla \boldsymbol{v} = \frac{\partial \boldsymbol{v}}{\partial x_j} \otimes \boldsymbol{e}_j = \frac{\partial v_i}{\partial x_j} \boldsymbol{e}_i \otimes \boldsymbol{e}_j$. The outward unit normal to the flat upper surface is $\boldsymbol{n} = \boldsymbol{e}_3$, and then its projection tensor is $\mathbb{P} = \boldsymbol{e}_1 \otimes \boldsymbol{e}_1 + \boldsymbol{e}_2 \otimes \boldsymbol{e}_2$ which was mentioned in (3a).

By (7) and the Kronecker delta, the surface gradients on the flat surface in Fig. 2 are

$$\nabla_s \phi = (\boldsymbol{e}_1 \otimes \boldsymbol{e}_1 + \boldsymbol{e}_2 \otimes \boldsymbol{e}_2) \frac{\partial \phi}{\partial x_i} \boldsymbol{e}_i = \frac{\partial \phi}{\partial x_1} \boldsymbol{e}_1 + \frac{\partial \phi}{\partial x_2} \boldsymbol{e}_2 \tag{11a}$$

and

$$\nabla_s \boldsymbol{v} = \left(\frac{\partial \boldsymbol{v}}{\partial x_j} \otimes \boldsymbol{e}_j \right) (\boldsymbol{e}_1 \otimes \boldsymbol{e}_1 + \boldsymbol{e}_2 \otimes \boldsymbol{e}_2) = \frac{\partial \boldsymbol{v}}{\partial x_1} \otimes \boldsymbol{e}_1 + \frac{\partial \boldsymbol{v}}{\partial x_2} \otimes \boldsymbol{e}_2. \tag{11b}$$

By (8), the normal derivatives on the surface in the example are

$$\frac{\partial \phi}{\partial n} = \boldsymbol{e}_3 \cdot \frac{\partial \phi}{\partial x_i} \boldsymbol{e}_i = \frac{\partial \phi}{\partial x_3} \quad \text{and} \quad \frac{\partial \boldsymbol{v}}{\partial n} = \left(\frac{\partial \boldsymbol{v}}{\partial x_j} \otimes \boldsymbol{e}_j \right) \boldsymbol{e}_3 = \frac{\partial \boldsymbol{v}}{\partial x_3}. \tag{12}$$

Using (9), together with (12), we can obtain the same surface gradients as (11). Similarly, using (10), together with (11b), we find the obvious answer that the curvature tensor $\mathbb{L}$ of the flat upper surface in Fig. 2 is

$$\mathbb{L} = -\nabla_s \boldsymbol{e}_3 = -\frac{\partial \boldsymbol{e}_3}{\partial x_1} \otimes \boldsymbol{e}_1 - \frac{\partial \boldsymbol{e}_3}{\partial x_2} \otimes \boldsymbol{e}_2 = \boldsymbol{0}. \tag{13}$$

As another illustration, we may consider the curvature tensor for a spherical surface of radius R. In spherical coordinates $\{r, \theta, \phi\}$ with orthonormal basis $\{\boldsymbol{e}_r, \boldsymbol{e}_\theta, \boldsymbol{e}_\phi\}$, the outward unit normal to the spherical surface is $\boldsymbol{n} = \boldsymbol{e}_r$, whose gradient is $\nabla \boldsymbol{e}_r = r^{-1}(\boldsymbol{e}_\theta \otimes \boldsymbol{e}_\theta + \boldsymbol{e}_\phi \otimes \boldsymbol{e}_\phi)$. By (7) and (10), the curvature tensor in this example is

$$\mathbb{L} = -\nabla_s \boldsymbol{e}_r = -(\nabla \boldsymbol{e}_r)\mathbb{P} = -\frac{1}{R}(\boldsymbol{e}_\theta \otimes \boldsymbol{e}_\theta + \boldsymbol{e}_\phi \otimes \boldsymbol{e}_\phi), \tag{14}$$

which is symmetric $\mathbb{L} = \mathbb{L}^T$ and tangential $\mathbb{L}^T \boldsymbol{e}_r = \boldsymbol{0}$.

2.2.2 Surface Divergence, Trace, and Mean Curvature

The *surface divergences* of a vector field $\boldsymbol{v}(\boldsymbol{x})$ and a tensor field $\boldsymbol{T}(\boldsymbol{x})$ are defined as follows:

$$\mathrm{div}_s\boldsymbol{v} = \mathrm{tr}(\nabla_s\boldsymbol{v}) \quad \text{and} \quad \boldsymbol{a} \cdot \mathrm{div}_s\boldsymbol{T} = \mathrm{div}_s(\boldsymbol{T}^T\boldsymbol{a}), \tag{15}$$

where "tr," here and henceforth, denotes the *trace* and $\boldsymbol{a} \in \mathbb{R}^3$ is an arbitrary constant vector. An important identity related to the surface divergence operator is

$$\mathrm{div}_s(\boldsymbol{T}^T\boldsymbol{n}) = \boldsymbol{n} \cdot \mathrm{div}_s\boldsymbol{T} + \boldsymbol{T} \cdot \nabla_s\boldsymbol{n}. \tag{16}$$

For further useful surface identities, the reader is referred to the work (Gurtin and Murdoch 1975b).

The *mean curvature* is then simply

$$\kappa = \frac{1}{2}\mathrm{tr}(\mathbb{L}) = -\frac{1}{2}\mathrm{tr}(\nabla_s\boldsymbol{n}) = -\frac{1}{2}\mathrm{div}_s\boldsymbol{n}. \tag{17}$$

For the same example in Eq. (11b), the corresponding surface divergence is

$$\mathrm{div}_s\boldsymbol{v} = \mathrm{tr}(\nabla_s\boldsymbol{v}) = \mathrm{tr}\left(\frac{\partial(v_i\boldsymbol{e}_i)}{\partial x_1} \otimes \boldsymbol{e}_1 + \frac{\partial(v_i\boldsymbol{e}_i)}{\partial x_2} \otimes \boldsymbol{e}_2\right) = \frac{\partial v_1}{\partial x_1} + \frac{\partial v_2}{\partial x_2}. \tag{18}$$

Similarly, for a second-order tensor $\boldsymbol{T} = T_{ij}\boldsymbol{e}_i \otimes \boldsymbol{e}_j$, its surface gradient is a vector, and its k-th component, by $(15)_2$, can be represented by

$$(\mathrm{div}_s\boldsymbol{T})_k = \boldsymbol{e}_k \cdot \mathrm{div}_s\boldsymbol{T} = \mathrm{div}_s(\boldsymbol{T}^T\boldsymbol{e}_k) = \frac{\partial T_{k1}}{\partial x_1} + \frac{\partial T_{k2}}{\partial x_2}, \tag{19}$$

where the identity $\boldsymbol{T}^T\boldsymbol{e}_k = T_{ki}\boldsymbol{e}_i$ and the example result in (18) are used. Regarding the examples of the curvature tensors (13) and (14), their mean curvatures are 0 and $-R^{-1}$, respectively.

2.2.3 Divergence Theorem for Surfaces

Consider a surface $\mathsf{S}_0 \subset \partial\Omega_0$ with a smooth boundary curve $\partial\mathsf{S}_0$. For a smooth vector $\boldsymbol{u}$ that is tangential on the surface S_0 and a smooth tensor field $\boldsymbol{T}$, the divergence theorem is defined by Gurtin and Murdoch (1975b) and Gurtin et al. (1998)

$$\int_{\mathsf{S}_0} \mathrm{div}_s\boldsymbol{u} = \int_{\partial\mathsf{S}_0} \boldsymbol{u} \cdot \boldsymbol{v}, \qquad \int_{\mathsf{S}_0} \mathrm{div}_s\boldsymbol{T} = \int_{\partial\mathsf{S}_0} \boldsymbol{T}\boldsymbol{v}, \tag{20}$$

where $\boldsymbol{v}$ is the outward unit normal to the boundary curve $\partial\mathsf{S}_0$.

3   Theoretical Framework for Surface Mechanics

With the mathematical preliminaries necessary for surface mechanics described earlier, we can now proceed in a rather standard manner to derive the pertinent governing equations. The original theory by Gurtin and Murdoch (1975b) was derived by employing stress as the primitive concept. We (following Huang and co-workers Huang and Wang 2006; Huang and Sun 2007) favor a variational approach where we take the surface energy as the primitive concept.

3.1   Kinematics

Assume a deformable solid that occupies the domain Ω_0 in the reference configuration shown in Fig. 3. The boundary of the domain is denoted by $\partial\Omega_0$, which can be divided into two parts: the displacement boundary $\partial\Omega_0^u$ and the traction boundary $\partial\Omega_0^t$. Mathematically, $\partial\Omega_0^u \cup \partial\Omega_0^t = \partial\Omega_0$ and $\partial\Omega_0^u \cap \partial\Omega_0^t = \varnothing$.

A material point is denoted by $x \in \Omega_0$. Consider a smooth mapping $y : \Omega_0 \to \mathbb{R}^3$, that is, $y(x) = x + u(x)$. Here u is the displacement vector. The deformation gradient is defined as $F = \nabla x$. The displacement and traction boundary conditions are

$$u = u_0 \quad \text{on } \partial\Omega_0^u \quad \text{and} \quad t = t_0 \quad \text{on } \partial\Omega_0^t. \tag{21}$$
Fig. 3 Schematic of a deformable body that occupies the domain Ω_0 with the boundary $\partial\Omega_0$. The material point is denoted by $x \in \Omega_0$, and the outward unit normal to $\partial\Omega_0$ is represented by n. The displacement boundary is $u = u_0$ while the traction boundary is $t = t_0$. In particular, the surface effect is shown on the surface $S_0 \subset \partial\Omega_0$. On the boundary curve ∂S_0 of the surface S_0, the outward unit normal to ∂S_0 is denoted by v

3.2 Energy Variation and Equations of Equilibrium

We explicitly assume that the surface or the interface does not "slip" from the rest of the material. Gurtin et al. (1998) have dealt with the special case where interfaces may not be coherent and admit jumps in displacements. We do not consider that complexity here. The energy functional of the general system shown in Fig. 3 is then:

$$\mathscr{F}[\boldsymbol{u}; \boldsymbol{x}] = \int_{\Omega_0} \Psi(\nabla \boldsymbol{u}) + \int_{\mathsf{S}_0} \Gamma_s(\nabla \boldsymbol{u}) - \int_{\partial \Omega_0^t} \boldsymbol{t}_0 \cdot \boldsymbol{u}, \qquad (22)$$

where Ψ is the strain energy function per unit volume of the bulk, Γ_s is the surface energy function per unit area of the surface $\mathsf{S}_0 \subset \partial \Omega_0$, and $\boldsymbol{t}_0$ is the dead load applied on the traction boundary $\partial \Omega_0^t$ in the reference configuration. The reference configuration taken here is actually the initial configuration, which is neither subjected to any body force nor tractions. We note that in the reference configuration, there exists the surface stress, which is regarded as "residual." The residual stress field can be described according to the surface energy function Γ_s. To further clarify the surface effects on the energy functional, Huang and Wang (2006, 2013) proposed an extra configuration, a "fictitious stress-free configuration." For further details on such subtleties, the reader is referred to their work.

We now invoke the principle of minimum energy to seek the equilibrium state of the deformed body:

$$\min\{\mathscr{F}[\boldsymbol{u}] : \boldsymbol{u} \in \mathscr{S}\}. \qquad (23)$$

Here the set $\mathscr{S}$ denotes the smooth function space over the domain Ω_0, and the displacement field must satisfy $\boldsymbol{u} = \boldsymbol{u}_0$ on $\partial \Omega_0^u$ in $(21)_1$.

If we assume the state $\boldsymbol{u}$ to be the minimizer of the energy functional in (22), then by the principle of energy minimization (23), we have

$$\mathscr{F}[\boldsymbol{u}] \leq \mathscr{F}[\boldsymbol{u} + \epsilon \boldsymbol{u}_1], \qquad (24)$$

where $\epsilon \in \mathbb{R}$ and $\boldsymbol{u} + \epsilon \boldsymbol{u}_1$ belongs to the set of all kinematically admissible deformations in the neighborhood of the deformation $\boldsymbol{u}$. We only consider small perturbations, so the norm $\|\epsilon \boldsymbol{u}_1\| \ll 1$. By the displacement boundary $(21)_1$, the variation $\boldsymbol{u}_1$ satisfies

$$\boldsymbol{u}_1 = \boldsymbol{0} \quad \text{on } \partial \Omega_0^u. \qquad (25)$$

The inequality (24) leads to the following first and second variation conditions

$$\delta \mathscr{F}[\boldsymbol{u}] = 0 \quad \text{and} \quad \delta^2 \mathscr{F}[\boldsymbol{u}] \geq 0. \qquad (26)$$

In this book chapter, we only limit our attention to the first variation that leads to the equilibrium equations and the natural boundary conditions. The first variation is written as

$$\delta \mathcal{F}[\boldsymbol{u}] := \left. \frac{\mathrm{d}\mathcal{F}[\boldsymbol{u} + \epsilon \boldsymbol{u}_1]}{\mathrm{d}\epsilon} \right|_{\epsilon=0}. \tag{27}$$

Using (27) and the chain rule, the first variation of (22) reads

$$\delta \mathcal{F}[\boldsymbol{u}] = \int_{\Omega_0} \boldsymbol{S} \cdot \nabla \boldsymbol{u}_1 + \int_{\mathsf{S}_0} \mathbb{S} \cdot \nabla \boldsymbol{u}_1 - \int_{\partial \Omega_0^t} \boldsymbol{t}_0 \cdot \boldsymbol{u}_1, \tag{28}$$

where

$$\boldsymbol{S} = \frac{\partial \Psi}{\partial \nabla \boldsymbol{u}} \quad \text{and} \quad \mathbb{S} = \frac{\partial \Gamma_s}{\partial \nabla \boldsymbol{u}}. \tag{29}$$

Here $\mathbb{S}$ in (29) is the first Piola-Kirchhoff surface stress tensor (Gurtin et al. 1998), and $\boldsymbol{S}$ is the first Piola-Kirchhoff bulk stress tensor.

Employing the surface gradient of a vector in $(9)_2$ as well as the property of the surface tensor $\mathbb{S}$, that is, $\mathbb{S}\boldsymbol{n} = \boldsymbol{0}$, the integrand $\mathbb{S} \cdot \nabla \boldsymbol{u}_1$ in (28) can be recast as

$$\mathbb{S} \cdot \nabla \boldsymbol{u}_1 = \mathbb{S} \cdot \nabla_s \boldsymbol{u}_1 + \frac{\partial \boldsymbol{u}_1}{\partial n} \cdot \mathbb{S}\boldsymbol{n} = \mathbb{S} \cdot \nabla_s \boldsymbol{u}_1. \tag{30}$$

In the work by Gurtin et al. (1998), they derived the identity $\mathbb{S}\boldsymbol{n} = \boldsymbol{0}$ on the surface S_0 (see their Eq.(37)) by assuming an arbitrary function $\frac{\partial \boldsymbol{u}_1}{\partial n}$ on the surface S_0. Here we obtain this identity through the definition of a surface tensor $(4)_2$, that is, for an arbitrary surface tensor $\boldsymbol{T}_s = \mathbb{P}\boldsymbol{T}\mathbb{P}$, we have $\boldsymbol{T}_s \boldsymbol{n} = \mathbb{P}\boldsymbol{T}\mathbb{P}\boldsymbol{n} = \mathbb{P}\boldsymbol{T}\boldsymbol{0} = \boldsymbol{0}$ since $\mathbb{P}\boldsymbol{n} = (\boldsymbol{I} - \boldsymbol{n} \otimes \boldsymbol{n})\boldsymbol{n} = \boldsymbol{0}$.

By the identity (16), we further have

$$\mathbb{S} \cdot \nabla_s \boldsymbol{u}_1 = \mathrm{div}_s(\mathbb{S}^T \boldsymbol{u}_1) - \boldsymbol{u}_1 \cdot \mathrm{div}_s\mathbb{S}. \tag{31}$$

Thus, by (31) and the divergence theorem (20), the second integral in (28) becomes

$$\int_{\mathsf{S}_0} \mathbb{S} \cdot \nabla \boldsymbol{u}_1 = \int_{\mathsf{S}_0} \left[\mathrm{div}_s(\mathbb{S}^T \boldsymbol{u}_1) - \boldsymbol{u}_1 \cdot \mathrm{div}_s\mathbb{S} \right] = \int_{\partial \mathsf{S}_0} \boldsymbol{u}_1 \cdot \mathbb{S}\boldsymbol{v} - \int_{\mathsf{S}_0} \boldsymbol{u}_1 \cdot \mathrm{div}_s\mathbb{S}. \tag{32}$$

Similarly, by using the divergence theorem in volume, we obtain

$$\int_{\Omega_0} \boldsymbol{S} \cdot \nabla \boldsymbol{u}_1 = \int_{\Omega_0} \left[\mathrm{div}(\boldsymbol{S}^T \boldsymbol{u}_1) - \boldsymbol{u}_1 \cdot \mathrm{div}\boldsymbol{S} \right] = \int_{\partial \Omega_0} \boldsymbol{u}_1 \cdot \boldsymbol{S}\boldsymbol{n} - \int_{\Omega_0} \boldsymbol{u}_1 \cdot \mathrm{div}\boldsymbol{S}. \tag{33}$$

Substituting (32) and (33) into (28), we have

$$\delta\mathscr{F}[\boldsymbol{u}] = -\int_{\Omega_0} \boldsymbol{u}_1 \cdot \mathrm{div}\boldsymbol{S} + \int_{\partial\Omega_0\backslash\mathsf{S}_0} \boldsymbol{u}_1 \cdot \boldsymbol{S}\boldsymbol{n} + \int_{\mathsf{S}_0} \boldsymbol{u}_1 \cdot (\boldsymbol{S}\boldsymbol{n} - \mathrm{div}_s\mathbb{S})$$
$$+ \int_{\partial\mathsf{S}_0} \boldsymbol{u}_1 \cdot \mathbb{S}\boldsymbol{v} - \int_{\partial\Omega_0^t} \boldsymbol{t}_0 \cdot \boldsymbol{u}_1. \tag{34}$$

It is known that $\partial\Omega_0^u \cup \partial\Omega_0^t = \partial\Omega_0$ and $\partial\Omega_0^u \cap \partial\Omega_0^t = \varnothing$ as well as $\mathsf{S}_0 \subset \partial\Omega_0$. However, the relation between S_0 and $\partial\Omega_0^t$ (or $\partial\Omega_0^u$) is not given before. To simplify the discussion, we regard S_0 as a subset of $\partial\Omega_0^t$, that is, $\mathsf{S}_0 \subset \partial\Omega_0^t$. Thus, the last integral in (34) can be reformulated as

$$-\int_{\partial\Omega_0^t} \boldsymbol{t}_0 \cdot \boldsymbol{u}_1 = -\int_{\partial\Omega_0^t\backslash\mathsf{S}_0} \boldsymbol{t}_0 \cdot \boldsymbol{u}_1 - \int_{\mathsf{S}_0} \boldsymbol{t}_0 \cdot \boldsymbol{u}_1. \tag{35}$$

Also, with $\boldsymbol{u}_1 = \boldsymbol{0}$ on $\partial\Omega_0^u$ in (25), the second integral in (34) reduces to

$$\int_{\partial\Omega_0\backslash\mathsf{S}_0} \boldsymbol{u}_1 \cdot \boldsymbol{S}\boldsymbol{n} = \int_{\partial\Omega_0^t\backslash\mathsf{S}_0} \boldsymbol{u}_1 \cdot \boldsymbol{S}\boldsymbol{n}. \tag{36}$$

Using (35) and (36), the first variation finally becomes

$$\delta\mathscr{F}[\boldsymbol{u}] = -\int_{\Omega_0} \boldsymbol{u}_1 \cdot \mathrm{div}\boldsymbol{S} + \int_{\partial\Omega_0^t\backslash\mathsf{S}_0} \boldsymbol{u}_1 \cdot (\boldsymbol{S}\boldsymbol{n} - \boldsymbol{t}_0) + \int_{\mathsf{S}_0} \boldsymbol{u}_1 \cdot (\boldsymbol{S}\boldsymbol{n} - \mathrm{div}_s\mathbb{S} - \boldsymbol{t}_0)$$
$$+ \int_{\partial\mathsf{S}_0} \boldsymbol{u}_1 \cdot \mathbb{S}\boldsymbol{v}. \tag{37}$$

Since the variation $\boldsymbol{u}_1$ in (37) is arbitrary, the vanishing of the first variation $\delta\mathscr{F}[\boldsymbol{u}] = 0$ and the fundamental lemma of calculus of variations (Courant and Hilbert 1953) leads us to the following set of governing equations

$$\left.\begin{aligned}
\mathrm{div}\boldsymbol{S} &= \boldsymbol{0} & \text{in } \Omega_0, \\
\boldsymbol{S}\boldsymbol{n} &= \boldsymbol{t}_0 & \text{on } \partial\Omega_0^t \setminus \mathsf{S}_0, \\
\boldsymbol{S}\boldsymbol{n} - \mathrm{div}_s\mathbb{S} = \boldsymbol{t}_0, \quad \mathbb{S}\boldsymbol{n} &= \boldsymbol{0} & \text{on } \mathsf{S}_0, \\
\mathbb{S}\boldsymbol{v} &= \boldsymbol{0} & \text{on } \partial\mathsf{S}_0.
\end{aligned}\right\} \tag{38}$$

Here we rewrite the equation $\mathbb{S}\boldsymbol{n} = \boldsymbol{0}$ on S_0 (see the statement above (30)) in (38). Equation (38), together with $(21)_1$ and (29), forms a well-defined boundary value problem. For the readers convenience, we reiterate the notations here: $\boldsymbol{S}$ denotes the first Piola-Kirchhoff stress, $\mathbb{S}$ the first surface Piola-Kirchhoff stress, $\boldsymbol{n}$ the outward unit normal to the surface, $\boldsymbol{v}$ the outward unit normal to the boundary curve, and $\boldsymbol{t}_0$ the applied dead load.

3.3   Constitutive Equations and Elastic Stress Tensors

In (29), we have defined the first Piola-Kirchhoff bulk stress tensor S and the first Piola-Kirchhoff surface stress tensor $\mathbb{S}$ through the partial derivative with respect to the displacement gradient ∇u. By the chain rule, these two first Piola-Kirchhoff stresses can also be defined as

$$S = \frac{\partial \bar{\Psi}(F)}{\partial F} \quad \text{and} \quad \mathbb{S} = \frac{\partial \bar{\Gamma}_s(F)}{\partial F}, \tag{39}$$

where $F = \nabla(x + u) = I + \nabla u$ and

$$\bar{\Psi}(F) = \Psi(\nabla u)\big|_{\nabla u = F - I} \quad \text{and} \quad \bar{\Gamma}_s(F) = \Gamma_s(\nabla u)\big|_{\nabla u = F - I}. \tag{40}$$

By the *frame indifference* in the strain energy functions (Gurtin et al. 2010) and the polar decomposition $F = RU$, $R \in \text{Orth}^+ = \{\text{all rotations}\}$, and U is the right stretch tensor, we have

$$\begin{aligned}
\bar{\Psi}(F) &= \bar{\Psi}(R^T F) = \bar{\Psi}(R^T R U) = \bar{\Psi}(U), \\
\bar{\Gamma}_s(F) &= \bar{\Gamma}_s(R^T F) = \bar{\Gamma}_s(R^T R U) = \bar{\Gamma}_s(U).
\end{aligned} \tag{41}$$

Using the relation $U = \sqrt{U^T U} = \sqrt{U^T R^T R U} = \sqrt{F^T F} = \sqrt{C}$, we can introduce strain energy functions $\hat{\Psi}(C)$ and $\hat{\Gamma}_s(C)$, such that

$$\begin{aligned}
\hat{\Psi}(C) &= \bar{\Psi}(\sqrt{C}) = \bar{\Psi}(U) = \bar{\Psi}(F), \\
\hat{\Gamma}_s(C) &= \bar{\Gamma}_s(\sqrt{C}) = \bar{\Gamma}_s(U) = \bar{\Gamma}_s(F).
\end{aligned} \tag{42}$$

Similarly, by the definition of the Green strain tensor $E = \frac{1}{2}(C - I)$, we can express strain energy functions $\Psi^*(E)$ and $\Gamma_s^*(E)$, such that

$$\begin{aligned}
\Psi^*(E) &= \hat{\Psi}(C) = \bar{\Psi}(U) = \bar{\Psi}(F), \\
\Gamma_s^*(E) &= \hat{\Gamma}_s(C) = \bar{\Gamma}_s(U) = \bar{\Gamma}_s(F).
\end{aligned} \tag{43}$$

In contrast to the two first Piola-Kirchhoff stresses (39), by (43) and $E = \frac{1}{2}(C - I)$, the two second Piola-Kirchhoff stresses are defined as

$$T = 2\frac{\partial \hat{\Psi}(C)}{\partial C} = \frac{\partial \Psi^*(E)}{\partial E} \quad \text{and} \quad \mathbb{T} = 2\frac{\partial \hat{\Gamma}_s(C)}{\partial C} = \frac{\partial \Gamma_s^*(E)}{\partial E}. \tag{44}$$

By (39), (43), (44), and the chain rule, the relations between the first P-K stresses (S, $\mathbb{S}$) and the second P-K stresses (T, $\mathbb{T}$) are (P-K is the abbreviation for the Piola-Kirchhoff stress.)

$$S = FT \quad \text{and} \quad \mathbb{S} = F\mathbb{T}. \tag{45}$$

The relations between the first P-K stresses $(\boldsymbol{S}, \mathbb{S})$ and the Cauchy stresses $(\boldsymbol{\sigma}, \sigma^s)$ are

$$\boldsymbol{S} = (\det \boldsymbol{F})\boldsymbol{\sigma}\,\boldsymbol{F}^{-T} \quad \text{and} \quad \mathbb{S} = (\det \boldsymbol{F})\sigma^s\boldsymbol{F}^{-T}. \tag{46}$$

3.4 Linearized Bulk and Surface Stresses and Constitutive Choice

A peculiarity of considering surface effects is the perceived presence of residual stresses – the surface tension-like quantity in solids is precisely a residual stress state. This becomes evident if we linearize the energy functions around a reference configuration which is not stress-free.

For small deformation, the Cauchy-Green tensor $\boldsymbol{C} = \boldsymbol{F}^T\boldsymbol{F} = (\mathbf{I} + \nabla \boldsymbol{u})^T(\mathbf{I} + \nabla \boldsymbol{u})$ can be reduced to $\boldsymbol{C} = \mathbf{I} + \nabla \boldsymbol{u} + \nabla \boldsymbol{u}^T$, $|\nabla \boldsymbol{u}| \ll 1$, by dropping the higher-order terms $o(|\nabla \boldsymbol{u}|)$. Thus, the strain tensor $\boldsymbol{E} = \frac{1}{2}(\boldsymbol{C} - \mathbf{I})$ in (44) may be approximated by the infinitesimal strain:

$$\boldsymbol{E} = \frac{1}{2}(\nabla \boldsymbol{u} + \nabla \boldsymbol{u}^T), \tag{47}$$

Using Taylor series, $(44)_1$ gives

$$\boldsymbol{T} = \left.\frac{\partial \Psi^*(\boldsymbol{E})}{\partial \boldsymbol{E}}\right|_{\boldsymbol{E}=0} + \left.\frac{\partial^2 \Psi^*(\boldsymbol{E})}{\partial \boldsymbol{E}^2}\right|_{\boldsymbol{E}=0} \cdot \boldsymbol{E} + o(|\boldsymbol{E}|), \tag{48}$$

where $o(|\boldsymbol{E}|)$ denotes the higher-order terms.

Since the reference configuration is assumed to be stress-free for the bulk portion of the material, it follows that $\left.\frac{\partial \Psi^*(\boldsymbol{E})}{\partial \boldsymbol{E}}\right|_{\boldsymbol{E}=0} = \boldsymbol{0}$ and the elasticity tensor is

$$\mathbb{C} := \left.\frac{\partial^2 \Psi^*(\boldsymbol{E})}{\partial \boldsymbol{E}^2}\right|_{\boldsymbol{E}=0}. \tag{49}$$

Thus, as usual, the linearized small-deformation stress-strain relation of bulk portion of the material is

$$\boldsymbol{T} = \mathbb{C}\boldsymbol{E}. \tag{50}$$

Consider the first P-K stresses $\boldsymbol{S} = \boldsymbol{F}\boldsymbol{T}$ in $(45)_1$ and the Cauchy stresses $\boldsymbol{\sigma} = (\det \boldsymbol{F})^{-1}\boldsymbol{S}\boldsymbol{F}^T$ in $(46)_1$ of bulk materials at small deformations. By the relation (50) and the infinitesimal strain (47), it is easy to show that to a first order

$$\boldsymbol{S} = \boldsymbol{T} = \boldsymbol{\sigma}. \tag{51}$$

The equivalence of the first P-K, the second P-K, and the Cauchy stresses in (51), however, does not hold for surface stresses due to the existence of the residual stress. This is rather important to note. In linearized elasticity (without residual stresses), it is usual to ignore the distinction between the various stress measures. For surface

elasticity, even in the linearized case, we must take cognizance of the different interpretations of the various stress measures. The first P-K stress measure is the most useful since it represents the force per unit *referential* area and is likely to be the quantity controlled in traction-controlled experiments (as opposed to Cauchy traction).

From previous works (see Eq. (40) in the work of Gurtin et al. 1998 and Eq. (7.9) in the work of Gurtin and Murdoch 1975b), we can show that the second P-K surface stress $\mathbb{T}$ in $(44)_2$ and the first P-K surface stress $\mathbb{S}$ in $(45)_2$ can be recast as

$$\mathbb{T} = \frac{\partial \Gamma_s{}^*(\boldsymbol{E}_s)}{\partial \boldsymbol{E}_s}, \quad \mathbb{S} = (\mathbb{I} + \mathbb{P}\nabla_s \boldsymbol{u})\mathbb{T}, \tag{52}$$

where $\boldsymbol{E}_s$, in contrast to the infinitesimal strain (47), is the infinitesimal surface strain

$$\boldsymbol{E}_s = \mathbb{P}\boldsymbol{E}\mathbb{P} = \frac{1}{2}[\mathbb{P}\nabla_s \boldsymbol{u} + (\mathbb{P}\nabla_s \boldsymbol{u})^T]. \tag{53}$$

Using the Taylor series for $(52)_1$, for small deformation, we have

$$\mathbb{T}(\boldsymbol{E}_s) = \left.\frac{\partial \Gamma_s{}^*(\boldsymbol{E}_s)}{\partial \boldsymbol{E}_s}\right|_{\boldsymbol{E}_s=\boldsymbol{0}} + \left.\frac{\partial^2 \Gamma_s{}^*(\boldsymbol{E}_s)}{\partial \boldsymbol{E}_s^2}\right|_{\boldsymbol{E}_s=\boldsymbol{0}} \cdot \boldsymbol{E}_s + o(|\boldsymbol{E}_s|). \tag{54}$$

With an appropriate choice of an elastic constitutive law (i.e., specification of $\Gamma_s{}^*$ and Ψ^*), we now have all the governing equations and can solve the pertinent boundary value problems of physical interest. Analytical solutions are rather hard to come by for the anisotropic case, and by far, most problems solved in the literature have been restricted to isotropic continua.

For isotropic linear elastic materials incorporating the residual surface stress, we have (Gurtin and Murdoch 1975a, b)

$$\tau_0\mathbb{I} := \left.\frac{\partial \Gamma_s{}^*(\boldsymbol{E}_s)}{\partial \boldsymbol{E}_s}\right|_{\boldsymbol{E}_s=\boldsymbol{0}}, \quad \mathbb{C}_s := \left.\frac{\partial^2 \Gamma_s{}^*(\boldsymbol{E}_s)}{\partial \boldsymbol{E}_s^2}\right|_{\boldsymbol{E}_s=\boldsymbol{0}}, \tag{55}$$

where $\tau_0\mathbb{I}$ is the residual stress and the surface elasticity tensor $\mathbb{C}_s$ gives

$$\mathbb{C}_s[\boldsymbol{E}_s] = \lambda_0 \mathrm{tr}(\boldsymbol{E}_s)\mathbb{I} + 2\mu_0 \boldsymbol{E}_s \tag{56}$$

with surface elastic moduli λ_0 and μ_0.

By (55) and (56), a general linearized constitutive law for isotropic linear materials in terms of the second P-K surface stress $\mathbb{T}$ in (54) can be written as

$$\mathbb{T}(\boldsymbol{E}_s) = \tau_0\mathbb{I} + \lambda_0 \mathrm{tr}(\boldsymbol{E}_s)\mathbb{I} + 2\mu_0 \boldsymbol{E}_s. \tag{57}$$

For solving actual boundary value problems (including the ones we present later in this chapter), we will need the first P-K stress tensor. To do so, we take cognizance

of the relation between the two P-K stresses. By $(52)_2$ and (57), the first P-K surface stress $\mathbb{S}$ becomes

$$\mathbb{S}(\nabla_s \boldsymbol{u}) = \tau_0 \mathbb{I} + \lambda_0 \text{tr}(\boldsymbol{E}_s)\mathbb{I} + 2\mu_0 \boldsymbol{E}_s + \tau_0 \nabla_s \boldsymbol{u}, \tag{58}$$

where the higher-order terms $|(\nabla_s \boldsymbol{u})\text{tr}(\boldsymbol{E}_s)|$ and $|(\nabla_s \boldsymbol{u})\boldsymbol{E}_s|$ are omitted. Here and henceforth, the difference between $\nabla_s \boldsymbol{u}$ and $\mathbb{P}\nabla_s \boldsymbol{u}$ is not specified for simplicity.

By $(46)_2$ and a similar argument as (52), the Cauchy surface stress σ^s and the first P-K stress $\mathbb{S}$ in (58) have the relation

$$\sigma^s = [\det(\mathbb{I} + \nabla_s \boldsymbol{u})]^{-1}\mathbb{S}(\mathbb{I} + \nabla_s \boldsymbol{u})^T. \tag{59}$$

For small deformation, $[\det(\mathbb{I} + \nabla_s \boldsymbol{u})]^{-1} = 1 - \text{tr}(\nabla_s \boldsymbol{u}) = 1 - \text{tr}(\boldsymbol{E}_s)$; thus, σ^s in (59) can be recast as

$$\begin{aligned}
\sigma^s &= [1 - \text{tr}(\boldsymbol{E}_s)][\tau_0 \mathbb{I} + \lambda_0 \text{tr}(\boldsymbol{E}_s)\mathbb{I} + 2\mu_0 \boldsymbol{E}_s + \tau_0 \nabla_s \boldsymbol{u}](\mathbb{I} + \nabla_s \boldsymbol{u}^T) \\
&= [\tau_0 \mathbb{I} + \lambda_0 \text{tr}(\boldsymbol{E}_s)\mathbb{I} + 2\mu_0 \boldsymbol{E}_s + \tau_0 \nabla_s \boldsymbol{u} - \tau_0 \text{tr}(\boldsymbol{E}_s)\mathbb{I}](\mathbb{I} + \nabla_s \boldsymbol{u}^T) \\
&= \tau_0 \mathbb{I} + \lambda_0 \text{tr}(\boldsymbol{E}_s)\mathbb{I} + 2\mu_0 \boldsymbol{E}_s + \tau_0 \nabla_s \boldsymbol{u} - \tau_0 \text{tr}(\boldsymbol{E}_s)\mathbb{I} + \tau_0 \nabla_s \boldsymbol{u}^T \\
&= \tau_0 \mathbb{I} + (\lambda_0 - \tau_0)\text{tr}(\boldsymbol{E}_s)\mathbb{I} + 2\mu_0 \boldsymbol{E}_s + \tau_0(\nabla_s \boldsymbol{u} + \nabla_s \boldsymbol{u}^T)
\end{aligned} \tag{60}$$

by dropping the higher-order terms related to the product between these terms $\text{tr}(\boldsymbol{E}_s)$, $\boldsymbol{E}_s$, $\nabla_s \boldsymbol{u}$, and $\nabla_s \boldsymbol{u}^T$.

Using the definition of surface strain in (53) and (60) finally becomes

$$\sigma^s = \tau_0 \mathbb{I} + (\lambda_0 - \tau_0)\text{tr}(\boldsymbol{E}_s)\mathbb{I} + 2(\mu_0 + \tau_0)\boldsymbol{E}_s = \tau_0 \mathbb{I} + \lambda_s \text{tr}(\boldsymbol{E}_s)\mathbb{I} + 2\mu_s \boldsymbol{E}_s. \tag{61}$$

Here

$$\lambda_s = \lambda_0 - \tau_0 \quad \text{and} \quad \mu_s = \mu_0 + \tau_0 \tag{62}$$

are the Lamé constants of the surface.

In contrast to the equivalence (51), $\mathbb{S}$ in (58), $\mathbb{T}$ in (57), and σ^s in (61) are not equivalent if the residual stress is nonzero $\tau_0 \neq 0$, namely:

$$\mathbb{S} \neq \mathbb{T} \neq \sigma^s \qquad \text{for} \quad \tau_0 \neq 0. \tag{63}$$

In the literature, sometimes (including the work by the corresponding author), the distinction between the various forms of the surface stress has often been blurred. For the most part, this does not lead to qualitative differences, but care must be exercised when solving surface elasticity problem to ascertain which precise stress measure and constitutive parameters are being deployed. As self-evident, there is a distinction between (λ_s, μ_s) and (λ_0, μ_0).

If we set the surface Lamé constants (λ_s, μ_s) to zero in (62), we obtain $\lambda_0 = \tau_0$ and $\mu_0 = -\tau_0$, and then the result in (58) is what is often called the *surface tension* (in the reference configuration) (Gurtin and Murdoch 1975a)

$$\mathbb{S} = \tau_0[1 + \text{tr}(\boldsymbol{E}_s)]\mathbb{I} - 2\tau_0\boldsymbol{E}_s + \tau_0\nabla_s\boldsymbol{u}. \tag{64}$$

This is to be contrasted with the expression in the current configuration where the Cauchy surface tension from (61) by setting (λ_s, μ_s) to zero will be in the form of isotropic "pressure"

$$\sigma^s = \tau_0\mathbb{I}. \tag{65}$$

4   Illustrative Examples

In this section we choose three illustrative examples that highlight both the use of the surface elasticity theory as well as provide insights into the physical consequences of surface energy at the nanoscale. These examples are inspired from Altenbach et al. (2013), Murdoch (2005), and Sharma et al. (2003) although, to be consistent with our own style (presented in the preceding sections), we have modified them slightly. Germane to the study of analytical study of nanostructures, we also note parallel developments in the literature on the so-called surface Cauchy-Born rule and numerical methods (Park et al. 2006).

4.1   Young's Modulus of a Nano-rod Considering Surface Effects

This example addresses how the elastic modulus of an isotropic nano-rod alters due to the influence of surface energy. This particular problem is inspired from the work by Altenbach et al. (2013) although there are some minor differences in our solution. Consider a circular cylinder (rod) with radius R_0 whose axis coincides with the $\boldsymbol{e}_z$ direction. To interrogate the elastic response, we assume that the rod is under uniaxial tension and the coordinate system used for this problem is cylindrical coordinate with basis $(\boldsymbol{e}_r, \boldsymbol{e}_\theta, \boldsymbol{e}_z)$ as shown in Fig. 4.

Fig. 4 A schematic of a nano-rod under a uniaxial tension. Surface effects are only considered on the radial surface $\partial\Omega_0$, and edge effects are ignored. Force $\boldsymbol{F}$ is exerted in the $\boldsymbol{e}_z$ direction
For isotropic elastic materials without surface effects, the uniaxial tension along the axial direction admits a homogeneous deformation. To simplify the discussion, we assume the deformation here incorporating the surface effect is also homogeneous, namely:

$$\boldsymbol{u} = Ar\boldsymbol{e}_r + Bz\boldsymbol{e}_z, \tag{66}$$

where A and B are constants. The assumed displacement (66) can be used for either small or finite deformation.

For the radial surface with outward unit normal $\boldsymbol{n} = \boldsymbol{e}_r$, the projection tensor is $\mathbb{P} = \boldsymbol{e}_\theta \otimes \boldsymbol{e}_\theta + \boldsymbol{e}_z \otimes \boldsymbol{e}_z$. By (66), the displacement gradient $\nabla \boldsymbol{u}$, the strain tensor $\boldsymbol{E} = \frac{1}{2}(\nabla \boldsymbol{u} + \nabla \boldsymbol{u}^T)$ for small deformation, the surface displacement gradient $\nabla_s \boldsymbol{u} = (\nabla \boldsymbol{u})\mathbb{P}$, and the surface strain tensor $\boldsymbol{E}_s = \mathbb{P}\boldsymbol{E}\mathbb{P}$ for small deformation become

$$\begin{aligned}
\nabla \boldsymbol{u} &= \boldsymbol{E} = A(\boldsymbol{e}_r \otimes \boldsymbol{e}_r + \boldsymbol{e}_\theta \otimes \boldsymbol{e}_\theta) + B\boldsymbol{e}_z \otimes \boldsymbol{e}_z, \\
\nabla_s \boldsymbol{u} &= \boldsymbol{E}_s = A\boldsymbol{e}_\theta \otimes \boldsymbol{e}_\theta + B\boldsymbol{e}_z \otimes \boldsymbol{e}_z.
\end{aligned} \tag{67}$$

By the constitutive law of isotropic linear materials and $(67)_1$, we have

$$\boldsymbol{S} = \lambda \mathrm{tr}(\boldsymbol{E})\mathbf{I} + 2\mu \boldsymbol{E} := \begin{bmatrix} S_{rr} & 0 & 0 \\ 0 & S_{\theta\theta} & 0 \\ 0 & 0 & S_{zz} \end{bmatrix}, \tag{68a}$$

where λ and μ are Lamé constants of bulk materials and

$$S_{rr} = S_{\theta\theta} = \lambda(2A + B) + 2\mu A, \quad S_{zz} = \lambda(2A + B) + 2\mu B. \tag{68b}$$

In addition, by the constitutive law (58) and by setting $\tau_0 = 0$, together with $(67)_2$, we have

$$\mathbb{S} = \lambda_0 \mathrm{tr}(\boldsymbol{E}_s)\mathbb{I} + 2\mu_0 \boldsymbol{E}_s := \begin{bmatrix} \mathbb{S}_{\theta\theta} & 0 \\ 0 & \mathbb{S}_{zz} \end{bmatrix}, \tag{69a}$$

where

$$\mathbb{S}_{\theta\theta} = \lambda_0(A + B) + 2\mu_0 A, \quad \mathbb{S}_{zz} = \lambda_0(A + B) + 2\mu_0 B. \tag{69b}$$

Using the Young-Laplace equation $(38)_3$, without external load $\boldsymbol{t}_0 = \boldsymbol{0}$ on the radial surface ($r = R_0$) with unit normal $\boldsymbol{e}_r$, we have the equality $\boldsymbol{S}\boldsymbol{e}_r = \mathrm{div}_s \mathbb{S}$. By (68a), the identity (16), and $\mathbb{S}^T \boldsymbol{e}_r = \boldsymbol{0}$ in $(38)_3$, we can obtain

$$S_{rr} = \boldsymbol{e}_r \cdot \boldsymbol{S}\boldsymbol{e}_r = \boldsymbol{e}_r \cdot \mathrm{div}_s \mathbb{S} = -\mathbb{S} \cdot \nabla_s \boldsymbol{e}_r. \tag{70}$$

Since $\nabla_s \boldsymbol{e}_r = (\nabla \boldsymbol{e}_r)\mathbb{P} = \left(\frac{1}{r}\boldsymbol{e}_\theta \otimes \boldsymbol{e}_\theta\right)(\boldsymbol{e}_\theta \otimes \boldsymbol{e}_\theta + \boldsymbol{e}_z \otimes \boldsymbol{e}_z) = \frac{1}{r}\boldsymbol{e}_\theta \otimes \boldsymbol{e}_\theta$, (70) implies

$$S_{rr} = -\frac{\mathbb{S}_{\theta\theta}}{R_0}. \tag{71}$$

By (68b), (69b), and (71) be written as

$$\lambda(2A + B) + 2\mu A = -\frac{\lambda_0(A + B) + 2\mu_0 A}{R_0}, \tag{72}$$

which gives the ratio

$$\frac{A}{B} = -\frac{\lambda + \lambda_0/R_0}{2\lambda + 2\mu + (\lambda_0 + 2\mu_0)/R_0}. \tag{73}$$

By (67) and (68b), the Young modulus for uniaxial tension is

$$E^{\text{rod}} = \frac{S_{zz}}{E_{zz}} = \frac{\lambda(2A + B) + 2\mu B}{B} = \lambda\left(1 + 2\frac{A}{B}\right) + 2\mu, \tag{74}$$

where the ratio A/B is given by (73). By the equilibrium of the rod in the axial direction (Altenbach et al. 2013), the effective Young's modulus can be defined as $E^{\text{eff}} = (S_{zz} + \frac{2}{R_0}\mathbb{S}_{zz})/E_{zz} = \lambda\left(1 + 2\frac{A}{B}\right) + 2\mu + \frac{2}{R_0}[\lambda_0(1 + \frac{A}{B}) + 2\mu_0]$.

This simple example makes clear that the effective or apparent elastic response of nanostructures becomes size-dependent as a result of surface energy effects and that with smaller R_0, the effective elastic modulus may become significantly different than its bulk value. We remark that if surface effects are ignored, that is, $\lambda_0 = \mu_0 = 0$ and the ratio $A/B = -\lambda/(2\lambda + 2\mu)$ in (73), then the Young modulus in (74) becomes $E^{\text{rod}} = \mu(3\lambda + 2\mu)/(\lambda + \mu)$–which is essentially the relation between bulk Young's modulus and the Lamé constants.

4.2   Influence of Surface Effects on the Thermoelastic State of a Ball

We consider the equilibrium state of a spherical ball (radius R_0) in vacuum undergoing thermal expansion – following Murdoch (2005). Only traction boundary conditions need to be considered here; hence, $(21)_1$ can be omitted. Moreover, $(38)_2$ and $(38)_4$ are also omitted since the entire surface of the sphere is considered, that is, $\mathsf{S}_0 = \partial\Omega_0 = \partial\Omega_0^t$.

We now proceed to solve the reduced boundary value problem that consists of $(38)_1$, $(38)_3$, and (29). As before, we assume the ball material to be isotropic and that the ball is in its natural, stress-free state in the reference configuration. Hence, we assume constitutive equations for the bulk and surface as follows:

$$S = \lambda_b \mathrm{tr}(E)I + 2\mu_b E - \alpha \Delta T I, \tag{75}$$

$$\mathbb{S} = \tau_0 \mathbb{I} + (\lambda_s + \tau_0)\mathrm{tr}(E_s)\mathbb{I} + 2(\mu_s - \tau_0)E_s + \tau_0(\nabla_s u) - \alpha_0 \Delta T \mathbb{I}, \tag{76}$$

where S is the first P-K stress field in the reference configuration, λ_b and μ_b are Lamé constants for the ball material, ΔT is the temperature difference, α is the coefficient of thermal expansion, and α_0 is the thermal expansion coefficient of the surface.

In this example we use spherical coordinates with basis (e_r, e_θ, e_ϕ) with the origin at the center of the ball. For the surface with outward unit normal $n = e_r$, the projection tensor is $\mathbb{P} = e_\theta \otimes e_\theta + e_\phi \otimes e_\phi$. Given that the problem is spherically symmetric, the form of the displacement field can be assumed to be

$$u = u_r(r)e_r. \tag{77}$$

Then the displacement gradient, the strain tensor, the surface gradient of the displacement, and the surface strain in (75) and (76) can be written, similar to (67), as

$$\nabla u = E = \frac{\partial u_r}{\partial r}e_r \otimes e_r + \frac{u_r}{r}(e_\theta \otimes e_\theta + e_\phi \otimes e_\phi),$$
$$\nabla_s u = E_s = \frac{u_r}{r}(e_\theta \otimes e_\theta + e_\phi \otimes e_\phi). \tag{78}$$

From (78), (75), and (76), we have

$$S = \lambda_b\left(\frac{\partial u_r}{\partial r} + \frac{2u_r}{r}\right)I + 2\mu_b\left(\frac{\partial u_r}{\partial r}e_r \otimes e_r + \frac{u_r}{r}(e_\theta \otimes e_\theta + e_\phi \otimes e_\phi)\right) - \alpha \Delta T I,$$

$$\mathbb{S} = \tau_0\mathbb{I} + \lambda_s\left(\frac{2u_r}{r}\right)\mathbb{I} + (2\mu_s + \tau_0)\left(\frac{u_r}{r}\right)(e_\theta \otimes e_\theta + e_\phi \otimes e_\phi) - \alpha_0 \Delta T \mathbb{I}. \tag{79}$$

Substituting (79)$_1$ into the equilibrium equation (38)$_1$, together with the divergence of a tensor in spherical coordinates, we obtain

$$r^2\frac{\partial^2 u_r}{\partial r^2} + 2r\frac{\partial u_r}{\partial r} - 2u_r = 0. \tag{80}$$

The general solution of (80) is $u_r(r) = Ar + Br^{-2}$, where A and B are constants to be determined by the boundary conditions. The displacement at the origin must vanish for the field to be bounded, i.e., and consequently $B = 0$ and then

$$u_r(r) = Ar. \tag{81}$$

Thus, the stresses (79) are reduced to

$$S = [A(3\lambda_b + 2\mu_b) - \alpha \Delta T]\mathbf{I}, \quad \mathbb{S} = [\tau_0 + A(2\lambda_s + 2\mu_s + \tau_0) - \alpha_0 \Delta T]\mathbb{I}. \quad (82)$$

We must now deploy the boundary condition in $(38)_3$. Since the ball surface is traction-free, that is, $\mathbf{t}_0 = \mathbf{0}$, $(38)_3$ can be reduced to $\mathbf{S}\mathbf{e}_r = \mathrm{div}_s\mathbb{S}$. By (82), we can further simplify this to

$$S_{rr} = \mathbf{e}_r \cdot \mathbf{S}\mathbf{e}_r = \mathbf{e}_r \cdot \mathrm{div}_s\mathbb{S} \quad \text{at } r = R_0. \quad (83)$$

By using the identity (16), $(82)_2$, $(38)_3$, and (14), we finally obtain

$$S_{rr} = \mathbf{e}_r \cdot \mathrm{div}_s\mathbb{S} = -\mathbb{S} \cdot \nabla_s \mathbf{e}_r = -\mathbb{S} \cdot \left\{ \frac{1}{r}(\mathbf{e}_\theta \otimes \mathbf{e}_\theta + \mathbf{e}_\phi \otimes \mathbf{e}_\phi) \right\} = -\frac{2\mathbb{S}_{\theta\theta}}{R_0}. \quad (84)$$

By (82) and (84), we have

$$3\lambda_b A + 2\mu_b A - \alpha \Delta T = -\frac{2}{R_0}\{\tau_0(1 + A) + 2A(\lambda_s + \mu_s) - \alpha_0 \Delta T\}. \quad (85)$$

By defining the *surface modulus* K_s as

$$K_s = 2(\lambda_s + \mu_s), \quad (86)$$

(85) yields the solution of A in the displacement (81), namely:

$$A = \frac{-2\tau_0/R_0}{(3\lambda_b + 2\mu_b + 2K_s/R_0 + 2\tau_0/R_0)} + \frac{(\alpha + 2\alpha_0/R_0)\Delta T}{(3\lambda_b + 2\mu_b + 2K_s/R_0 + 2\tau_0/R_0)}. \quad (87)$$

This example, as can be noted from (87), nicely shows how a positive surface residual stress τ_0 may hinder the thermal expansion in a size-dependent manner.

4.3   Effect of Residual Stress of Surfaces on Elastic State of Spherical Inclusion

The solution of an embedded inclusion in another material is a canonical problem in classical solid mechanics (known as Eshelby's inclusion problem) and has been applied to situations as diverse as phase transformation to effective properties of composites. Accordingly, in this section, we consider the problem of spherical inclusion with radius R_0 but incorporating surface effects. The solution here is a slight modification of the work by Sharma et al. (2003). We use spherical coordinates with basis $(\mathbf{e}_r, \mathbf{e}_\theta, \mathbf{e}_\phi)$ with the origin at the center of the sphere in this problem. We assume that a far field stress is exerted on the matrix as follows:

$$S_{rr}\big|_{r\to\infty} = S^\infty. \quad (88)$$

To make analytical progress, we further stipulate that the inclusion, the matrix, and the interface are isotropic and that the inclusion is in its natural state in the reference configuration. The constitutive equations for the bulk are as follows:

$$S = \lambda_v \text{tr}(E)\mathbf{I} + 2\mu_v E, \tag{89}$$

where S is the first Piola-Kirchhoff stress and λ_v and μ_v are Lamé constants of the material corresponding to either the inclusion(I) or the matrix(M). For the surface we use the constitutive equation defined in (58), i.e.:

$$\mathbb{S} = \tau_0 \mathbb{I} + (\lambda_s + \tau_0)\text{tr}(E_s)\mathbb{I} + 2(\mu_s - \tau_0)E_s + \tau_0(\nabla_s u). \tag{90}$$

Like the previous example, this problem also has spherical symmetry and accordingly the displacement vector is of the form

$$\boldsymbol{u} = u_r(r)\boldsymbol{e}_r. \tag{91}$$

Therefore, the displacement gradient and the strain are similar to (78). Hence, the stress in the bulk and on the surface stress can be expressed as

$$S = \lambda_b \left(\frac{\partial u_r}{\partial r} + \frac{2u_r}{r} \right) \mathbf{I} + 2\mu_b \left(\frac{\partial u_r}{\partial r} \boldsymbol{e}_r \otimes \boldsymbol{e}_r + \frac{u_r}{r}(\boldsymbol{e}_\theta \otimes \boldsymbol{e}_\theta + \boldsymbol{e}_\phi \otimes \boldsymbol{e}_\phi) \right),$$

$$\mathbb{S} = \tau_0 \mathbb{I} + \lambda_s \left(\frac{2u_r}{r} \right) \mathbb{I} + (2\mu_s + \tau_0)\left(\frac{u_r}{r} \right)(\boldsymbol{e}_\theta \otimes \boldsymbol{e}_\theta + \boldsymbol{e}_\phi \otimes \boldsymbol{e}_\phi). \tag{92}$$

We have used (38) in spherical coordinates. The boundary value problem that consists of $(38)_1$–$(38)_3$ becomes

$$\left. \begin{aligned} r^2 \frac{\partial^2 u_r}{\partial r^2} + 2r\frac{\partial u_r}{\partial r} - 2u_r = 0 \qquad & r \leqslant R_0, \\[2mm] r^2 \frac{\partial^2 u_r}{\partial r^2} + 2r\frac{\partial u_r}{\partial r} - 2u_r = 0 \qquad & r > R_0, \\[2mm] [\![S_{rr}]\!] = \frac{2\mathbb{S}_{\theta\theta}}{r} \qquad & r = R_0, \\[2mm] S_{rr}\big|_{r\to\infty} = S^\infty \qquad & r \to \infty. \end{aligned} \right\} \tag{93}$$

The "$[\![\cdot]\!]$" denotes the jump across the interface. Similar to (80), the general solutions of $(93)_1$ and $(93)_2$ are

$$u_r(r) = \begin{cases} A\,r + B\,r^{-2} & r \leqslant R_0, \\ C\,r + D\,r^{-2} & r > R_0, \end{cases} \tag{94}$$

where A, B, C, and D are constant. Since $u_r(0) = 0$, $B = 0$. Substituting $(94)_2$ into $(92)_1$, the far field $(93)_4$ gives $C = S^\infty/(3K_M)$, where $K_M = \lambda_M + 2\mu_M/3$. Using the continuity of the displacement at the interface, that is, $[\![u_r]\!] = 0$ at $r = R_0$, and

the Young-Laplace equation $(93)_3$, we obtain two algebraic equations of A and D. The routine calculation is not shown here and we just list the final results. Thus, the displacement (94) is obtained as

$$
u(r) = \begin{cases} \alpha r & r \leqslant R_0, \\[2ex] E^\infty r + (\alpha - E^\infty) \dfrac{R_0^3}{r^2} & r > R_0, \end{cases} \tag{95}
$$

where $E^\infty = S^\infty/(3K_M)$, $\alpha := \dfrac{(3K_M + 4\mu_M)E^\infty - 2\tau_0/R_0}{4\mu_M + 3K_I + 2K_s/R_0 + 2\tau_0/R_0}$, $K_I = \lambda_I + 2\mu_I/3$ is the inclusion bulk modulus, and $K_s = 2(\lambda_s + \mu_s)$ is defined as the surface modulus.

In particular, by setting $\lambda_I = 0$ and $\mu_I = 0$, we obtain the much-studied case of a void in a solid. The displacement $(95)_2$ for this special case is

$$
u(r) = E^\infty r + \beta \frac{R_0^3}{r^2} \qquad r > R_0, \tag{96}
$$

where $\beta := \dfrac{(3K_M + 4\mu_M)E^\infty - 2\tau_0/R_0}{4\mu_M + 2K_s/R_0 + 2\tau_0/R_0} - E^\infty$ and $E^\infty = S^\infty/(3K_M)$. Thus, the bulk stress $(92)_1$ in the matrix $(r > R_0)$ is

$$
\boldsymbol{S} = S^\infty \mathbf{I} + 2\mu_M \beta \frac{R_0^3}{r^3} \left(\mathbf{I} - 3\boldsymbol{e}_r \otimes \boldsymbol{e}_r \right). \tag{97}
$$

If there is no far stress field, $S^\infty = E^\infty = 0$, the bulk stress $\boldsymbol{S}$ becomes

$$
\boldsymbol{S}^0 = 2\mu_M \left(\frac{-2\tau_0/R_0}{4\mu_M + 2K_s/R_0 + 2\tau_0/R_0} \right) \frac{R_0^3}{r^3} \left(\mathbf{I} - 3\boldsymbol{e}_r \otimes \boldsymbol{e}_r \right). \tag{98}
$$

Assume a nonzero far stress field, $S^\infty \neq 0$. By (97) and (98), we may then define the stress concentration factor at $r \to R_0$ as

$$
S.C. = \left. \frac{S_{\theta\theta} - S_{\theta\theta}^0}{S^\infty} \right|_{r \to R_0} = 1 + \frac{1}{2} \left(\frac{1 - 2\left(K_s + \tau_0\right)/(3K_M R_0)}{1 + K_s/(2\mu_M R_0) + \tau_0/(2\mu_M R_0)} \right). \tag{99}
$$

In the absence of surface energy effects, i.e., $\tau_0 = K_s = 0$ in (99), we obtain a stress concentration factor of 1.5 which is the well-known classical elasticity result for a spherical void under hydrostatic stress. We have graphically plotted the results in Fig. 5 that illustrates the qualitative behavior of how stress concentration on a void alters due to size and the surface elasticity modulus (Interestingly, the surface elasticity modulus can have negative values as shown via atomistic simulations by Miller and Shenoy 2000.).
Fig. 5 Stress concentration on a spherical void under hydrostatic stress is plotted with respect to the size of the void for three different surface modulus K_s. For coarser void size, the stress concentration asymptotically approaches the bulk value of $3/2$. For the plot, we have chosen properties of Aluminum as bulk, with ($\lambda_M = 62.29$ GPa, $\mu_M = 36.71$ GPa). The surface properties are the following: *Case* (a) considering positive surface modulus $K_s = 2(\lambda_s + \mu_s)$ by using $\lambda_s = 6.842\,N/m$, $\mu_s = -0.3755\,N/m$, and $\tau_0 = 0$; *Case* (b) without considering surface effects; and $K_s = 0$; *Case* (c) considering negative surface modulus $K_s = 2(\lambda_s + \mu_s)$ by using $\lambda_s = 3.48912\,N/m$, $\mu_s = -6.2178\,N/m$, and $\tau_0 = 0$. (The surface and material properties are taken from Miller and Shenoy 2000; Cammarata et al. 2000)

5   Perspectives on Future Research

Despite extensive work on surface elasticity, some aspects of this field are still somewhat understudied and represent avenues for future exploration. We briefly articulate them below:

- As well-motivated by Steigmann and Ogden (1999, 1997), under certain circumstances, the dependence of surface energy on curvature must be accounted for. This was recently explored by Fried and Todres (2005), who examined the effect of the curvature-dependent surface energy on the wrinkling of thin films, and Chhapadia et al. (2011) who (using both atomistics and a continuum approach) explained certain anomalies in the bending behavior of nanostructures. However, due to the complexity of the Steigmann-Ogden curvature-dependent surface elasticity, relatively few works exist on this topic.
- Intriguing recent experiments by Style and co-workers (Style et al. 2013, 2017) on capillarity and liquid inclusions in soft solids have revealed that the pertinent size effects due to surface effects may be observed at *micron* length scales (in contrast to the nanoscale for hard materials). This represents an important future direction and requires the use of *nonlinear* surface elasticity due to the need to account for the inevitable large deformations in soft matter. Arguably, the

study of capillarity in soft matter will also require the development and use of numerical methods cf. Henann and Bertoldi (2014).

- Finally, the literature on coupling of capillarity with electrical and magnetic fields is quite sparse.

Glass Science and Technology: Predictive Modeling

Modeling of Glasses: An Overview

80

Mehmet C. Onbaşlı and John C. Mauro

Contents

Abstract

Glass modeling includes unique advantages and challenges with respect to other fields of materials modeling owing to lack of long-range order, strong dependence on temperature and pressure history, statistical nature of glass-forming liquid, and the availability of almost the entire periodic table for constituents in glass. In this chapter, we introduce a range of methods used for glass modeling and overcoming these challenges. We first briefly compare how glass modeling is different from crystalline materials. Next, we briefly outline some of the techniques used for modeling glass and finally present the outstanding challenges in glass modeling and design. As glass modeling merges

empirical techniques (i.e., data-driven machine learning, finite element models for mechanical and acoustic properties, composition/property/processing relationships) with fundamental physical methods (i.e., statistical physics, diffusion, first principles quantum mechanical theories, energy landscapes), many orders of magnitude in time- and length scales may be simultaneously modeled across vast composition spaces whose experimental exploration would be prohibitively expensive.

1   Introduction

In current and emerging technologies, functional glasses play a critical role due to their unique final properties such as optical transparency, mechanical strength and elasticity, thermal insulation, chemical durability, liquidus temperature, and refractory compatibility. Traditionally, glass research has been based on trial-and-error experimentation on structure, property, and processing relationships. Compared with other classes of materials such as crystals, glass lacks long-range order and glass structure changes over short- and intermediate-range orders on different length scales, which dramatically alters macroscopic properties. In glass, local bonding and packing of cations and anions are composition dependent and typically differ from those in the compositionally analogous crystals. Since nearly all elements of the periodic table are available for glass formation, one can explore virtually infinitely many glass compositions. As glass structure also evolves as a strong function of its thermal and pressure history, one also needs to trace microstructural evolution in glass as a function of thermal input and pressure changes. As molecular topology is driven by the statistical nature of glass-forming liquid, the intermediate properties of this liquid are critical in understanding and engineering of glass composition and properties. Hence, due to the compositional and structural complexity of glass, a rigorous understanding of composition, property, and processing relationship through modelling has been difficult and glass-modeling studies have been limited.

Recent developments in ab initio models for organic-glass adhesion, constitutive mechanical modeling of metallic glass, data-driven models of glass, and other modeling methods have made major strides in accurately predicting glass properties and in optimizing competing manufacturing-related glass attributes and final glass properties. In this book chapter, we introduce the recently developed glass modeling methods, which enable accurate prediction of final glass properties and manufacturing related attributes. These methods also help bridge modeling across multiple time- and length scales and merge insights from fundamental physical and empirical models.

This chapter serves as an introduction to this part "Glass Science and Technology: Predictive Modeling" of the handbook. Owing to the complexity of glass properties and structure, one may classify glass-modeling methods in terms of their empirical or fundamental physical origins. Depending on the range of length and timescales, the number of constituents involved, the properties of interest, the types

of fundamental physical insights to be captured, and error tolerance for coarse-graining, researchers pick from the methods shown on Fig. 1 or develop new modeling methods.

Figure 1 shows the range of methods that one may use for glass modeling. Each method has its own advantage and disadvantage and depending on the modeling purpose (i.e., kinetic, thermodynamic, or multicomponent glass phase diagrams), different limitations arise. As shown in the classification of Fig. 1, one may use purely empirical modeling techniques such as regression, neural networks, and data mining approaches. In these methods, one starts with an experimental data set for glass composition-property relationships. Then, regression analysis is used to identify linear relationships and correlations between glass composition and major glass properties. When the process and composition parameters interact nonlinearly, neural network models with many layers and neurons might be more useful in capturing the subtle correlations within many-component glass systems. The use cases for regression and machine learning methods such as artificial neural networks are described in ▶ Chap. 81, "Mechanical and Compositional Design of High-Strength Corning Gorilla® Glass," of the glass modeling part (Onbasli et al.).

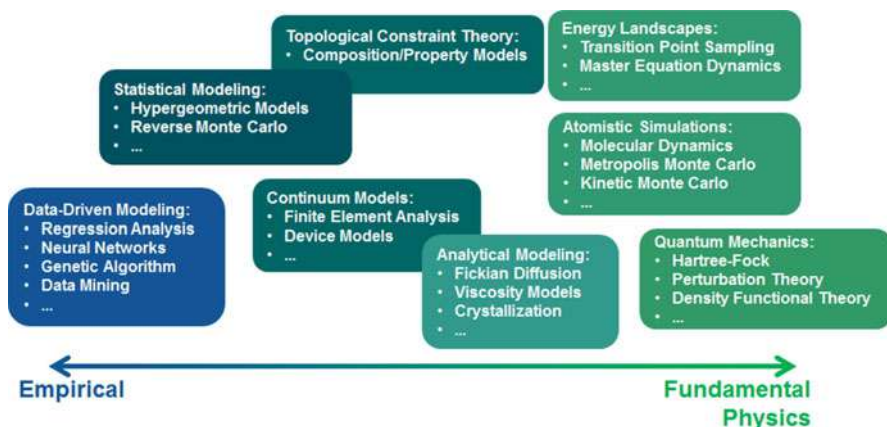
In this section on glass modeling, there are four chapters, which use different sets of methods. These methods span multiscale finite element modeling, high-


Fig. 1 Glass modeling methods based on their length-scale and the classes of techniques involved. The methods based on first principles calculations such as quantum mechanics, molecular dynamics, and energy landscapes involve shorter length scales while capturing the glass behavior more rigorously. The methods, which involve longer length scales (microscopic) as continuum and thermodynamic models, are introduced in the middle category. These methods cover finite element modeling, diffusion models, topological constraint theory, viscosity, and crystallization models. Finally, as much longer length, time, and composition spaces are involved, statistical and nonlinear machine learning models prove to be more effective in capturing the overall change in glass properties with empirical and data-driven approaches. (Reprinted with permission from Mauro et al. 2016, 2016, American Chemical Society.)

throughput compositional screening, and data science techniques to gain insight into glass composition-property relationships as well as industrially viable glass property predictions. The second chapter of this part, ▶ Chap. 81, "Mechanical and Compositional Design of High-Strength Corning Gorilla® Glass" (Onbasli et al.), describes a purely data-driven approach into composition optimization for obtaining commercially viable Corning Gorilla® Glass liquidus temperature, Young's modulus, and viscosity. The fact that more than 10 elemental and compound constituents in glass composition increase the composition space significantly and exploring this vast parameter space experimentally becomes prohibitively expensive in expenses and in time. As a result, Corning's unique advantage of its long experimental records of glass trial-and-errors has been used to empirically predict and classify glass compositions, which may be promising for the desired ranges of liquidus temperature, Young's moduli, and viscosities.

As mechanical properties of glass are modeled across micrometer to centimeter length scales, one needs to use multiscale formalisms such as finite element methods (FEM) and numerical analysis techniques. The bridge between macroscopic and mesoscopic length scales requires an accurate modeling of the constitutive relationships of mechanical properties of glasses and metallic glass compositions. On Fig. 1, these techniques are classified as continuum models, which do not consider the discrete molecular structure of glass. Avoiding the molecular precision allows for bridging granular mechanical behavior to macroscopic mechanical properties of materials without significantly compromising accuracy. The predictive accuracy of these mechanical FEM models is mostly determined by the accuracy of the constitutive mechanical property models for materials. As a result, we include the third chapter, ▶ Chap. 82, "Constitutive Modeling in Metallic Glasses for Predictions and Designs" (Li), in this glass modeling section to address the multiscale modeling challenge for analyzing and designing mechanical properties of metallic glasses. This chapter demonstrates how constitutive modeling can help engineer new high-strength metallic glasses with superior optimized mechanical properties and the same techniques could be used for mechanical modeling and rational design of other materials.

The next chapter in glass modeling is ▶ Chap. 83, "Fundamentals and Applications of Organic-Glass Adhesion" which focuses on first-principles calculations with rigorous physical insights into the thermodynamics of adhesion of organic molecules on glass (Goyal et al.). In this chapter, density functional theory and molecular dynamics models are used to predict the binding energies of different common organic molecules such as polyimide on silica. Molecular dynamics models help develop predictive power over the binding kinetics up to nanometer length scales. This predictive power originates from the development of accurate force fields such as ReaxFF and Interface FF. Once the accurate force fields are used in the molecular dynamics simulations, one can design and optimize organic/glass interfaces of desired strength (i.e., binding energies), which would be necessary for technological display applications.

The final chapter in glass modeling is ▶ Chap. 84, "Design and Modelling of High-Strength, High-Transmission Auto Glass with High Sound Transmission Loss" which uses laminated composite glass-polymer layers for enhanced sound transmission loss and sound isolation while retaining the mechanical strength, wide elastic range, scratch resistance, and high optical transparency (Onbasli, this volume). For automotive, industrial, and architectural purposes, glass must have high sound transmission loss to achieve good sound isolation. While engineering glass compositions allows for tuning the mechanical properties of glass for high strength and scratch resistance, geometric requirements of applications and acoustic phonon band structure of glass originating from its composition limit the flexibility on tuning the sound transmission loss via intrinsic band structure engineering. As a result, composite multilayers need to be used such that the mass density and effective acoustic impedance can be engineered for maximum reflection over audible sound frequency ranges. In this chapter, this challenge is posed as a multilayer composite materials optimization problem in which optical transmission and mechanical properties must be retained while the effective wideband acoustic impedance can be maximized. For enhancing acoustic impedance, sound wave equation, constitutive relations, and appropriate boundary conditions are defined to model the acoustic reflection, transmission, and absorption spectra of glass. Once the formalism is established and the key modeling steps are streamlined, optimization for automotive and other wide area glass applications becomes feasible.

In the rest of this chapter, the methods used in these studies are described as an overview. The methods covered also find emerging and groundbreaking uses in multiscale modeling for other materials classes. By finite element modeling and accurate constitutive modeling, one can achieve multiscale modeling of materials. Through data-driven approaches, one can systematically screen vast composition spaces and defect states with high-throughput and streamline material property optimization. DFT- and MD-based techniques help bridge material behavior at mesoscopic (i.e., molecular interfaces) and microscopic (i.e., experimentally easily accessible micron-scale properties) scales. This introductory chapter ends with a short overview of new glass modeling problems. A multiscale modeling approach in which the advantages of the methods discussed here could be merged might address these glass modeling problems.

2   Methods in Glass Modeling

In this part, we describe the three categories of methods used in the glass modeling section of the handbook. These categories are:

1. Data-driven and high-throughput compositional screening
2. Multiscale finite element modeling
3. DFT- and MD-based first-principles modeling

2.1   Data-Driven and High-Throughput Compositional Screening

In the data-driven materials modeling approach, the main purpose is to understand and predict the structure-property and processing relationships in glass by using statistical models as well as nonlinear machine learning models (such as artificial neural networks or genetic algorithms). The main advantage in this approach is that if an experimental data set is available to partially describe the structure-property and processing relationships, one may develop predictive models for the key properties such as liquidus temperature, viscosity, and Young's modulus of multicomponent glass systems treated under different conditions. By spanning more than ten main and trace components in glass, one can computationally narrow down on the composition subspaces, which may yield the optimal liquidus temperature, viscosity, and Young's modulus and many other desired properties. A disadvantage of this approach is that an experimental dataset must be available to build descriptive and predictive analytical models and building this dataset might be expensive. The models are coarse-grained in the sense that some of the effects of trace components may not necessarily be captured within the predictive error margin of a data-driven model. Nevertheless, such models help identify trends and effects of composition on final glass properties and manufacturing-related attributes, which could later be studied in finer detail using fundamental physical or finite element models. Below is a brief description of the data-driven methodology used for glass composition development for optimized liquidus temperature, viscosity, and Young's modulus predictions.

From a high-impact commercial research and development standpoint, final glass properties and manufacturing-related attributes need to be optimized simultaneously. Glass composition design can thus be posed as a multiobjective optimization problem with constrains on the stoichiometry and percentage weights of the constituents and the range of each stoichiometry. One objective function for each property can be given as a range ($70\ \text{GPa} \leq E \leq 85\ \text{GPa}$) or lower-bounded range ($AP \geq 800\ °C$). Corning's proprietary glass composition and property database developed over many years span key constituents and linear regression models are used whenever existing experimental data may coincide with the desired properties. For conflicting constraints or nonlinear material behavior, nonlinear optimization and machine learning models need to be used. Below is the description of the steps involved in data-driven materials modeling for glass.

Data consolidation and cleaning: Regardless of the type of data-driven approach used, data quality is the most important aspect that determines the success of the models to be built. Data quality is defined in terms of both data organization and the signal-to-noise ratio at which data were acquired. In typical data-driven projects, data consolidation and cleaning consists of restructuring the data in a format and structure that could be computationally processed. In data cleaning, the gaps within the data structure are eliminated by either interpolation or complete elimination of the data row associated with the missing measurement. Once the dataset is constructed, regression and machine learning models are built for predictions.

In ▶ Chap. 81, "Mechanical and Compositional Design of High-Strength Corning Gorilla® Glass," Corning researchers used the proprietary Corning glass composition and property relations. These data sets are based on Corning's proprietary experimental data from the company's long history of glass composition research. The composition information has been stored as the weight or atomic or molar percentages of each oxide constituting glass. For outputs, the viscosities η, Young's moduli E, glass transition temperatures T_g, densities ρ, as well as the liquidus temperatures T_L are used. For commercial purposes, Corning researchers had to optimize glass compositions, which would help achieve a high enough strength and scratch resistance while allowing for high enough manufacturing yield through low enough viscosities. The purpose of the models therefore is to find the composition that yields the optimal mechanical, chemical, or rheological properties of glass.

After data consolidation and cleaning comes a step called *feature detection*. This step is a group of computational algorithms used for input data sets without labeled response variables (i.e., properties). These algorithms help detect anomalous data entries. These algorithms help group different composition types and predict based on their measured mechanical properties. As part of this step, we describe cluster analysis, regression, genetic algorithms, and neural networks.

Cluster analysis: For building a reliable model, one needs to break down the data into subspaces of glass compositions. Since manual identification of systematic glass compositional variations is not feasible and is error-prone, a classification algorithm called cluster analysis is developed. First, the proximity and similarity between each data point in the data are calculated. Then, a criterion function is defined for effective clustering based on the proximity and similarity metrics. Dissimilar data items are grouped under different clusters. As a result, trends within subsections of glass composition space can be analyzed. Since glass composition data span more than 15 orders of magnitude; their values cannot be directly used in models as numerical computational errors may become larger than the weights of the properties with smaller values. In order not to cause one column to dominate distances based on their absolute values, each value is normalized to index values before calculating the distances. A conversion formula is defined in the beginning for each property or column for converting these normalized values back to their original scales. After normalization, the distances between each data point can be found.

Principal component analysis (PCA): PCA is a dimension reduction technique that allows omitting variables, which do not have significant effect on the desired glass property (▶ Chap. 81, "Mechanical and Compositional Design of High-Strength Corning Gorilla® Glass," Onbasli et al.). This method uses an orthogonal mathematical transformation on data to convert a mapping of possibly correlated variables into a set of values of linearly uncorrelated variables called principal components. The number of principal components is less than or equal to the number of original variables. The first principal component has the largest possible variance, and every next component has progressively lower variances. The output of PCA is a set of vectors transformed out of the original data. These vectors form an

uncorrelated orthogonal basis set. As variances depend on the absolute mean values of each variable, PCA output vectors strongly depend on the relative scaling of the initial variables. Therefore, normalizing each variable is essential before running PCA calculations. After running the PCA algorithm on data, a significance threshold is determined for the eigenvectors. This threshold step helps determine the most significant variables in a glass composition project and focus on cluster analysis using those fewer and more important variables (Kullback and Leibler 1951). PCA reduces computational costs by reducing the number of variables involved while allowing for a small enough prediction error due to the omitted eigenvectors. PCA is one of the steps that enable higher throughput screening across large composition spaces.

Regression analysis: PCA may fail to capture nonlinear correlations among variables and regression analysis might be necessary to distinguish if there are hidden complex dependencies. In regression analysis, the conditional expectation $E(X|H)$ is estimated when the independent variables are given. In other words, either a generalized linear model is constructed by using a multivariable linear superposition of independent variables or a least squares fit is solved numerically among variables to identify if there is a nonlinear correlation.

Multivariable linear regression: This is a generalized linearization method that assumes one or more independent variables:

$$Y_i = \alpha_0 + \alpha_1 X_1 + \alpha_2 X_2 + \cdots + \alpha_n X_n + \varepsilon \tag{1}$$

where each X is an independent variable and ϵ i is an error term which is minimized until the optimal set of regression coefficients α_0 to α_n are found. These coefficients also indicate the relative significance of each independent variable.

Least squares regression model: This fitting model assumes a sophisticated nonlinear correlation between variables. No closed-form solutions are assumed here and one may pick a Taylor expansion or a different basis set to fit the dependent variable by minimizing the sum of the squared residuals S.

Genetic algorithms: Genetic algorithms (GA) are methods for solving constrained optimization problems based on an evolutionary natural selection process. An iterative convergence into the optimal solution is essential in any optimization problem. In a classical numerical solution algorithm (i.e., Newton's method solving the zeros of equations), one generates a single point at each iteration. The sequence of points progressively approaches the solution. In GA, instead of iterating only on one point, a population of points are generated at each iteration and the best point in population approaches the solution.

A key difference between classical algorithms and GA is that in GA, each successive population is generated using random number generators and some combinations from the best solutions of the previous iteration instead of deterministic computation. GA are useful for accelerated global optimization problems where there are multiple objectives with competing requirements. GA can also be used for maximization, minimization, constrained optimization, multidimensional fitting, classification, and prediction problems. GA are therefore beneficial for composition development.

Below is a description of a simplified GA for solving a generic multi-objective optimization problem: The GA starts by generating a random population of glass compositions. The GA then evaluates the glass composition population based on their predicted properties and the fitness values. The GA then scores each composition of the current population by computing the fitness value for each and normalizing their scores for comparisons. The GA picks a few candidates from the population (parents) based on their fitness. Some of the individuals in the current population that have lower fitness are chosen as elite. These elite individuals are passed to the next population (children). Children are produced either by making random changes to a single parent (mutation) or by combining the vector entries of a pair of parents (crossover). Then, the algorithm replaces the current population with the children to form the next generation. The GA then creates a sequence of new populations and successive generations. At each step, the GA uses the compositions in the current generation to create the next population. The algorithm stops when the output meets the stopping criteria. The stopping criteria may include a maximum number of generations, time limit for iterations, fitness limit for population (when the fitness function for the best point in the population is less than or equal to the fitness limit), and marginal change limits per generation (i.e., when the average change over each generation is less than a functional tolerance limit). The algorithms mentioned can be implemented in MATLAB, R, or Python.

Neural Networks: Neural networks (NN) are a set of machine learning algorithms that can be used to predict nonlinear behavior of different systems. A neuron is a nonlinear and parameterized function of input variables. Therefore, a neural network is the composition (weighted sum) of nonlinear functions of two or more neurons. The nonlinearity of neural networks helps model nonlinear behaviors that may not otherwise be captured in regression models or in linear techniques such as PCA. Despite the biological flavor of the term neural network, neural networks in machine learning are pure mathematical constructs. For glass modeling, this handbook covers feedforward networks, which do not include feedback. In an optimized NN model, a sequence of neurons may also yield physical insight about a given physical parameter and help develop physics-based models later. Although correlations may not necessarily imply causality, consistent trends in NN models may guide fundamental physical models on composition spaces not studied previously.

A NN model consists of a graph structure where each edge indicates the weight of the given variable entering the node (neuron). Each node indicates the nonlinear activation function that captures the nonlinear glass behavior. The outputs of each activation function are entered into the next layer of activation functions with different weights. After such successive nonlinear active calculations are done, the output neuron, which is the node at the output, calculates the final classification or prediction result. The rest of the layers between the inputs and the output neuron are hidden layers of neurons. In NN optimization, the number of hidden layers, the number of neurons in each layer, the activation function of each layer (tanh, sigmoid, inverse tangent), and the learning rate (continuous number between 0.0001 and 0.1) are optimized by entering the data set as training data. After the prediction outputs

are obtained, these outputs are compared with the final glass properties and error rate is calculated as a percentage difference. The data are fed into the NN model to optimize the model parameters until the error rate converges to a minimum.

2.2   Multiscale Finite Element Modeling

Finite element modeling is class of modeling techniques that can be applied to multiple different scales and physics from mesoscopic to microscopic and classical mechanical models to acoustic sound transmission. Finite element modeling is a geometric divide-and-conquer technique for modeling the local material behavior for given physics (i.e. Maxwell's equations, mechanical elasticity/plasticity or flow relations, acoustic wave equation relations, semiclassical electronic properties etc.), constitutive relations which capture material properties and the appropriate boundary conditions for known behaviors of interfaces (i.e. rigid or absorbing boundaries). In glass modeling section of this handbook, finite element methods have been used to describe the mechanical strength and ductility of metallic glasses and to describe sound transmission loss of optically clear, high-strength automotive glasses. In both cases, finite element modeling describes the geometries in mesh structures and the adjacent meshes affect each other's response variables such as deformation or displacement or sound transmission. In this part, first, finite element modeling (FEM) used in describing the mechanical behavior metallic glasses is introduced. Next, FEM used in acoustic sound transmission of glass is presented.

2.2.1   FEM for Designing High Strength and Highly Elastic Metallic Glasses

Metallic glasses include metallic elements and have amorphous structure. These materials have extraordinary high strength and high elastic limits at room temperature. Metallic glasses are brittle and suffer from inhomogeneous deformation characteristics of shear banding, flow serration and cavitation. The net-shape forming ability is typically observed for most glasses when heated above glass transition temperature, but metallic glasses deform in a homogeneous manner. Understanding both the homogeneous and inhomogeneous deformation in metallic glasses is important for designing metallic glasses with improved ductility while preserving their high strength and elasticity. As a result, finite element modeling accurate constitutive models for metallic glasses are necessary to understand the deformation behavior of metallic glasses and develop their ductility.

In the glass modeling section of this handbook, ▶ Chap. 82, "Constitutive Modeling in Metallic Glasses for Predictions and Designs" (Li, this volume) has been included to address the multiscale modeling challenge for analyzing and designing mechanical properties of metallic glasses. Constitutive modeling captures the homogeneous and inhomogeneous deformation behavior and helps identify brittle failure conditions as a function of loading, shear banding and flow serration and cavitation.

The finite element models in this chapter use a free volume model-based constitutive relationship to describe homogeneous and inhomogeneous plastic flow. Since the atoms in an amorphous metallic glass are arranged in a disordered and non-closely packed manner, the excess space of the structure is described as free volume per atom. This volume is quantified as the difference between the average atomic volume in an amorphous structure and that in an ideal ordered structure. In the free volume model, macroscopic plastic flow is assumed to be induced by a number of individual atomic jumps. When no external force is applied, these jumps are driven by thermal activation energy. A dynamic equilibrium is assumed such that the number of atoms jumping forward balances the number of those jumping backward. Therefore, no net macroscopic flow occurs. When a shear stress is assumed due to an external force, a net flux of atoms along one direction are going to be observed. This net flux describes the irreversible macroscopic deformation. When shear deformation is modeled in a simplified 1D case, the plastic shear strain rate is the fraction of the thermally activated atomic jumps within the free volume where the success rates of the jumps are determined by temperature and the activation energy barrier (ΔG^m):

$$\frac{\partial \gamma_p}{\partial t} = 2f \, \exp\left(-\frac{\alpha v^*}{v_f}\right) \exp\left(-\frac{\Delta G^m}{k_B T}\right) \sinh\left(\frac{\tau \Omega}{2k_B T}\right), \qquad (2)$$

where f is the frequency of the atomic vibrations, α is a geometric factor, v^* is the hard-sphere volume of an atom, v_f is the average free volume per atom, is the activation energy, Ω is the atomic volume, k_B is the Boltzmann constant, and T is the temperature in Kelvin.

In this standard viscoplastic model description shown with Eq. (2), the strain softening effect found in metallic glasses cannot be fully accounted for. To account for strain softening, the free volume, v_f, is treated as an order parameter whose creation and annihilation govern the structural disordering and reordering processes in metallic glasses. The free volume can be created by a sufficiently high stress squeezing an atom into a neighboring vacancy of smaller volume; it can be annihilated by diffusional atomic jumps. The net rate of free volume increase is:

$$\frac{\partial v_f}{\partial t} = v^* f \exp\left(-\frac{\alpha v^*}{v_f}\right) \exp\left(-\frac{\Delta G^m}{k_B T}\right) \left\{ \frac{2\alpha k_B T}{v_f C_{\text{eff}}} \left[\cosh\left(\frac{\tau \Omega}{2k_B T}\right) - 1\right] - \frac{1}{n_D} \right\},$$
$$(3)$$

where n_D is the number of atomic jumps needed to annihilate a free volume equal to v^* and is usually below 10, and the effective modulus is $C_{\text{eff}} = E/3(1 - v)$ with E and v being the Young's modulus and Poisson's ratio, respectively. Equations (2) and (3) describe the inelastic portion of the continuum mechanics of deformation mechanism in metallic glasses. In conjunction with an elasticity formula given below, a complete one-dimensional isothermal constitutive law for metallic glasses is formed

$$\frac{\partial \gamma_e}{\partial t} = \left(\frac{\dot{\tau}}{G}\right)_T \tag{4}$$

where G is the shear modulus. In addition to this isothermal model, thermal transport equation is also used to take plastic energy dissipation and heat conduction into account. As a result, the yield criteria for metallic glasses under multiaxial stress states could be modeled. Further details on these models are presented by W. Li in ▶ Chap. 82, "Constitutive Modeling in Metallic Glasses for Predictions and Designs" of this handbook. These models can be implemented in ABAQUS software for numerical modeling of multiaxial shear strain effects with respect to J_2 plasticity, which assumes that the hydrostatic stress does not cause plastic flow or any changes in free volume.

In addition to free volume model, constitutive models could also be built phenomenologically to capture the macroscopic mechanical response of metallic glasses. Anand and Su (2005) developed a finite-deformation constitutive theory that captures some of the essential inelastic deformation features in metallic glasses. These features include the hydrostatic-stress dependence of yielding, plastic dilatation, and plastic strain localization. This model was first developed for room temperature and then extended to high homologous temperatures within $0.7T_g \lesssim T \lesssim 0.9T_g$ for simulating homogeneous plastic flow (Anand and Su 2007) and $0.9T_g \lesssim T \lesssim T_x$ (Henann and Anand 2008) for the transition from a viscoelastic-plastic solid-like response to a Newtonian fluid-like response for isothermal condition.

Plastic deformation does work on atoms during mass transport and dissipates heat. As a result, temperature changes during plastic deformation need to be incorporated into the models for more accurate description of the thermomechanical changes. Yang et al. (2006) consider the temperature rise in metallic glasses resulting from the conversion from plastic work to heat but treats the system as adiabatic. Thamburaja and Ekambaram (2007) applied fundamental thermodynamic laws and the principle of microforce balance to develop a thermomechanically coupled finite-deformation model for predicting within supercooled liquid regime. This model was further developed to include a damage criterion to simulate impact and damage processes (Ekambaram et al. 2011). These constitutive models have been implemented in commercial finite-element program ABAQUS by writing a user-defined material script for the explicit (VUMAT) or the implicit procedure (UMAT). The model by Anand and Su at room temperature (Anand and Su 2005) has been used extensively. Further details on the models are presented in ▶ Chap. 82, "Constitutive Modeling in Metallic Glasses for Predictions and Designs," by Li, this volume.

2.2.2 Finite Element Modeling for Sound Transmission Loss Calculations

In the second half of the FEM part, acoustic transmission modeling of glass is introduced. Sound transmission loss of laminated composite glass layers is

modeled with using linear acoustic wave equations and constitutive relations. After defining the geometry of the structure, the material properties of each layer are defined and the boundary conditions are established. Next, a commercial software package solves for the temporal and spatial evolution of the sound-induced pressure inside glass and external medium. Finally, the pressure and associated power distribution is calculated and normalized with respect to the incoming acoustic wave energy density to find sound transmission loss as a function of sound excitation frequency.

In linear acoustics, pressure changes are assumed to be small with respect to the mean pressure:

$$p = p_0 + p', p' \ll p_0 \tag{5}$$

Momentum and mass are conserved as described by Eqs. (6) and (7):

$$\frac{\partial \overrightarrow{v}_a}{\partial t} = -\frac{1}{\rho_0} \nabla p_a + \frac{4\mu}{3\rho_0} \nabla \left(\nabla \cdot \overrightarrow{v}_a \right) \tag{6}$$

$$\frac{1}{\rho_0 c_0{}^2} \frac{\partial p_a}{\partial t} = -\nabla \cdot \overrightarrow{v}_a + \frac{Q}{\rho_0} \tag{7}$$

where ρ_0 is the mass density of the medium (kg·m^{-3}), p_a is the acoustic pressure (N·m^{-2}), v_a is the sound velocity (m·s^{-2}), and the Q/ρ_0 term (s^{-2}) is that captures mass loss due to sound wave-medium interaction. Using Eqs. (6) and (7), the equation captures the spatial and time dependence of linear acoustic pressure profile is derived:

$$\nabla \cdot \left(\frac{1}{\rho_0} \nabla p_a \right) - \frac{1}{\rho_0 c_0{}^2} \frac{\partial^2 p_a}{\partial t^2} + \nabla \cdot \left[\frac{1}{\rho_0} \left(\frac{4\mu}{3} + \mu_B \right) \nabla \left(\frac{1}{\rho_0 c_0{}^2} \frac{\partial p_a}{\partial t} \right) \right]$$
$$= -\frac{\partial}{\partial t} \left(\frac{Q}{\rho_0} \right) + \nabla \cdot \left[\frac{1}{\rho_0} \left(\frac{4\mu}{3} + \mu_B \right) \nabla \left(\frac{Q}{\rho_0} \right) \right] \tag{8}$$

This equation is used for solving for the pressure distribution across finite elements. The solution types to the acoustic transmission problem include:

- *Mode solutions*, in which eigenmodes of the system are found.
- *Harmonic solutions*, in which sound pressure level and power distribution at each junction is found. This helps understand the sound transmission loss spectrum of a laminated windshield glass. ▶ Chapter 84, "Design and Modelling of High-Strength, High-Transmission Auto Glass with High Sound Transmission Loss" (Onbasli, this volume), we focus on harmonic solutions.

- *Transient solutions*, in which time evolution of the spatial dependence of sound pressure or acoustic energy density profile is solved.

2.2.3 Material Properties

The material properties that govern sound isolation simulations include mass density, sound speed in the material, and dynamic viscosity. Dynamic viscosity is defined as $\eta = F/(A \times SR)$, where F is force, A is area, and SR is the shear rate. Dynamic viscosity is a term in units of Pa·s and it introduces dissipative effects and sound absorption losses, which is maximized for high sound transmission loss applications.

Sound wave propagation in air is modeled as a nonuniform ideal gas and differently than in glass. The spatial and temporal evolution of sound waves in air is described using Eqs. (9), (10), and (11):

$$\nabla \cdot \left(\frac{1}{\rho_0\left(\overrightarrow{r}\right)} \nabla p \right) - \frac{1}{\rho_0\left(\overrightarrow{r}\right) c^2\left(\overrightarrow{r}\right)} \frac{\partial^2 p}{\partial t^2} = -\frac{\partial}{\partial t}\left(\frac{Q}{\rho_0\left(\overrightarrow{r}\right)} \right) \tag{9}$$

$$c^2\left(\overrightarrow{r}\right) = \gamma R T\left(\overrightarrow{r}\right) \tag{10}$$

$$P_{state}\left(\overrightarrow{r}\right) = \rho\left(\overrightarrow{r}\right) R T\left(\overrightarrow{r}\right) \tag{11}$$

The solutions to the acoustic wave equation strongly depend on the boundary conditions and how they are defined (i.e., Dirichlet, Neumann, or mixed). The boundary conditions in acoustics are defined as follows:

- *Perfectly matched layer boundary (PML)*: absorbs incoming pressure waves
- *Sound-hard surface*: A surface on which particle normal velocity is zero (or Neumann boundary with $\widehat{n} \cdot \nabla p = 0$)
- *Sound-soft surface*: A surface on which sound pressure is constrained (also known as Dirichlet boundary, where $p = p_0$ fixed pressure)
- *Mixed boundary*: The surface whose frequency-dependent wave transmission properties are modeled using a mixed impedance mismatch model, where acoustic impedance is defined as $Z = p/(vS)$, with p being pressure, v sound velocity, and S being the surface area.
- *Wave absorbing boundary conditions*: The domain or open medium is terminated with infinite, homogeneous, inviscid fluid (gas) and thus, outgoing propagating waves keep propagating outwards and do not reflect back.

Among these boundary conditions, radiation and absorbing fluid element boundaries are used for all types of analyses (modal, harmonic, and transient) and perfectly matched layers are used for harmonic analysis. In FEM, mesh sizes are typically chosen as $\lambda/10$–$\lambda/5$ where $\lambda = c_0/f$.

2.2.4   Definition of Sources

Depending on the application, the sound wave source is defined in different forms including incident pressure plane wave $P_{inc} = P_{inc,0}e^{j\varphi}e^{-j\vec{k}_i(\vec{r}-\vec{r_s})}$ and particle velocity $v_{n,f} = \frac{1}{\omega\rho_0}\hat{n} \cdot \vec{k}_i p_{inc}$. Here, the mass density and the sound speed in the given environment must be known to solve for sound transmission loss.

After the simulations are completed, sound pressure level and sound transmission loss are calculated:

$$SPL \; (dB) = 10\log_{10}\left(\frac{\sum_{i=1}^{N}p_i^2}{p_{ref}^2}\right) \tag{12}$$

Sound pressure level at the threshold of human hearing is 0 dB, which has the same pressure as the reference pressure, $p_{ref} = 2 \times 10^{-5}$ Pa. Here, p_i terms are pressures at the sampled frequencies. To calculate sound transmission loss, time-averaged sound power through an area S is calculated:

$$P_W = \frac{1}{2}\iint\limits_{S} p\vec{v}^* \cdot \hat{n}ds \tag{13}$$

$$\text{Sound transmission loss (TL) (dB)} = 10\log_{10}\left(\frac{P_{in}}{P_t}\right) \tag{14}$$

$$\text{Sound reflection loss (RL) (dB)} = 10\log_{10}\left(\frac{P_{in}}{P_{ref}}\right) \tag{15}$$

Sound transmission here is described in terms of reflected and transmitted fractions of incoming acoustic power. The transmitted acoustic power fraction is determined by each layer or mesh's acoustic impedance Z, which is defined as $Z = p/(vS)$, here, p is pressure, v is sound velocity, and S is the surface area. The reflections occur due to impedance mismatch between two dissimilar layers.

2.3   DFT- and MD-Based First-Principles Modeling

First-principles modeling provides an atomic scale description of glass structure, its surface binding properties, as well as the effects of each atomic dopant on the local electronic properties. Since density functional theory (DFT) is an approximate solution to the Hamiltonian describing the glass system, the electron density solutions are not strictly exact solutions. Nevertheless, DFT solutions provide accurate enough predictions for the electronic properties including band structures and gaps as well as the equilibrium structure. While DFT models can only describe the structure and electronic properties within a few nanometers at most, molecular dynamics (MD) models could describe the physical movements of atoms and

molecules within a few tens of nanometers. In these models, the positions of the molecules are first initialized according to the configuration of interest (i.e., an interface) and then force distributions are then calculated based on the potential profile originating from the electrostatic or other force field-profiles of molecules. Based on the force fields, the positions of the molecules are updated within a step size of Δt by accounting for the acceleration that molecules acquire. Such iterations are repeated successively until the structure converges to an equilibrium distribution of molecules. By developing more accurate force fields, one may describe the behavior of glass molecules and their interactions with organics, fluids, or other classes of materials as a function of time and different constituents.

In glass modeling, one application that has immediate technological application is organic/glass adhesion. In this application, the organic, such as polyimide, needs to bind on glass with sufficient strength (i.e., large enough binding energy), but the organic layer must later be easy to peel away without damaging the glass surface. As a result, the binding energy must also be low enough for practical peeling forces. ▶ Chapter 83, "Fundamentals of Organic-Glass Adhesion" describes this challenge and presents DFT and MD-based numerical solutions to organic/glass adhesion.

The models for characterizing adhesion are developed at two different scales: electronic (DFT) and atomic levels (MD). While DFT-based approaches are rigorous and more accurate, they are computationally more expensive than MD-based solutions to the adhesion problem. While MD-based solutions are less accurate than DFT-based electronic structure solutions, longer time- and length scales are accessible using MD. By employing a multiscale approach, the effect of polymer chemistry, polymer rigidity, structure of inorganic substrates, and inorganic surface attributes such as the role of hydroxylation and surface roughness can be studied. The key aspect that allows the multiscale approach is the potential energy profile between the organic and glass interface. The Interface potential consists of Lennard Jones and Columbic interactions as nonbonded interactions, harmonic bonds to mimic covalent bonds, and harmonic angles to model the structure of polymers more accurately. One major example is the PCFF-interface potential, which is an extension of the well-established PCFF potential:

$$
\begin{aligned}
E_{pot} = {} & \sum_{ij, \text{nonbonded } 1,2 \text{ and } 1,3 \text{ excluded}} \varepsilon_{ij} \left[2 \left(\frac{\sigma_{ij}}{r_{ij}} \right)^9 - 3 \left(\frac{\sigma_{ij}}{r_{ij}} \right)^6 \right] \\
& + \frac{1}{4\pi\varepsilon_0} \sum_{ij, \text{nonbonded } 1,2 \text{ and } 1,3 \text{ excluded}} \frac{q_i q_j}{r_{ij}} + \sum_{ij, \text{bonded}} k_{r,ij} \left(r_{ij} - r_{0,ij} \right)^2 \\
& + \sum_{ijk, \text{bonded}} k_{\theta,ijk} \left(\theta_{ijk} - \theta_{0,ijk} \right)^2
\end{aligned}
$$

$$(16)$$

MD-based modeling focuses on physisorbed systems consisting only of non-bonded interactions between the organic and glass interface. Hydrogen bonding,

surface roughness, electrostatics, and the flexibility of organic molecules affect adhesion significantly. This result was also found to be consistent across length scales for polymers ranging from molecular fragment scale to full polymer film thickness. Based on such MD models with more accurate force field descriptions, one may capture both the dynamics, kinetics, and the chemical interaction between different molecules and glass. Such models have significant applications in engineering and optimizing the functional performance of organic/inorganic multilayers as they are becoming ubiquitous in smartphones and other embedded electronic devices.

3   Open Challenges in Glass Modeling and Design

Owing to the range of emerging technological applications of glass ranging from smart windows, smartphones, ultra-strong and ductile (metallic) glasses, and biocompatible glass surfaces and containers, new glass chemistries and processing capabilities must be developed. In this quest, multiscale modeling as well as fundamental physical models are going to continue to deliver many insights into the intrinsic mechanical, structural and rheological properties of glass and how glass surfaces interact with organics of different molecular structures and polarities, metals and other kinds of materials. From a glass composition engineering standpoint, developing streamlined machine learning models and experimental datasets for training these models for different chemistries are necessary for more accurate predictions. Below, we present and briefly discuss some of the open questions in glass modeling.

Data-driven models for new glass compositions with optimized mechanical, optical, electronic, acoustic, surface, and rheological properties: While the chapter presented in this section focuses on the rheological and mechanical properties, many other key properties could be improved by developing new glass chemistries through a data-driven optimization approach. These properties include surface conductivity, microwave transmission, impedance matching, as well their simultaneous optimization with optical transmission and mechanical properties.

Merging fundamental physical insights with data-driven approaches: Data-driven approaches can span large composition spaces owing to dimension reduction techniques such as PCA and ICA without compromising accuracy significantly. Since this approach is highly coarse-grained, the effects of defect chemistry as well as thermal history may not necessarily be captured properly. Therefore, insights on defect and constituents from fundamental physical models such as molecular dynamics and DFT need to be incorporated into genetic algorithms and NN models. There are multiple ways to incorporate fundamental insights into the models. The first way could be training the models with a narrower range of chemistries and their corresponding properties such that the effects of small concentrations of dopant oxides could be captured more effectively. The second way could be training the NN models with different kernel functions that actually resemble the physical behavior such as thermal activation, rectified linear, or other mechanisms. The third way

could be directly applying GA and NN models to fundamental physical models for high-throughput prediction of glass chemistries and their properties of interest. Instead of training with experimental data sets, which are expensive to acquire, the results of ab initio models could be used for training NN models and predicting the properties of vast composition spaces. Iterative NN and DFT/MD model building helps identify the physical mechanisms and new chemistries that may lead to optimized glass properties. Optimized chemistries predicted from NN models could be studied in greater detail using DFT and MD to elucidate the new physics yielding superior glass properties.

Nontraditional glass chemistries: Glass industry specialized on borosilicate glasses, but there are many other new chemistries with potentially higher mechanical, thermal, optical, and functional performance. Bulk metallic and chalcogenide glasses have attracted significant research interest due to their unique functionalities. Metallic glasses have brittle-to-ductile transition, which yields increased fracture toughness. Chalcogenide glasses have unique optical properties for infrared bands. Since the length- and timescales relevant for these glasses can span more than nine orders of magnitude, molecular dynamics or other approaches are not feasible for metallic and chalcogenide glasses. Data-driven approaches could help identify the compositions that can optimize multiple functionalities.

Finite element modeling with improved constitutive relationships: Constitutive models help capture the novel physics and the micromechanical behavior that enables high strength and high ductility in emerging metallic glasses. The constitutive models, once implemented in a finite element program as user subroutines, can be used for guiding material, product, or process designs. This capability is one of the most remarkable advantages in the continuum mechanics modeling that is unmatched by experiments and atomistic simulations. Finite element modeling could be used for designing metallic glasses for high ductility, strength, and toughness at room temperature and optimizing the net-shape forming processes of metallic glasses at high homologous temperatures.

Modeling adhesion of physisorption of nanometer thick polymers on glass across larger length- and timescales: As inorganic/organic interfaces are becoming ubiquitous in the glass world, the bonding chemistry at the interface needs to be understood in atomic scale detail using DFT-based calculations. Due to the computational cost of DFT, the length scale of models cannot exceed a few atoms. As a result, DFT-based models cannot provide microscopic description of inorganic/organic interfaces. As a result, microscopic factors such as surface roughness, steric effects which are nonbonding interactions that influence the molecule shapes and reactivity cannot be described. Although force fields such as ReaxFF and INTERFACE are used to describe the chemistry, the parameterization is still a demanding task. As a result, new force fields which are computationally inexpensive and which can capture bond chemistry with electronic structure accuracy are needed for a wide variety of functional organics on glass and other inorganic materials.

there is no physically predictive model. There are requirements imposed on the end properties of glass and manufacturability requirements such as appropriate liquidus temperature and sufficiently low viscosity at a given temperature. These competing requirements necessitate the development of data-driven machine learning models of glass composition and properties. These models enable accurate and systematic prediction of glass properties such as Young's moduli and liquidus temperature. Research companies with long track records of exploratory experimental research are in unique position to develop data-driven models by compiling and using their earlier internal experimental results. In this chapter, we present how Corning used this unique advantage for developing neural network and genetic algorithmic models for predicting compositions that would yield a desired liquidus temperature and Young's modulus.

1 Introduction

Glass is a transparent and non-crystalline inorganic material used in virtually all aspects of human life, and it is a key enabler for our civilization. Glass can be manufactured in sheets, wires, fibers, or arbitrary forms. The growing need for highly functional, manufacturable, and inexpensive glasses has prompted glass researchers to engineer glass compositions using almost the entire periodic table. As a result, state-of-the-art commercial glass may contain more than eight different oxides and substituents with desired weight fractions. In glass composition and property engineering, each of these constituents significantly influences the structural, rheological, thermal, and mechanical properties. These properties are critical for display applications. For different glass applications, the desired glass properties are different, and glass composition must be engineered accordingly. In addition, rheological and thermomechanical properties of glass affect the fusion draw rates in production and ultimately determine glass production throughput and yield. As a result, for low-cost and high-volume manufacturing of glass, rheological (viscosity) and thermomechanical properties (liquidus temperature, Young's modulus) must be engineered simultaneously through glass composition. Sometimes, the manufacturability requirements and end property requirements may pose competing constraints on glass composition. As a result, engineering glass composition becomes a complex multi-objective optimization problem for which a physics-based predictive solution is not currently available.

Traditional glass research have been using experimental trial-and-error approach for improving glass properties through composition engineering and measuring the properties of each new composition. Corning Glass Research also have been investigating the mechanical, optical, rheological, and other properties of glass samples as a function of glass composition over more than a century. As a result, Corning accumulated a vast internal glass composition-processing-property database. Since a fully physics-based solution is not currently available for designing new glass compositions and since experimentally spanning and testing the entire composition space is prohibitively expensive and time-consuming

for consumer electronics and other major display glass applications, Corning started developing data-driven machine learning models to accelerate glass and ceramic materials engineering. As data-driven models require a reliable set of glass composition, processing and property data, Corning is in a unique position to draw from its century-old glass research data (Sullivan and Taylor 1919) and build machine learning (ML) models. Such models enabled Corning to accelerate glass research significantly. A detailed description of Corning's glass research achievements has been presented in Tandia et al. (2019) and Mauro et al. (2016).

In this chapter, we present how data-driven models can be developed for accurately predicting display glass properties for given compositions. In particular, we present neural network-based composition models for predicting glass liquidus temperature and genetic algorithm-based glass models for predicting Young's moduli for given compositions. The liquidus temperature is a key property which must be known for the given composition to prevent the formation of crystalline phases during fusion draw and high-volume production of display glass. Young's modulus is a key stiffness metric that must be engineered for display applications. Using both linear and nonlinear data-driven models, we demonstrate how material properties can be accurately predicted and optimized.

Corning developed extensive expertise on functional glass compositions and properties that span tough, strong, and ultralow CTE (coefficient of thermal expansion) borosilicates with different dopants and tunable glass transition temperatures to different fusion draw rates for controlling production throughput and yield. Publicly available inorganic materials databases and high-throughput screening of materials (Curtarolo et al. 2013; Pilania et al. 2013; Potyrailo et al. 2011; Xiang et al. 1995; Mueller et al. 2015) mainly focus on crystalline materials studies. Therefore, a combination of glass manufacturing parameters and composition-property relationship data must be used from Corning's internal database for reliable modeling. The data analysis and prediction methods as well as composition and process information presented herein are intended to describe some of Corning's research and to guide the readers in doing similar data-driven studies on different materials databases. Corning's internal database, which was used for this study, includes composition, property, and process parameters. These properties include experimental characterization results on the structural (topology and defect structure, stoichiometry, microstructure), electrical, thermomechanical (glass transition temperature, viscosity, fictive temperature), and mechanical properties (elastic modulus, stress-strain profile) of different glass compositions at different temperatures.

The chapter continues with Sect. 2, which is an overview of methods necessary for building data-driven models. The methods section is a tutorial on initial data modeling (unsupervised learning, cluster analysis, and regression), genetic algorithms (GA), and neural networks (NN). Next, in Sect. 3, the data-driven models are presented. In the first part of Sect. 3, neural network-based composition models for predicting glass liquidus temperature are presented and discussed. In the second part of Sect. 3, genetic algorithm-based glass models are presented for predicting Young's moduli for given glass compositions. Finally, in Sect. 4, new glass and other materials discovery opportunities with data-driven approaches are discussed.

The next section describes the materials modeling methods used for predicting new glass compositions.

2   Methods

In this section, the methods used for predicting glass properties from glass compositions are presented in four major steps (Dreyfus 2004): data consolidation and cleaning, initial data modeling, genetic algorithms, and neural networks. These statistical learning methods provide the basis for developing data-driven models for predicting properties for a given glass composition.

Data consolidation and cleaning: The predictive accuracy and robustness of any data-driven model depends on the accuracy and quality of the input data. In order to build the models in this study, proprietary Corning glass composition and property relations have been used. The predictive models for compositional and mechanical properties of glass use training, validation, and test data sets. These data sets are Corning's proprietary experimental data drawn from decades of glass composition research. Weight or atomic or molar percentages of each oxide constituting glass were used for training data set. For outputs, the viscosities η, Young's moduli E, glass transition temperatures T_g, densities ρ, as well as the liquidus temperatures T_L are stored. At Corning Glass Research, the composition experiments were done at different dates and by different staff. For each sample, an extensive sample preparation record (date, time, technician name, furnace name, process monitor parameters) is saved. On a later date, characterization reports (one for each of mechanical, electrical, chemical, rheological properties) have been recorded. These records were accumulated over multiple years, and many reports were entered manually into digital records. This step has been one of the most time-consuming aspects of the model as an automated processing for thousands of such reports was impossible. The reports had also gaps in entries and a data cleanup procedure needed to be developed. The data cleanup is an iterative process that is updated as more data were entered into the system.

Corning's earlier glass composition development experiments focused on refining composition toward improving the glass properties for a specific product at the time. Some products required specifications related to mechanical properties such as Young's modulus. The experiments then focused on Young's modulus and relevant mechanical properties. If a glass sample with a given composition fails to be within Young's modulus threshold, no further experiments were done on that sample and the other mechanical, chemical, or rheological properties of glass were not recorded. These missing entries must be handled either by using statistical methods such as interpolation of Young's modulus values between glasses with similar compositions or simply by ignoring the entire sample's data row. If the model requires numerous rows of missing entries (i.e., predicting viscosity without density or temperature or other relevant data), then the samples with missing rows are needed to be ignored. If the model results can have strong dependence on the preprocessing procedures for filling in the gaps, then the model is likely not going to be accurate. As a result,

the model accuracy was determined during these data curation steps long before the actual model parameters or architectures were determined. In each of these data consolidation and cleanup steps, the purpose is to keep reliable and accurate data and minimize useless data while preserving similar naming conventions.

2.1   Initial Data Modeling

Unsupervised learning is a group of initial algorithms used for input data sets without labeled response variables (i.e., properties). These algorithms allow a "divide-and-conquer" strategy for distinguishing misbehaving or outstanding data entries (if any). In addition, unsupervised learning methods help group different composition types and classify and predict based on their generalized behavior. For instance, this could be a systematic dopant dependence study of coefficient of thermal expansion (CTE) in alumino-borosilicate glasses within a more controlled and lower-dimensional composition space. Below, we describe cluster analysis, principle component analysis, and regression methods. These methods could be used to identify subgroups in the data sets to assess generalization capabilities of models.

Cluster analysis: The glass composition data could consist of more than ten dimensions where some parameters such as dopant fractions were systematically varied. Since manual identification of systematic variations in the input space is not feasible, a classification algorithm based on unsupervised learning has been used. This method is also known as feature selection. In unsupervised learning, one first calculates the proximity and similarity between each data point in the data and then defines a criterion function to maximize the quality of clustering based on the proximity and similarity metrics. Finally a clustering function is computed such that its values satisfy the criterion function for all data points when mapped to each data point in the data. These steps were followed to cluster experimental data:

1. Assemble composition-property database with composition entries, CTE, Young's moduli, and viscosities.
2. Normalize CTE, Young's moduli, and viscosity scales.
3. Describe a proximity criterion function (i.e., function whose output depends on the distance between data points) (Ullman et al. 2016).
4. The function gives numerical category values based on separation thresholds.
5. Customize the clustering function thresholds based on the desired properties and iterate until classification converges.

Here, we define a cluster as a collection of data point with "similar" features (i.e., composition, property, chemistry, etc.), and dissimilar data items are grouped under different clusters. Since the values in the glass composition data span more than 15 orders of magnitude, their absolute values cannot be directly used. For instance, there are significant scale differences among parameters such as CTE (10^{-7} to 10^{-6} $(°C)^{-1}$) and weight percentages (10^{-5}–10^{-1}) and Young's moduli ($\sim 10^{11}$ GPa) and

viscosities (10–10^5 Pa·s). In order not to cause one column to dominate distances based on their absolute values, each value is normalized to index values before calculating the distances. A conversion formula is defined in the beginning for each property or column for converting these normalized values back to their original scales. After normalization, the distances between each data point can be found either using Euclidean distance, which is translation-invariant, or using Manhattan distance or their generalized version which is Minkowski distance as discussed in more detail by Tandia et al. (2019) and Mauro et al. (2016).

After distances are calculated, similarity indices can also be calculated to specify if compositions are nearly identical. Then, a criterion function needs to be defined to set the rules for distinguishing different clusters. For instance, this function can impose multiple specific conditions, such as eliminating hazardous dopants like lead for a given application or requiring lead for an x-ray shield glass application ($x_{Pb} > 10^{-6}$), and impose distance threshold conditions based on overall calculated separations or material property differences (high versus low viscosity samples, etc.). The definitions of the clustering criteria are the points where materials engineering and specifications for the given application may also be built into the models. Since models can later be trained with subsets of clusters, one may filter for data in model training and testing stage as well. After defining cluster criteria, a clustering function is calculated such that all data entries are grouped to satisfy the criteria. This clustering function can be implemented with MATLAB, R, or Python. The clustering algorithms can be grouped in three types: hierarchical, partitional, and Bayesian. In the hierarchical approach (i.e., inductive method), each data row can start as a separate cluster, and based on differences and distance criteria, clusters can be merged. In the divisive hierarchical approach (i.e., deductive method), all data rows belong to one cluster and can then differentiate based on distance criteria and similarity metrics. The details of these algorithms are presented by Tandia et al. (2019) and Mauro et al. (2016).

While implementing clustering algorithms, one must make sure that the clusters are not sensitive to random seeds. Cluster analysis should be repeated sufficiently many times to prevent different random seeds from altering the way the data are clustered. In addition, outlier data points from this clustering calculation can be separately analyzed by glass scientists. These points could be removed from analysis to prevent any unintentional bias in cluster centroids. Visualization methods may help in reporting clusters and identifying outliers.

Principal component analysis (PCA): PCA is a dimension reduction technique that allows omitting variables, which do not have significant effect on the desired glass property (Jolliffe 2002; Ringner 2008). This method uses an orthogonal mathematical transformation on data to convert a mapping of possibly correlated variables into a set of values of linearly uncorrelated variables called principal components. The number of principal components is less than or equal to the number of original variables. The first principal component has the largest possible variance, and every next component has progressively lower variances. The output of PCA is a set of vectors transformed out of the original data. These vectors form an

uncorrelated orthogonal basis set. As variances depend on the absolute mean values of each variable, PCA output vectors strongly depend on the relative scaling of the initial variables. Therefore, normalizing each variable is essential before running PCA calculations.

One can view PCA as fitting a multidimensional ellipsoid to the data. The axes of the ellipsoid are called principal components. Whenever the data have weak dependence on an independent variable, the variance with that variable is small, and the corresponding axis of the ellipse is small. As a result, ignoring that variable of **ellipsoid** is not going to cause a significant loss in information. Instead, this simplification reduces the number of variables and reduces the eventual model complexity. The detailed steps for implementing PCA are presented by Tandia et al. (2019).

After PCA, one can define a variance threshold for an eigenvector to be accepted as significant and pick only the eigenvectors with variances above the threshold. This threshold step helps researchers determine the most significant variables in a glass composition project and focus on cluster analysis using those fewer and more important variables (Kullback and Leibler 1951; Kullback 1959). While PCA reduces computational costs, consider the following limitations of PCA in initial data processing:

1. **Initial data scaling has strong impact on PCA vector variances:** The relative ranges and absolute values of each variable can distort the PCA ellipsoid and alter the covariance matrix. The principal components must be normalized properly to avoid such distortion.
2. **PCA relies on linear variances:** PCA cannot capture information gain from variables which have complex nonlinear correlations. As a result, PCA may add spurious variables. Nonlinear correlations must also be considered.
3. **PCA may fail at blind signal separation cases:** PCA assumes that when a variable has a large variance, the variable is going to have low covariance hence high importance. This assumption helps eliminate the noise and pick up the major variables. In specific problems called blind signal separation (or blind source separation) however, multiple signal sources can have almost equally significant effects and lead to a mixed signal response. In such multiple source effects that may lead to competing driving forces, one must run an independent component analysis (ICA) in addition to PCA.
4. **Mean and covariance do not describe some distributions:** Mean and covariance values generally describe Gaussian distributions, but there are many common statistical distributions in which mean and covariance do not describe the distribution functions. Other ways of testing significance of variables such as information gain analysis (also known as Kullback-Leibler divergence or Gram-Schmidt) must also be used.

Regression analysis: Since PCA may fail to capture nonlinear correlations among variables, regression analysis is necessary to distinguish if there are hidden

complex dependencies. In regression analysis, the conditional expectation (E(X|H) of variable X given H) is estimated when the independent variables are given. In other words, either a generalized linear model is constructed by using a multivariable linear superposition of independent variables or a least squares fit is solved numerically among variables to identify if there is a nonlinear correlation. Most common regression methods are presented below:

Multivariable linear regression: This is a generalized linearization method that assumes one or more independent variables:

$$Y_i = \alpha_0 + \alpha_1 X_{i1} + \alpha_2 X_{i2} + \cdots + \alpha_n X_{in} + \epsilon_i,$$

where X_{i1} to X_{in} are independent variables and ϵ_i is an error term which is minimized until the optimal set of regression coefficients α_0 to α_n are found. These coefficients also indicate the relative significance of each independent variable.

Least squares regression model: This fitting model assumes a sophisticated nonlinear correlation between variables. As no closed-form solutions are assumed, one may pick a Taylor expansion or a different basis set to fit the dependent variable behavior by minimizing the sum of the squared residuals S:

$$S = \sum_{i=1}^{n} (y_i - f(x_i, \beta))^2$$

Domain expert interpretation of statistically identified causalities: Although correlations can be identified using regression analysis, identifying causality requires an extra layer of physical interpretation by glass scientists. Linear and nonlinear regression models can be implemented in MATLAB, R, or Python.

Genetic algorithms: Genetic algorithms (GA) are methods for solving constrained optimization problems based on an evolutionary natural selection process. In a classical numerical solution algorithm (i.e., Newton's method solving the zeros of equations), one generates a single point at each iteration. The sequence of points progressively approaches the solution. In GA, instead of iterating only on one point, a population of points are generated at each iteration and the best point in population approaches the solution.

A fundamental difference between classical algorithms and GA is that in GA, the next population is generated using random number generators and some combinations from the best solutions of the previous iteration instead of deterministic computation. GA are useful for accelerated global optimization problems where there are multiple objectives with competing requirements. GA can also be used for maximization, minimization, constrained optimization, multidimensional fitting, classification, and prediction problems. In this chapter, glass models are optimized with respect to multiple competing objectives. As a result, GA are particularly beneficial for composition development. Below is a description of a simplified GA for solving a generic multi-objective optimization problem:

1. The GA generates a random initial population of glass compositions.
2. The GA then evaluates the glass composition population based on their predicted properties and the fitness values:
   (a) Scores each composition of the current population by computing its fitness value and normalizing these scores for comparisons.
   (b) Picks a few candidates from the population (parents) based on their fitness.
   (c) Some of the individuals in the current population that have lower fitness are chosen as elite. These elite individuals are passed to the next population (children).
   (d) Children are produced either by making random changes to a single parent (mutation) or by combining the vector entries of a pair of parents (crossover).
   (e) Replaces the current population with the children to form the next generation.
3. The GA then creates a sequence of new populations. At each step, the GA uses the compositions in the current generation to create the next population.
4. The algorithm stops when the output meets the stopping criteria. The stopping criteria may include a maximum number of generations, time limit for iterations, fitness limit for population (when the fitness function for the best point in the population is less than or equal to the fitness limit), and marginal change limits per generation (i.e., when the average change over each generation is less than a functional tolerance limit). GA can be implemented in MATLAB, R, and Python.

Neural Networks: Neural networks (NN) are a set of machine learning algorithms (supervised or unsupervised) that can be used to predict nonlinear behavior of different systems. A neuron is a nonlinear and parameterized function of input variables. Therefore, a neural network is the composition of nonlinear functions of two or more neurons. The nonlinearity of neural networks can help model nonlinear behaviors that may not otherwise be captured properly in regression models or other linear techniques such as PCA. Despite the biological flavor of the term neural network, neural networks in machine learning are pure mathematical constructs that consist of either feedforward or feedback networks (recurrent). For glass modeling, we focus on feedforward networks.

A feedforward neural network (static network) is a nonlinear function of its inputs and their corresponding weighting parameters. So a feedforward network consists of functions of its neurons which are nonlinear functions of inputs.

Figure 1 shows a representation of a feedforward neural network in which information flows only in forward direction. In this graph, the vertices are the neurons, while the edges are the connections. Different from feedback networks, feedforward NN have a noncyclic graph topology. The neurons at the outputs are called output neurons, and the rest of the layers between the inputs and the output neurons are hidden networks. In an optimized NN model, a sequence of neurons may also yield physical insight about a given physical parameter and help develop physics-based models later.

Feedforward networks are static and their outputs are constant when their inputs are constant. A mathematical representation of the single-layer static network in Fig. 1 that uses nonlinear sigmoid activation functions is:

Fig. 1 Feedforward neural network, which consists of multiple n inputs, N_c hidden neurons and N_o output neurons

N inputs   Hidden   Output
                  neurons   neurons
$$g\left(\mathbf{x}, \mathbf{w}\right) = w_{N_c+1,0} + \sum_{i=1}^{N_c} \left[w_{N_c+1,i} \cdot \tanh\left(\sum_{j=1}^{n} \left(w_{ij}x_j + w_{i0} \right) \right) \right]$$

where $\mathbf{x}$ is the input vector (size: n elements) and $\mathbf{w}$ is a vector of size $(n + 1)N_c + (N_c + 1)$. The hidden neurons are numbered from 1 to N_c, and the output neuron is indexed as $N_c + 1$. The parameter w_{ij} is assigned to a connection from neuron (or input edge) j to neuron i. The output function g(x,w) is a linear function of the parameters in the last connection layer (between the final hidden layer to the output neuron), and the connections between the inputs and the hidden layers are nonlinear functions of the inputs. In g($\mathbf{x}$, $\mathbf{w}$), the activation function is a hyperbolic tangent although other activation functions such as step, linear, sigmoid, rectified linear, and exponential functions can be used.

3   Data-Driven Development for Glass Composition Design

The design of glass compositions for a targeted application is a long process due to many product specifications and the manufacturing technology. Glass specifications vary among different applications. Many customer requirements for display glasses include strain point (SP), annealing point (AP), softening point (SfP), coefficient of thermal expansion (CTE), density, Young's modulus (E), dimensional stability, and fracture toughness (FT) for strengthened glasses. Corning Incorporated use the fusion draw technology to deliver surface pristine glass products. This technology imposes manufacturability requirements for a given glass composition. Some of the most important ones are the liquidus temperature, the viscosity at the liquidus temperature, and the temperatures at 20 Pa·s and 3500 Pa·s.

Glass composition design can be posed as a multi-objective optimization problem with constrains on the sum of the variables (different oxides that make up the glass

composition) and the range of each variable (oxide). One objective function for each attribute can be given as a range (70 GPa $\leq$ E $\leq$ 85 GPa) or lower-bounded range (AP $\geq$ 800 °C). Corning's proprietary glass composition and property database developed over many years span key constituents, and linear regression models are used whenever existing experimental data may coincide with the desired properties. For conflicting constraints or nonlinear material behavior, nonlinear optimization and machine learning models must be used.

Liquidus temperature (T_L) and viscosity are two important properties for glass design. T_L of glass is defined as the temperature at which the first crystalline phase precipitates from a glass melt of a given composition when it is cooled very slowly. The accurate knowledge of the T_L is critical for both glass property prediction and manufacturing purposes. During glass manufacturing using an isopipe, as used by Corning, knowing the T_L is important when the melt is flowing on the isopipe surface. The temperature of the melt can be maintained above the T_L of the melt to avoid its crystallization on the isopipe. If crystalline phases nucleate, the isopipe, which is a multimillion-dollar equipment, can be damaged. Depending on the desired sheet thickness, the melt must have a viscosity at the liquidus higher than a required threshold. This last requirement necessitates the accurate knowledge of the viscosity-temperature curve for the glass melt. Both T_L and viscosity-temperature curve are critical melt properties tightly related to the manufacture of surface pristine glass sheets when drawn from an isopipe. For display applications or for ion-exchange glasses for damage-resistant layer, the knowledge of the viscosity-temperature is also important for the final glass attributes or process parameters such as annealing temperature, softening temperature, or the viscosity at a given temperature. Despite the necessity for the knowledge of these parameters for industrial glasses in display applications, there is no known accurate or generalizable physics-based models for glass melt T_L or melt viscosity. Therefore, using Corning's large glass composition database and robust machine learning techniques, accurate predictive models for both liquidus and viscosity have been developed. In this chapter, we present the model development for T_L and Young's moduli. The viscosity model is presented in Springer Handbook of Glass as a separate chapter (Tandia et al. 2019).

One of the approaches to finding glass compositions that meet both material specifications and manufacturing requirements is to use a fine grid search on the composition space and compute each property at the grid. Developing accurate and robust ML models and running on this grid is the challenge addressed in this section. Most ML methods consist of many parameters. For neural networks, one has to optimize the number of layers, the number of neurons in each layer, and the functional form to use for the activation function for the most accurate predictions. Depending on the type of optimizer to be used, additional parameters such as learning rate and momentum need to be added in the list of parameters. For genetic algorithm, key parameters to optimize for during the model design are population size, different probabilities for crossover, and mutation, along with the fraction of new random solutions to be generated at each iteration. Optimizing the model parameters through an exhaustive search for the best architecture for either

the NN or GA is prohibitively time-consuming due to the parameter space size and due to continuous parameters such as learning rate. Although one can use Monte Carlo methods, i.e., randomly select values/states for the model parameters and run the decided number of simulations, one cannot guarantee that a global optimum can be achieved by random parameter selection. In this study, we use Bayesian optimization (BO), which is a method of finding the maximum/minimum of cost functions (Shahriari et al. 2016). BO is based on the Bayesian method to set up a priori over the model objective function and combine it with evidence to find the posterior function. BO is applicable to cases where we do not have a closed-form formula for the objective function, but where we can collect observations of the objective function.

In the following subsections, we describe the composition-dependent models for liquidus temperature and Young's modulus.

3.1   Neural Network-Based Composition Models for Predicting Glass Liquidus Temperature

The liquidus data used in this study were sampled from Corning's internal liquidus data, which represents a historical collection with clusters of different sizes. First, a neural network model for liquidus temperature was build using the whole data set. The initial liquidus model is built using the flowchart in Fig. 2. In model development, one needs to split data into training, validation, and test sets. Each subset must have a similar statistical distribution as the whole set. Methods such as Kullback-Liebler divergence can be used in testing if two distributions are different (i.e., divergence is 0 if statistical distributions are similar). The design of optimal neural networks architecture is going to be based on the incremental increase of

Fig. 2 Flowchart describing the steps for the liquidus model development
model complexity through more neurons in any given layer or an increase of the numbers of hidden layers. For each NN architecture with given parameters, a series of training steps are conducted. Next, the root mean square error (RMSE) and R^2 on the test set and validation set are recorded. R-squared (R^2), also known as the coefficient of determination, is a statistical measure of how close the experimental and predicted data are to each other. The optimal architecture is the one with the smallest number of parameters (least complexity) and for which the RMSE and R^2 are about the same for all three sets (training, validation, and testing). One may also systematically study the effect of the choice of the activation function for each layer in the NN as part of the optimization process, except the output neuron, which is kept as a linear activation function.

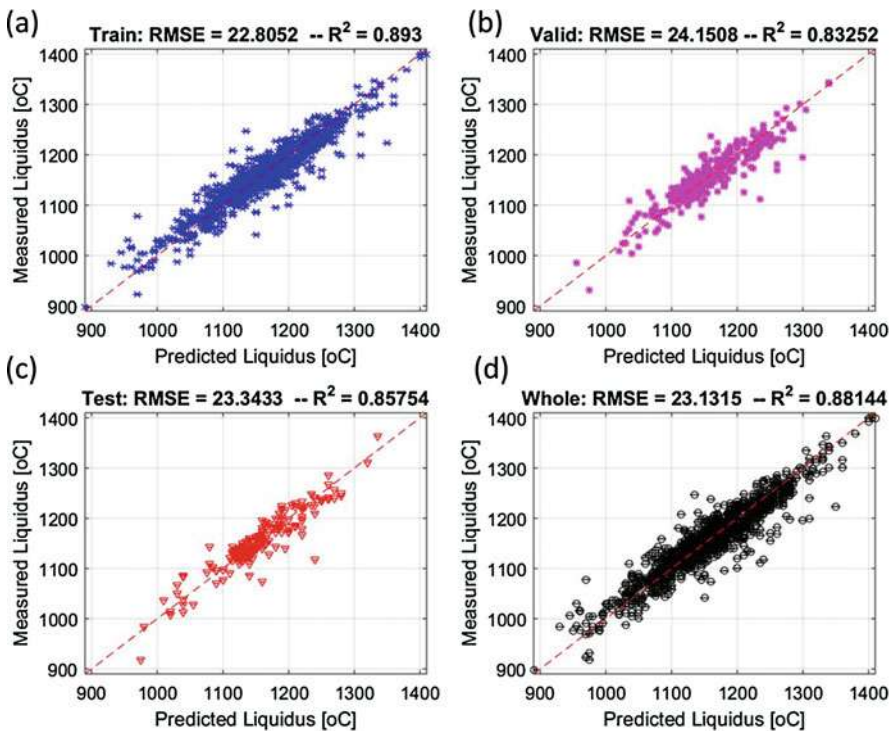
Once an optimal NN architecture is identified, the model is then trained for a few hundred times. The model is trained to increase the likelihood of finding a set of parameters that give an output set of parameters that minimize the objective function. For this training, we found that the optimal architecture has two layers (first, ten neurons; second, eight neurons), and both layers have a Gaussian activation function. On Fig. 3, a close look in the plot of the predicted liquidus for the test set suggests that there are points with high accuracy and others with low


Fig. 3 Best liquidus model based on the whole data set. RMSE on all sets are about the same but higher than the experimental values ($\sim$10 °C). (**a**) represents the training data, (**b**) validation data, (**c**) the test set or blind prediction, and (**d**) the whole data set

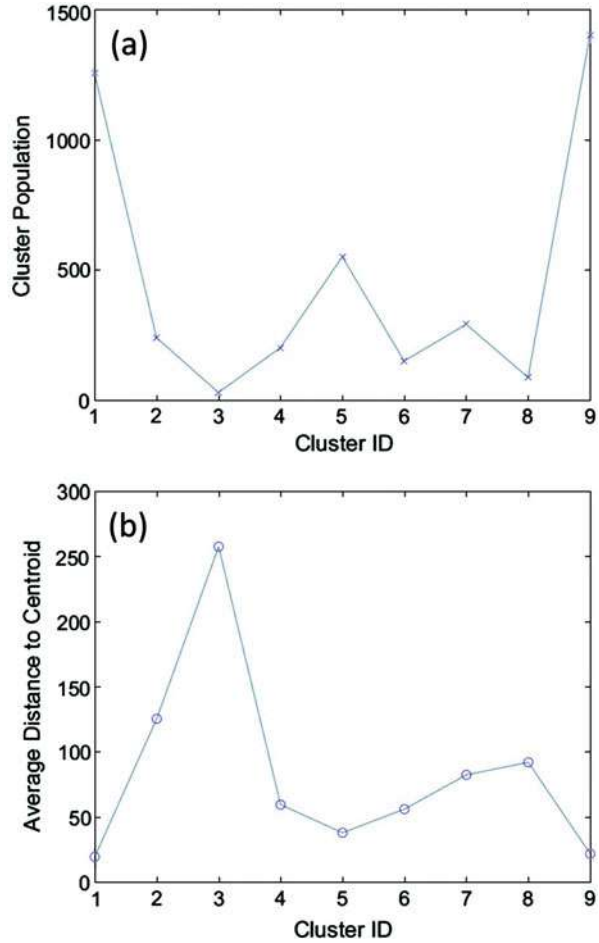
accuracy. Given that the original data is historical data and were not based on a design of experiments, one may expect that the original data might be a clustered data set.

We ran a k-means cluster analysis to better understand how the data are organized. Since we do not know a priori the number of clusters to consider, we will assume the number of clusters between 2 and 15. The choice of the optimal number of clusters to consider will depend on how well the chosen clusters separate from each other. This is determined by the similarity between elements of the same cluster. In 1986, Peter J. Rousseeuw defined a metric called silhouette, which is a robust way of interpretation and validation of regularity within clusters of data. The technique provides a concise graphical representation of how well each object lies within its cluster or how similar an object is to other members in its own cluster compared to other clusters. The silhouette ranges from −1 to 1, where a high value indicates that the object is well matched to its own cluster and poorly matched to neighboring clusters. If most objects have a high value, then the clustering configuration is suitable. If many points have a low or negative value, then the clustering configuration may have too many or too few clusters. The silhouette can be calculated with any distance metric. Average silhouette in each cluster for all 14 clusters we consider is plotted in Fig. 4. It appears that the data is best split in nine clusters. Further analysis of the different clusters shows the cluster's population.
Fig. 4 Average silhouette value for all 14 clusters considered in the k-means cluster analysis

Fig. 5 (**a**) Clusters population for liquidus temperature data set. (**b**) Average distance to centroid for all 14 clusters we considered in the k-means cluster analysis


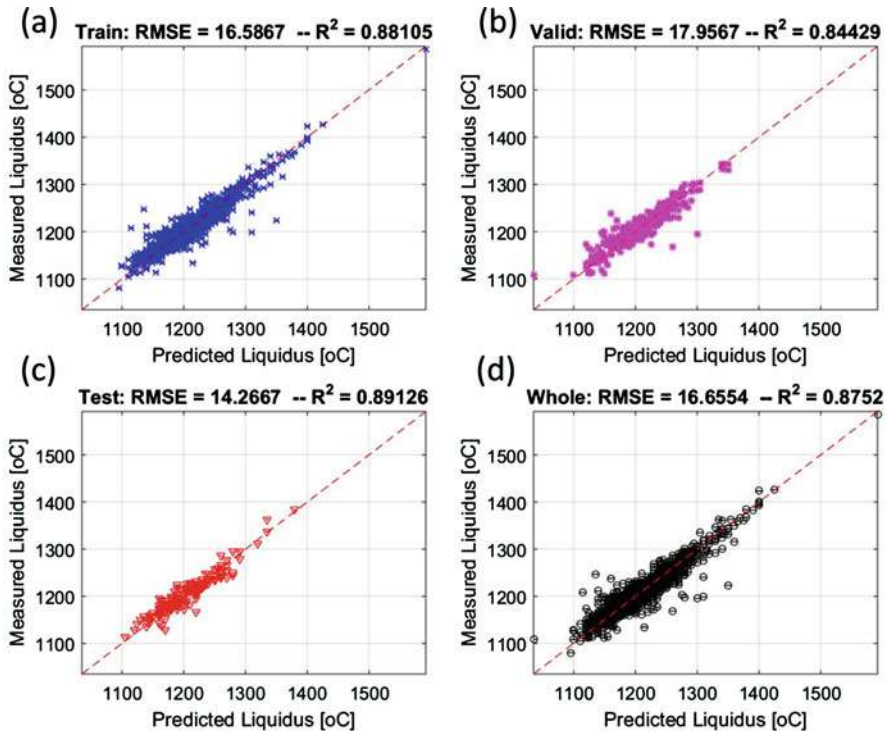
For the liquidus data, the clusters have different population sizes. In Fig. 5a, two clusters stand out with populations higher than 1100 compositions. The third largest cluster has about 500 compositions. The six remaining cases have populations lower than 300 compositions. Other than the cluster population, the average distance of a cluster population to the cluster centroid also characterizes the cluster. The smaller the average distance the more compact the cluster is. We observe in Fig. 5b that the two most populated clusters (1, 9) have the smallest average distances to their respective centroids. Being most populated and most compact, clusters 1 and 9 are suitable to be used for building localized liquidus models. Using the same procedure for splitting the data into training, validation, and test sets, we conducted a best architecture search for data in cluster 1. We found the same architecture as when we used the whole set although this is not necessarily the case for all cases.


Fig. 6 Best liquidus model based on the data in the largest cluster. RMSE on all sets are about the same, within few degrees of difference. They are higher than the experimental values ($\sim$10 °C) but much better than the RMSE we got when we used the whole data set to build a global model. (**a**), (**b**), (**c**), and (**d**) represent the training data, the validation data, the test set or blind prediction, and the whole data set, respectively

We see from Fig. 6 a significant improvement of the predicted liquidus temperature for the test sets. Over all the RMSE of the test set decreased significantly with the use of the largest cluster (14 °C), compared to (23 °C) when we used the whole data set. The liquidus model we built from the second largest cluster also has a lower RMSE on the test set (15 °C). To make liquidus temperature predictions from both models will require that the composition of interest to be a member of cluster 1 or cluster 9. This is very likely to be the case since these clusters are the largest ones in the set. When using this approach for designing glass compositions with low liquidus temperature, one has to start by selecting compositions that are only in cluster 1 or cluster 9 and then use the corresponding cluster based model to make the prediction.

We now consider a case in which we have many different models from N_c different clusters. One can consider an ensemble prediction which consists of building a model for each cluster, make a prediction from each cluster based model, and take the ensemble average computed as the mean predicted value. This mean

predicted value is the average from the cluster-based predictions over the distance from the composition of interest to the centroid of each cluster:

$$T_{Liq} = \frac{\sum\limits_{i=1}^{Nc} \frac{T_i}{d_i}}{\sum\limits_{i=1}^{Nc} \frac{1}{d_i}}$$

N_c is the total number of clusters for which we have built a liquidus model from, T_i is the liquidus predicted by the model built from cluster i, while d_i is the Euclidian distance from the point of interest to the centroid of the cluster i. The coordinates of the composition can be in mole percent (mol %), weight percent (w %), or atomic percent (at %) depending on the coordinates that was used to do the cluster analysis.

Based on the above model development description, optimizing the NN model architecture is tedious. We have searched for the best architecture by starting with a simple one-layer model with a small number of neurons, and we increase its size one or two neurons at a time for a fixed activation function. We increased the number of neurons depending on the ratio between the RMSE of the training and validation sets, which we want to keep close to one. At some point, we can insert a second hidden layer to resolve the nonlinearity of the liquidus temperature. Let us consider for a moment the number of variables we can play with in the design of the neural network architecture, without being explicit:

- Number of hidden layers (1, 2) and number of neurons in each layer (6 to 20)
- Activation function of each layer (tanh, sigmoid, inverse tangent)
- Learning rate (continuous number between 0.0001 to 0.1)

  Simulating all possible architectures is a prohibitively expensive computational task. Although one could randomly select a few architecture cases to run from the whole parameter composition space, there is no guarantee of having the optimal architecture in the selected cases. Ideally, one would like to find the optimal neural network architecture without having to run thousands of simulations. Bayesian optimization (BO) offers that possibility. In this step, by using BO, we rebuild a liquidus model by splitting the data into two sets: a training and a validation set. BO enables an accelerated optimization of the architecture with its modeling parameters such as the number of layers, neurons in each layer, the learning rate, and the activation function for each hidden layer.

3.2   Genetic Algorithm-Based Glass Models for Predicting Compositions for Desired Ranges of Young's Moduli

Young's modulus is a critical glass property for many different applications. When alkali-free glasses are used in the thin-film transistor manufacturing process, they are sought to have high Young's modulus to help reduce stress-induced distortions.

RMSE=11.9°C R²=96.4%
Fig. 7 Best liquidus model based on the validation set. Use of the Bayesian optimization framework helped improve the RMSE and the R^2 on the validation set

In Corning's design of glass compositions with native damage resistance, composi-tions with low Young's modulus are of critical interest. Glass compressive stress due to ion exchange is given by formula in which Young's modulus is a key contributor:

$$CS = \frac{BE\Delta C}{1 - \alpha}$$

B is the network dilation coefficient, E Young's modulus, ΔC an atomic concen-tration variation, and α the glass Poisson ratio. If everything is kept constant, the higher the Young's modulus, the higher the compressive stress CS.

The development of an accurate and robust model for Young's modulus is very important for glass composition design for different applications. The model's accuracy and robustness is important. Young's modulus was not measured for each glass that had been melted. This lack of systematic measurement led to scarcity of Young's modulus data. As a result, the extrapolation of any Young's modulus model can be a major challenge. Neural networks typically do not extrapolate very well when the input deviates too far from the training data. One cannot extrapolate over composition space as no composition-dependent physics-based model exists yet.

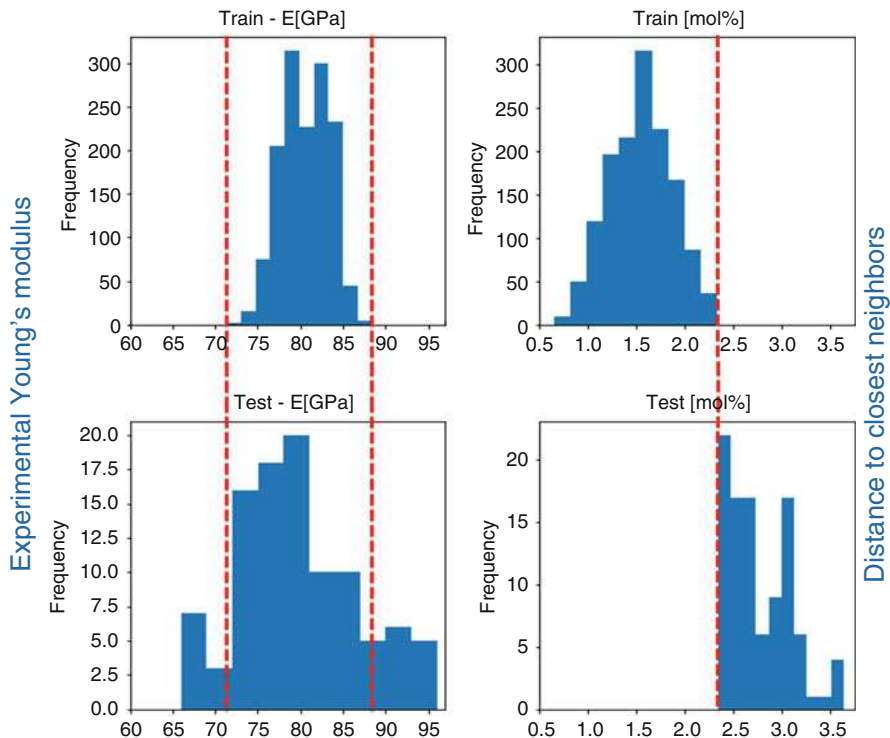
With proper parameter choices and optimization however, one can build genetic algorithmic models with much better extrapolation capability than neural networks. Genetic algorithms (GA) converge slowly, and many more iterations are required when building models. The model's accuracy and robustness depends on the size of the population under consideration and the number of trials. To build GA models,


Fig. 8 Modeling of Young's modulus with genetic algorithm. Horizontal axis on the right-hand side is for the distance to the closest neighbor in the whole set. Compositions we selected for the test set are the ones very far from their closest neighbors meaning the ones at the boundary. A look at their corresponding Young's modulus shows that they have higher Young's modulus

we used an in-house GA modeling tool similar to Python. Once we constrained the tool to simple models by penalizing complexity and large number of parameters of long and complex solutions, we find more accurate Young's modulus models, which extrapolate over the training data set. One extreme situation to build such models where to extract data that are at the boundary of the whole data set and use it as a test set for validation and selection of the best model (Figs. 7, 8, 9, and 10).

Overall, we see that GA makes very accurate extrapolated predictions. If we use the same data splitting with a neural network model, the results are not as accurate, as one can see in Fig. 11.

4   Conclusions and New Glass Modeling Opportunities

In this chapter, we presented an overview of glass material composition and property modeling based on GA and NN. These models were used to develop glass compositions that achieve low-cost and high-volume manufacturing and the desired
Fig. 9 GA makes good predictions for the compositions in the training set
Fig. 10 GA makes good predictions for the compositions in an extrapolated region

Young's modulus. By the end of 2015, Corning's damage-resistant glass products have been in over 4.5 billion devices including smartphones, tablets, smartwatches, automotive glass, and in interior architecture. Billions of display devices are expected to use Corning Gorilla® Glass as display substrates (Materials Innovation
Fig. 11 NN makes poor predictions for the compositions in an extrapolated region

Case Study 2016). Data-driven models for CS, as well as integrated computational materials engineering (ICME) approach that incorporated both materials design for performance and manufacturing-related models, are key ways to consider in design of glass compositions for damage resistance applications.

Using data-driven GA and NN models, one can predict and engineer glass liquidus temperature and Young's modulus as discussed in Sect. 3. Data-driven glass modeling and prediction allows researchers to accelerate the materials invention process by computationally screening tens of thousands of different chemical compositions and their corresponding predicted or measured properties.

For a display application with a desired set of glass property specifications, a database of materials properties must be constructed by using Corning's internal experimental database of glass compositions and structural, optical, mechanical, and rheological properties. Next, data simplification methods such as PCA, ICA, data cleaning, cluster, and regression analysis techniques should be used to identify the properties that have the most significant effects on the desired end properties. Finally, GA and NN models should be used to predict the properties of a given stoichiometry over a target chemical composition space to identify (new) compositions with optimal mechanical and rheological properties. Rheological properties such as viscosity and liquidus temperature determine the high-volume and low-cost manufacturability of glass. Young's modulus, chemical composition, and other mechanical and structural properties determine how well the glass composition meets the desired specifications. Eliminating a subgroup in a composition space (i.e., due to topology restrictions, known behavior of dopants, etc.) can help simplify the NN and GA models' parametric sweep over the phase diagram.

In terms of fundamental glass modeling, we believe that data-driven predictive methods for chemical compositions and their corresponding physical properties offer the following opportunities (Mauro 2014):

New glass compositions with minimal crack propagation: Damage-resistant glass compositions are engineered to prevent crack propagation and eliminate failure modes induced by external impact. Chemical strengthening on the surface of glass reduces stress concentration and the likelihood of crack propagation. New failure modes are emerging with new use cases. Different form factors such as automobile windshield, smartwatch, tablet, or smartphone display glasses cause differences in stress distribution and dopant concentration profiles. Enhancing glass strength both through the bulk glass composition and through the surface dopant profile is needed for display applications. Data-driven predictive modeling can help identify new surface dopants, bulk chemical compositions, and the effect of any other post-processing recipes and their parameters that can enhance the ductility and fracture toughness of glass.

Borate and phosphate glass chemistry: Major oxide glasses such as borate and phosphates offer interesting scientific challenges as well as useful technological applications. Different effects can be observed when incorporating these network-forming oxides into a silicate glass matrix. Modeling approaches similar to this chapter can help identify structure-property relations previously not known for these less explored glass chemistries.

Nontraditional glass chemistries: Bulk metallic and chalcogenide glasses have attracted significant interest due to their unique functionalities. Metallic glasses have brittle-to-ductile transition, which yields increased fracture toughness. Chalcogenide glasses have unique optical properties for infrared bands. These materials are fundamentally different from silicate, phosphate, or borate glasses in terms of their chemistries and optical, thermal, and mechanical properties. Since the length and timescales relevant for the functionalities of these materials can span more than nine orders of magnitude, molecular dynamics or other approaches are not feasible modeling approaches for engineering or understanding the properties of these materials. Data-driven approaches can help identify the compositions that can optimize multiple functionalities with respect to a range of elemental constituents whose behaviors are partially understood.

High pressure glass formation: Corning uses fusion drawing of glass melt at high temperature and reasonably lower viscosities for large volume manufacturing of state-of-the-art glasses (Mauro et al. 2009; Vogel 1921). A fundamental and practical open research area is high-pressure glass formation, which occurs for volcanic and magmatic systems. Today's glass production is done at ambient pressure. As high-pressure glass fabrication experiments can be expensive, data-driven modeling of volcanic or magmatic glasses may help develop pressure-based glass fabrication methods. These methods may enhance new combinations of glass properties, which may not necessarily form by thermal history.

Polyamorphism: In polyamorphism, two glasses of identical chemistries may display different short-range structural ordering. The short-range order differences significantly alter the observed properties. Since the glass chemistries which may

exhibit polyamorphism are not well understood, one may construct a data set of polyamorph glasses and their corresponding chemistries. Then running a data-driven model can help identify the most important parameters and defect chemistries and conditions that may alter short-range order for identical chemistries. As a result, one may predict mechanical and rheological properties based on data-driven polyamorph glass models.

Constitutive Modeling in Metallic Glasses for Predictions and Designs

Contents

Abstract

Metallic glasses, made of metallic elements yet possessing an amorphous structure, have attracted considerable interest due to their unique mechanical properties and excellent net-shape forming ability. In terms of mechanical properties, they are extraordinary in elastic limit and strength but inferior in ductility at room temperature, where the inhomogeneous deformation characteristics of shear banding, flow serration, and sometimes cavitation prevail. The net-shape forming ability surfaces when the temperature rises above T_g (i.e., the glass transition temperature), where metallic glasses deform in a homogeneous manner. Understanding both the homogeneous and inhomogeneous deformation in metallic glasses is pivotal for promoting their potential applications. In this

course, the continuum mechanics constitutive modeling has played a critical role. The constitutive modeling can be used for either predicting the mechanical responses of metallic glasses under various loading conditions or guiding material, product, and process designs. In this chapter, a number of important constitutive models for metallic glasses are reviewed; their applications in predicting both the homogeneous and inhomogeneous plastic flows are presented; and finally, the attempts of using the constitutive modeling to assist the design of ductility and net-shape forming processes are discussed.

1   Introduction to Metallic Glasses

Depending on the composition and cooling rate, metallic melts could solidify in either a crystalline or an amorphous form, which are two completely distinct solid states. The former arranges atoms in an ordered lattice structure whereas the latter in a disordered configuration. While the use of crystalline metals has accompanied the human history and civilization, the first metallic glass (or termed amorphous alloy) was synthesized in 1960, in the thin-ribbon Au-Si system cooled at a very high rate of $\sim$ 105–106 K·s^{-1} (Klement et al. 1960). This field was not fast-moving until the late 1980s and early 1990s, when metallic glasses in a bulk form were successfully produced in multicomponent La-, Mg-, Zr-, Pd-, Fe-, Cu-, and Ti-based alloy systems at relatively low cooling rates of 1–100 K·s^{-1} (Inoue et al. 1989, 1990, 1991; Peker and Johnson 1993; Telford 2004). After these discoveries, metallic glasses have been extensively studied and persistently pursued for applications due to their unparalleled functional and structural properties originating from their amorphous microstructure.

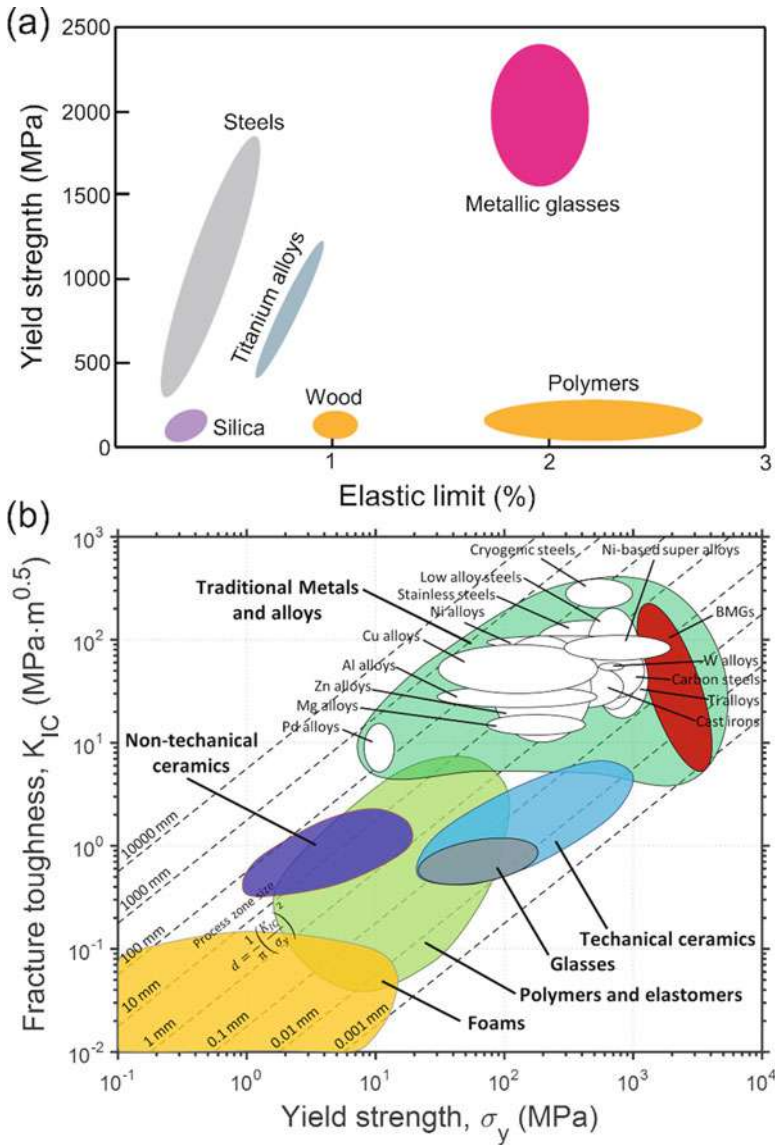
While a limited number of metallic glass systems were commercialized by virtue of their exceptional functional properties (e.g., Fe-based metallic glasses for low-loss power distribution transformers due to their low magnetization loss), large space in structural applications is still expected and actively explored. This high expectation originates from two facets of the merits found in metallic glasses. The first merit is their excellent room-temperature mechanical properties, including the superior yield strength ($\approx$ 2.0 GPa), high elastic limit ($\approx$ 2%), and potentially high fracture toughness (1–100 MPa·m$^{1/2}$) (Anand and Su 2005; Schuh et al. 2007), which are obvious when comparing with many other materials in Fig. 1. The second merit is their thermoplastic forming ability in the supercooled liquid region ($T_g < T < T_x$, where T_g and T_x are the glass transition and crystallization temperature, respectively), which enables metallic glasses to be easily processed into complicated shapes as plastics and oxide glasses. All these advantageous properties, however, are compromised by their lack of macroscopic ductility and brittle fracture at temperatures well below T_g, because of shear localization. For instance, under unconstrained uniaxial tension, a metallic glass often undergoes catastrophic failure along a predominant shear band, generating near-zero plastic strain. This drawback, again, is attributed to the amorphous structure of metallic glasses in which any strain-hardening and crack-blunting mechanisms are missing.


Fig. 1 (**a**) The comparison of the yield strength and elastic limit of metallic glasses with other materials including crystalline metals (Telford 2004). (**b**) Ashby plot of the fracture toughness versus yield strength of metallic glasses along with traditional metals/alloys and other material classes, with the dashed lines roughly representing the process zone size, $\frac{1}{\pi}\left(\frac{K_{IC}}{\sigma_f}\right)^2$, at the crack tip (Ashby 2005; Li et al. 2016c)

Given that brittleness is the biggest barrier preventing metallic glasses from extensively commercialized applications, designing improved ductility in these materials has been a constant pursuit of numerous studies in the past few decades. Along this line of endeavor, some extrinsic means have been proposed and proven to effectively enhance the ductility of metallic glasses through inducing abundant shear bands. Examples of such extrinsic methods include coating metallic glasses with ductile films (Jia et al. 2014), fabricating metallic glass composites (Jia et al. 2015), creating built-in compressive residual stress on surface layers (Wang et al. 2011), and imposing geometric constraints (An et al. 2012; Liu et al. 2012). Despite many different attempts, these extrinsic approaches do not solve the intrinsic brittleness problem in metallic glasses. Therefore, a multitude of efforts are focused on fundamentally understanding the micro-mechanisms of the inelastic deformation in metallic glasses (Argon 1979; Langer 2006; Li et al. 2013, 2015; Spaepen 1977). Along this line of work, the structural heterogeneity has been widely recognized as an intrinsic microstructural element that governs the ductility or brittleness of metallic glasses. The structural heterogeneity originates from the spatial fluctuation in the atomic packing density of metallic glasses and exhibits varied mechanical responses at different locations, usually at the micro- or sub-microscale (Li et al. 2013, 2015). A high density of structural heterogeneities helps retain good ductility of metallic glasses; on the contrary, reducing the amount of structural heterogeneities (e.g., by annealing) leads to significant embrittlement (Li et al. 2013, 2015).

2 Constitutive Models for Metallic Glasses

Constitutive models developed at the continuum level are useful in predicting the macroscopic mechanical behaviors of metallic glasses under various conditions and revealing the deformation phenomena that are difficult to observe in experiments. The constitutive models developed for metallic glasses include those motivated by the underlying deformation micro-mechanisms and those purely based on phenomenological considerations. Below we briefly summarize these two types of constitutive models for metallic glasses.

2.1 Physics-Based Free-Volume Model

Atoms in an amorphous structure are arranged in a disordered and non-closely packed manner. This naturally leaves some extra space for interstitial atoms. The excess space averaged on each atom is termed as the free volume per atom, which can be quantified as the difference between the average atomic volume in a real amorphous structure and that in the ideally ordered structure (Gao 2006). In an amorphous solid, the free volume is statistically distributed over all atoms. The free volume is not just a fictitious concept but actually a physical observable which has been explicitly measured by different experiments (Flores et al. 2011; Slipenyuk and

Eckert 2004; Yavari et al. 2005). The concepts and facts outlined above underlie the free-volume constitutive model. In the free-volume model, it is assumed that the macroscopic plastic flow in a metallic glass is induced by a number of individual atomic jumps. In the absence of external forces, atomic jumps are caused by thermal fluctuations, which obey an Arrhenius dependence on the activation energy, and the number of atoms jumping forward is balanced by that of those jumping backward. As a result, no net macroscopic flow is produced in the metallic glass. On the other hand, when the energy landscape is biased by applying an external stress, e.g., shear stress, there will be more jumps in one direction than the other. Consequently, there will be a net flux of atoms in one direction, the metallic glass exhibiting irreversible deformation. Under a simple one-dimensional shear problem, the plastic shear strain rate is thought of as the fraction of potential jump sites times the net number of atomic jumps on each of such sites per second (Spaepen 1977). With the free-volume theory (Cohen and Turnbull 1959; Spaepen 1977), the fraction of potential jump sites under homogeneous deformation is calculated as $exp\left(-\frac{\alpha v^*}{v_f}\right)$. Under the applied shear stress, τ, the net number of atomic jumps on each potential site per second is $f\left[exp\left(-\frac{\Delta G^m - \tau\Omega/2}{k_B T}\right) - exp\left(-\frac{\Delta G^m + \tau\Omega/2}{k_B T}\right)\right]$, where the first and second terms represent the forward and backward fluxes of atomic jumps, respectively (Spaepen 1977). As a result, the plastic flow equation is given as (Spaepen 1977)

$$\frac{\partial \gamma_p}{\partial t} = 2f \, exp\left(-\frac{\alpha v^*}{v_f}\right) exp\left(-\frac{\Delta G^m}{k_B T}\right) sinh\left(\frac{\tau\Omega}{2k_B T}\right), \quad (1)$$

where γ_p is the plastic shear strain, t is the time, f is the frequency of the atomic vibration, α is a geometric factor on the order of 1, v^* is the hard-sphere volume of an atom, v_f is the average free volume per atom, ΔG^m is the activation energy, Ω is the atomic volume, k_B is the Boltzmann constant, and T is the absolute temperature.

Equation (1) is a standard viscoplasticity model that alone cannot account for the strain-softening effect found in metallic glasses. To account for strain softening, the free volume, v_f, is treated as an order parameter whose creation and annihilation govern the structural disordering and reordering processes in metallic glasses. Specifically, the free volume can be created by a sufficiently high stress squeezing an atom into a neighboring vacancy of smaller volume; it can be annihilated by diffusional atomic jumps. Considering the competition of these two processes, the net rate of free volume increase is written as

$$\frac{\partial v_f}{\partial t} = v^* f \, exp\left(-\frac{\alpha v^*}{v_f}\right) exp\left(-\frac{\Delta G^m}{k_B T}\right)\left\{\frac{2\alpha k_B T}{v_f C_{eff}}\left[cosh\left(\frac{\tau\Omega}{2k_B T}\right) - 1\right] - \frac{1}{n_D}\right\}, \quad (2)$$

where n_D is the number of atomic jumps needed to annihilate a free volume equal to v^* and is usually taken to be 3 (Gao 2006; Huang et al. 2002; Steif et al. 1982), and

the effective modulus is $C_{eff} = E/3(1 - v)$ with E and v being the Young's modulus and Poisson's ratio, respectively.

Equations (1) and (2) constitute the inelastic portion of the continuum mechanics description of the deformation mechanism in metallic glasses. At constant T, a complete one-dimensional isothermal constitutive law for metallic glasses can be formed by combining Eqs. (1) and (2) with Hooke's law for elasticity

$$\frac{\partial \gamma_e}{\partial t} = \left(\frac{\dot{\tau}}{G} \right)_T,$$ (3)

where γ_e is the elastic shear strain and G is the shear modulus.

The isothermal model can be further extended to be a thermomechanically coupled constitutive relation by incorporating the following thermal transport equation encompassing the heat conduction (first term) and plastic energy dissipation (second term) (Bergman et al. 2011; Gao 2006)

$$\dot{T} = \frac{1}{\rho C_P} \left(k \frac{\partial^2 T}{\partial x^2} + \alpha_{TQ} \tau \dot{\gamma}_p \right),$$ (4)

where T is the temperature, k is the thermal conductivity, α_{TQ} is the Taylor-Quinney coefficient representing the fraction of the plastic work converted into heat, ρ is the material density, C_P is the specific heat, and ρC_P denotes the volumetric heat capacity of a material (Bergman et al. 2011).

The one-dimensional partial differential equations, i.e., Eqs. (1) - (3) that form the isothermal model as well as Eqs. (1) - (4) that form the thermomechanically coupled model, can be solved numerically. Solving the isothermal model gives the evolution of the stress, τ, and free volume, v_f, with the shear strain, γ (usually from 0 to 1), or time, t (in seconds), in metallic glasses undergoing homogeneous deformation. Solving the thermomechanically coupled model can, in addition, give the evolution of the temperature, T. The one-dimensional isothermal and thermomechanical models are only applicable to the case of simple shear. To extend their applicability to arbitrary multiaxial stress states, models need to be generalized with appropriate yield criteria. Simply put, the shear stress, τ, in the one-dimensional constitutive equations needs to be replaced with an equivalent stress under a given yield criterion in the process of generalization, to form the constitutive equations for arbitrary stress states. One of such generalizations is to use the J_2 plasticity on the basis of von Mises yield criterion, which assumes that the hydrostatic stress does not cause plastic flow and changes the internal state variable – free volume (Gao 2006). If considering the contribution from the hydrostatic stress, a generalization based on the Drucker-Prager criterion was made by Zhao and Li (2011a). Finally, a generalized constitutive model, based on any yield criterion, can be implemented into a finite element program (e.g., ABAQUS) through developing a user-material subroutine to maximize its usage (Gao 2006; Zhao and Li 2011a).

2.2   Phenomenological Elastic-Viscoplastic Models

In addition to the physics-based free-volume model, many researchers have attempted to develop constitutive models that can phenomenologically capture the macroscopic mechanical responses of metallic glasses. Anand and Su (2005) developed a finite-deformation, Mohr-Coulomb-type constitutive theory that captured some of the essential inelastic deformation features in metallic glasses, which include the hydrostatic stress dependence of yielding, plastic dilatation, and plastic strain localization. This model was initially developed for room-temperature applications but later extended to high homologous temperatures in the range of $0.7T_g \lesssim T \lesssim 0.9T_g$ for simulating the homogeneous plastic flow (Anand and Su 2007) and $0.9T_g \lesssim T \lesssim T_x$ (Henann and Anand 2008) for the transition from a viscoelastic-plastic solid-like response to a Newtonian fluid-like response. Nonetheless, the applications of these models were limited to the isothermal condition. The finite-deformation constitutive model developed by Yang et al. (2006) considers the temperature rise in metallic glasses resulting from the conversion from plastic work to heat but simply treats the thermal problem as adiabatic. Later, Thamburaja and Ekambaram (2007) applied fundamental thermodynamic laws and the principle of micro-force balance to develop a thermomechanically coupled finite-deformation model, targeting for predictions in the supercooled liquid region. This model had also been augmented to include a damage criterion to simulate damage processes (Ekambaram et al. 2011).

All these constitutive models have been implemented in the commercial finite element program, ABAQUS, by writing a user-material subroutine either for the explicit procedure (VUMAT) or implicit procedure (UMAT) (Manual 2013). The former is easy for implementation, but the computation is conditionally stable, whereas the latter is unconditionally stable but more difficult to implement. Given that the model by Anand and Su at room temperature (Anand and Su 2005) has been used rather extensively, below we briefly outline the key governing equations for this model. For the details of the other models, one is referred to the relevant references (Anand and Su 2007; Ekambaram et al. 2011; Henann and Anand 2008; Thamburaja and Ekambaram 2007; Yang et al. 2006).

In the finite-deformation framework, a multiplicative decomposition of the deformation gradient tensor into elastic and plastic parts is used to map the initial, stress-free reference configuration to the current, deformed configuration (Bower 2009):

$$\mathbf{F} = \mathbf{F}^e\mathbf{F}^p, \tag{5}$$

where $\mathbf{F}^p$ is the plastic deformation and rotation mapping the initial reference configuration to an intermediate, unstressed configuration, whereas $\mathbf{F}^e$ is the elastic deformation and rotation mapping the intermediate configuration to the current configuration. The free volume is made to be associated with the plastic volumetric strain $\eta = \ln J^p$, where $J^p = \det \mathbf{F}^p$. The plastic flow in metallic glasses is assumed

to result from shearing along with dilatation relative to potential slip systems. As no preferred directions other than the principal direction of stress exist in amorphous isotropic materials, six potential slip systems are defined relative to the principal directions of Kirchhoff stress. Each slip system is specified by a slip direction, $\mathbf{s}^{(a)}$, and a slip plane normal, $\mathbf{m}^{(a)}$, where $a \in \{1, 2, \ldots, 6\}$ represents the ath slip system. Based on the Mohr-Coulomb criterion, the six potential slip systems are defined as

$$
\begin{aligned}
\mathbf{s}^{(1)} &= \cos\theta\widehat{\mathbf{e}}_1 + \sin\theta\widehat{\mathbf{e}}_3, & \mathbf{m}^{(1)} &= \sin\theta\widehat{\mathbf{e}}_1 - \cos\theta\widehat{\mathbf{e}}_3, \\
\mathbf{s}^{(2)} &= \cos\theta\widehat{\mathbf{e}}_1 - \sin\theta\widehat{\mathbf{e}}_3, & \mathbf{m}^{(2)} &= \sin\theta\widehat{\mathbf{e}}_1 + \cos\theta\widehat{\mathbf{e}}_3, \\
\mathbf{s}^{(3)} &= \cos\theta\widehat{\mathbf{e}}_1 + \sin\theta\widehat{\mathbf{e}}_2, & \mathbf{m}^{(3)} &= \sin\theta\widehat{\mathbf{e}}_1 - \cos\theta\widehat{\mathbf{e}}_2, \\
\mathbf{s}^{(4)} &= \cos\theta\widehat{\mathbf{e}}_1 - \sin\theta\widehat{\mathbf{e}}_2, & \mathbf{m}^{(4)} &= \sin\theta\widehat{\mathbf{e}}_1 + \cos\theta\widehat{\mathbf{e}}_2, \\
\mathbf{s}^{(5)} &= \cos\theta\widehat{\mathbf{e}}_2 + \sin\theta\widehat{\mathbf{e}}_3, & \mathbf{m}^{(5)} &= \sin\theta\widehat{\mathbf{e}}_2 - \cos\theta\widehat{\mathbf{e}}_3, \\
\mathbf{s}^{(6)} &= \cos\theta\widehat{\mathbf{e}}_2 - \sin\theta\widehat{\mathbf{e}}_3, & \mathbf{m}^{(6)} &= \sin\theta\widehat{\mathbf{e}}_2 + \cos\theta\widehat{\mathbf{e}}_3,
\end{aligned}
\tag{6}
$$

where $\widehat{\mathbf{e}}_1$–$\widehat{\mathbf{e}}_3$ represent three orthogonal unit vector, $\theta = \frac{\pi}{4} + \frac{\varphi}{2}$, $\varphi = \tan^{-1}\mu$ is the angle of internal friction, and μ is the friction coefficient.

The plastic volumetric strain (or free volume) evolves according to

$$
\dot{\eta} = \beta \sum_{a=1}^{6} \dot{\gamma}^{(a)},
\tag{7}
$$

where β is the dilatancy function and $\dot{\gamma}^{(a)}$ is the plastic shearing rate on the ath slip system, which are defined, respectively, as

$$
\dot{\gamma}^{(a)} = \dot{\gamma}_o \left\{ \frac{\tau^{(a)}}{c + \mu\sigma^{(a)}} \right\}^{1/m},
\tag{8}
$$

$$
\beta = g_o \left(1 - \frac{\eta}{\eta_{cv}} \right)^p,
\tag{9}
$$

where c is the internal variable named cohesion and its initial value, c_o, is related to the uniaxial tensile yield stress through $\sigma_o = 2c_o/(\cos\varphi + \mu(1 + \sin\varphi))$. $\tau^{(a)}$ and $\sigma^{(a)}$ are the resolved shear stress and compressive normal stress for the ath slip system. $\dot{\gamma}_o$ is the reference shearing rate, and m is the rate sensitivity constant. η_{cv} is the saturation value of the plastic volumetric strain. g_o and p are the positive-valued material parameters.

Equations (7) - (9) represent the evolution of the free volume toward an equilibrium value, η_{cv}, after metallic glasses yield. In addition, strain softening induced by the increase in the free volume is phenomenologically modeled by a decaying cohesion, c. Specifically, c has an initial value $c_0 = c_{cv} + b$ and decays according to

$$c = c_{cv} + b\left(1 - \frac{\eta}{\eta_{cv}}\right)^q, \tag{10}$$

where c_{cv}, b, and q are the positive-valued material constants. It is seen from Eq. (10) that after yielding the cohesion c will drop from c_0 gradually to c_{cv}, reflecting the strain softening in metallic glasses. Equations (7) - (10) essentially constitute the core of the Anand-Su model (Anand and Su 2005). During the practical finite-element implementations, the initial cohesion, c_0, is usually perturbed by a statistical distribution over the domain of interest to trigger random and simultaneous nucleation of shear localization at multiple sites (Anand and Su 2005).

In the model, physically observable material parameters (e.g., μ and c_0) can be evaluated by conducting experiments, e.g., compression and instrumented indentation tests; some phenomenological material parameters (e.g., c_{cv}, b, and q) need to be estimated by curve-fitting procedures, i.e., carrying out numerical simulations and physical measurements under identical conditions and then adjusting the values of the material parameters in the simulations to match certain curves from experiments; finally, for other material parameters that are difficult to be estimated from either way aforementioned (e.g., η_{cv}, g_o, and p), reasonable assumptions have to be made for their values. The example procedures for obtaining the values of all material parameters appearing in the model can be found in Anand and Su (2005) and Su and Anand (2006).

3   Prediction of the Homogeneous Plastic Flow

The homogeneous deformation in metallic glasses occurs at low-stress levels and high temperatures ($> 0.7\, T_g$) and is close to the Newtonian viscous state. In uniaxial tension, a specimen thins down uniformly accompanied with extensive and stable plastic deformation until failure takes place by necking. Such a deformation model is very similar to many superplastic materials. Deformation in this regime usually exhibits notable strain-rate sensitivity (Spaepen 1977), in sharp contrast to the strain-rate insensitivity in the inhomogeneous flow which will be discussed shortly. A set of representative uniaxial true stress-strain curves at different strain rates, measured for homogeneously deformed $Pd_{40}Ni_{40}P_{20}$ metallic glass ($T_g = 577$ K) at $T = 564$ K, are given as solid curves in Fig. 2 (Anand and Su 2007; de Hey et al. 1998; Ichitsubo et al. 2004). Different than the strain hardening in crystalline metals and alloys, the absence of dislocation-mediated plasticity in metallic glasses leads to strain softening in the plastic flow. As shown in Fig. 2, following the occurrence of stress overshoot right after yielding, the flow stress drops until a steady state is reached at a strain of ~ 0.1. As the strain rate increases, the entire stress-strain curve is elevated, the stress drop at the overshoot becomes more precipitous, and the steady state is reached more slowly. The prediction of stress-strain responses at a constant T with a constitutive model involves numerically solving the coupled plastic flow and state-variable evolution equations, i.e., Eqs. (1) - (3) for the free-volume model and

Fig. 2 True stress-strain curves of the pre-annealed $Pd_{40}Ni_{40}P_{20}$ metallic glasses measured experimentally at 564 K and four different strain rates (solid lines) (de Hey et al. 1998) along with the simulated data from the isothermal Anand-Su model (dashed lines) (Anand and Su 2007)
Eqs. (5) - (10) for the Anand-Su model. After estimating the values of the material parameters by curve-fitting to experimental data the isothermal Anand-Su model (Anand and Su 2007) predicts the stress-strain curves as dashed lines in Fig. 2. All characteristics manifested on the experimental stress-strain responses are essentially captured by the model.

The isothermal free-volume model (Eqs. 1) - (3) can also capture the strain-softening characteristic in the uniaxial stress-strain curves of metallic glasses (Gao 2006; Steif et al. 1982). The strain softening in the free-volume model is regulated by the evolution of the order parameter – free volume. According to Eq. (2), the free-volume evolution is a stress-driven process. The increase in the applied stress gives rise to a net accumulation of free volume, as shown by the initial sharp rise in Fig. 3a. Using the viscosity definition $\eta = {}^{\tau}\!/\!_{\dot{\gamma}_p}$ and Eq. (1), the viscosity of a metallic glass is calculated as (Gao et al. 2007)

$$\eta = \frac{\tau}{2 \sinh \left(\tau \Omega / 2 k_B T\right)} f^{-1} \exp \left(\frac{\alpha v^*}{v_f}\right) \exp \left(\frac{\Delta G^m}{k_B T}\right). \tag{11}$$

From Eq. (11), it is seen that the increase in the free volume, v_f, causes a reduction in the viscosity and thus weakens the material. The material weakening caused by the structural disordering is observed as a stress drop on a stress-strain curve (e.g., Fig. 2). The decrease in the flow stress, in turn, slows down the increase of the free volume, as seen from Eq. (2). At some point, the rate of free-volume annihilation by atomic diffusion (second term in Eq. (2)) catches up that of stress-driven free-volume creation (first term in Eq. (2)). An equilibrium state of free volume is therefore established, and the flow stress becomes steady, as denoted by the dashed line in Figs. 3a and 2, respectively.
Fig. 3 The normalized (**a**) free volume, $v_f/\alpha v^*$, and (**b**) temperature, T/T_0, as a function of the applied shear strain, γ, pertaining to the homogeneous deformation in a metallic glass. The dashed line is calculated from the one-dimensional isothermal free-volume model, while the solid lines are from the thermomechanically coupled free-volume model. The reference temperature $T_0 = 300$ K and the initial free volume $v_f/\alpha v^* = 0.05$ (Gao et al. 2007)

The homogeneous deformation predicted from a thermomechanically coupled free-volume model Eqs. (1) - (4) shares some similarities with that from the isothermal free-volume model. But, there are also major differences in the predictions of these two models. First, since the thermomechanical model considers the heat generation induced by the plastic work dissipation, the temperature does not remain constant as in the isothermal model but increases gradually as the plastic work accumulates. The temperature rise is slow at the beginning but starts becoming rapid once passing over the stress overshoot, as seen from Fig. 3b in which $\gamma = 0.05$ is approximately where the peak stress happens. According to the free-volume evolution equation (i.e., Eq. (2)), the increase in temperature facilitates the atomic diffusion and therefore the annihilation of free volume. This prediction is shown as the solid curve in Fig. 3a. Unlike the isothermal case, the free volume keeps decreasing after the peak value as shear strain γ increases. No equilibrium is established for the free volume under the thermomechanical scenario.

4   Prediction of the Inhomogeneous Plastic Flow

4.1   Shear Banding

The inhomogeneous deformation in metallic glasses takes place at relatively high stresses (roughly $-2 < \log \frac{\tau}{G} < 0$, where τ and G are the shear stress and shear modulus, respectively) and low temperatures (<0.7 T_g) (Spaepen 1977; Suryanarayana and Inoue 2017). One of the most striking features is that in this

deformation mode, the plastic strain is highly localized into thin bands termed as shear bands. Under unconfined loading conditions such as uniaxial tension, an initiated shear band can propagate promptly throughout the entire specimen, leading to brittle failure. For loading conditions that impose geometric constraints on metallic glass samples (e.g., uniaxial compression (Liu et al. 2012) or indentation (An et al. 2012; Jia et al. 2014), the propagation of shear bands tends to be blocked or redirected by the geometric constraints, consequently resulting in the formation a high density of shear bands. With more shear bands available for bearing the plastic strain, a significant amount of plasticity is possible to achieve (An et al. 2012; Jia et al. 2014; Liu et al. 2012). Therefore, understanding the shear-banding behavior is essential to reveal the deformation mechanism of metallic glasses under various conditions. Diversified experimental techniques have been utilized for fundamentally understanding the nature of shear bands, and a comprehensive summary can be found in ref. (Greer et al. 2013). In complement to experiments, modeling and simulation at the continuum level, particularly with the use of metallic-glass constitutive models, are useful in predicting the shear band-related phenomena.

The shear band inclination angle under uniaxial tension and compression has been an active research topic for years. In crystalline metallic materials, as the yielding is controlled merely by the shear stresses, failure usually occurs along the plane at which the resolved shear stress is maximum, i.e., 45° from the loading axis for both tension and compression (Dieter and Bacon 1986). Nonetheless, the shear band inclination angle and the failure plane in metallic glasses are experimentally found to deviate from 45° (Gao et al. 2011). The angle is greater than 45° in tension and smaller than 45° in compression. Besides, the deviation from 45° for tension and compression is not necessarily symmetric for the same material. To predict the shear band inclination angle in the inhomogeneous deformation mode, the one-dimensional constitutive models of metallic glasses have been generalized for multiaxial stress states based on different failure criteria, including the von Mises (Gao 2006), Mohr-Coulomb (Anand and Su 2005), and Drucker-Prager (Zhao and Li 2011a). The von Mises generalization assumes zero contribution from the hydrostatic stress to yielding, and thus predicts a shear band angle of 45° for both tension and compression, as given in Fig. 4a and d. This assumption is oversimplified and fails to predict the deviation of the shear band angle. The amendment was made by using either the Mohr-Coulomb or Drucker-Prager criterion, both of which are primarily used in soil and rock mechanics considering the contribution of the hydrostatic stress to failure. The Drucker-Prager criterion is simply an extension of the von Mises criterion by adding a term of hydrostatic stress (i.e., Eq. (12) without the I_1 term is the von Mises criterion),

$$Y = aI_1 + \sqrt{J_2} - k = 0, \tag{12}$$

where Y is the yield function; I_1 and J_2 are the first invariant of the stress tensor and the second deviatoric stress invariant, respectively; and a and k are the constants.
Fig. 4 Shear bands formed under (**a–c**) uniaxial plane-strain tension and (**d–f**) compression. The predictions are, respectively, from the (**a, d**) free-volume model based on the von Mises failure criterion (Zhao and Li 2012), (**b, e**) free-volume model based on the Drucker-Prager criterion (Zhao and Li 2012), and (**c, f**) Anand-Su model based on the Mohr-Coulomb criterion (Anand and Su 2005)

By considering the contribution from the hydrostatic stress, i.e., the first term in Eq. (12), the deviated shear band angles can be accurately predicted. Figures 4b and e give the predicted angles being 47° under tension and 40° under compression. The asymmetry in the angle deviation for tension and compression is captured as well. Additionally, the predicted angles are likely to be further fine-tuned to align more closely with the experimentally observed ones for a given metallic glass by changing the value of a in Eq. (12). Changing a effectively regulates the weight of the hydrostatic stress contribution. The Mohr-Coulomb criterion, whose yield surface is a non-smooth version of that in the Drucker-Prager criterion, can also account for the

dependence of yielding on the hydrostatic stress. But differently, the Mohr-Coulomb model needs a predetermination of shear planes along which inhomogeneous plastic flow could occur, i.e., "slip systems." With the slip systems properly defined, the Mohr-Coulomb model is also capable to predict the asymmetrically deviated shear band angles in tension and compression, as given in Fig. 4c and f (Anand and Su 2005).

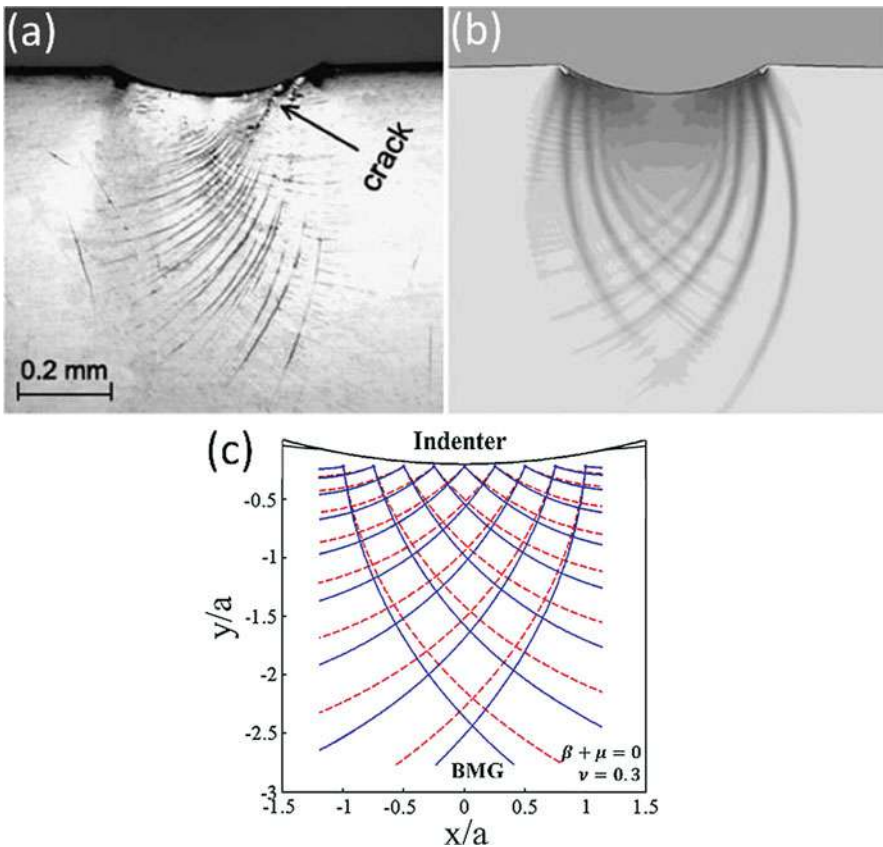
The constitutive models can also be used for predicting the shear band activities under more complicated stress states. One of the most widely used applications is to predict shear band patterns under indentations. Figure 5a gives the shear band pattern experimentally observed on the cross-section plane of the $Zr_{56.06}Cu_{23.39}Ni_{15.54}Ta_{2.27}Al_{1.62}Ti_{1.11}$ metallic glass using the bonded-interface


Fig. 5 Shear band patterns from the (**a**) experimental observation on the bonded interface of a Zr-based metallic glass specimen subjected to plane-strain indentation (Su and Anand 2006), (**b**) numerical simulation with the Anand-Su model (Su and Anand 2006), and (**c**) prediction by the Rudnicki-Rice instability theory, with the solid blue curves representing the shear-band directions and the dashed red curves the principal shear-stress directions (Jia et al. 2014)

technique (Su and Anand 2006). The metallic glass was subjected to the plane-strain indentation. As a result, radial shear bands emanating from the contacting interface and intersecting shear bands were observed. The prediction with the Anand-Su model (Su and Anand 2006) in Fig. 5b replicates the shear band pattern closely. Moreover, the initial shear band pattern is also likely to be predicted by a bifurcation theory, considering the onset of strain localization is a result of material instability from the continuum mechanics point of view (Rudnicki and Rice 1975). The exact formulation of the critical condition for strain localization was derived by Rudnicki and Rice (1975). Simply put, the shear band is parallel to the second principal stress component in the principal stress space and is calculated as

$$\theta_0 = \pm \tan^{-1} \sqrt{\frac{\xi - N_{min}}{N_{max} - \xi}}, \tag{13}$$

where $\xi = \frac{1}{3}(1 + \nu)(\mu + \beta) - N(1 - \nu)$, ν is Poisson's ratio, μ is the coefficient of the internal friction (for generally pressure-sensitive materials like metallic glasses), β is the dilatancy factor (describes the flow normality, associated flow if $\mu = \beta$),

$$N_{max} = \sqrt{3}\frac{\sigma'_{\mathrm{I}}}{\sigma_{mises}}, \quad N_{mid} = \sqrt{3}\frac{\sigma'_{\mathrm{II}}}{\sigma_{mises}}, \quad N_{min} = \sqrt{3}\frac{\sigma'_{\mathrm{III}}}{\sigma_{mises}}, \tag{14}$$

and σ'_{I}, σ'_{II}, and σ'_{III} are the principal deviatoric stress components. To apply the Rudnicki-Rice instability theory, the elastic field resulting from a loading condition needs firstly to be obtained either from analytical approaches or finite element simulations. When showing all the shear-band directions on a regular grid, one can construct "streamlines" that are tangent to the shear-band directions at any material point. The constructed streamlines depict the shear band pattern under the given loading condition. The shear band pattern predicted with this approach for a Rockwell indentation is shown in Fig. 5c, which resembles those in Fig. 5a and b (Jia et al. 2014). This procedure has found numerous successful applications in reasonably predicting the shear band patterns under a number of different indentation problems, such as Berkovich indentation and film/substrate systems (An et al. 2012; Gao et al. 2011; Jia et al. 2014).

In addition to predicting the shear band pattern, the constitutive modeling is also useful in revealing other shear band-related quantities that are difficult to be precisely measured by experiments. For instance, the shear band velocity can be traced from the initiation to the final stage of propagation. With the free-volume model, it is found that the propagation of shear bands actually manifests a nonuniform speed, that is, a rather slow stage from the initiation followed by a rapid propagation when they reach the sample surfaces (Zhao et al. 2011). The average speed was estimated to be 100 m/s, with a maximum value of 1400 m/s. The shear band speed assessed with the modeling approach is more thorough than most of the experimental techniques like high-speed camera, SEM, and strain gage (Chen et al. 2009; Song et al. 2010; Yang et al. 2004) because most experiments

are restricted by limited temporal and spatial resolutions and unlikely to detect the initiation and propagation of embryonic shear bands. If a thermomechanically coupled model is applied, local temperature rise inside a propagating shear band can be modeled without significant computational cost as well. Such a modeling method overcomes the measurement uncertainties found in many experiments, as most measurements have to be conducted on the surfaces of samples, e.g., using the infrared imaging and fusible coating methods (Lewandowski and Greer 2005; Yang et al. 2005). The maximum local temperature rise in shear bands measured with the modeling approach was suggested to be a few tens of degrees (Zhao and Li 2011b).

4.2   Flow Serration

Various degrees of plasticity may occur when metallic glasses are loaded in a confined manner, such as uniaxial compression and nanoindentation. In such cases, serrated plastic flows are often observed, manifesting as stress drops on compressive stress-strain curves (Dubach et al. 2009) or displacement bursts ("pop-ins") on nanoindentation load-depth curves (Song and Nieh 2009). The serrated flow in metallic glasses is strain-rate dependent and is believed to be associated with the activation and propagation of individual shear bands (Dubach et al. 2009). The free-volume model, Anand-Su model, and many others render smooth stress-strain or load-depth curves, and only very largely spaced single stress drops or displacement bursts can be captured following the formation of catastrophic shear bands. To capture the flow serration, special treatments are required in the process of developing a constitutive model. One of such models was built up on the rugged free energy landscape, in which the deformation within shear bands is through a continuous transformation from one low energy state to another (Ruan et al. 2011). Since the energy in metallic glasses varies quasiperiodically from peaks to valleys in a rugged free energy landscape, the plastic strain also experiences a quasiperiodic variation as the deformation runs between peaks and valleys. As a result, the serrated flow in metallic glasses is also captured. Conducting uniaxial plane-strain compression tests with this model successfully catches the flow serration on the stress-strain curves, as shown in Fig. 6 (Ruan et al. 2011). The serrated flow appears on all three compressive stress-strain curves conducted at different strain rates even though each exhibits different global plasticity. Alongside shown in Fig. 6 are the tensile stress-strain curves obtained from the identical strain rates, in which brittle failure happens and the serrated flow is absent. These predictions are qualitatively consistent with experimental observations (Dubach et al. 2009).

Another phenomenological model that can also capture the serrated flow in metallic glasses is a rheological model that considers the periodic appearance of flow serration as a result of the interplay of strain softening and strain hardening (Yousfi et al. 2013). As in many other models, strain softening is assumed to originate from the decrease of viscosity following the shear band formation. Strain hardening, on the other hand, is caused by the arrest of shear band propagation by nanocrystalline particles precipitated within the shear zone. Alternating strain

Fig. 6 The stress-strain curves of a metallic glass under plane-strain tension and compression tests at three different strain rates, predicted by the constitutive model based on the rugged free energy landscape (Ruan et al. 2011). The compressive stress-strain curves exhibit different degrees of plasticity, and the serrated flows are reasonably reproduced, whereas brittle failure with zero plasticity features the tensile curves
softening and hardening occurs periodically and results in serrated flow. The model, after numerical implementation and determining the material parameters by a data fitting procedure, has already reproduced the serrated flow observed in experiments. Nevertheless, simply assuming that the strain hardening is a result of nanocrystallization lacks generality, as nanocrystallization does not necessarily happen for all metallic glasses exhibiting flow serration. A more generalized serration model should take into account the correlation between the serrated flow and shear-band activation events, and the dependence of the serrated flow on applied strain rates should also be reasonably captured (Schuh and Nieh 2003).

4.3   Cavitation

Some metallic glasses fracture in a sort of ductile manner with profuse shear bands accommodating the large-scale plasticity near the crack or notch tips. On the contrary, many others (e.g., Mg-based metallic glasses) fail in a perfectly brittle manner along a single fast-propagating shear band, just as silicate glasses (Li et al. 2013, 2015; Xi et al. 2006). Observations of the fracture surfaces also reveal salient distinctions: the fracture surfaces of somewhat ductile metallic glasses exhibit vein patterns, whereas the very brittle ones are characteristics of misty-mirror morphologies (Li et al. 2013, 2015). Further inspection of the misty-mirror

morphologies with the high-resolution scanning electron microscopy (SEM) reveals periodic stripes at the nanoscale, which are usually termed as nano-corrugations (Wang et al. 2007, 2008; Xi et al. 2006). It is inferred that these nano-corrugations are formed as a result of the nucleation and coalescence of cavities at the nanoscale, because the atomic force microscopy (AFM) observations found that a peak-to-peak matching relation existed for the nano-corrugations from two complementary fracture surfaces of a Mg-based metallic glass (Wang et al. 2007). The inference was confirmed later by molecular dynamic (MD) simulations of model glasses (Guan et al. 2013; Murali et al. 2011). Additionally, MD simulations suggest that brittle metallic glasses fluctuate spatially in their atomic density and cavities tend to nucleate in the regions of reduced density (Murali et al. 2011). Since the reduced density implies weakened strength, such a finding is linked with another direction of active research, namely, structural heterogeneities in metallic glasses. With the nanoindentation technique, it has been proven that there exists strength fluctuations in metallic glasses. Based on strength fluctuations in metallic glasses, a structure model consisting of a strong matrix and distributed weak zones was suggested (Li et al. 2013, 2015).

Based on these findings, Singh et al. attempted to use finite element simulations to gain more insights on the cavitation in metallic glasses (Singh et al. 2013, 2014, 2016). In their early work, the finite element model of a heterogeneous solid containing a distribution of weak zones was used for representing brittle metallic glasses with structural heterogeneities (Singh et al. 2013, 2014). Both the background material and weak zones were treated as elastic-plastic materials following the J_2 flow theory. The yield strength of the weak zones is reduced in comparison to that of the background material, and after yielding further deformation is bounded by the power law hardening rule. To trigger cavitation, a tiny void was placed at the center of each individual weak zone. By subjecting the heterogeneous solid to equibiaxial stretching under the plane-strain condition, it was demonstrated that the presence of the weak zones permitted cavities to nucleate at substantially lower hydrostatic stresses in comparison with a homogeneous solid. Besides, the critical hydrostatic stress for the onset of cavitation in a heterogeneous solid was dependent on the local properties of the weak zones. These early studies did not explicitly simulate the cavitation process yet gave the cause of nano-cavitation in metallic glasses from the continuum mechanics standpoint, that is, the existing heterogeneities (weak zones) can reduce the cavitation stress and cavitation-induced failure would occur once the properties and distribution of these heterogeneities reach some critical values.

However, a preferable way to simulate the cavitation-induced fracture process in brittle metallic glasses is to assign a more realistic constitutive law to the heterogeneous body. One of such options is to use the Anand-Su model (Anand and Su 2005) based on the Mohr-Coulomb criterion. In the later work by Singh et al. (2016), the heterogeneous metallic glass, by symmetry, was simulated as a classical semicircular domain of radius R_o with three equally spaced weak zones of radius $r_w = 0.13 L_o$ located on the right-half symmetry line (WZ-I, WZ-II, and WZ-III from center to the perimeter). The distance between two consecutive weak zones and from the domain center to WZ-I is L_o. The entire domain was assigned

with the constitutive behavior defined in the Anand-Su model, but a reduced yield strength, σ_{ow}, was used for the weak zones relative to the matrix material strength, σ_o. A small-scale yielding (SSY) fracture problem was simulated by inserting a semicircular notch of length of R_o and diameter of $b_o = 3.3 \times 10^{-3} R_o$ along the left-half symmetry line ahead of the first weak zone and creating a small circular void of radius $r_o = 0.013 L_o$ at the center of each individual weak zone to facilitate cavitation. With such a method, two fracture mechanisms, shear banding-induced fracture and cavitation-induced fracture, are incorporated, and their competition and interplay are therefore likely to be captured. The shear banding process is captured by the constitutive model, and the cavitation is presumed to commence when the void area starts increasing rapidly following the peak of the macroscopic hydrostatic stress, which is defined as

$$\sum_{hw}(t) = \frac{1}{V_w(t)} \int_{V_w(t)} \sigma_h(\mathbf{x}, t) \, dV, \tag{15}$$

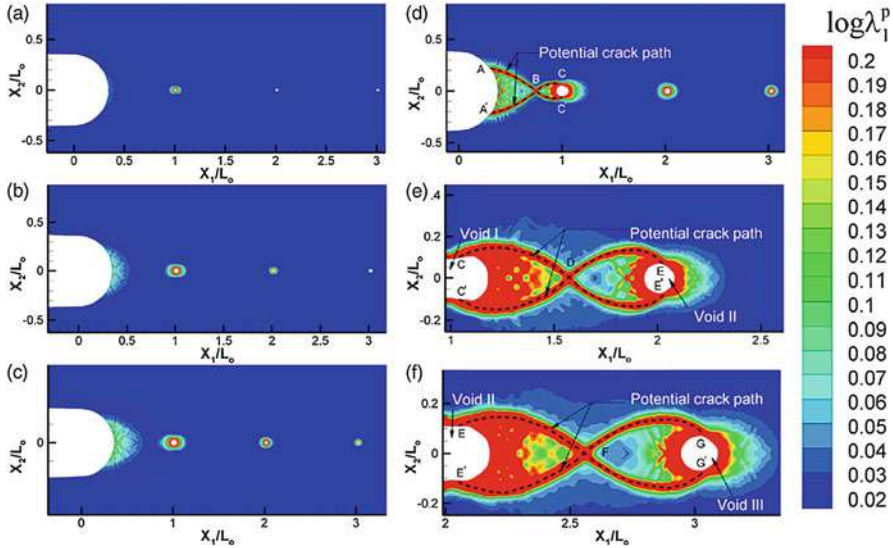
where $\sigma_h(\mathbf{x}, t)$ is the current Cauchy (microscopic) hydrostatic stress and $V_w(t)$ is the current volume of a weak zone. The simulated fracture process in such a heterogeneous brittle metallic glass with $\frac{\sigma_{ow}}{\sigma_o} = 0.1$ is depicted in Fig. 7 by the evolution of the principal logarithmic plastic strain $\log \lambda_1^p$ at different values of load parameter $K/\left(\sigma_0 \sqrt{L_0}\right)$. For clarity, only a region containing the notch and weak zones is truncated for display, and the contours are generated to the full domain through symmetry. The cavitation of WZ-I commences first, while the plastic deformation at the notch tip is still negligibly small (Fig. 7a). Progressively, cavitation in WZ-II and WZ-III starts as well, and all three cavities expand rapidly (Fig. 7b and c). In the meantime, yielding occurs at the notch root and shear bands start emanating (Fig. 7b and c). As shear bands continue to evolve and cavities expand, at some point two primary curved shear bands emitting from the notch root exclusively grow, crossing each other and ultimately linking with the growing cavities (Fig. 7d). As loading progresses, these two shear bands keep growing in a sinusoidal manner and connect all three cavities, as shown in Fig. 7e and f. This process is known as void coalescence, and the two wavy shear bands are where failure would happen once the plastic strain inside exceeds a critical value (note that the actual fracture process through crack initiation and propagation was not simulated), as marked by the black dashed lines in Fig. 7d–f. With this simulation, a number of important implications on the brittle fracture of metallic glasses can be observed. First, cavitation prevails in a heterogeneous metallic glass when the strength of weak zones is significantly lower than that of the matrix material, because the critical cavitation stress in such a scenario is substantially below the yield strength of the matrix material (e.g., 0.2–0.25 σ_o for $\frac{\sigma_{ow}}{\sigma_o} = 0.1$). Second, cavities grow unstably due to the absence of strain hardening. Third, the occurrence of void coalescence is by the failure of wavy shear bands that run through neighboring cavities, unlike ductile crystalline metals in which cavities coalesce through necking. This special cavity coalescence behavior explains the formation


Fig. 7 The simulated course of cavitation ahead of a notch tip in a metallic glass, as conveyed by the evolution of the maximum principal logarithmic plastic strain $\log \lambda_1^p$ at $K / \left(\sigma_0 \sqrt{L_0} \right)$ of (**a**) 0.67, (**b**) 0.96, (**c**) 1.21, (**d**) 1.45, (**e**) 2.09, and (**f**) 2.37 for $\frac{\sigma_{ow}}{\sigma_o} = 0.1$ (Singh et al. 2016). The metallic glass (yield strength, σ_o) is simulated with the Anand-Su constitutive model (Anand and Su 2005), and three circular weak zones with the reduced yield strength σ_{ow} (radii $r_w = 0.13L_o$ with L_o being the distance between two consecutive zones) are placed ahead of the notch to mimic the density fluctuations in brittle metallic glasses. Each weak zone has a small circular void (radii $r_o = 0.013L_o$) in the center for triggering cavitation. The black dashed lines is indicative of potential crack propagation paths

of nano-corrugations on the fracture surfaces of brittle metallic glasses. Fourth, the failure is brittle because of the unstable cavity growth and rapid void coalescence through confined shear bands and also because non-diffuse formation of shear bands involves minimal plastic dissipation.

4.4 Fracture

Many mechanistic aspects of shear localization-induced fracture in "ductile" metallic glasses and cavitation-induced failure in brittle ones have been covered in the previous subsections. A topic that deserves special treatment in this section is the transition in failure mechanism, particularly when edge notches are present in a metallic glass sample. In a brittle solid (e.g., ceramics and oxide glasses), the introduction of notches tends to bring down strength. This phenomenon is called positive notch effect. However, in metallic glasses different types of notch effects are observed in experiments, including the positive notch effect, notch insensitivity, and

inverse notch effect in which the notched sample has higher fracture strength than the one without a notch (Pan et al. 2015). A number of researchers have attempted to use continuum mechanics modeling to understand the origin of these notch effects, particularly the inverse notch effect. A modified Anand-Su model that accounts for the strongly nonlinear and eventually softening, dilatational volumetric elastic response of metallic glasses was used to simulate the notch-tip fracture initiation in a representative metallic glass under small-scale yielding (SSY) and plane-strain mode-I loading (Henann and Anand 2009). The simulations suggest that the fracture toughness of the notched metallic glass sample increases linearly with the square root of the notch-tip radius and decreases with the increasing ratio of the shear modulus to the bulk modulus. Systematic analysis of the shear band patterns near the notches of different sizes with the free-volume model and the Rudnicki-Rice instability theory by Li et al. (2016a) indicates that increasing the notch-tip radius tends to promote the formation of a higher density of shear bands, corroborating the conclusion by Henann and Anand (2009). In addition, when the notches are shallow (e.g., ≤2 mm), only four branches of radial shear bands far apart from each other emit from the notch roots; as the notches gradually become deep (e.g., ≥5 mm), a new category of semicircular shear bands connecting the two notches emerges, and radial shear bands start intersecting with each other (Li et al. 2016a). This implies that the fracture is transiting from a brittle manner to a ductile one as the notches become deep. Since cavitation processes are missing from the free-volume model, a transition in the failure mechanism cannot be captured explicitly. As a result, all considerations are based on the operation of shear bands. Nevertheless, molecular dynamic (MD) simulations did indicate a transition in the failure mechanism from shear banding at the notch tip to cavitation and void coalescence as notches become deep (Pan et al. 2015).

Other factors that the constitutive modeling has found to have crucial effects on the fracture toughness of notched metallic glasses include the internal friction of the material and mode mixity (Li et al. 2016b; Tandaiya et al. 2007, 2009). Higher internal friction tends to suppress the brittle fracture by microcracking and promotes crack-tip plasticity through the formation of multiple shear bands, thereby toughening metallic glasses. Furthermore, it was conjectured that the large plastic strains resulting from high internal friction may give rise to nucleation and coalescence of microvoids (Tandaiya et al. 2007). As for the mode mixity, the increase in mode-II component can significantly enlarge the plastic zone size and elevate the plastic strain near the notches, stimulating ductile fracture (Tandaiya et al. 2009). Finally, it should be noted that even though many insights have been gained on the fracture mechanism of notched metallic glasses by the constitutive modeling, all previous works are limited to analyzing the deformation/stress fields or shear banding activities ahead of notch tips. A comprehensive constitutive model that unifies the cavitation failure mechanism and shear-banding failure mechanism is still lacking for painting a more sensible mechanistic picture for the failure mechanism transition.

5   Design Applications

In addition to the predictive capability, the constitutive models, once implemented in a finite element program as user subroutines, can be used for guiding material, product, or process designs (Dunne and Petrinic 2005). This capability is one of the most remarkable advantages in the continuum mechanics modeling that is unmatched by experiments and atomistic simulations. Finite element modeling has been used for design purposes in multiple areas in metallic glasses. Broadly, these applications can be classified into two categories: (1) designing metallic glasses for high ductility, strength, and toughness at room temperature and (2) optimizing the net-shape forming processes of metallic glasses at high homologous temperatures. In both types of applications, the constitutive laws have been used.

The first category of design applications in metallic glasses driven by finite element modeling is pertinent to material or product designs. Given that the brittleness is the biggest hurdle limiting large-scale practical applications of metallic glasses, finite element modeling under multiaxial stress scenarios is useful for designing routes for improving their ductility, strength, and toughness. Designs can be at the macroscopic scale (e.g., sample size in mm or above) by manipulating the propagation of shear bands in metallic glasses. Existing proven ways that can effectively improve ductility include creating geometric gradients in a metallic glass sample (Liu et al. 2012), coating a bulk metallic glass with a thin film (An et al. 2012; Jia et al. 2014), making metallic glass matrix composites (Jia et al. 2015), and creating porous structures (Sarac et al. 2014). Fracture toughness and strength of metallic glasses can be improved by changing a wide notch into a narrow and deep one in a metallic glass sample to induce many intersecting shear bands (Li et al. 2016a, b). It is also possible to optimize the design for a specific application consideration. For instance, simulations suggest that when the yield strength is a more important consideration than ductility, the periodic alternating pore configuration design in a metallic-glass porous structure should be the designer's first choice over others (Sarac et al. 2014). On the other hand, if the ductility is the primary concern, the stochastic pore distribution comprised of two different pore sizes is more useful (Sarac et al. 2014). Furthermore, innovative design concepts might be explored to perceive novel composite structures. Examples of such explorations include designing metallic-glass composites filled with discrete particles or with network structures (Jiang et al. 2017).

Designs can be also at the microscopic scale (e.g., atomic level) by controlling the initiation site of shear bands and the way they interact with each other. This is achieved by manipulating the distribution of free volume. It has already been proven by experiments that structural heterogeneities exist in metallic glasses at the micro- or sub-microscale and their amount and distribution govern the intrinsic fracture toughness and ductility of metallic glasses (Li et al. 2013, 2015). But the question about at what amount and distribution a metallic glass can gain most in its fracture toughness is still elusive. While this question is not trivial for experimentalists to answer, it is much more tangible by utilizing the low-cost and efficient optimization capability in the finite element modeling. As the free volume is a microscale quantity

Fig. 8 Top row: the shapes of a miniature gear component achieved by the superplastic forming of the $La_{61.4}Al_{15.9}Ni_{11.35}Cu_{11.35}$ metallic glass in experiments. Bottom row: the shapes obtained from the simulation with the use of a metallic-glass constitutive model at high homologous temperatures (Thamburaja and Ekambaram 2007). (**a**) Initial shape, (**b–d**) intermediate shapes, and (**d**) final shape. The forming process is conducted at an ambient temperature of 432 K with the use of a pre-made die (Ekambaram et al. 2010)

implemented in many constitutive models, manipulating the distribution of the free volume is analogous to manipulating that of structural heterogeneities. For this reason, designing the distribution of the free volume with finite element simulations can give promising results. For instance, it was found that certain controlled free-volume gradients could help boost the strength and toughness of metallic glasses (Wang et al. 2017a). Also, a bimodal distribution of the free volume is more effective than a Gaussian-like distribution in toughening and hardening metallic glasses (Wang et al. 2016). These modeling results provide important insights on designing metallic-glass-matrix composites with enhanced ductility and toughness. Specifically, in order to obtain the best performance in toughness, the type and distribution of the two phases in an experimental metallic-glass composite system should be adjusted in such a way that the free-volume distribution matches the optimal scenarios predicted from simulations (Wang et al. 2016, 2017a, b).

The second category of design applications in metallic glasses driven by finite element modeling involves forming process designs. Within the supercooled liquid region, metallic glasses have very low viscosity and excellent formability. As metallic glasses near supercooled region can flow very easily and exhibit superplastic-like deformation characteristics, these materials are much more advantageous than any other metallic materials in the net-shape forming of complex components. Superplastic forming processes like blow molding and injection molding commonly used in the formation of plastic components are all likely to be utilized for metallic glasses in this temperature regime. As in many other metal forming processes,

finite element simulations can find unparalleled values in optimizing the superplastic forming process of metallic glass components. With the metallic-glass constitutive model at high homologous temperatures implemented in finite element software (Thamburaja and Ekambaram 2007), attempts of this kind have been made in the process of designing metallic glass miniature gears (Ekambaram et al. 2010, 2011). The top row in Fig. 8 progressively shows the component shapes formed at different experimental forming stages at an ambient temperature of 432 K (Ekambaram et al. 2010). The bottom row is the prediction at the corresponding stages by the finite element model, whose material parameters have been determined by fitting the constitutive model to a set of stress-strain data obtained from uniaxial compression tests conducted at various strain rates and temperatures. It is seen that the model is capable of precisely replicating the entire forming process achieved in experiments. If a damage criterion is included, the simulation is also able to predict potential failure spots during the forming process (Ekambaram et al. 2011).

Abstract

In this work, we review recently developed methods for quantifying the fundamentals of organic-glass adhesion. This chapter will explore modeling methods, which serve to further develop the known scientific knowledge available. The problem of building more advanced models for characterizing adhesion is approached at two different scales, viz., electronic and atomistic levels. Implementing a multiscale approach, we present our findings on the role of polymer chemistry, polymer rigidity, structure of inorganic substrates, and inorganic surface attributes such as the role of hydroxylation and surface roughness. This work is focused on physisorbed systems consisting only of nonbonded interactions between the organic and glass interface. We find that hydrogen bonding, surface roughness, electrostatics, and the flexibility of organic molecules affect adhesion the most. This result is consistent across length scales for polymers ranging from the subunit or molecular fragment scale to the full polymer film thickness. Based on this work, we propose a few salient steps to drive the modeling capabilities towards assessing functional performance of organic inorganic multilayers, which are increasingly becoming an integral part of various electronic devices.

1   Introduction

1.1   Importance of Adhesion of Organics Onto Glass

Organic-inorganic adhesion is critical for numerous practical applications, such as protective coatings, adhesives, thin-film transistors. Each organic and inorganic surface is unique and confers its own material attributes (e.g., Young's modulus or coefficient of thermal expansion) to the interface. Inorganic glass substrates including high-purity fused silica, ion-exchanged aluminosilicate glass, glass-crystal composites, soda lime silicate, and borosilicate glasses are commercially available and are widely used in industry. Thermally stable organic polymers such as polyimide (e.g., Kapton, UPILEX) are often used in high-temperature applications such as flexible display substrates, protective coatings, and adhesives because of their excellent mechanical, thermal, and chemical-resistant properties (Escott et al. 1990; Liaw et al. 2012).

Although conventional plastic materials are shock-resistive, lightweight, chemically stable, easy to form into various shapes, suitable for continuous process, insulating, and optically transparent; their poor thermal stability has limited their use as flexible substrates for display applications (Whittingham 2014; Wong and Salleo 2009). Specifically, during flexible display manufacturing, the processing temperature can rise above 300 °C, above which most plastic materials decompose (Wong and Salleo 2009). Due to these limitations, Polyimide (PI) materials have generated significant technical interest due to their thermal stability, mechanical properties, and electrically insulating nature (Chen et al. 1995; Cheng et al. 1991; Liaw et al. 2005; Ghosh and Mittal 1996). These properties have led to PI being used for a wide range of engineering applications, including laminated automobile windshields, polymer-coated optical communication fibers, and pharmaceutical glass labware with antifriction polymer coatings (Ghosh and Mittal 1996; Ni et al. 2015; Fryd and Mittal 1984). In particular, PI is one of the most favorable substrate materials used in the production of flexible displays as they largely determine performance and reliability of the display (Ni et al. 2015; Choi et al. 2010). Due to the aforementioned reasons, this chapter is dedicated to understanding the interface between PI and glass. We choose silica as the glass of interest as it helps us simplify the chemistry and understand the effect of structure and surface properties on the PI-glass interface.

The properties of glass and polymers undergo changes during processing and the unique interfacial characteristics could potentially introduce variability to both the process and the product attributes. A practical issue to contend with, during the process of flexible display manufacturing, is that PIs tend to delaminate from the supporting glassy material. This potentially increases the risk of structural failure at the organic glass interface. For these systems, the adhesion between polyimide and glass needs to be understood to avoid structural failure (Juhl et al. 2014; Chaudhury et al. 1987). The failure in these composite systems can occur at the interface between polyimide and glass, known as adhesive failure, or within the polyimide layer or the underlying inorganic layer, known as cohesive failure. Adhesive failures is one group of the dominant failure modes in electronics (Klee and Hocker 1999) and hence is the focus of this chapter.

Adhesion is the key interfacial phenomenon observed in the assembly and packaging process for electronic devices, and this interfacial adhesion is complex and is driven by many different factors such as the physical (e.g., roughness) and chemical nature of the glass surface, types of polymers, rigidity, thermal behavior, humidity, chemistry of the coupling layer between the glass and the polymer (Lacombe 2006; Awaja et al. 2009). Specifically, adhesion between polymer and glass can be influenced by the inorganic glass surface roughness (Peterson et al. 2011), surface and bulk composition (Gellert and Turley 1999), density of hydroxylated groups (Choi et al. 2008), zeta potential (Klee and Hocker 1999), and physisorbed water layers (Holbery and Houston 2006); all of which, in turn, could affect the overall functionality of the glass-polymer application.

For a functional flexible display substrate, efficient control of the adhesion between the PI substrate and the carrier glass is particularly important. This is because the adhesive interaction must be strong enough to maintain structural

integrity while also being weak enough to allow for separation of the PI from the glass; thus, the adhesion energy should be neither too strong nor too weak. If it is too strong, the detachment process causes unrecoverable damage at the interfacial region, resulting in structural failure. If it is too weak, then the glass carrier cannot perform its function of holding PI and the other components placed on its surface during assembly. Hence, developing an understanding of the adhesion mechanism and determining the governing parameters at the interface of PI and glass is critical for improving the manufacturing process.

1.2   Characterizing Adhesion Via Experiments

The degree of adhesion can be measured by experiments and is referred to as practical adhesion (Pizzi and Mittal 2003). Multiple direct measurement techniques can be used to obtain the practical adhesion (Ferreira et al. 2005; Friedrich et al. 2005; Chen et al. 2007; Mathieson and Bradley 1996; Lacombe 2006; Beake et al. 2002; Dai et al. 2006), and the most commonly used techniques are the peel and pull-out tests. In these tests, a tape or a stud is placed on the sample and pressure is applied until failure. This force or pressure required to cause failure is used to calculate the practical adhesion. While these tests provide quantitative measures of adhesion, plastic deformation in film, patterns of mechanical loading, and other factors cause inaccuracies in the measured adhesion values (Piggot 1997; Favre et al. 1997; Hampe and Marotzke 1997). An experimental study for aromatic PI films on SiO_2 suggests that no chemical bond is observed at the interface and the nonbonded interaction between the materials would play a key role in determining the adhesion strength (Miwa et al. 1993). In addition, a surface structure of PI modified by longer curing time and UV-exposure can increase the adhesion strength between PI and Si based substrates (Grady et al. 2014).

Many experimental studies exist on the topic of understanding polymer adhesion to substrates, such as glass, metals, and ceramics (Brown 2000). The literature suggests that there is continuous development of processes for improving experimental measures of adhesion (Zeng et al. 2016). Adhesion of polymer to substrates without surface treatment may be good initially; however, adhesion can deteriorate when temperature and humidity changes. Therefore, in most cases, surface modification is important to enhance adhesion of polymer to solid surfaces. Some surface treatment methods may include industrial technologies such as UV, ozone, plasma, as well as chemical modifications. In addition, microstructures on the substrate or on the film could enhance adhesion through mechanical interlocking (Larsson and Ahmad 2006). Another work highlighted the importance of van der Waals and capillary interactions for enhanced adhesion. Studies on Geckos showed the nature of adhesion of submicron features. Authors discussed that each gecko hair could produce a minuscule force $\sim 10^{-7}$ N (Geim et al. 2003). Polymer-substrate, specifically polymer-glass interactions and strength, is typically dominated by hydrophobic, hydrophilic interactions and hydrogen bonds. When coupling reagents are applied, the agents could react with adsorbed water on the surface, reducing its surface energy and by reacting with the surface hydrogen and oxides to form

covalent bonds. In some cases, physical entanglement between three chemical layers – surface, adhesion promoter, and polymer – could take place. End groups on most coupling agents such as silane could determine the type of interaction between polymer and glass. Atomic Force Microscopy (AFM) and contact angle results indicate that the type of chemical functional group in the coupling agents play a key role in determining the strength and nature of polymer-surface interactions (Dvir and Gottlieb 2009). For chemical-based treatments, typically aminosilane coupling agents are reported as effective treatment for polyimide (PI). The most popular silane, for PI, is GAPS, γ-aminopropyltrialkoxysilane that bonds to glass and PI. Typically, for chemical interactions, monolayers of silanes are preferred. For the case of thicker adhesion promoters however, adhesion could yet improve by creating an interpenetrating network in the interfacial region and the polymer matrix leading to mechanical interlocking. It is recommended to maintain the thickness of the coupling agent within 50 nm or lower for good adhesion. Overall, both chemical and physical (mechanical) interlocking have been shown to enhance adhesion of polyimide to inorganic substrates like glass (Ghosh and Mittal 1996).

As the application of glass broadens to a wider range of display devices and microelectromechanical systems (MEMS), it is important to fundamentally understand the key factors at a molecular level that determine the bonding and debonding of polymers to/from substrates. There is limited information in the literature that shows the impact of substrate-film compositions and environmental conditions such as humidity, temperature, and time. Sufficient experimental data are also lacking on morphological and surface roughness effects on adhesion. It is also relevant to understand interfacial failure modes of polymer films at the time of debonding.

1.3 Computation of Adhesion and the Need for Development

Computational modeling is a powerful tool that can be used to study the adhesion behavior of organic molecules on inorganic surfaces. Among the many tractable computational approaches for the organic-inorganic interfaces, molecular dynamics with classical atomistic force fields has been used to study a variety of inorganic glass systems (Gruenhut et al. 1997; Yang et al. 2016; Priezjev 2016; Luo et al. 2016; Zhao et al. 2016; Mantisi et al. 2015; Deb Nath 2013) and their properties, including chemical diffusivity, structure, and mechanical properties. Similarly, this approach has been used to elucidate polymer attributes, including packing ability and structure factors (Sliozberg et al. 2016; Jung et al. 2016; Aoyagi 2015), adsorption processes (Mashio et al. 2016; Shoravi et al. 2016), and rheological properties (Kang et al. 2010; Sirk et al. 2016; Sablic et al. 2016; Jabbarzadeh 2006). When combining the glass and polymers together in a molecular dynamics simulation however, a deficiency in the available tools and parameters prevents the accurate modeling of the interfacial properties (e.g., adhesion). There is some published work on characterizing certain interfacial attributes of silica nanoparticles in a polyimide matrix (Marotzke and Hampe 1997; Pizzi and Mittal 2003; Cheng and Wagner 2009). These papers do not capture the effects of electronic structure of the chemical

environment of these atoms or how they interact with the inorganic surface atoms in a concerted manner, to either enhance or limit the overall adhesion of the monomer – and ultimately the polymer – onto the surface. To address such questions at this level, we need to use more detailed methods such as density functional theory (DFT) or ab initio molecular orbital theory.

In the literature, DFT has been used to investigate different glassy systems containing atoms in the low hundreds (<400) to address problems such as the structural evolution of germanium melts (Bouzid et al. 2015), embedded clusters in silica (Du and Kroll 2010), bioactivity mechanisms of soda-lime phospho-silicate glasses (Berardo et al. 2013), interface of silicon surfaces with water (Pham et al. 2014), densification of silica (Izvekov and Rice 2012), molten glass structures (Ohkubo et al. 2016), and nanocomposite materials for solar energy collection (Wippermann et al. 2014). These studies used B3LYP (Becke 1993), PBE0 (Adamo and Barone 1999), and PW91 (Perdew and Wang 1992) functionals that have shown good predictions for the structure, effects of compositional changes on structure and electronic band structure and band gap. Using a similar set of functionals, DFT studies on polymers have included prediction of polyvinyl refractive optical properties (Yu et al. 2007), entropy of mixing and phase transitions of homopolymers (McMullen and Freed 1990), stability and reactivity of polyimides for fuel cells (Lopez-Chavez et al. 2014). The literature is very limited when it comes to the characterization of the organic-inorganic interfacial system. The closest references include carbon dioxide (Cui et al. 2016), hydrogen (Lahmer 2015), or other small molecules (Muhich et al. 2015; Gleizer et al. 2014; Ren et al. 2009) reacting on metallic transition metal surfaces.

To understand adhesion phenomena in the interfacial system comprehensively, the computational model should be capable of capturing complete atomistic details while spanning nanometer length scales which are the typical thicknesses of such interfaces. From this point of view, molecular dynamics (MD) is ideal to generate a microscopic understanding of the interaction mechanisms at the interface. Typically, for simulating inorganic materials like silica glasses, nonbonded or partially bonded force fields like Pedone et al. (2006, 2008) and BKS (Beest et al. 1990) have been used to study glass structures. Simulations with these nonbonded force fields have been used to understand the bulk properties, structure of silica, and the interfacial properties with other inorganic materials like silicon (Lee et al. 2007). These force fields, while allowing for dynamic bond breakage and formation as reflected by changes in local structure, cannot accurately describe the structure of organic molecules, which require explicitly defined angles and dihedrals. Hence, for organic molecules, bonded force fields such as PCFF (Sun et al. 1994), CVFF (Dauber-Osguthorpe et al. 1988) and COMPASS (Sun 1998) have commonly been used. While these bonded force fields have elucidated the bulk properties, structure, and changes in interfacial density distribution of the polyimide at the interface between polyimide and silica (Yang et al. 2012; Komarov et al. 2013; Odegard et al. 2005), they have not been used to systematically study the adhesion properties at the interface.

This gap in understanding of the organic-glass interfaces is partially due to the absence of reliable force fields that can accurately predict their interfacial

interaction. Since we are primarily interested in the interfacial interactions of an inorganic surface with a polymer, it is important to use a force field that accurately describes them. Potentials such as PCFF, CVFF, and COMPASS predict polymer properties well but are not optimized for interfacial interactions and surface properties such as surface tension and binding energy. Recently two force fields, ReaxFF (Mueller et al. 2010; Chenoweth et al. 2008; ACTv et al. 2001) and Interface FF (Heinz et al. 2013; Emami et al. 2014a), have shown promise in addressing these problems. Both of these force fields have their own advantages and disadvantages. ReaxFF, a force field based on bond order, is able to model reactions by describing bond formation and breakage between the molecules. The large computational time with this force field however limits the system size of the interface under study. On the other hand, the Interface FF requires less simulation time and accurately predicts properties such as contact angle, heat of immersion (Emami et al. 2014a), and adsorption of peptides (Emami et al. 2014b) but cannot be used to model reactive surfaces.

For example, a simulation study for the interfacial properties within a glassy polymer reveals that the adhesion is governed by the relation between the strength of adhesive (attraction between different materials) and cohesive (attraction within the same materials) interactions (Xia et al. 2014). This study suggests that the cohesive interaction can be affected by incorporation of adhesion agents or altering the degree of the side chain functionalization. For the adhesive interaction, its strength depends on the interface coupling and relaxation of chains at the adherent layer. In addition, Tam et al. suggest moisture as another adhesion-determining factor, which can deteriorate the adhesion strength of epoxy-silica interfaces (Tam and Lau 2015). Despite several experimental and computational investigations, comprehensive understanding of adhesion determining factors is still lacking.

The current computational literature in the area of polyimide interactions with glass does not have detailed studies of how the individual subunits constituting the organic monomers interact with the glass surface. Further, there is currently limited or no effort to understand how these interactions at the subunit level scale up to the monomer scale. Finally, the effect of adhesion of polymer chains of these polyimides on glass has also not been addressed in the literature.

1.4   Focus of This Chapter

In this chapter, we share computational methods to study the fundamentals of the organic glass interactions at three different length scales.

Electronic scale simulations for organic subunits interacting with glassy surfaces: Given the gap in understanding the detailed interactions between polyimide monomers and silicate surfaces, we focus on addressing this specific interfacial system. The composite model of polymers on a glass surface requires large system sizes to explore this question. A typical polyimide monomer, for example, BPDA 1,4,4-APB, has around 60 atoms and a small inorganic surface has around 350 atoms, hence to consider the entire system would result in a fairly large system (>400 atoms) by DFT/ab initio standards. On the other side of the interface, the

glass requires a reasonably large system size, for example, at the very least 300 atoms (for its nonperiodicity), making the interfacial system with the added polymer computationally expensive. To address the system size problem, we used two approaches to scale down the model to access more accurate quantum mechanical approaches to probe the interfacial interactions properly. To handle the polymer length, we propose an initial approach of dividing the monomer into its constituent organic subunits/molecules and probe the interaction of each of these subunits with the inorganic surface. While this simplified approach cannot address the larger scale morphological physics of the polymer material on a surface, it should allow us to capture the unique interactions between the materials more accurately than classical approaches. The learnings from this model could then potentially be used to either perform a few select studies for a larger system or develop better parameters to then study the larger system with a classical force field. To further reduce the system size, we identify surrogate crystal structures like a two dimensional (2D) silica bilayer which has certain attributes of glassy silica. Then, we systematically look at different crystalline variants (with compositions representative of industrial glasses) like kaolinite and hydroxylated albite where we investigate the effect of surface structure and composition (atomically smooth vs. more opened hydroxylated surface), compositional variation like role of Si, Al, Na, and effect of hydroxylation of the surface in controlling the adhesion. By understanding the interactions between the five different inorganic surfaces with five different organic subunits (that constitute the BPDA 1,4,4 APB polyimide), we achieve significant fundamental understanding of the key factors that drive the stickiness of inorganic surfaces to certain types of organic molecules. In our analysis, we will show a level of theory comparison for different DFT methods, explore an adhesion of single and double aromatic ring molecules across all glassy silica surfaces, a closer inspection of their adhesion to hydroxylated surfaces, and analysis of the overall trends of all subunits and surfaces.

Organic monomer interactions with glassy surfaces: At the monomer glass scale to better understand the complex nature of the interactions, in this chapter, we focus on elucidating the molecular origins of this adhesion, the effect of silica structure and hydroxylation, and the effect of polyimide structure and chemistry in greater detail. To address these questions, we present a framework to study this adhesion systematically. Specifically, we begin with careful calibration for the ability of the Interface FF to describe the bulk properties of polyimide and the surface properties of silica. We then use Interface FF to demonstrate the use of the Steered Molecular Dynamic (SMD) approach to study the effect of polyimide monomer adhesion onto crystalline and glassy silica with and without hydroxylation for four different polyimide monomers. Using the developed framework, we elucidate the role of surface structure, degree of hydroxylation, and polyimide chemistry.

Interaction of polymer chains with glassy surfaces: Finally, at the polymer chain glass scale, we attempt to understand fundamental aspects of the interfacial adhesion phenomena for various types of PIs placed on SiO_2 glass. Among several methodologies for measuring adhesion properties, the pulling test is chosen to mimic the experimental detaching process of PI from the carrier glass during the

manufacture of the display. The pulling method is applied within the framework of the Steered Molecular Dynamics (SMD) method, which has been successfully implemented in simulations by employing the same physical protocols of pulling in experiments (Tam and Lau 2015; Yang et al. 2013; Büyüköztürk et al. 2011; Lee et al. 2014). During a pulling test, adhesion determining properties such as the potential of mean force (PMF), pulling distance, and detaching force are calculated with the reactive force-field (ReaxFF). Furthermore, characteristic responses depending on the thermal properties of the polymer chains are obtained, using both coefficient of thermal expansion (CTE) values from experiments and supplemented qualitatively through simulation of variations in the chain conformation. The change in chain conformation during detachment is also examined in detail, particularly at the interfacial region. In addition, each energy term in the potential is decomposed to clearly determine which term contributes significantly to deformation during the pulling process. Finally, an investigation of the failure mechanism is performed to determine whether adhesive or cohesive failure occurs at the interface.

2 Electronic Methods

We calculate the energy of the combined system (i.e., organic subunit in the lowest energy configuration on the surface) and subtract the total of the energy of the inorganic surface and the organic subunit in vacuum. This difference is what is reported as the adhesion energy for the rest of our study.

2.1 Description of the Inorganic Surfaces

A glass surface has many attributes such as the degree of hydroxylation, density and types of cations, and type of hydroxylated species (e.g., Si vs. Al). To systematically understand the role of these different glass surfaces' attributes on the binding of organic molecules, we construct a series of surfaces that start with the simplest two dimensional silica bilayer (Sirk et al. 2016) and gradually increase the complexity by hydroxylating and adding cations. The progression of simple to complex surfaces considered for this study is shown in Fig. 1 where, following the left branch in the figure, the 2D silica bilayer is first translated into a full three dimensional (3D) silica structure, and by a hydroxylation procedure, generates the hydroxylated quartz surface. With the introduction of sodium and aluminum, we obtain a hydroxylated albite surface. Similarly, following the right branch in the figure and again starting with the 2D silica bilayer, we introduce a 3D silica structure along with the aluminum cation resulting in the kaolinite system. Kaolinite $(Al_2Si_2O_5(OH)_4)$ presents two different surfaces to the organic subunits, an aluminum and silica rich side. To distinguish these sides, we will use the notation Al-kaolinite or Si-kaolinite to indicate the respective surface being studied. Kaolinite does have aluminols as part of its crystal structure. With the addition of sodium and modification of the hydroxyl groups of kaolinite, one obtains the hydroxylated albite surface. The
Fig. 1 Progression of surfaces, simple (2D silica) to complex (hydroxylated albite) used in this study to understand the role of surface composition. The coloring scheme that will be used for all figures is as follows: sodium (blue spheres), silicon (yellow), aluminum (pink), oxygen (red), and hydrogen (white)

Table 1 Surface number densities per nm^2 of each cluster

Surface	Hydroxyl	Sodium	Aluminum	Silicon
2D Silica	0	0	0	17.5
Kaolinite	0	0	8.8	11.3
Hydroxylated Quartz	4.9	0	0	13.0
Hydroxylated Albite	3.5	3.5	4.2	12.1

dimensions of these surfaces are roughly 20 Å × 20 Å × 10 Å, containing ~180 atoms for each system. The surfaces are net neutral in charge (by end capping with hydrogen atoms) and are obtained from the American Mineralogist Crystal Structure Database. The number densities of each elemental species are provided in Table 1.

2.2 Description of the Organic Molecules

We focus on polyimides and specifically the BPDA 1,4,4-APB since this is a commonly used system. A single monomer of BPDA 1,4,4-APB has roughly 60 atoms. To study the adhesion of a single monomer onto the inorganic surface, the

overall system would have over 300 atoms. These calculations are computationally expensive for the different levels of theory. To manage the computational cost while maintaining reasonable accuracy for interfacial interactions, we computationally decompose the polyimide monomer into five different subunits as shown below in Fig. 2 as explained in the Introduction. The five subunits can be divided into two categories: one-aromatic ring molecules (benzene and phenol) and two-ringed molecules (phthalimide, N-phenylmaleimide, and diphenyl ether). The differences in the chemical nature of these subunits are listed below in the Fig. 2, where it can be seen that all of the molecules besides benzene are either hydrogen bond (H-bond) donors or acceptors, suggesting that they can participate in hydrogen bond formation with the silicate surfaces. This is important since the differences in the strength of the interactions between these are almost always directly related to their hydrogen bonding tendencies.

2.3   Level of Theory Calibration and Selection of Computational Approach

We investigate both periodic and cluster systems to calibrate the optimum level of theory required for the simulation. Using the ab initio methods, we are restricted to working with a cluster model. On the other hand, DFT is used to study both cluster and periodic systems to ensure accuracy of the cluster model and of the DFT

comparison to ab initio results. By grounding our cluster calculations with the ab initio MP2 (Møller and Plesset 1934) method, we intrinsically expect to capture the van der Waals interaction more accurately and therefore better compare among all levels of theory. Additionally, we studied the DFT method with the Grimme correction (Grimme 2006a), DFT-D2, which is meant to capture the effect of van der Waals more accurately than with ordinary DFT (Grimme 2006a, b). Similar to our study, simple organic molecule adsorption on metal surfaces used DFT-D2 and was found to overestimate the adhesion energy (Tonigold and Grob 2010; Andersson 2013). The proper treatment of DFT-D parameters of metal atoms at this point remains an open question. Due to these concerns, we do not attempt to optimize the DFT-D2 correction parameters.

2.4   Initial Model Setup

For the cluster calculations, we need a good starting configuration using a periodic system to determine the important surface groups and their configuration to carve out the cluster model. First, we generate 100 initial configurations using a standalone script. This script applies rotations and translations to the organic subunits with respect to the surface. These configurations are used for geometry optimization in VASP (Kresse and Hafner 1993) using PBE (Perdew and Wang 1992) with PAW (Blochl 1994) and a plane wave cut-off energy of 250 eV with a vacuum size of 30 Å. From these 100 different configurations, a certain fraction (typically 10%) was discarded due to unfavorable contacts with the surface. We identify the lowest energy configuration of each structure to create the cluster system, which is used for the level of theory calculations and other analyses.

2.5   Differences in Adhesive Behavior of Phenol and Phthalimide on the Five Different Inorganic Surfaces

In this section, we compare two subunits (single ring phenol and double ring phthalimide) across all the different surfaces. From Fig. 2 we recall that phenol has a hydroxyl group that can participate in hydrogen bond formation. The phthalimide has two carbonyl oxygen groups, which can again participate in hydrogen bond formation. The other structural difference to note is that phenol has one aromatic ring, while phthalimide has one aromatic ring in conjunction with a five-membered ring containing nitrogen. The presence of nitrogen also contributes to the increased electronegativity, which could promote further interactions.

Given these structural differences, we see that the adhesion of both of these molecules increases when progressing from 2D silica to hydroxylated albite. For phenol, moving from the 2D silica to Si kaolinite surface the adhesion energy increases only slightly from −11.6 kJ/mol to −11.7 kJ/mol. Although the Si kaolinite surface structure does have an aluminol embedded, its surface is very similar to 2D silica including the adhered. When we consider the interaction between phenol

and the Al kaolinite surface, the adhesion increases to -12.1 kJ/mol. Phenol adhered structures are much more planar on the Al kaolinite surface than on the Si kaolinite. The phenol distance from the surface is similar between both Si and Al kaolinite (since this measurement is taken from the plane of the Al (for Al kaolinite) or Si (for Si kaolinite)). The hydroxyl hydrogens in kaolinite are there for charge compensation of the alumina layer. Due to this charge compensation and confined Al geometry, upon adhesion, these hydrogens are not able to rotate as much as a hydroxyl group found in other hydroxylated surfaces (e.g., hydroxylated quartz).

On hydroxylated quartz, we see that the H-bond distance of the phenol is shorter than on Al kaolinite with an angle of 35° vs. 15° (more inclined and less planar), clearly suggesting that the increased adhesion (by 3.2 kJ/mol compared to Al kaolinite) is being driven by the enhanced hydrogen bonding between both the surface hydroxyl groups and that of phenol. Finally, on hydroxylated albite, which presents Si/Al/Na/O and OH groups on the surface, we see that the adhesion increases by 8.7 kJ/mol with respect to 2D silica. Furthermore, when we compare the adhesion with respect to Si kaolinite and Al kaolinite, we see an increase of 7–8 kJ/mol. Comparing hydroxylated quartz with hydroxylated albite, we see an increase of ∼5 kJ/mol. We also observe that the distance of phenol from the inorganic surface is greatest for the hydroxylated albite substrate; however, the hydroxylated albite surface has inherent roughness and hence the distance is less well defined compared to the other smooth surfaces likes 2D silica. The orientation of these organic molecules are also less planar on hydroxylated albite, but now two hydrogen bonds are observed, one being mediated by the surface hydroxyl groups and the other interestingly by the sodium atoms. This allows us to conclude that the presence of sodium atoms on the surface enhances the adhesion by close to 5 kJ/mol and is largely due to the electrostatic nature of the interaction between the positively charged cation (Na) and the negatively charged hydroxyl group (OH) on phenol. The presence of surface sodium also brings the surface hydroxyl groups closer to the sodium, which potentially strengthens the hydrogen bonding between these hydroxyl groups and that on phenol.

Turning our attention to the adhesion of phthalimide, we see some similarities in the behavior with phenol and some interesting differences. As with phenol, the adhesion energy of phthalimide progressively increases from 2D silica to hydroxylated albite. For both the kaolinite surfaces, these two subunits adhere in a more planar configuration due to the same two reasons: (1) Si kaolinite is atomically smooth like 2D silica and (2) the rigid noninteracting aluminols prevent any direct hydrogen bonding. However, the degree of adhesion of phthalimide onto Si kaolinite and Al kaolinite is weaker compared to phenol on the same two surfaces. We attribute this difference to the fact that phthalimide is a larger molecule containing two rings, which enhances its rigidity and steric hindrances, especially for less planar surfaces. Notice the difference between phenol and phthalimide on the hydroxylated quartz surface. Here, the adhesion energy is similar (phenol -15.3 kJ/mol vs phthalimide -16.3 kJ/mol) but the angle, which the subunit makes with respect to the surface, is very different (35° for phenol vs. 16° for phthalimide). This difference in orientation is driven by the fact that phthalimide makes three

hydrogen bonding contacts with the surface while phenol makes only one. These additional bonds restrict the orientation on the surface increasing the planarity of the molecule.

When we examine the behavior of phthalimide on hydroxylated quartz and hydroxylated albite, we see that phthalimide finds these two surfaces highly adhesive. On hydroxylated quartz, the presence of the surface hydroxyl groups clearly mediates at least 3 hydrogen bonds, resulting in a much flatter orientation of the phthalimide with respect to the surface. This change in orientation clearly allows more of the phthalimide groups to interact with the surface, which results in an increase of adhesion energy by 1 kJ/mol compared to phenol. On hydroxylated albite, the presence of the positively charged cation appears to increase the overall electrostatic interactions between the two negatively charged carbonyl oxygens on phthalimide and the electronegative nitrogen atom and contribute to an 8 kJ/mol increase in the adhesion. This is greater than the 5 kJ/mol increase we saw with phenol's adhesion moving from hydroxylated quartz to hydroxylated albite.

These two comparisons bring out some of the fundamentals of adhesion of organic molecules onto surface. There is a balancing act between the polar groups' nonbonded interactions and the subunit's planarity/rigidity that drives how close the adhered molecule can approach the surface. From the surface perspective, composition changes can alter both structure and electrostatic environment as seen from both the Si kaolinite and the Al kaolinite surfaces. Understanding these adhered configurations with respect to surface and subunit characteristics, one could possibly formulate an optimized adhesive material by manipulating either the inorganic surface attributes like type of cation or tailoring the organic moieties like presence/absence of ring like structure, nature of chemical groups, size, etc., through computer-aided material design techniques.

2.6   Differences in Adhesive Behavior of the Five Different Organic Molecules on Hydroxylated Inorganic Surfaces

2.6.1   Behavior of Single Ringed Organic Molecules

When we compare the behavior of benzene and phenol adhesion to the two hydroxylated surfaces, it is to be expected that phenol binds more strongly on both these surfaces (due to hydrogen bonding) and further overall adhesion to hydroxylated albite is tighter. This is in line with the analysis presented in the earlier section where the presence of surface hydroxyl groups, sodium cations, and aluminum were all involved with enhancing the adhesion energy of hydroxylated albite. The increase in adhesion energy between phenol and benzene is -12.2 kJ/mol on hydroxylated quartz, while on hydroxylated albite it is -12.5 kJ/mol. The overall adhesion of both benzene and phenol individually increased on hydroxylated albite, while the net difference in adhesion was comparable to that observed on hydroxylated quartz.

2.6.2   Behavior of Double Ringed Organic Molecules

With respect to the double-ringed structures, we explained earlier that phthalimide has three key atoms that play a role in enhancing the adhesion: the two carbonyl oxygen atoms and the nitrogen atom. When we compare the N-phenylmaleimide structure with the phthalimide structure, we note that they both contain these two carbonyl oxygen atoms and the nitrogen atom. However, N-phenylmaleimide's nitrogen serves as the linker atom between the 5 membered ring structure (forming tertiary amine) and the phenyl group while in phthalimide the nitrogen atom is freely available (forming secondary amine) and is bonded to a hydrogen atom. This small but subtle change from a tertiary to secondary amine is likely to result in differences in the adhesive behavior because the nitrogen can access the aromatic ring's delocalized π cloud (lowering nitrogen's affinity to any surface group) and this is a planar sp^2 imide nitrogen.

Diphenyl ether has two aromatic rings that are linked by the ether bond through the oxygen atom. This oxygen has reasonable access to the delocalized pi electrons from either of the aromatic rings, and the ether bond is known to be less rigid than the nitrogen-carbon bond seen in N-phenylmaleimide. This is likely to confer overall a slightly larger flexibility for the two aromatic rings that constitute the ether, which could potentially handle steric hindrances a bit more effectively. When we look at N-phenylmaleimide and diphenyl ether, one might have expected that the N-phenylmaleimide should have had stronger adhesion given that functionally it has the two carbonyl oxygens and the nitrogen atom. We however observe that the adhesion energy is comparable to that of diphenyl ether and perhaps just a bit higher (-0.8 kJ/mol) on hydroxylated quartz while actually being a bit lower on the albite surface (-0.5 kJ/mol). These results in light of the earlier analysis reinforces that the electronegativity of the N-phenylmaleimide while helping adhesion is perhaps being limited by its intrinsic rigidity or limited conformational flexibility.

The chemical nature of the organic molecules plays a large role in modulating the adhesion. Specifically, certain locations can alter the chemical environment significantly. For instance, N-phenylmaleimide has the same three chemical groups as phthalimide, but changes in rigidity and limited availability of all the atoms to participate in the surface interaction limit the overall adhesion. In addition, the size of molecules affects adhesion and smaller molecules have lower steric hindrances and hence greater access to the surface, but the presence of certain functional groups like the carbonyl oxygens and nitrogens can enable better interactions with surface groups, which could offset the steric hindrances with heightened adhesive interactions. In other words, larger molecules may experience larger steric hindrance but can adhere more tightly due to the increased interactions of the additional functional groups. These trends help in explaining the fundamental nature of what drives the interactions and what can be leveraged to modulate the surface interactions.

2.7   Summary and Conclusions

The overall result summary is shown in Fig. 3. Benzene is found to have the weakest adhesion which is understandable given that it is an aromatic molecule with very little to no groups that can have nonbonded interactions with our inorganic surface either through hydrogen bonding or electrostatic interactions. Having an easily rotatable bond, phenol has relatively strong adhesion on all surfaces and does follow the progressive trend from 2D silica to hydroxylated albite. Being able to both hydrogen bond donate and accept is a key attribute to increase adhesion on hydroxylated surfaces as seen by phthalimide. From the most complex in compositional space and being hydroxylated, albite was the most adhesive surface. To summarize, we observe four points that mediate interactions at the organic-inorganic interface;

1. Hydrogen bond formation is a critical factor in mediating the nonbonded interactions.
2. Electrostatics can play a significant role as seen from the role of sodium in the presence of negatively charged groups like hydroxyl.
3. Changes in surface composition can alter both structure and electrostatic environment as seen from both the kaolinite surfaces which hydrogen bond accepting subunits are favored to bind on the alumina side.
Fig. 3 Plot showing the combined trends of hydroxylation, aluminol addition, and cation across all surfaces and subunits. Arrows indicate the adhesion trends going from 2D silica to kaolinite (blue arrow), to hydroxylated quartz (red arrow), then to hydroxylated albite (green arrow)

4. Rigidity of the organic subunit can enhance the adhesive contact by lowering the conformational degrees of freedom, which allows for additional stability with respect to the surface interactions. For instance, N-phenylmaleimide has the same three groups as phthalimide, but changes in rigidity limit the availability for all the atoms to participate in the surface interaction thereby limiting the overall adhesion.

Lastly, our analysis shows good agreement between classical and DFT-based reconstituted monomer adhesion ratios of Kapton to BPDA 1,4,4-APB, which also gives us some confidence in the classical Interface force field (Brown 2000). Our future work will involve using DFT to characterize the torsional potentials for the nitrogen groups in the Interface potential. We believe this can potentially help better characterize the stacking observed with these kinds of polyimides.

3   Atomistic Methods

3.1   Monomer-Glass Adhesion

3.1.1   Simulation Details

The specific steps that we follow in setting up our simulations are described in this section. First, we create and validate silica structures. We then combine polyimide monomers with silica structures to form the interfacial system and use Steered Molecular Dynamics (SMD) to calculate the adhesion between them. We describe the details of the methods for each of these steps in the sections below.

Force Field

The interface force field, developed by the Heinz group in the past few years, is a classical force field for organic, biomolecules, and inorganic components at the 1–100 nm scale (Heinz et al. 2013). The core of this force field is based on the consistency of classical Hamiltonians for organic and inorganic force fields like PCFF, CVFF, CHARMM, etc., and has been extended to accurately model interfaces for surface energy (Heinz et al. 2013), biomaterials (Patwardhan et al. 2012), and polymers (Emami et al. 2014a). This extension has been carried out by tuning force field parameters to match experimental and ab initio results for surface phenomenon like hydration energy of a silica surface in water (Xia et al. 2014), adsorption isotherms of water on silica (Xia et al. 2014), and selective peptide recognition and binding to silica surfaces (Emami et al. 2014b). The Interface potential consists of Lennard Jones and Columbic interactions as nonbonded interactions, harmonic bonds to mimic covalent bonds, and harmonic angles to model the structure of polymers more accurately.

In our work, we have used the PCFF-interface potential, which is an extension of the well-established PCFF potential. This is a class II potential and has the form

$$
\begin{aligned}
E_{pot} = &\sum_{ij, nonbonded\ 1,2\ and\ 1,3\ excluded} \varepsilon_{ij} \left[2\left(\frac{\sigma_{ij}}{r_{ij}}\right)^9 - 3\left(\frac{\sigma_{ij}}{r_{ij}}\right)^6 \right] \\
&+ \frac{1}{4\pi\varepsilon_0} \sum_{ij, nonbonded\ 1,2\ and\ 1,3\ excluded} \frac{q_i q_j}{r_{ij}} + \sum_{ij, bonded} k_{r,ij}\left(r_{ij} - r_{0,ij}\right)^2 \\
&+ \sum_{ijk, bonded} k_{\theta, ijk}\left(\theta_{ijk} - \theta_{0,ijk}\right)^2
\end{aligned}
$$

More details on the formulation and the description of individual terms can be found in the original paper (Heinz et al. 2013).

Creating Silica Structures

The Interface FF requires the bonds and angles between atoms to be explicitly defined, which makes generating a silica structure slightly more complex than when using a nonbonded potential. To ensure that our approach can readily be extended to other inorganic materials, we start by generating the silica glass structure using the well-established nonbonded Pedone potential (Pedone et al. 2006, 2008) and a simulated annealing procedure (Tandia et al. 2012). A flat surface is created by opening the simulation box and hydroxylating the under-coordinated oxygen atoms exposed to the surface to achieve a surface density of ~ 4.7 OH/nm^2. A corresponding nonhydroxylated surface was made by deleting –H and –OH pairs and introducing Si-O-Si bonds, followed by energy minimization. This method mimics the extreme condition of dehydration and provides a surface that is free of high-energy dangling bonds. The crystalline silica under study is the α-quartz structure obtained from the model structure database shared with the interface potential (Emami et al. 2014a). This structure is generated by cleaving bulk α-quartz along the $(00\bar{1})$ plane, which creates a perfect Q3 surface (where each silicon at the surface is bonded to three bridging oxygen atoms), and on hydroxylation of these silica surfaces, a system with 4.7 OH/nm^2 hydroxyl density is obtained. The size of the glassy silica surface is 4.03 nm $\times$4.14 nm and for α-quartz it is 3.33 nm $\times$3.34 nm.

Polyimides Under Study

We choose four different polyimide monomers for this study. Three of them have the same $3,3'4,4'$-biphenyl tetracarboxylic dianhydride (BPDA) with one of three different APB isomers: 1,3-bis(3-aminophenoxy)-benzene, 1,3-bis(4-aminophenoxy)-benzene, or 1,4-bis(4-aminophenoxy)-benzene. BPDA has been chosen as the benchmark reference case for its bulk properties and microstructure is available in the literature. The final polyimide under study is pyromellitic dianhydride and 4, $4'$-oxydiphenylamine (Kapton) which is one of the most commonly used polyimide. Throughout this chapter, they will be abbreviated as BPDA 1,3,3-APB, BPDA 1,3, 4-APB, BPDA 1,4,4-APB, and Kapton, respectively. Among them, the first three BPDA series have the same chemical compositions except for the oxygen linkage connecting the benzene rings in the APB section. BPDA 1,3,4-APB has one meta linkage and two para linkages, while 1,3,3-APB and 1,4,4-APB have three meta
Fig. 4 Repeat units for the Polyimide monomers for three BPDAs (left) and Kapton (right)

and three para linkages, respectively. Kapton has a different chemical structure from the BPDA series (See Fig. 4 for the structure in detail). By choosing these polyimide sets, we expect to see the effect of conformational variability (BPDA) and in chemical composition (BPDA vs. Kapton) on adhesion. Details for creation of the bulk polymer are provided in literature (Goyal et al. 2016).

Modeling the Composite System
We model the polyimide-silica composite to consist of the silica surface with and without hydroxylation (0% and 100%) and a polymer phase. The silica surfaces considered are the α-quartz crystalline surface and the glassy silica surface. The polyimide monomers considered are BPDA 1,3,3-APB, BPDA 1,3,4-APB, BPDA 1,4,4-APB, or Kapton. We use thermal annealing to equilibrate the polyimide monomers on the silica. In order for the monomer on the silica to arrive at the equilibrium conformation completely, the thermal annealing and relaxation procedures are performed by MD simulation with the Interface-CVFF force field. The composite structure is relaxed at 500 K for 500 ps followed by annealing to 300 K for 500 ps with the NVT ensemble using the Nosé-Hoover thermostat. Then, the final equilibration is performed at 300 K for 500 ps with both NVT and NPT ensembles. This procedure helps the monomer to overcome the local minima in the free energy landscape and thus quickly reach the global equilibrium state. The time step was 1 fs, the cutoff for van-der-Waals interactions was 12 Å, and the Particle-Particle Particle-Mesh (PPPM) solver was used for the summation of long-range Coulomb interactions with the precision of 10^{-4}.

3.1.2   Steered Molecular Dynamics
Calculations for the work of adhesion as well as the investigation of the local chain relaxation require performing simulations for a system with more than several hundred atoms as well as considerable relaxation time. In addition, the adhesion behavior between polymer and glass is highly affected not only by their interfacial interactions, but also by the strength of interactions within polymer chains themselves. Within these considerations, the classical Molecular Dynamics (MD) method is a suitable tool for the examination of dynamics at the atomic level

accounting for energy contributions of the interfacial strength and chain dynamics. Within the MD framework, the SMD methodology can be used to examine the chain conformational behaviors at the interfacial region (Park et al. 2003; Jarzynski 1997; Park and Schulten 2004). The SMD method has been widely utilized for investigation of various materials such as polymeric systems and bio-materials (Hamdi et al. 2008; Isralewitz et al. 2001; Davis et al. 2009; Chabria et al. 2010). It is particularly useful to provide insights for deformation-induced conformational changes and subsequent energetic variations in the system.

During SMD simulations, atoms are attached to so-called dummy atoms via a virtual spring. The dummy atoms are displaced by applying a constant velocity (v) to them. A harmonic spring model is used to generate the potential (U), which is defined as

$$U = \frac{1}{2}k\left[vt - \left(\overrightarrow{r} - \overrightarrow{r}_0\right) \cdot \overrightarrow{n}\right]^2 \tag{1}$$

where k is the spring constant, t is time, $\overrightarrow{r}$ and $\overrightarrow{r_0}$ are the current and the initial positions of the atoms, and $\overrightarrow{n}$ is a unit vector in the direction of pulling. While the pulling test is being performed, the atoms are still allowed to relax. The generated force ($\overrightarrow{F}$) due to the applied velocity is defined as,

$$\overrightarrow{F} = -\nabla U \tag{2}$$

The averaged work of adhesion is based on Jarzynski's equality, which relates the equilibrium quantity (i.e., the potential of mean force (PMF)) to the nonequilibrium process (Park et al. 2003; Jarzynski 1997; Park and Schulten 2004). The PMF value is computed from the following Eq. (Ghosh and Mittal 1996).

$$PMF = -\frac{1}{\beta} \log\left\langle e^{-\beta W}\right\rangle \tag{3}$$

where $\beta = 1/(k_B T)$ with the Boltzmann constant kB and the temperature T of the system, W is the work done during the pulling test, and the angular bracket indicates the ensemble average of the given quantity. T is the temperature which is 300 K for our simulations. In our simulations, we use a spring constant, *k*, equal to 100 kcal/mol/Å^2.

To obtain accurate evolution of the PMF with polyimide on silica, the SMD simulation should be maintained in the quasi-equilibrium state during the entire process. In this regard, as stated above, testing the effect of pulling velocity is of great importance for the precise calculation of the adhesion between the polyimides and silica substrates. It is particularly true for the monomer structures, which are very sensitive to any driving force toward a nonequilibrium state.

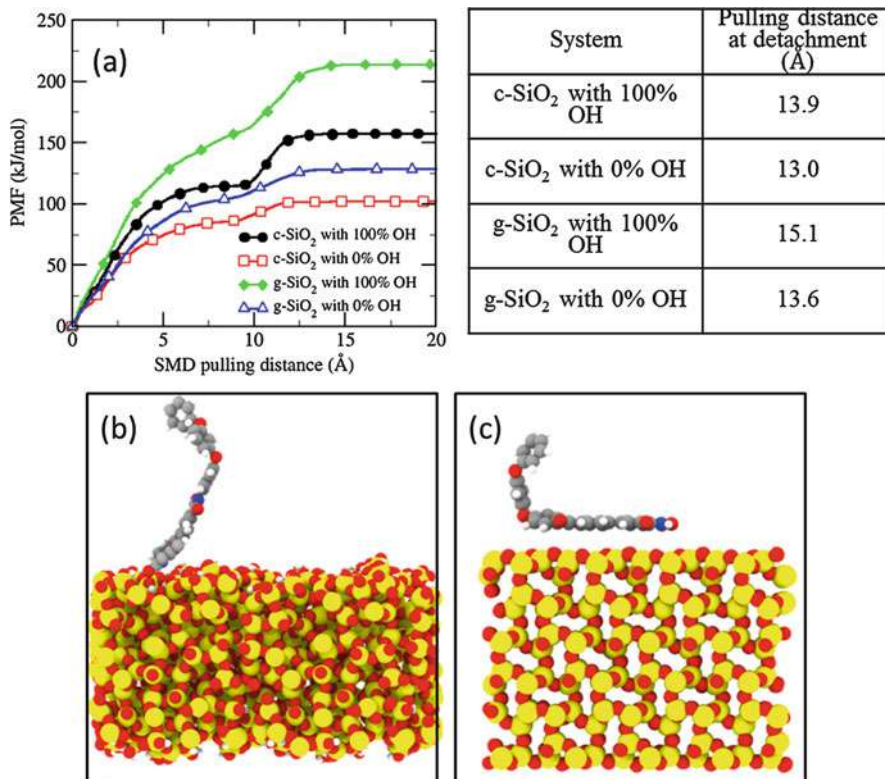
System	Pulling distance at detachment (Å)
c-SiO$_2$ with 100% OH	13.9
c-SiO$_2$ with 0% OH	13.0
g-SiO$_2$ with 100% OH	15.1
g-SiO$_2$ with 0% OH	13.6


Fig. 5 (**a**) The distance at which BPDA separates from the silica surface. We observe that hydroxylated and glassy surfaces need higher separation for completely detaching. The reason for the larger separation distance is the extended hydrogen bonding which can be observed in hydroxylated surfaces as shown in (**b**) but is absent in nonhydroxylated surfaces as shown in (**c**)

3.1.3   Effect of Surface Hydration and Silica Structure

We start our analysis by studying the adhesion of BPDA 1,4,4-APB on various silica structures and surface hydroxylation. First, we analyze the effect of hydration on adhesion for both the crystalline and glassy silica surfaces. We observe that hydroxylated silica has higher adhesion by 50 kJ/mol for α-quartz and 100 kJ/mol for glassy silica; the PMF curve is shown in Fig. 5a. This trend is independent of silica structure as this result holds true for both crystalline silica as well as glassy silica. We find that the enhanced adhesion of hydroxylated silica vs. nonhydroxylated silica can be explained by the extended interactions between the silica surface and the polyimide. The presence of surface hydroxyl groups causes an increase in hydrogen bonding between the polyimide and surface hydroxyls, resulting in an increased adhesion, as well as a longer pulling distance.

In addition, we observe that the adhesion for glassy silica is always higher than that for their crystalline counterparts by $\sim$75 kJ/mol for fully hydroxylated surfaces

and ~25 kJ/mol for nonhydroxylated surfaces. To understand the detachment process, we next analyze the distance at which the monomer completely detaches from the silica surface. From Fig. 5a, we can see that a longer separation distance is required to detach the monomer from glassy silica when compared to crystalline silica, and for hydroxylated structures when compared to nonhydroxylated structures. This is illustrated in the snapshots of the systems shown in Fig. 5b and c where due to the presence of hydroxyl layers and glassy structure, the polyimide monomer clearly has a stronger interaction with silica. Furthermore, the glassy silica structure has a higher adhesion and a larger saturation distance than crystalline silica. We speculate this occurs due to the increased sites for polymer-surface interaction for the random surface of glassy silica as compared to a uniform surface for the crystalline α-quartz. We find that these results are influenced by the silica structure and hence do not deviate upon changing polyimide chemistry.

3.1.4 Effect of Polyimide Chemistry

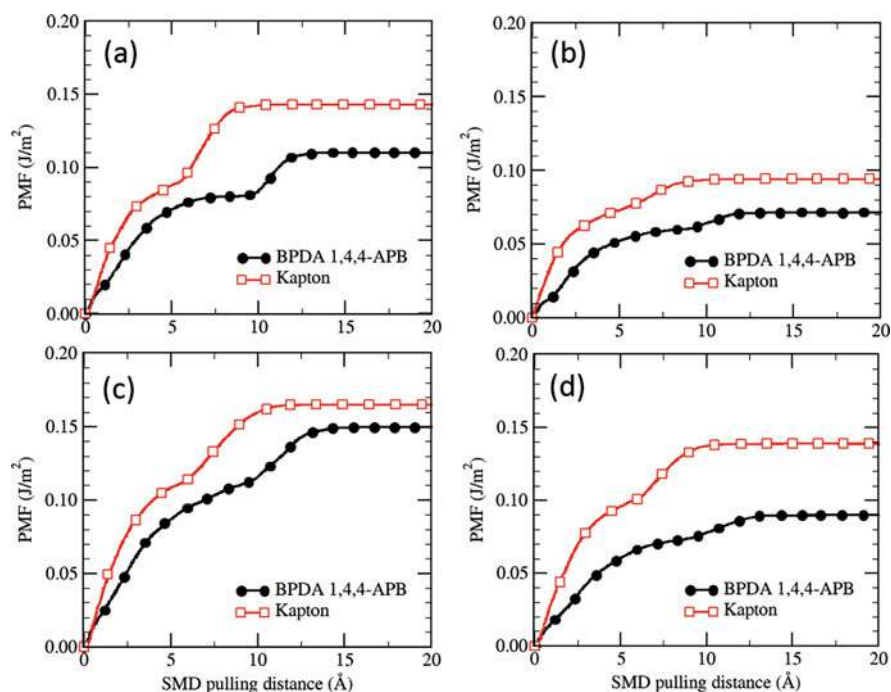
To understand the effect of polymer chemistry on adhesion, we compare the adhesion of BPDA 1,4,4 and Kapton monomers on various silica structures with and without hydroxylation. The results are shown in Fig. 6 which shows the results


Fig. 6 Comparison of adhesion of polyimide and silica for BPDA (black) and Kapton (red) per projected surface area for (**a**) crystalline silica fully hydroxylated, (**b**) crystalline silica with no hydroxylation, (**c**) glassy silica with full hydroxylation, (**d**) glassy silica with no hydroxylation

for the normalized adhesion and Kapton adheres more strongly than BPDA for every silica structure interaction.

To understand the molecular origin of this discrepancy, we split the polyimide + hydroxylated silica system into multiple subsections and track the potential energy change during the SMD process. This allows us to understand the evolution of interactions between the silica and polyimide surfaces during the detaching process. The system is broken up into the following subgroups: (1) the bulk silica system, (2) the surface atoms for hydroxylated silica, (3) carbon backbone of polyimide, (4) hydrogen attached to polyimide, (5) nitrogen in polyimide, and finally (6) oxygen on the polyimide. It should be noted that all oxygen, carbon, and hydrogen atoms on the polymer are not identical, and hence this analysis is only useful to obtain a qualitative contribution to adhesion by each element. To understand the effect of monomer constituents on adhesion, we normalize the potential energy change by the net surface area of the respective groups of atoms, calculated using the van-der Waal radii. The results are shown in Fig. 7, and we find that the major contributor to the potential energy change per unit area is in the following order: oxygen > carbon ~ nitrogen > surface hydroxyls > hydrogen in polyimide. This clearly suggests that for a given surface area of polymer, the higher the number of oxygen atoms, the higher will be the net adhesion with silica. On comparing BPDA to Kapton, we find that the concentration of oxygen is significantly higher in Kapton (almost 1.5 times), which leads to a higher adhesion per unit area when compared to BPDA. The higher net
Fig. 7 The adhesion per atom per unit area for each of the subgroups studied in Fig. 8. Note that bulk silica has been omitted due to its minimal effect on adhesion. We can clearly see that oxygen has the largest effect on adhesion followed by carbon, nitrogen, surface hydroxyls, and finally hydrogen

adhesion of BPDA is due to a longer carbon chain (34 for BPDA vs. 22 for Kapton) which is the second highest contributor to potential energy. However, the number of carbon atoms per unit area is similar between Kapton and BPDA, and therefore carbon does not contribute to the overall trend for adhesion per unit area. Hence, we conclude that due to the higher concentration of oxygen in Kapton, the adhesion per unit area is higher than BPDA.

3.2   Polymer Glass Adhesion: REAXFF

We next study the adhesion between silica glass and polymer film to understand the effect of chain rigidity.

3.2.1   Simulation Details with REAXFF

The Reactive Force-Field (ReaxFF) was proposed by van Duin and has been recognized to accurately define the bond formation and dissociation with consideration of bond order at every time step (Liaw et al. 2012; Chen et al. 1995). Hence, this potential is expected to capture the complex adhesion behavior at the interfacial region of PIs and SiO$_2$. ReaxFF describes the connectivity between atoms by the following energy terms:

$$E_{system} = E_{bond} + E_{val} + E_{tors} + E_{over} + E_{under} + E_{pen} + E_{conj} + E_{H-bond}$$
$$+ E_{vdW} + E_{Coul} \tag{4}$$

Each term in Eq. (4) represents bond (E_{bond}), valence-angle (E_{val}), torsion (E_{tors}), over-coordination (E_{over}), under-coordination (E_{under}), penalty (E_{pen}), conjugation effect (E_{conj}), hydrogen bonding (E_{H-bond}), van der Waals interaction (E_{vdW}), and Coulomb interaction (E_{Coul}) energies, respectively.

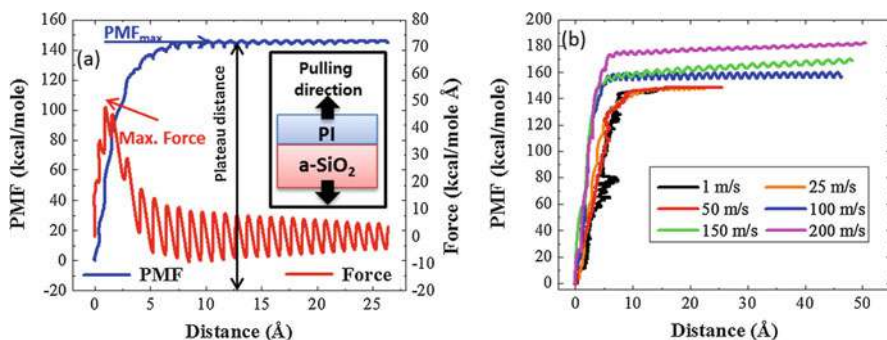
Initial atomic structures of PIs are constructed using the Amorphous Cell generator in Materials Studio. All PIs are built from five chains of linear PI, each six monomers long. The PIs and glassy SiO$_2$ structures are confined in the z-direction to have a surface area of 28.51 Å by 28.51 Å in x-, y-direction with periodic boundary conditions along those axes. The layer thickness of both structures is around 20 Å. After PI construction, it is placed onto the surface of SiO$_2$ with a vacuum distance of 100 Å in the z-direction, followed by structural relaxation. The hybrid structure is first relaxed with the NVT ensemble for 1 ns at 300 K then with the NPT ensemble for another 1 ns at 1 atm and 300 K. The NPT ensemble is applied only along the x- and y-directions to preserve the vacuum in the z-direction. MD simulations are conducted using the LAMMPS package (Gruenhut et al. 1997). The Nosé-Hoover thermostat and barostat are applied for the temperature and pressure control with damping parameters of 100 fs and 1000 fs, respectively. The velocity-Verlet time integration scheme is used with a time step of 0.5 fs. After structural relaxation, the pulling test using SMD is performed under the NVT ensemble with a constant


Fig. 8 (**a**) The schematic description for adhesion properties of PMFmax, maximum force, and plateau distance. (Inset) Schematic view of pulling process. (**b**) The PMF convergence as a function of SMD rate for DHBZ-BTDA on SiO$_2$

velocity of 50 m/s. The pulling force is applied perpendicular to the interface of SiO$_2$ and PI with a spring constant of 100 kcal/mol/Å^2.

The adhesion behavior at the interface can depend on the velocity used for the SMD simulation; thus, it is critical to ensure that the adhesion properties are converged under various ranges of velocities. Here, the convergence behavior of the PMF for BTDA is obtained when an applied velocity is decreased from 200 m/s to 1 m/s, as shown in Fig. 8. At velocities slower than 50 m/s (i.e., 25 m/s and 1 m/s), PMF responses are observed to be independent of SMD rates. Consequently, a velocity of 50 m/s is chosen as an optimal value and applied to the rest of the simulations.

3.2.2 Structural Properties

Initial (bulk) structural properties for all PI structures are shown in Table 2. An initial density is computed to be 1.25–1.32 g/cm^3 for all structures. In addition, the radius of gyration (Rg) and the end-to-end distance of a chain (REE) are calculated to compare differences in initial chain conformation between PI structures. Rg is defined as

$$R_g = \sqrt{\frac{1}{N+1} \sum_{i=0}^{N} \left\langle (\vec{r_i} - \vec{r_G})^2 \right\rangle} \tag{5}$$

$$r_G = \frac{1}{N+1} \sum_{i=0}^{N} r_i \tag{6}$$

where N is the number of atoms, r$_i$ is the location of the ith atom, and r$_G$ is the center of mass.

REE is defined as REE $= |r_N - r_n|$, where r$_N$ and r$_0$ is the coordinate of the atom at both ends in the polymer chain. R$_g$ and REE values are averaged over all individual chains.

Table 2 Temperature dependent adhesion properties for DHBZ-BPDA and DHBZ-DTDA on a-SiO$_2$

Structure	[DHBZ-BPDA] + SiO$_2$			[DHBZ-DTDA] + SiO2		
	300 K	450 K	550 K	300 K	450 K	550 K
Adhesion energy [kcal/mole•Å^2]	0.1787	0.0983	0.1023	0.1673	0.1132	0.1031
Plateau distance [Å]	5.01	8.37	8.24	22.46	17.59	15.20
Maximum force [kcal/mole•Å]	76.12	49.35	48.807	39.60	37.949	32.48
Fig. 9 The molecular structure of (**a**) DHBZ + BPDA, (**b**) DHBZ + BTDA, and (**c**) DHBZ + DTDA. (**d**) The coefficient of thermal expansion (CTE) for polyimide structures from experiment. The solid line is the experimental data and the dashed line is the fitted data to obtain CTE values between 50 °C and 150 °C

R$_g$ and REE values provide qualitative information that can be used to describe flexibility/rigidity of polymer chains (Yang et al. 2016; Priezjev 2016). For example, BPDA exhibits the largest R$_g$ and REE, indicating that its chain is easily bent or twisted under external force when compared to other types of polymer chains having smaller values of Rg and REE. The rigidity of polymers can be further characterized by experimental CTE values shown in Fig. 9, since polymers with higher rigidity tend to exhibit lower CTE values (Luo et al. 2016; Zhao et al. 2016). As expected, BPDA has the smallest CTE value, which is consistent with its larger values of R$_g$ and REE. Finally, to explain the rigidity difference in polyimides, Young's modulus (E) is obtained based on the stress-strain curve.

E values at 300 K for BPDA, BTDA, and DTDA are computed to be 8.2 ± 0.5, 5.3 ± 0.3, and 3.2 ± 0.2 GPa, respectively. This means the structures with lower CTE values exhibit the superior mechanical property. This demonstrates the correlation between CTE, Rg, REE, and the mechanical property in a consistent

manner. Accordingly, we associate these four properties to represent the chain rigidity and explain subsequent differences in adhesion properties for PIs.

3.2.3   Adhesion Properties and SMD Rate Dependency

Calculation of the binding energy at the PI/glass interface is a common way of defining how strongly they interact. However, it cannot provide atomistic information to predict the actual dynamic behavior such as how the chain conformation would evolve when entangled polymer chains are being separated from the glass. In this regard, it is essential to introduce properties that can broaden the understanding of interfacial behaviors. For a quantitative comparison of the adhesion behavior between PI and SiO_2 glass, three descriptive properties are introduced in this study. These are shown in Fig. 10a and include adhesion energy (EAdh), maximum force (FMax), and pulling distance (D_p) at the plateau of EAdh. The EAdh is defined as the potential of mean force (PMF) divided by the projected interfacial area when PI and SiO_2 are fully separated from each other. FMax is the maximum force that the system reaches during detachment. D_p is the center-of-mass distance between PI and SiO_2 when they are completely detached.

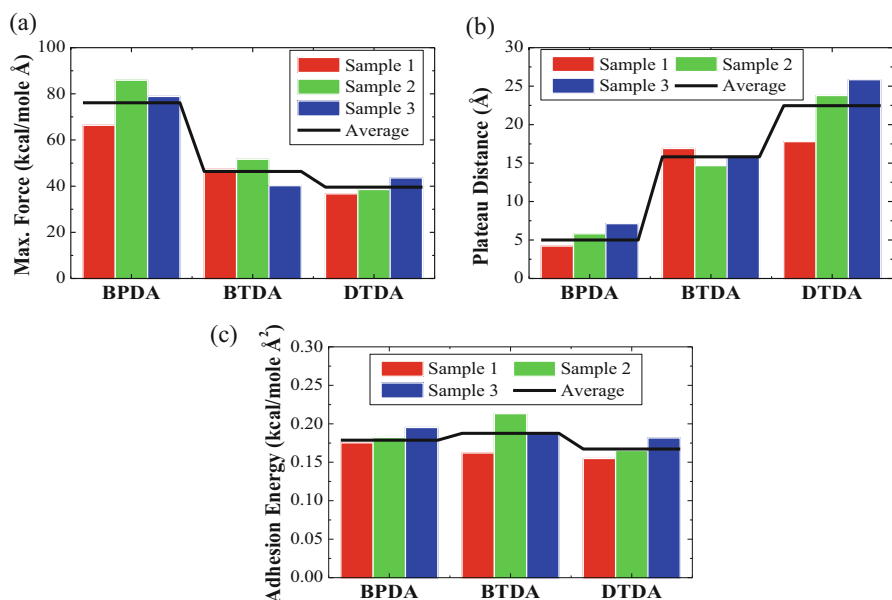
The adhesion behavior at the interface could be dependent on the velocity used for the SMD simulation; thus, it is critical to capture the converged value of the adhesion properties under various ranges of velocities. Here, the convergence behavior of PMF for BTDA is obtained when an applied velocity is decreased from


Fig. 10 (**a**) Maximum force, (**b**) plateau distance, and (**c**) adhesion energy for all structures of the polyimide on SiO2. The black lines represent the average values

200 m/s to 1 m/s, as shown in Fig. 10b. At velocities slower than 50 m/s (i.e., 25 m/s and 1 m/s), PMF responses are observed to be independent of SMD rates.

Consequently, a velocity of 50 m/s is chosen as an optimal value and applied to the rest of simulations. Calculated adhesion properties for different types of PIs are presented in Fig. 10c. For better statistical results, pulling tests are repeated for three samples of each PI structure. First, it clearly indicates that results from the same type of the PI exhibit consistency for all adhesion properties (i.e., no outliers appear). More importantly, each adhesion property shows a distinctive trend as the CTE value is lowered (the order of CTE values: BPDA < BTDA < DTDA). For example, the largest value of FMax is required to detach BPDA from the SiO2 surface, while the shortest value of required DP for BPDA. On the other hand, the DTDA structure displays the smallest value of FMax but the largest pulling distance when two substrates are completely detached. To summarize, a more rigid PI needs a larger force for detachment (FMax: BPDA > BTDA > DTDA), while a less rigid PI requires a longer pulling distance (Dp: DTDA > BTDA > BPDA). It means that the PI with a lower value of CTE requires a larger force to detach from SiO2, but detachment occurs at the shorter distance. Since the structure with a larger CTE value has the weaker interaction between chains based on the nature of the CT complex, it is reasonable of DTDA exhibiting a larger pulling distance (Choi et al. 2010; Chaudhury et al. 1987). The larger pulling force shown in BPDA can be explained from investigation on Coulomb energy changes during detachment, which is covered in Sect. 3.3. However, in terms of the adhesion energy, it is interesting to note that its value is almost equivalent among all structures.

For further analysis of the temperature effect, adhesion properties at 450 K and 550 K for BPDA and DTDA structures are obtained (Table 2). It shows that even at higher temperatures, the same adhesion behavior, i.e., a shorter plateau distance and a larger maximum force in BPDA, and comparable adhesion energy for both structures, is obtained comparing to the case at 300 K. It is also important to mention that the adhesion energy at higher temperatures is lower than that at 300 K, which is associated with a smaller force required to detach PIs. This could be because the atomic thermal vibration at the interface is amplified at the higher temperature. Therefore, an important perspective can be obtained from the above results that although the same work of adhesion (PMF) is required for full detachment of any structures considered here, the underlying mechanism is different depending on structural characteristics; thus, the further analysis performed provides detailed insight on the nature of adhesion.

3.2.4 Structural Changes During Pulling Process

During the pulling process, it is highly probable that polymer chains located closer to the interfacial region would play an important role in determining adhesion properties. Hence, understanding the underlying mechanism of adhesion between PIs and SiO2 glass at the atomistic level is of importance because the inter- and intra-material interaction inside bi-materials governs the adhesion failure mode at the interface. Accordingly, it is critical to perform an analysis for the response of

each chain in detail to elucidate relevant physics and dynamics. For comparison, the most thermally stable/high rigidity (BPDA) and the least thermally stable/least rigid (DTDA) PIs are chosen.

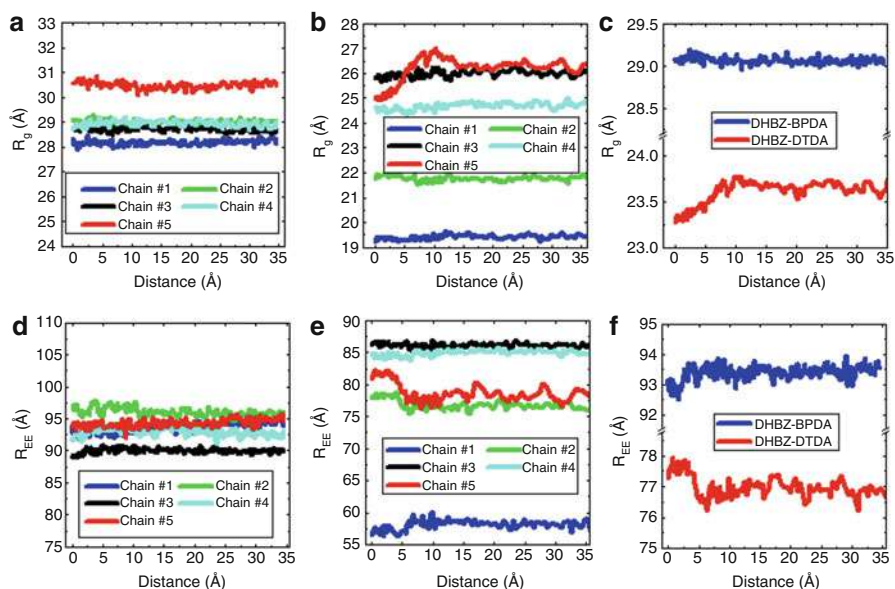
First, an overall outlook of the detachment process can be provided from atomic snapshots. For a case of BPDA, geometric configurations in polymer chains at the interface are not strongly affected during detachment. On the other hand, for DTDA structure, polymer chains located nearer to the SiO2 surface are stretched in the direction of pulling and experience significant modification in the chain conformation. A detailed insight into the variation of chain conformation is examined from computing the variation of Rg and REE during pulling process as shown in Fig. 11. This can provide direct information how an individual chain in PIs is deformed during detachment. First, initial Rg and REE values and initial conformation from each chain in BPDA and DTDA are presented in Fig. 10. It should be mentioned that for all chains, averaged values of initial Rg and REE obtained from DTDA are smaller than those from BPDA. This result indicates that DTDA is more deformable/flexible, which is consistent with results from the bulk system of PIs. In addition, the standard deviation of Rg (2.72 Å) and REE (12.03 Å) from DTDA is more than three times larger than those from BPDA (it is 0.87 Å and 3.00 Å for Rg and REE, respectively), which could be another indication of the higher chain flexibility in DTDA. Further analysis can be found in our publication (Kyoungmin et al. 2016).


Fig. 11 Radius of gyration (Rg) and chain end-to-end distance (REE) variation in individual polyimide chains during pulling process for the structure of (**a**), (**d**) DHBZ-BPDA and (**b**), (**e**) DHBZ-DTDA on SiO2. Averaged values for (**c**) Rg and (**f**) REE are plotted. The number of chain is increased when the chain is located closer to the SiO2 surface

3.2.5   Failure Mode

Finally, the failure mode at the bi-material interface is investigated to determine whether it exhibits adhesive or cohesive failure over the course of detachment. In general, adhesive failure occurs when two materials are completely detached without internal failure in either material; hence, a "clean" surface at the interface is formed. In contrast, cohesive failure occurs when a polymer experiences internal chain breaking at failure due to the overly strong adhesion at the interface. In order to examine the failure mode, we modified the region where the pulling force is applied, i.e., the force is applied to only the half region from the top of PI in z-direction (denoted case H for "half"), whereas for all previously discussed systems, the force was applied to all atoms in PI (denoted case A for "all"). For case H, PI chains near the surface are being pulled by the other PI chains at the top. Therefore, it is possible that PI chains would experience cohesive failure if their inter-chain interactions are weak or their adhesion to the SiO_2 surface is too strong. However, for the current study, the cohesive failure is not observed for either BPDA or DTDA structures; a clean interface is always formed when PIs are fully detached. It should be noted that all PIs in this study possess very low CTE values compared to other types of polymers. Considering the fact that the charge transfer complex between PI chains is very strong, there are strong attractive forces between chains, preventing cohesive failure (Choi et al. 2010; Chaudhury et al. 1987).

3.3   Effect of Glass Roughness on Adhesion

Creating flat surfaces for molecular modeling is perhaps trivial. For cleaved crystalline surfaces with small unit cells, the manual operation of adding hydrogen to the surface oxides can be done without much difficulty (Mishra et al. 2013). In most studies flat surfaces are primarily used, there are several advantages of flat surfaces: They lend themselves well to the use of density profiles, as most species form orderly structures as a function of distance from the surface, and the explanation that surface roughness features tend to be perceived at wavelengths longer than the simulation length. When considering a glass or other amorphous structure, even the flattest surface has heterogeneities that cause a certain degree of atomic level roughness. With amorphous structures and nanoscale roughness, it becomes less obvious how to create or manage the surface. In some of these cases, the surface configuration with minimum energy can be used, some can be found with temperature gradient protocols (Mishra et al. 2013, 2014). But without a reacting force field, such as reaxFF (Manzano et al. 2012), these approaches are of limited use. The underlying chemical nature of the structure must be understood to properly select for minimum energy surfaces.

3.3.1   Method for Creating Surface Roughness on Glass

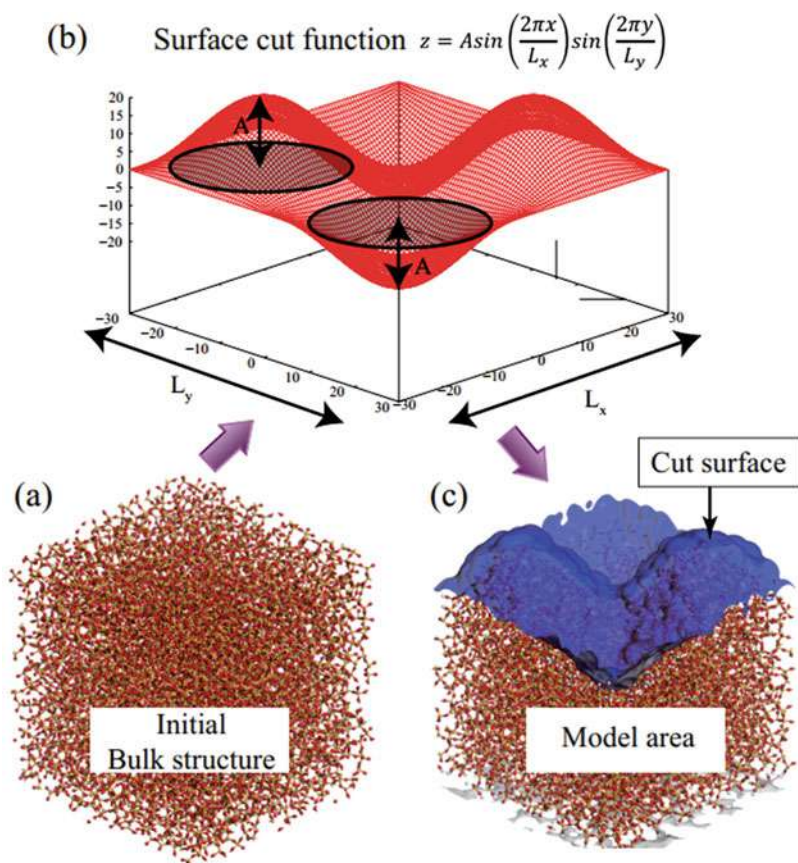
To create roughness on the surface, we cut a bulk glassy silica with a predefined surface. As shown in Fig. 12, we firstly define a shape of the surface by a specific mathematical function and then cut an initial bulk structure along the surface.


Fig. 12 Schematic procedure of generating rough surface. (**a**) Initial bulk glassy silica, (**b**) predefined surface with sine function, $z = A\sin\left(\frac{2\pi x}{L_x}\right)\sin\left(\frac{2\pi y}{L_y}\right)$, (**c**) prepared rough glassy silica surface, blue shaded area represents cut surface by sine function

Roughness can be adjusted depending on the defined surface function. Since nano-sized roughness is formed by varying amplitudes and spacing (Chen et al. 2007), we applied a sinusoidal function to adjust both parameters as follows,

$$z = A\sin\left(\frac{2\pi x}{L_x}\right)\sin\left(\frac{2\pi y}{L_y}\right) + \bar{z} \tag{7}$$

where A, Lx, and Ly represent roughness amplitude and spacing of each axis, respectively. Various amplitudes (A= 0, 5, 10, 15, 20 Å) and spacings (Lx = Ly = 20, 30, 60, 120 Å) are considered to analyze the effect of each parameter in this work. Experimentally, the amplitude parameter is usually represented as the height variation of the surface compared to a reference plane, and arithmetic average, Ra, is the most common parameter to represent the amplitude of the roughness. Thus, Ra

is measured for the prepared structure and listed as an amplitude parameter instead, A in this work. Ra is calculated using atomic coordination of surface atoms with the following equation,

$$R_a = \frac{1}{n} \sum_{i=1}^{n} |z_i - \bar{z}| \tag{8}$$

where z_i is the z coordinate of each element and $\bar{z}$ is average value. Due to the symmetric shape of a sine function, Ra is almost half of the amplitude value (A). As the amplitude values increase from 0 to 5, 10, 15, and 20 Å, Ra varies from 1.0 Å to 2.4, 4.4, 6.5, and 8.4 Å, respectively. The spacing of roughness corresponds to the period of a sine wave (Lx or Ly in the function) and hence, period is listed as the spacing parameter of the roughness. More specific details on this approach can be found in literature.

3.3.2   Results

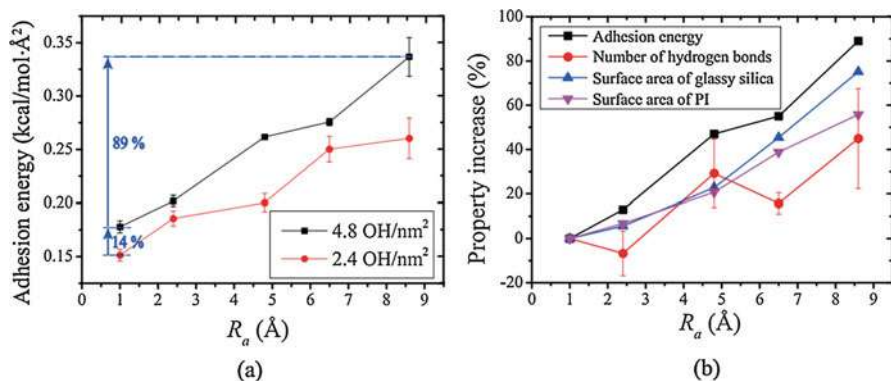
For the systematic analysis of roughness, both amplitude and spacing parameters of roughness are considered with various hydroxylation densities. Figure 13a presents the adhesion energy variation with different Ra and hydroxylation densities. As the Ra or hydroxylation density increases, adhesion energies increase. When hydroxylation density is increased from 2.4 OH/nm2 to 4.8 OH/nm2, the number of hydroxyl groups becomes two times larger, i.e., 100% increase, but increased adhesion energies by 10 ~ 20% for any given Ra value. On the other hand, when R_a is changed from 1.0 Å to 8.5 Å with the same hydroxylation density of 4.8 OH/nm2, adhesion energy is increased about 89%. Adhesion energy continuously increases with Ra higher than 8.5 Å, and thus we can conclude that the amplitude of roughness, Ra, is more effective to enhance adhesion between glassy silica and polymer than hydroxylation density in nano-scale roughness.


Fig. 13 (**a**) Variation of adhesion energy as a function of Ra (1.0 ~ 8.4 Å) and hydroxylation density (2.4 and 4.8 OH/nm2), (**b**) increment (%) of adhesion energy, number of hydrogen bonds, surface area of glassy silica, and PI

For the analysis of the hydrogen bond contribution to the adhesion, we counted hydrogen bonds at the interface (exhibited as red circles in Fig. 13b). Hydrogen bonds gradually increase with Ra due to the expansion of the surface area, but the amount of increased adhesion energy is always higher than that of increased hydrogen bonds. When the adhesion energy is enhanced about 89%, the number of hydrogen bonds increases only 45%. Thus, the effect of Ra on adhesion is the sum of the increased hydrogen bonds and additional nonbonded interactions by surface expansion. Adhesion energy variation depending on Ra follows two steps. As shown in the figure, both glassy silica and PI surface areas (blue and purple triangles) match well with each other when Ra is lower than 4.4 Å and hence, the effect of roughness might be maximized within this range. However, when Ra is larger than 4.4 Å, the two surfaces begin to mismatch due to the high amplitude of roughness. PI is not completely attached on the glassy silica surface, and thus the effect of roughness on the adhesion declines and adhesion energy saturates at a higher Ra value.

Figure 14 represents the calculated adhesion energy variation on Ra and period. Considering the slope change of the adhesion, it is concluded that period is less effective on the adhesion than Ra within the considered conditions. Adhesion energy can be enhanced by expanding surface area with a reduced period, but maximum adhesion is observed with the longest period (120 Å) in this work. Thus, for an increment of surface area with a reduced period may not be directly related with the adhesion enhancement within the considered period range. For the detailed analysis of reducing adhesion with decreasing period, vacant volume at the interface is measured and presented in Fig. 14b. When the period is 120 Å, the vacant volume is negligible. However, as the period decreases, there exists a distinctively increasing amount of vacant pores at the interface, and due to the vacant pores, contact area between the two surfaces is lowered and hence, adhesion energy is decreased.

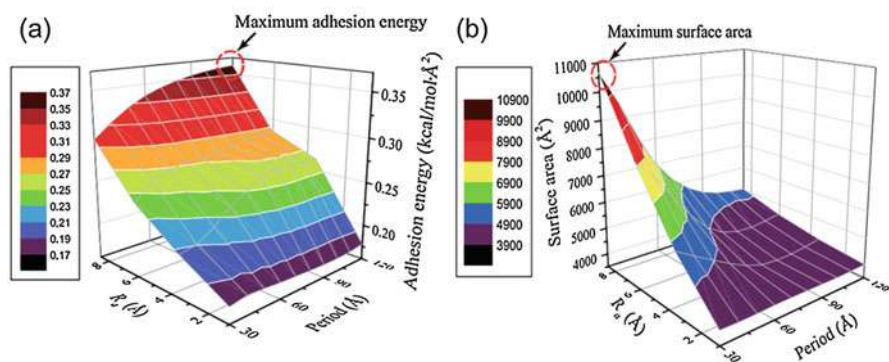
Figure 15 shows a schematic trend of adhesion energy between glassy silica and PI depending on period. The adhesion energy trend with period is affected by both surface area and vacant volume at the interface. As the period decreases, surface area expands, and thus adhesion energy increases (blue solid line). However, if


Fig. 14 Variation of (**a**) adhesion energy and (**b**) surface area as a function of Ra and period of roughness
Fig. 15 Schematic trend of adhesion energy as a function of roughness period. Black dotted line represents variation of adhesion energy, and blue and red lines represent variation of adhesion energy due to surface area or vacant volume, respectively. Green dotted line represents adhesion energy for flat surface (Ra = 1 Å with infinite period). Adhesion energy increases at Region I and decreases at Region II

vacant volume exists at the interface, adhesion energy decreases (red solid line). The overall adhesion energy reflects both effects, and hence one can predict the trend of adhesion energy (black solid line) in two separate regions as follows. In region I, adhesion energy increases with decreasing period which implies the surface area expansion is dominant, and adhesion energy decreases in region II which indicates that vacant volume is critical for these periods. At the border of the two regions, there is a specific period which provides the maximum adhesion energy of a system. A black dotted line in Fig. 15 presents the adhesion energy trend of this work, and maximum adhesion energy is observed with a period of 120 Å. The existence of vacant volume varies depending on Ra and flexibility of polymer, and hence maximum adhesion energy can change with these conditions. If we introduce higher Ra than 8.5 Å or a more rigid polymer than the current PI, the period for maximum adhesion will be longer than 120 Å.

3.4   Conclusion

In this book chapter, we have presented a multiscale modeling approach which established methods, and some guiding principles for modulating adhesion between

organic. Electronic structure calculations revealed the importance of hydrogen bonding and of sodium cation in increasing adhesion. Furthermore, the organic subunit rigid can enhance the adhesion by decreasing the conformational degree of freedom.

On investigating monomer glass adhesion, we find that hydroxylated silica surfaces have higher adhesion than nonhydroxylated surfaces. We also find that glassy silica has a higher adhesion than crystalline silica. The reason for this appears to be the additional hydrogen bonding interactions possible in the presence of surface hydroxylation and due to a rougher surface for silica glass allowing more interactions. On decoupling the interaction forces, we find that adhesion with silica for polyimides with higher oxygen density would be higher.

Scaling up to polymer interaction on glass, we find that PI materials with lower CTEs require a larger maximum force to detach them from the glass substrate. In addition, the pulling distance for complete detachment is shorter for the lower CTE polymers. A detailed analysis for the chain conformation change confirms that during the pulling process, the polymer chains near the surface region mainly determine the interfacial adhesion behavior. When pulled, the conformation of BPDA chains at the interface is not significantly affected, while those of DTDA experience substantial changes. This is the cause of a larger pulling distance required for complete detachment for DTDA compared to BPDA. Furthermore, the variation in decomposed energy terms during detachment indicates that the main factors determining the adhesion behavior are bond and coulomb interactions. Finally, the current systems under study are always expected to experience adhesive rather than cohesive failure when detached.

Finally, upon investigating the role of nanoscale roughness on glassy silica, and the calculated results reveal that R_a exhibits the highest effect on the adhesion change among the parameters considered. The energetic contribution to the adhesion is analyzed with energy decomposition during the pulling process, and it is revealed that not only the increase of hydrogen bond but also the increase of Coulomb energy contributes to the adhesion energy variation by R_a. The contribution of Coulomb energy becomes more significant when R_a is higher. From the structural analysis, the trend of adhesion energy variation depending on R_a and period is predicted. R_a can enhance adhesion energy, but the impact of R_a on the adhesion is also determined by the period. When the period is the shortest, normalized adhesion energy by PI surface is similar for any value of R_a.

4   Potential Vistas in Interface Modeling

We have so far discussed adhesion of physisorption of nanometer thick polymer films on glasses, which are bound by columbic and van der Waals interactions. There is a pertinent need to extend this study to be able to incorporate reactions at the interface and to perform simulations that scale larger length scales. To achieve this, there is a need to develop coarse grained models for interfaces which capture accurate polymer and glass physics, along with chemistry of interface evolution.

Recently developed has focused on incorporate bonding at the interface in classical MD and evaluating the potential of coarse-grained simulations (Bulacu 2008; Yang and Qu 2014; Xia et al. 2014) to traverse our understanding to larger length and timescales.

Design and Modeling of High-Strength, High-Transmission Auto Glass with High Sound Transmission Loss

84

Mehmet C. Onbaşlı

Contents

Abstract

Development of high-strength, scratch-resistant and highly transparent glass with good sound isolation properties is necessary for automotive, industrial and architectural applications. While major progress has been achieved in developing the mechanical strength, scratch resistance and elasticity of highly transparent glass compositions, achieving broadband sound isolation in glass has remained a challenge due to the intrinsic thicknesses and the phonon band structure of the glass layers used. Since phonon band structure of high-strength glass limits the tunability of its acoustic transmission spectrum, composite multilayer glass designs need to be used to enhance sound transmission loss while maintaining the mechanical and optical merits. In this chapter, the design of high-strength, highly transparent and sound isolating glass is posed as a composite acoustic

(meta)material design and optimization problem. Sound transmission loss within human audible range, particularly within 1–10 kHz, must be maximized toward 30 dB or more for good sound isolation while maintaining good optical and mechanical properties over large areas. Next, constitutive and wave equation relations for acoustic modeling of sound transmission loss are presented with example results for polymer/glass sandwich layers. Finally, future research opportunities on new glass materials with tunable phononic band structures, new metamaterial topologies and modeling methods are discussed.

1 Introduction

Glass is a multifunctional material that could be made transparent in optical, radio-frequency, or infrared bands, mechanically strong, highly elastic, and thermally insulating over large areas. These functionalities and the low cost of glass make this material be used ubiquitously. Glass is used in large volumes and areas in automotive, industrial, photovoltaic, and architectural applications, which demand glass to be mechanically strong, scratch-resistant, and highly transparent (Pambianchi et al. 2016). Glass must also have sound isolation capabilities for residential or commercial office user comfort, industrial process control, and driver safety. For instance, the windshield and the side and rear glass of a vehicle both protect drivers from particles or wind and isolate from thermal climate from the outside. In addition, these glass pieces must also isolate from noise originating from other vehicles, which may become a road hazard on highways or noisy urban settings (Leonhard et al. 2015). Some of the major glass manufacturers have developed mechanical properties through experimental and data-driven glass composition development (Mauro et al. 2016; ▶ Chap. 81, "Mechanical and Compositional Design of High-Strength Corning Gorilla® Glass"). These examples show that state-of-the-art glass compositions and manufacturing processes can yield scratch resistance and superior strength in large volumes at low cost.

While mechanical properties mentioned above have been developed significantly with respect to those of soda lime glass through composition research (Tandia et al. 2019), sound isolation of glass has not been developed enough for rational design of acoustic transmission spectrum and enhanced sound transmission loss (Shengchun et al. 2010). These properties need to be developed with a materials modeling and engineering methodology while meeting manufacturability and mechanical and optical end property requirements simultaneously. These simultaneous requirements limit the flexibility in engineering sound absorption and reflection properties of glass. Engineering glass compositions do not yet seem to be a feasible direction toward optimizing acoustic phonons. In this chapter, I pose this challenge as a multi-constraint optimization problem and multilayer solution methods and examples are presented for enhancing sound transmission loss, particularly within 1–10 kHz (Leonhard et al. 2015). For good sound isolation, sound transmission loss within human audible range, particularly within 6–9 kHz, must be maximized beyond

30 dB or more. Acoustic constitutive relations and numerical models are presented to describe some of the multilayer solutions to this multi-objective materials optimization problem.

Sound signal is a time-dependent vibration of molecules in space, and this vibration brings a change in particle velocity when sound signal hits molecules. For solids such as a glass slab, due to limited particle displacement in compact molecular arrangement, a pressure gradient through the thickness of glass can be observed. In addition to this pressure gradient, the intrinsic molecular absorption due to acoustic phonon bands of the material leads to phase shift and absorption of the sound energy impinging on the glass slab. As a result, the transmitted acoustic signal is partially reflected and attenuated. This reflection and attenuation determines the fraction of sound energy that is transmitted through glass panes such as windshields and auto glass. The molecular vibration frequencies in the transmitted sound energy constitute the transmission spectrum of sound. When the transmitted sound power intensity is normalized with respect to the incoming sound power, one can determine the frequency response of glass panes. This frequency response is determined on a decibel (dB) scale, and thus sound transmission loss (STL) is defined as $STL = 10 \times \log_{10}(P_{transmitted}/P_{in})$. The purpose in this chapter is to overview composite glass pane designs for enhanced STL. Typically, multilayer planar glass/polymer/glass sandwiches are used for sound isolation. The polymer in most cases is polyvinyl butyral (PVB), which is a transparent resin that binds strongly on glass. Hence, the optical and mechanical properties of laminated composite glass-PVB structure help approach the desired specifications (Leonhard et al. 2015).

The acoustic transmission behavior of glass is determined by the mechanical properties, density, thickness, and elastic moduli of glass materials. The intrinsic acoustic scattering behavior of a single sheet of glass is determined by the electronic and phononic band structure of glass. In particular, acoustic phonons play a key role in absorption and scattering of incoming sound intensity and make up the intrinsic glass behavior. These band structures depend strongly on the composition and microscopic glass topology. Since glass is an amorphous material, rational design of phonon band structure of glass has been difficult. As a result, the intrinsic specific sound transmission loss behavior of a glass sheet is traditionally taken as a function of glass composition. Since glass composition leads to an essentially fixed acoustic transmission behavior, composite multilayer sandwich structures have been investigated more rigorously (Leonhard et al. 2015) for simultaneously optimizing mechanical, optical, and acoustic properties.

A key requirement in automotive glass design for windshields is lightweight, and this requirement is imposed on automotive industry by US regulations FMVSS 205 (ANSI Z26.1) and European requirements as defined in ECE R43 Rev. 3 for windshield applications. As a result, the auto glass panel designs should be as thin as possible. The automotive glass industry has traditionally been using trilayers of glass/polymer/glass-laminated composites for high strength, high optical transparency, and good sound and thermal isolation. Glass layers depend on the specific glass compositions developed by each glass manufacturer, and they can

be annealed soda-lime glass or other proprietary compositions. Polymer layer is typically chosen as standard polyvinyl butyral (SPVB), which binds strongly on glass and retains mechanical strength of the structure while providing good optical transparency. While fundamentally new glass compositions may emerge, end user windshield applications are most likely going to contain glass/polymer composites as the industry is strongly driven by high-volume manufacturability and well-established standards. As a result, successful glass models should be able to solve for sound transmission loss of multilayer composites in time, frequency, and real space domains. New emerging physics of acoustics and wave phenomena indicate that fundamental breakthroughs in sound isolation are also imminent (Yang and Sheng 2017).

In the following part, constitutive material relations and the wave equations used for acoustic modeling of sound transmission loss are presented with example results for polymer/glass sandwich layers. In the final part, future research opportunities on new glass materials with tunable phononic band structures, new (meta)material topologies, new mechanisms, and modeling methods are discussed.

2   Auto Glass Design: Materials and Acoustic Modeling

The second part of this chapter covers the acoustic wave equation formalism, model details, and example results on the sound transmission behavior of laminated glass/polymer composites. In the first subsection of the second part, the equations used for modeling the constitutive relations of glass/polymer composites are presented with a brief discussion of each term in the wave equation for sound transmission, boundary conditions, source definitions, and the details of finite element modeling steps. In the second subsection, example results on the sound transmission behavior of laminated glass/polymer composites are presented and discussed.

2.1   Constitutive Relations and Modeling Sound Transmission Loss

Sound transmission loss of laminated glass composites are modeled with finite element modeling using linear acoustic wave equations and material constitutive relations. In order to understand the acoustic transmission, reflection, and attenuation behavior of materials, one may use commercial acoustic finite element method solvers such as ANSYS MAPDL, ANSYS Acoustics ACT, Siemens LMS, MSC ACTRAN, or COMSOL Multiphysics Acoustics module. In the finite element model, first, the geometry of the structure to be simulated is defined. The sound wave or the pressure oscillates inside the enclosed structure and then exits the structure to the exterior medium.

In linear acoustics, pressure changes are assumed to be small with respect to the mean pressure:

$$p = p_0 + p', \quad p' \ll p_0 \tag{1}$$

Momentum and mass are conserved as described by Eqs. (2) and (3):

$$\frac{\partial \overrightarrow{\mathbf{v}}_a}{\partial t} = -\frac{1}{\rho_0} \nabla p_a + \frac{4\mu}{3\rho_0} \nabla \left(\nabla \cdot \overrightarrow{\mathbf{v}}_a \right) \tag{2}$$

$$\frac{1}{\rho_0 c_0{}^2} \frac{\partial p_a}{\partial t} = -\nabla \cdot \overrightarrow{\mathbf{v}}_a + \frac{Q}{\rho_0} \tag{3}$$

where ρ_0 is the mass density of the medium (kg·m^{-3}), p_a is the acoustic pressure (N·m^{-2}), v_a is the sound velocity (m·s^{-2}), and the Q/ρ_0 term (s^{-2}) is that captures mass loss due to sound wave-medium interaction. SI units are typically used. Here, constant and ambient temperature is assumed. Using Eqs. (2) and (3), the governing equation that describes the spatial and time dependence of linear acoustic pressure profile is found:

$$\begin{aligned}
\nabla \cdot \left(\frac{1}{\rho_0} \nabla p_a \right) &- \frac{1}{\rho_0 c_0{}^2} \frac{\partial^2 p_a}{\partial t^2} + \nabla \cdot \left[\frac{1}{\rho_0} \left(\frac{4\mu}{3} + \mu_B \right) \nabla \left(\frac{1}{\rho_0 c_0{}^2} \frac{\partial p_a}{\partial t} \right) \right] \\
&= -\frac{\partial}{\partial t} \left(\frac{Q}{\rho_0} \right) + \nabla \cdot \left[\frac{1}{\rho_0} \left(\frac{4\mu}{3} + \mu_B \right) \nabla \left(\frac{Q}{\rho_0} \right) \right]
\end{aligned} \tag{4}$$

In the models presented here, while no acoustic fluid-structural interaction is assumed, polymers may undergo glass transition with temperature, and their elastic moduli may change. As a result, temperature variations must also be modeled. This investigation is, however, beyond the scope of this chapter. For a deeper analysis of acoustic fluid-structural interaction with example cases, readers may refer to (Bouayed and Hamdi 2013; Kinsler et al. 2000; Kruntcheva 2007; Todo 2005).

2.1.1 Solution Types

Equations (2), (3), and (4) are solved for each node in the linear finite element acoustic model. The model types can be classified into three categories:

- *Modal solutions*, in which eigenmodes of the system are found. Understanding the modes of a given geometry could be important when unintentional resonances can emerge within the structure. These resonances may localize sound pressure and cause potential nonlinear structural damage. Therefore, one needs to avoid resonances within the audible range inside the glass/polymer composites to eliminate nonlinear sound localization and structural damage.
- *Harmonic solutions*, in which sound pressure level and power distribution at each port are found. This helps understand the sound transmission loss spectrum of a laminated windshield glass. In this chapter, we focus on harmonic solutions.

- *Transient solutions*, in which time evolution of the spatial dependence of sound pressure or acoustic energy density profile is solved. These solutions could be important in automotive glass product development as the windshield of a vehicle or the sound source is a moving part and the actual behavior of sound transmission loss may need to be accounted for using transient simulations of different angular orientations, relative velocities, and temperatures. In transient solutions, the temporal spacing between each sample is typically defined as $\Delta t = 1/(2f_{max})$, where f_{max} is the maximum frequency component of the sound wave incident on the structure. This definition originates from Nyquist theorem, which requires sampling a signal of maximum frequency f_{max} using a sampling rate of $2f_{max}$ in order to avoid aliasing. Aliasing is a misidentification of the frequency of a sound signal.

2.1.2   Material Properties

The material properties that govern sound isolation simulations include mass density, sound speed in the material, and dynamic viscosity. Density and the sound speed are fundamental material properties, which generally depend on temperature and sound frequency. Dynamic viscosity is defined as $\eta = F/(A \times SR)$, where F is the force, A is the area, and SR is the shear rate. Dynamic viscosity is a term in units of Pa·s, and it introduces dissipative effects and sound absorption losses. This viscosity term is both frequency and temperature dependent.

Sound wave propagation in outer medium such as air is modeled as a nonuniform ideal gas. In such media, the spatial and temporal evolution of sound waves is described using Eqs. (5), (6), and (7), which describe the pressure state and speed of sound (Kinsler et al. 2000):

$$\nabla \cdot \left(\frac{1}{\rho_0\left(\overrightarrow{r}\right)} \nabla p \right) - \frac{1}{\rho_0\left(\overrightarrow{r}\right) c^2\left(\overrightarrow{r}\right)} \frac{\partial^2 p}{\partial t^2} = -\frac{\partial}{\partial t} \left(\frac{Q}{\rho_0\left(\overrightarrow{r}\right)} \right) \tag{5}$$

$$c^2\left(\overrightarrow{r}\right) = \gamma RT\left(\overrightarrow{r}\right) \tag{6}$$

$$P_{state}\left(\overrightarrow{r}\right) = \rho\left(\overrightarrow{r}\right) RT\left(\overrightarrow{r}\right) \tag{7}$$

While these equations capture the dynamics of sound transmission, the interaction of pressure gradient with a rigid wall needs to be modeled using boundary conditions. For cases where temperature differences are also considered, viscous-thermal effect (pressure wave interaction with a perfect rigid wall or flexible wall) is introduced by solving the pressure equation coupled with Navier-Stokes equation (Zhao 2017).

2.1.3   Boundary Conditions

The boundary conditions in acoustics are defined by first introducing the following terminology:

- *Perfectly matched layer boundary (PML)*: absorbs incoming pressure waves.
- *Sound-hard surface*: A surface on which particle normal velocity is zero (or Neumann boundary with $\widehat{n} \cdot \nabla p = 0$).
- *Sound-soft surface*: A surface on which sound pressure is constrained (also known as Dirichlet boundary, where $p = p_0$ fixed pressure).
- *Mixed boundary*: The surface whose frequency-dependent wave transmission properties are modeled using a mixed impedance mismatch model, where acoustic impedance is defined as $Z = p/(vS)$, with p being the pressure, v being the sound velocity, and S being the surface area.
- *Port*: An exterior surface on which incident pressure is launched into the model.
- *Transparent port*: The pressure is reflected back to the infinity through this port.
- *Boundary layer impedance model*: Boundary layer thickness is much lower than the thickness of domains (or actual materials). The wavelength is also much greater than these layers (Zhao 2017).
- *Low reduced frequency model*: When the sound wavelength is much greater than the geometric feature sizes and boundary layer thicknesses, one can simplify the sound wave equation into:

$$j\overrightarrow{v}^{pd} = -c_0 \frac{1}{\overline{k}\gamma} \frac{1}{p_0} \nabla^{pd}\overline{p} + \frac{l^2}{s^2}\Delta^{cd}\overrightarrow{v}^{pd}$$

$$\frac{\overrightarrow{p}}{p_0} = \frac{\overline{\rho}}{\rho_0} + \frac{\overline{T}}{T_0}$$

$$l\nabla \cdot \overrightarrow{v} + \overline{k}c_0 \frac{\overline{\rho}}{\rho_0} = 0$$

$$j\overline{T} = \frac{l^2}{s^2\sigma^2}\Delta^{cd}\overline{T} + j\frac{\gamma - 1}{\gamma}\frac{T}{p_0}\overline{p}$$

where $s = l\sqrt{\frac{\rho_0\omega}{\mu}}$, $\overline{k} = \frac{\omega l}{c_0}$, $\gamma = \frac{c_p}{c_v}$, $\sigma^2 = \frac{\mu C_p}{\lambda}$

- *Wave absorbing boundary conditions*: The domain or open medium is terminated with infinite, homogeneous, inviscid fluid (gas), and, thus, outgoing propagating waves keep propagating outward and do not reflect back.

Among these boundary conditions, radiation and absorbing fluid element boundaries are used for all types of analyses (modal, harmonic, and transient), and perfectly matched layers are used for harmonic analysis. In the calculations of pressure profile on boundaries and inside materials, finite element mesh sizes are typically chosen as $\lambda/10$-$\lambda/5$ where $\lambda = c_0/f$.

2.1.4   Definition of Sources

The sound wave source is defined in different forms including incident pressure plane wave $P_{inc} = P_{inc,0}e^{j\varphi}e^{-j\overrightarrow{k}_i(\overrightarrow{r}-\overrightarrow{r_s})}$ and particle velocity $v_{n,f} = \frac{1}{\omega\rho_0}\widehat{n} \cdot \overrightarrow{k}_i p_{inc}$. Here, the mass density and the sound speed in the given environment must be known

for numerical calculation of sound transmission loss. While plane wave is the most fundamental source, other sound pressure sources are also used:

- Monopolar or spherical incident waves for a sphere of radius a

$$P_{inc} = aP_a e^{jka} \frac{e^{-j\vec{k}_i(\vec{r}-\vec{r}_s)}}{|\vec{r}-\vec{r}_s|} \tag{8}$$

- Dipolar waves as a combination of two monopoles with opposite signs and separation of distance d.
- Loudspeakers with monopole or dipole circular pressure radiators.
- Diffuse sound fields where pressure waves are launched with amplitude $A_n(\omega)$, distance d_n along N directions, and phase angles $\Psi_n = 0\text{--}2\pi$

$$p(r, \omega) = \sum_{n=1}^{N} A_n(\omega) e^{j\Psi_n} e^{-j\vec{k}_n d_n} \tag{9}$$

The last source type can also be used for studying the angular dependence of sound transmission loss. With the definitions of sources, we also define acoustic port modes, which are the junctions of entry and exit of the sound pressure waves. For a two-port structure, the amplitudes and phases of the incoming/outgoing sound pressure waves are defined as follows: P_{11} (wave incident from Port 1, reflected from Port 1), P_{21} (wave incident from Port 1 and exits from Port 2), P_{22} (wave incident from Port 2, reflected from Port 2), and P_{12} (wave incident from Port 2 and exits from Port 1). These parameters are used for describing the sound transmission loss in decibel scale by calculating P21 in postprocessing.

2.1.5 Postprocessing

After the simulations are completed, sound pressure level and sound transmission loss are calculated:

$$SPL \ (dB) = 10\log_{10}\left(\frac{\sum_{i=1}^{N} p^2_i}{p^2_{ref}}\right) \tag{10}$$

Here, sound pressure level at the threshold of human hearing is 0 dB, which has the same pressure as the reference pressure, $p_{ref} = 2 \times 10^{-5}$ Pa. Here, p_i terms are pressures at the sampled frequencies. To calculate sound transmission loss, time-averaged sound power through an area S must be calculated:

$$P_W = \frac{1}{2} \iint\limits_{S} p\vec{v}^* \cdot \hat{n} ds \tag{11}$$

$$\text{Sound transmission loss (TL) (dB)} = 10\log_{10}\left(\frac{P_{in}}{P_t}\right) \qquad (12)$$

$$\text{Sound reflection loss (RL) (dB)} = 10\log_{10}\left(\frac{P_{in}}{P_{ref}}\right) \qquad (13)$$

The wave description can also be viewed as a network of acoustic impedances connected to each other, where each layer or mesh's acoustic impedance Z is defined as $Z = p/(vS)$, where p is the pressure, v is the sound velocity, and S is the surface area. The reflections occur due to impedance mismatch between two dissimilar layers.

When reflections are calculated, one can plot the frequency dependence of sound pressure level and transmission loss on a given port based on Eqs. (10) and (12). By using symmetry of the geometry, one can also simplify the calculations and find far-field parameters, reflection, and sound transmission loss outside the finite element mesh region. Symmetry considerations also simplify the calculations of angular dependence of transmission loss, far-field sound power level, and sound pressure levels over multiple octave bands at far-field points.

2.1.6   High-Performance Computing (HPC) Considerations

As sound transmission loss simulations for automotive glass applications involve 3D mesh and calculations, high-performance computation is necessary. The commercial solvers can easily reduce solution times by an order of magnitude with respect to typical workstation computers with single-core central processing units. HPCs can reduce calculation times by using optimal mesh sizes, multiple acoustic models for different parts of the model structure, and efficient job distributions on HPC cores.

2.2   Sound Transmission Loss Models in PVB-Glass Multilayer Composites

Glass industry has well-established fabrication methods of fabricating polyvinyl butyral (PVB) layers on glass for acoustic and thermal isolation. This polymer is an optically transparent resin, which binds strongly on glass surfaces, thus retaining the mechanical strength and optical transparency of multilayer laminate composite materials (Pambianchi et al. 2016). Polymeric inner layers are used for composites because of their density and elastic modulus contrast with glass and because of their lightweight. Automotive emission regulations require each part in the automotive to be lighter, and thus polymers are preferred by glass industry for more than the past five decades. For instance, Corning Incorporated, which is one of the leading glass research and manufacturer companies, develops structures as thin as 3.56 mm using Corning's Gorilla Glass for Automotive (GGfA) applications. These glass layers are combined with annealed soda-lime glass (ASLG) and standard PVB layers (SPVB). Traditionally, glass laminate composite windshields are fabricated

as ASLG/SPVB/ASLG layers with 4.96 mm thickness. By substituting one of the ASLG layers with GGfA, the total glass layer thickness required for achieving similar strength is reduced as GGfA is strengthened using Corning's ion exchange process (Leonhard et al. 2015) as shown in Fig. 1. This process is a glass strengthening method, which prevents crack propagation due to Na/K ion concentration and stress gradient near glass surface. These layers are then tested and qualified to meet US regulations FMVSS 205 (ANSI Z26.1) and European requirements as defined in ECE R43 Rev. 3 for windshield applications.

While state-of-the-art glass composition engineering enables improvements in scratch resistance and mechanical strength of glasses, modeling the sound transmission loss of laminated sandwich panels is necessary in achieving enhanced sound isolation. In the rest of this part, sandwich panel modeling results are presented for laminated sheets of glass and a structural middle layer. These modeling results are representative of common sandwich panel design trade-offs in STL.

In this part, the sound transmission loss spectra of unbounded orthotropic sandwich panels shown in Fig. 2 are investigated. The modeled structure is a three-layer sandwich of glass top and bottom face sheets and a honeycomb structural core. Sound waves impinge on the top face sheet and cause transverse shear deformation in the layers. As a result, the thickness, rigidity, and other mechanical properties of the layers become important. In this model, Young's modulus of the face sheet

Fig. 1 Automotive windshield glass is traditionally designed as sandwiches of annealed soda-lime glass (ASLG) and standard PVB layers (SPVB). Using Corning's ion exchange process, one can strengthen glass and substitute one of the glass layers with Corning's Gorilla Glass for Automotive (GGfA) applications. As a result, the total windshield thickness is reduced from 4.96 to 3.56 mm (Leonhard et al. 2015, reprinted with permission from SAE International)
Fig. 2 Structure of the multilayer orthotropic sandwich panel (glass/honeycomb core/glass) under acoustic excitation. Here, sound transmission loss (STL) is defined as STL = $10 \times \log10(P_t/P_{in})$ (Shengchun et al. 2010, reprinted with permission from Elsevier Ltd.)

has been taken as 6.37 GPa, face sheet's density as 630 kg/m^3, face sheet thickness as 6.35 mm, Poisson's ratio of face sheet as 0.33, shear modulus of the core as G_{xz} = 23 MPa and G_{yz} = 50 MPa, core density as 28 kg/m^3, and core thickness as 73.5 mm.

Parametric studies were done to determine the effects of shear rigidity and thickness of the panel face sheets on STL. The acoustic wave equation solutions have been calculated based on FEM discussed in Part 2.1. Shear rigidity of the honeycomb layer transforms an incoming longitudinal acoustic pressure wave into an in-plane transverse stress gradient, and, thus, STL is enhanced at a wide range of frequencies. A caveat of this approach has been found in the low-frequency regime, in which STL decreases to a few dB when shear rigidity increases from 10^6 to 10^7 N/m as shown in Fig. 3. Figure 4 shows the dependence of STL on the top glass sheet thickness, which yields an STL dip for higher frequencies (1–10 kHz) due to resonant coupling and transmission of sound pressure waves. Since these thicknesses are necessary for structural and mechanical strength of the layers, a trade-off in STL at higher frequencies emerges. This trade-off could be overcome by adding further layers into the structure and reducing the resonance strength of the dips shown in Fig. 4.

3   Conclusions and Future Work

3.1   Glass Composite Models for Enhanced Sound Isolation Loss

Glass industry is highly conservative in the manufacturing processes and layer structures for windshields. As a result, glass models for enhancing sound transmis-
Fig. 3 The effect of increasing shear rigidity of the core on field STL of orthotropic sandwich panel. Higher rigidity shifts STL dip to lower frequencies (Shengchun et al. 2010, reprinted with permission from Elsevier Ltd.)

sion loss must continue to follow laminated glass/PVB/glass or similar multilayer composites. While simplified models may assume infinitely long composite sheets, realistic models need to account for the finite size effects as well. In addition, the angular uniformity of STL of curved composite windshield layers becomes another important figure of merit, which should be maximized. Since both geometric and material properties become important in these laminated composite structures, simultaneous iterative models of both material properties and windshield geometry should be developed.

3.2 Opportunities for New Glass Models and Materials with Improved Sound Isolation

Simultaneous optimization of mechanical strength, scratch resistance, optical transmission, and sound isolation is a challenge due to the intrinsic trade-offs imposed from the phononic band structure, microstructure, and geometric requirements. For high mechanical strength and elastic modulus, the glass composition space must include some key dopant constituents to allow for wide dynamic range for strain in the elastic deformation regime. In addition, since auto glass applications also demand fabrication of clear sheets of glass over large areas, one needs compatibility with large-area and large-volume manufacturing methods such as Corning's fusion
Fig. 4 Effect of face glass sheet thickness on STL of the sandwich panel. Increasing glass panel thickness shifts the STL transmission spectrum dip from about 8 to 2.5 kHz (Shengchun et al. 2010, reprinted with permission from Elsevier Ltd.)

draw process or other large-volume production methods (▶ Chap. 81, "Mechanical and Compositional Design of High-Strength Corning Gorilla® Glass"). While these simultaneous requirements pose a complex challenge, researchers have been addressing some of these complexities by introducing new fundamental composite structures with unique effective mechanical and optical properties as well as design paradigms. Below is a list of fields in acoustics and wave phenomena in general which are promising in developing models and composites that could address the sound-isolating, strong, elastic, and transparent glass design problem with a few constraints at a time.

Acoustic Metamaterials: Metamaterials are composites, which are rationally designed with key geometric features to achieve desired effective Young's moduli and Poisson's ratios not found in nature. In metamaterials, the overall material properties become strong functions of geometry, symmetry, and microscopic composite periodicity than would otherwise be in a regular single-phase structural material. As a result, one can engineer the density (ρ) and compressibility (C) of the effective metamaterial structure. For instance, resonant coupling of materials in a Helmholtz coil configuration may lead to negative dynamic C (C < 0, ρ > 0), or materials could be engineered to oscillate in or out of phase with the force when the drive frequency is below or above the resonance frequency, respectively. Thus, negative dynamic density could be achieved through out-of-phase time harmonic motion of the moving mass. Evanescent acoustic modes can be engineered to have much stronger effects by design to achieve negative C or ρ or both. For further overview,

readers are referred to excellent reviews on this subject (Wu et al. 2018; Yang and Sheng 2017; Fang et al. 2006; Ma and Sheng 2016; Cummer et al. 2016; Maldovan 2013; Greaves et al. 2011; Yamamoto 2018). With resonant metamaterial structures, giant sound loss enhancements could be engineered at the desired sound frequencies by design. As the components of metamaterials could also be optically transparent, metamaterial design strategy could be a solution to the sound isolation loss problem. For engineering of the intrinsic glass properties, readers are referred to the other glass design chapters in this section (▶ Chaps. 83, "Fundamentals of Organic-Glass Adhesion," and ▶ 81, "Mechanical and Compositional Design of High-Strength Corning Gorilla® Glass").

Simultaneous Sound and Heat Isolation: Since acoustic transmission is determined by electron and phonon band structure, transmission of sound and heat waves through glass composites are tightly coupled. Therefore, a natural outcome of designing for high sound isolation loss could be enhanced thermal insulation as well. Previously, Raman and Brillouin scattering studies experimentally indicated the coupling of phonons and photons, but, recently, a mechanism involving the simultaneous localization of mechanical and optical waves by using acoustic and optical cavities has been introduced to significantly enhance sound and light interactions (Maldovan 2013). As a result, one may design and use a new class of acousto-optical crystal that can integrate the combined management of phonons and photons (Maldovan 2013). Acoustic transmission spectra can be controlled using nonlinear acousto-optic metamaterials whose phonon band structures are a strong function of "capacitive and inductive" behavior of the vibration spectrum of the periodic lattice. As a result, one can achieve large-scale thermal diode behavior with large sound isolation loss. An excellent review paper (Maldovan 2013) describes phonon cavity engineering principles and presents examples for bridging mesoscopic and microscopic designs of phononic band structures for the desired sound and heat transmission loss. The engineering of phonon band structure may help simultaneous achievement of strength and sound isolation loss in glass composites.

Active Control of Sound Transmission Loss: Acoustic transmission spectra could also be controlled on demand by applying voltage. If mechanical properties of one of the layers in a glass/polymer composite depend on voltage, then sound transmission loss could be enhanced by voltage bias to stiffen or soften the structural layer within laminated glass sheets. As a result, glass could be operated in "silent mode" with voltage bias (Zheludev and Kivshar 2012). Two key requirements for such a design are, first, a sizable elastic modulus and density change upon voltage for sound isolation enhancement and, second, a negligible or no change in optical transparency. In order to achieve such demanding properties, one may use 2D materials with transparent contacts or functionalized PVB layers (Kraft et al. 2006). While major research on electrochromic windows progressed enough for commercialization (Wang et al. 2016), electroacoustic glasses may become an emerging area for research.

Elastic Wave Manipulation with Nonreciprocity and PT Symmetry: Recent investigations in wave phenomena indicate that one can engineer the photonic,

electronic, phonon, and spin-resolved band structures with certain symmetries. These symmetries include point or planar inversion, parity, time-reversal, rotational, and translational symmetry. Some of these symmetries such as rotational, translational, and inversion symmetries are observed in real space, while time-reversal symmetry is observed in time or wave vector (or frequency) space. When these symmetries are broken, one can control the propagation and attenuation of photons, phonons, spins, and wave particles on demand. For instance, introducing a magnetic dopant into a material and applying magnetic field in a direction allows for asymmetric photon and phonon transport for positive and negative wave vectors of the same frequency, and thus $\omega(k) \neq \omega(-k)$. A time-dependent control of density or elastic modulus of glass layers can also enable time-reversal symmetry breaking. Using these symmetry-breaking principles, one can engineer one of the layers in glass pane composites to yield nonreciprocal sound transport properties, thus yielding high sound transmission loss. Since glass and PVB are amorphous materials, there are no real space lattice symmetries to break. On the other hand, one can use time or frequency domain symmetry-breaking methods such as controlling density or elastic modulus of one of the layers using time-dependent voltage or magnetic field. This control allows for nonreciprocal propagation of sound. Thus, glass/PVB laminate composites could be engineered for high nonreciprocal sound transmission loss and isolation (Ma and Sheng 2016; Haberman and Norris 2016; Yang and Sheng 2017; Fang et al. 2006; Cummer et al. 2016; Popa and Cummer 2014; Greaves et al. 2011; Krushynska et al. 2018; Yan et al. 2018; Kushwaha et al. 1993).

Bioinspired Acousto-optic Structural Materials Engineering: Natural structural materials are formed out of a limited number of organic/inorganic compounds at room temperature. These layers consist of hard and soft materials organized in complex hierarchical architectures, with characteristic dimensions ranging from the nanoscale to the macroscale. As a result, these materials are lightweight and commonly have unique combinations of strength and toughness, although synthetic replication of these materials has been challenging (Fig. 5).

The room temperature formation kinetics, the hierarchical structure, and the unique mechanical properties of biological materials may enable enhanced sound transmission loss.

Hybrid-Nonlinear Acoustic Materials: In this chapter, the intensity of sound pressure level has been assumed to remain small enough with respect to mean pressure as shown with Eq. 1, such that wave transport always remains in the linear regime. On the other hand, when this assumption is relaxed, acoustic transmission spectra can be controlled using nonlinear acousto-optic filtering. In nonlinear acoustic transmission, sound isolation and nonreciprocal sound transmission can be achieved through asymmetric frequency conversion and filtering the fundamental frequency.

To exploit nonlinearities in sound isolation, the medium needs to be a nonlinear acoustic material and a frequency-selective mirror (i.e., a periodic phononic crystal). These two layers need to be used together as shown on Fig. 6. The structure consists of a frequency-selective surface (FSS) and a nonlinear acoustic layer. The mirror
Fig. 5 Ashby plot for classes of structural materials with respect to their specific strength and specific stiffness values. Naturally occurring biological materials (shown in pink) yield unique strength/stiffness combinations (Wegst et al. 2014). (Reprinted with permission from Springer Nature)

reflects the fundamental frequency (f_0) but transmits the second or higher-order harmonic ($2f_0$ or nf_0). The nonlinear acoustic layer is first excited from the left side (i.e., from inside windshield) of the filter at fundamental frequency in the audible range, and sound waves are reflected by the structure as shown on Fig. 6. When the structure is excited from the right-hand side of the structure (from outside), the nonlinear layer converts most of the incoming acoustic energy to the second or higher harmonic frequency, which is transmitted through the frequency-selective mirror. Thus, the sound frequencies transmitted from outside (right) to inside (left) could be tuned to beyond audible range (Fig. 6).

Nonlinear acoustic materials are modeled using non-Hermitian Hamiltonians, which describe systems with loss and/or gain or other higher-order effects, which may upconvert incoming sound frequencies to beyond audible range and help enhance sound isolation below 20 kHz.
Fig. 6 Bilayer of frequency-selective surface (FSS) and nonlinear acoustic layer helps eliminate sound transmission at audible frequencies from outside (right) to inside (left of the structure). The FSS reflects sound back inside at the fundamental frequency, while the incoming sound from outside is upconverted to second- or higher-order harmonics with high efficiency to avoid audible range (Cummer et al. 2016). (Reprinted with permission from Springer Nature)

Jaime Marian and Ram Devanathan

Contents

Abstract

The performance of materials used in nuclear technologies is controlled by mechanisms that have their origin at the atomic level. Materials modeling is needed in conjunction with theory and experimental observations to develop fundamental understanding of energetic processes that span disparate scales in space and time. Modeling of nuclear materials has been in use continuously since the early developments in the 1950s. It is by no means a mature field, with constant advances still being made on many levels, including theory, simulation, and algorithms. This can be ultimately linked to the fact that we do not currently have a complete theory of irradiation damage in materials. Multiscale materials modeling has stepped up to fill that gap and continues to address the research

needs of the nuclear materials community. This section provides the reader with a rigorous and practical description of the different elements of multiscale modeling that have had and are having the broadest impact on the field.

1   Introduction

The chapters in this section provide a detailed description of methods used to model nuclear materials from the electronic to continuum scales. While modeling of nuclear materials takes advantage of both established and novel techniques being developed within the multiscale modeling framework (Curtin and Miller 2003) for other purposes, the particularities of irradiation exposure and the associated material property degradation effects demand specific modifications – if not full-blown reformulations – that now make it a specific branch within multiscale modeling of materials (MMM). This should come as no surprise, as it is well known that energetic particle irradiation is an inherently multiscale process, acting at the nanometer scale in its primary form and transferring its effects to the engineering scales. Likewise, femtosecond-scale processes propagate themselves through time until their effects are felt after hours and even months and years of continued operation. This complexity is compounded by the fact that the effects brought about by energetic particle irradiation are of strikingly varied nature: alloy chemistry, heat transfer, mechanical behavior, melting, and diffusion, among many others, are all known to play an important role at some point or another along the spatiotemporal sequence (Zinkle and Busby 2009). This multidisciplinarity is an inherent characteristic of multiscale modeling of irradiated materials and is reflected in the group of authors contributing to this section. These contributions integrate well with the chapters of Part VII of MTM, entitled "Modeling of Microstructure Evolution: Mesoscale Challenges" edited by Stan and Sarrao in MTM, with Part XIV "Modeling of Radiation Damage in Materials: Best Practices and Future Directions" edited by Nordlund and Short and other stand-alone publications that provide a foundational understanding of models of radiation-induced changes in microstructure and properties of materials.

2   Contributions

This overview offers a brief commentary on the different chapters to introduce the reader to the field. ▶ Chapter 86, "Density Functional Theory Calculations Applied to Nuclear Fuels," by Andersson focuses on electronic structure calculations in nuclear fuels. This is an extremely challenging problem due to the strongly correlated nature of $5f$ electrons in uranium, which makes the use of standard exchange-correlation schemes within density functional theory (DFT) insufficient to capture the properties of fuels based on UO_2. Advances in this field are critical to push along in the development of advanced fuels such as metallic fuels, UN, or U_3Si_2.

The author discusses in detail calculations of point defects, both under thermal equilibrium and under far-from-equilibrium situations (under irradiation), and the structure and properties of Xe atoms generated as a fission product and its implications for fission gas accumulation in the fuel. This is one of the most important issues in the long-term structural integrity of fuel elements in nuclear reactors, and although semiempirical calculations are gaining traction for their ability to deal with larger systems, DFT and its variants are still a fundamental piece in our modeling portfolio to study the complex structure of U-based compounds.

Given the short length and time scales accessible to DFT-based methods, there is a need to develop empirical potentials to study energetic radiation damage processes in materials using molecular dynamics and Monte Carlo simulations. ▶ Chapter 87, "Interatomic Potentials for Nuclear Materials," by Devanathan provides an overview of commonly used potential functions and reviews the suitability of different potentials to model defects and radiation effects in materials, such as α-Fe, SiC, pyrochlores, and UO_2. This chapter serves as a bridge between Andersson's chapter devoted to DFT and subsequent chapters on molecular dynamics and kinetic Monte Carlo methods. DFT data are often used along with experimental data to fit interatomic potentials. In addition to fitting to elastic constants and lattice constants from DFT, fitting to forces derived from DFT calculations for representative model liquids is a promising strategy to develop reliable interatomic potentials. Several interatomic potentials have been developed for commonly studied materials, such as Fe and UO_2. DFT results for defect properties not used to fit the potential can be used as a standard against which the results of the potentials can be compared. Often, no single potential stands out as being clearly superior for modeling dynamic defect properties due to the limitations of the functional forms used. The combination of high-throughput DFT calculations and machine learning has the potential to identify new functional forms and parameters for potentials to simulate radiation damage. Ultimately, the development of reliable interatomic potentials is closely tied to the reliability of MD simulations of radiation damage presented in the next chapter.

Djurabekova and Nordlund provide a comprehensive overview of the uses of molecular dynamics for simulations of energetic particle irradiation in ▶ Chap. 88, "Molecular Dynamics Simulations of Non-equilibrium Systems." Molecular dynamics (MD) is a fundamental tool in the computational modeling portfolio due to its intrinsic high temporal and spatial resolution, efficiency and scalability, versatility to study all kinds of systems and geometries, etc. As it relates to bulk irradiation damage from high-energy particles such as neutrons or heavy ions, MD has provided key insights into the primary damage production process, including the start of the displacement cascade, the thermal spike, quenching phase, and defect survival phases. For example, MD conclusively showed that primary damage production does not scale linearly with recoil energy, an assumption in place in the irradiation damage community for decades, but that it follows instead a power law due to breakup into subcascades or, in some selected cases, saturates above a threshold energy. As well, it was through MD simulations that cornerstone theories such as the production and dislocation bias models have been verified, a fact that has had very large implications in our understanding of irradiation damage processes.

This would not have been possible without the capability to simulate tens and even hundreds of millions of atom systems, which are now routine in many research groups thanks to very successful optimization efforts over the years to make MD codes efficient and scalable on massively parallel architectures. The authors also discuss the role played by electron-phonon coupling as a viable way of extracting heat from the molten zone following the thermal spike. This is typically modeled via two-temperature models cast over the underlying particle dynamics.

MD simulations have also proven critical to study light-ion deposition processes on material surfaces, e.g., as in the case of fusion first walls exposed to H and He plasma ions. Simulations have given researchers access to the mechanisms behind physical and chemical sputtering in graphite surfaces, erosion in W and B materials, and surface morphology evolution in W. The authors make a convincing case for molecular dynamics to continue being an essential element of the modeler's toolbox for years to come to study irradiation processes in materials.

In ▶ Chap. 89, "Kinetic Monte Carlo Algorithms for Nuclear Materials Applications," Balbuena, Caturla, and Martinez cover the kinetic Monte Carlo (KMC) technique and its application to irradiation damage accumulation in representative structural metals. KMC simulations have established themselves in this field by providing access to time and length scales that range between those covered in molecular dynamics simulations and those accessible with mean field rate theory calculations. As such, they are ideally suited to study post-primary damage kinetics while retaining full three-dimensional spatial resolution. For example, they are able to capture the fine details of defect evolution in stages II, III, and IV of resistivity recovery experiments, including correlated recombination, cascade aging, and the early stages of damage accumulation. Often, KMC is offered in contraposition to rate theory calculations, which, although capable of reaching longer time scales and irradiation doses, fail to capture the highly heterogeneous nature of irradiation damage in metals. One of the reasons hindering progress in the time scale front for KMC simulations is the disjoint nature of defect diffusion in metals, with self-interstitials moving practically athermally along rectilinear trajectories at very high rates and vacancy clusters displaying very low mobilities. This results in time evolutions controlled by high rate processes with slow time progress. Another difficulty intrinsic to the KMC method is the stochastic nature of time evolution, which makes it difficult to take advantage of parallelization, in contrast with almost all other methods. While new algorithmic advances have shown some promise, there are opportunities for more improvement in this topic. The authors also discuss the development of new methods that determine events "on the fly," that is, calculating locally in space and time the different transitions available to a given evolving species. Following new efficiency improvements, these methods have opened the door to unprecedentedly complex systems, such as neutron-irradiated materials with changing chemical inventory as well as multicomponent alloys. The future promises to be bright for KMC practitioners as more improvements are made and the capabilities of the technique are expanded.

However, achieving the high doses required in power devices, or in next-generation reactor concepts, is still an insurmountable task for direct KMC

calculations. For that, one must give up some level of resolution in order to gain computational expediency. In ▶ Chap. 90, "Rate Theory of Radiation Damage," Ghoniem provides a rigorous overview of the "mean field" kinetic theory of defects, identifying the steps taken to arrive at systems of rate equations describing defect accumulation evolution. The mean field representation is accomplished by spatial averaging of defect populations and treatment of those populations under classical nucleation theory. This intrinsically assumes that all cluster species are homogeneously distributed spatially, something dubious in the early stages of cascade evolution, and evolve by either absorption or emission of monomers. This is valid when clusters are assumed to be immobile, implying that growth/shrinkage is mediated by the motion of single vacancies or self-interstitial atoms. The internal microstructure is accounted for in terms of defect sinks such as dislocations, grain boundaries, and/or inclusions and precipitates. The chapter discusses breakthroughs in the application of rate theory models to radiation damage such as the production and dislocation bias models, which have been instrumental in explaining features such as swelling and hardening in nuclear materials. While rate theory methods have become the de facto computational "workhorse" for radiation damage accumulation calculations, they are nonetheless riddled by some strong limitations, such as the absence of fluctuations in a highly heterogeneous scenario or the phenomenon of "combinatorial explosion," i.e., the nonlinear growth in the number of equations with the number of distinct chemical species. This limits their application to situations with a rich chemical diversity (e.g., as in the case of nuclear transmutation). Despite this, these methods continue to be an essential tool to provide us with long-dose estimates of defect evolution.

▶ Chapter 91, "Discrete Dislocation Dynamics Simulations of Irradiation Hardening in Nuclear Materials," by Marian, Fitzgerald, and Po provides a comprehensive review of the use of the dislocation dynamics (DD) technique in the context of irradiated materials. The authors discuss key features of the approach, and specific enhancements both in terms of theory and implementation develop to study hardening in irradiated microstructures. In addition to all the challenges surrounding accurate and efficient DD simulations in unirradiated materials to study strain hardening, the presence of irradiation defects adds yet another layer of complexity to the approach. The main types of defects that emerge during irradiation of materials can be broadly classified into three main groups. Dislocation loops can be treated directly within linear elasticity, and in principle they require the least amount of implementation effort. However, osmotic forces must be introduced to balance elastic attraction forces which can result in artificial loop shrinkage if untreated. As well, faceting of loops – a well-known feature in anisotropic crystals – has been dealt with by developing efficient formulations of anisotropic linear elasticity. The second type of defects considered is precipitates and/or inclusions. These are generally treated using Eshelby's solutions for elliptical inclusions in elastic media and are now routine in most DD codes. Finally, voids and bubbles can be challenging to deal with, as they involve free surfaces and image forces. However, recent finite element implementations, albeit costly, are now also routinely employed for this purpose. Present DD codes are now also capable of simulating plastic flow localization, a key

feature of microstructural evolution in high-dose irradiation in metals. Challenges remain, not the least of which is pushing the envelope in the amount of plastic strain that can be simulated, and to formalize the coupling of DD with crystal plasticity or continuum theories of deformation. From a physics point of view, perhaps, a remaining challenge not yet tackled to the same level of other developments is that of irradiation-enabled climb and its greater implications for creep at high temperature. In all, the chapter highlights the state of the art of dislocation dynamics simulations of irradiated materials as a healthy field that has and is contributing with key findings to our understanding of nuclear and ion-implanted materials.

▶ Chapter 92, "Mesoscopic Modelling of Irradiation Damage Processes: Bridging Many-Body Mechanics and Thermodynamics in Rate Processes," by Woo explores the mesoscopic connection between statistical mechanics and macroscopic thermodynamics. Progress in bridging the quantum mechanical world of discrete energy and the engineering world of temperatures and thermodynamic functions is assessed, and the effects of many-body dynamics and quantum statistics on reaction kinetics are discussed. The discussion is centered on the basic assumptions that underlie traditional efforts to model irradiation damage using continuum theory and their limitations, especially when it comes to treating low activation barrier events. To overcome these limitations, a Langevin equation scheme in the Mori-Zwanzig formalism is presented. The approach is especially relevant to understanding clustering of defects produced by radiation damage. The author identifies new mesoscale science frontiers, such as materials response to extreme environments and defect processes in ferromagnetic metals.

Spencer, Schwen, and Hales offer an overview of the governing equations for modeling materials in nuclear reactor environments in ▶ Chap. 93, "Multiphysics Modeling of Nuclear Materials," by Spencer et al. This chapter begins by reviewing the physics behind the behavior of fuels and structural components in a reactor, presents numerical methods and discretization techniques, and concludes with examples of relevant multiphysics problems. For light water reactor fuel performance modeling, the fuel microstructural evolution is of great interest. Thermal and stress gradients present in the fuel affect the migration of chemical species and defect clusters produced by irradiation. The modeling scheme has to consider ballistic radiation damage, chemical mixing, added fission products, fission gas resolution from bubbles, creep, and fracture. These conditions are clearly far from equilibrium. The fuel centerline temperature is an important quantity of interest because of its influence on neutronics and fuel performance. This temperature depends on the thermal conductivity of the fuel, which is affected by the thermal gradient in the fuel pellet and the extent of radiation damage. The heat transfer equation is thus nonlinear, and there is a need to couple models of thermal conductivity and mechanical behavior. The multiphysics approach includes models for cladding creep and fission gas release. The models must deal with unusual conditions, such as reactivity insertion accidents, localized stresses due to a chipped fuel pellet, and stress corrosion cracking of cladding. In the case of cladding embrittlement due to hydride formation, the modeling must account for volume changes, misfit strains, stored mechanical energy, changes in the chemical potentials

of the diffusing species, local plastic deformation, and microstructure evolution. The chapter provides a good representation of currently used algorithms and multiphysics codes.

When spatiotemporal information is of the essence for microstructural evolution, phase field models provide a very good alternative to standard methods while still keeping computational cost in check. ▸ Chapter 94, "Phase-Field Modeling of Microstructure Evolution in Nuclear Materials," Ahmed and El-Azab describe the potential of the method to simulate microstructure evolution in nuclear materials, without a doubt one of the most challenging applications that phase field simulations have had to tackle yet. Phase fields evolve according to a free energy functional that represents bulk processes as well as interfaces separating spatial fields characterized by different values of the order parameter. This order parameter can represent different solid phases, clusters of defects, bubbles or voids, different grain orientations, etc. By way of their two main variants, the order parameter can evolve according to an Allen-Cahn or a Cahn-Hilliard equation, both of which originate from rigorous thermodynamic principles that satisfy the first and second laws of thermodynamics. Familiar parameters, such as diffusivities, reaction coefficients, absorption coefficients, etc., are all naturally part of the formulation, dictating the time scale as they do in rate theory or kinetic Monte Carlo models. As well, thanks to its thermodynamic formulation, driving forces such as irradiation, mechanical stresses, and thermal gradients can be incorporated into the formulation in a straightforward manner. The combination of all of these features has allowed researchers to study phenomena such as irradiation-induced segregation and precipitation, formation of voids/bubble formation, nucleation, growth, and coarsening of dislocation loops, both in nuclear fuels and irradiated structural materials. Several limitations still remain such as the theoretical treatment of homogeneous nucleation and artifacts introduced by the smoothening of nominally sharp interfaces. In addition, resolution of interfaces via smooth gradients comes at a price in terms of computational cost, although much progress has been achieved over the last few years by way of application of spectral solvers, finite elements, and others. Finally, phase field simulations must be fed parametric information from lower scales, which calls for a tighter coupling with atomistic simulations before the predictive capabilities of the method can be brought to quantitative standards.

In ▸ Chap. 95, "Thermodynamic Modeling of Nuclear Fuel Materials," McMurray and Besmann describe the framework of classical and computational thermodynamics leading to predictions of phase diagrams for complex systems. The problem of predicting stable phases of fuel materials is extraordinarily complex due to its highly dynamical nature, governed by burnup, transmutation, and temperature, and the high number of components present at any given point. The authors first give an overview of classical thermodynamics, with special emphasis on pointing out the corrections and correlations used in practice to calculate free energies of multicomponent systems. They then introduce the CALPHAD approach, a technique that has enjoyed great success over the last few decades to furnish approximate phase diagrams of systems of – practically – arbitrary complexity. While fuels under service are assumed to not reach equilibrium at any given moment, and thus not

expected to attain any one of the phases present in the predicted phase diagrams, knowledge of these is important to define the driving forces that govern the evolution of these materials under irradiation conditions. Of particular interest is the role played by electronic structure calculations in parameterizing CALPHAD, which is bringing in a level of unprecedented predictive potential to these calculations. The authors discuss unary, binary, and ternary diagrams for selected systems, including uranium-based fuels such as U-C, U-N, and UO_2. In all, thermodynamic modeling is a fundamental piece of radiation damage modeling, particularly as it concerns expected states of solid and liquid fuels to further define and refine other multiphysics models.

3   Summary and Outlook

Treatises discussing the state of the art in the field of multiscale modeling of nuclear materials are a relatively recent occurrence. Their genesis can probably be tied to efforts by ASTM in the early 2000s to compile papers presented at specialized conferences into a single reference bound volume for researchers to use (e.g., Kirk and Natishan, 2003). While specific topics related to nuclear materials modeling were included in Parts A and B of the first edition of the *Handbook of Materials Modeling* (Yip, 2005), where multiscale materials modeling at large was covered, (i) the renewed interest in nuclear energy as a mitigatory source of energy of the effects of climate change and (ii) recognition that the field has grown over the last decade to extents deserving of its own section in the handbook are the main drivers behind the present collection of chapters.

The growth of the field is readily appreciable by looking at the number of workshops, symposia, and conferences available to the nuclear materials modeling community today, ranging from general professional conferences, such as TMS and MRS, to significant portions of modeling-specific international conferences such as MMM, to specialized technical meetings such as NuMat. This interest has been galvanized by the community in the form of publications as well, among which probably stands out *Comprehensive Nuclear Materials* (Konings 2012), where modeling techniques are brought into the limelight of fission and fusion reactor material research and accelerator systems. The contents of this section must be seen as one more effort by the community to organize their thoughts and compile the existing state of the art into a series of chapters that can help researchers mount future efforts or maximize ongoing ones.

While there is considerable potential for applying the methods discussed here to extend the life span of existing nuclear reactors, develop accident-tolerant nuclear fuel and cladding, and design new materials for advanced reactors, the contents of this section also reflect the growth of a field over the last several years and the continuing challenges in an era of exceptional computational resources and method development. These remaining challenges are in fact testimony to the tremendous difficulties associated with the field of irradiation damage and the progress made by the community to solve them. In this sense, this section will give the nonspecialist

reader a broad overview of the catalog of methods available for studying the behavior of irradiated materials across the entire spatiotemporal spectrum, while, for the specialist, it can serve to judiciously select from among the methods at our disposal depending on the relevant conditions and material class and to steer them along defined research directions to augment specific capabilities.

David Andersson

Contents

Abstract

The goal of nuclear fuel performance modeling is to assess the margin to failure, and it is used by researchers, industry, and regulators to develop fuel designs, optimize reactor operation, and evaluate accident scenarios. Accurate models of material properties and the evolution of material properties as a function time in the reactor (burnup) are critical for accomplishing predictive fuel performance simulations. Historically, these models were fitted to reactor test data and they were empirical in nature, which limited their application to the range of conditions covered by the available test data. By developing mechanistic models that resolve the microstructure, its evolution, and impact on properties,

predictive simulations can be achieved. This requires a multi-scale modeling framework that at the atomistic scale uses density functional theory (DFT) calculations to determine model parameters governing, for example, point defect and fission gas thermodynamics and kinetics as well as thermal conductivity. This chapter reviews DFT methods applicable to these problems and exemplifies results for primarily UO_2, which is the most common fuel in light water reactors. Additionally, advanced fuels such as U_3Si_2, metallic uranium, and UN are briefly discussed. Challenges, opportunities, and limitations as well as the role of DFT calculations in the multi-scale modeling framework are also covered.

1   Introduction

Density functional theory (DFT) calculations start from a quantum mechanical description of the interaction between electrons, and at the most fundamental level, they predict the density distribution of electrons in a material and the corresponding total energy (Jones 2015). The electron density governs bonding. Many other properties are functions of the electron density and the total energy. They can be attained through perturbations of the material, such as changing the volume or shape of the unit cell (which gives access to equilibrium lattice constants and elastic constants), displacing atoms (which enables calculation of phonons and migration barriers), and removing or adding atoms (which provides defect formation energies and information about phase diagrams). Phonons and defect thermodynamics and kinetics are important properties underlying nuclear fuel performance. DFT calculations have become an important and reliable tool for studying these properties, often leveraged in a multi-scale modeling and simulation framework to connect the fundamental properties accessible from this computationally expensive technique with more complex properties governing materials performance in reactor applications (Tonks et al. 2017; Devanathan et al. 2010).

DFT maps the vast quantum mechanical many-body electron problem in a material into a set of single-particle equations, which typically rely on a periodic representation of the material to further reduce the computational cost (Jones 2015). The key theorems underlying DFT state that the ground-state properties of a many-electron system are uniquely determined by the electron density and that this ground-state density minimizes the total energy functional of the system (Hohenberg and Kohn 1964; Kohn and Sham 1965). In this formalism, the difficult many-body effects that arise from the electron-electron interactions are captured by the so-called exchange-correlation potential (Kohn and Sham 1965). Accurate representation of materials properties requires a good approximation for the many-body electron effects. Over the years, several of the improved predictive capabilities of DFT calculations have been accomplished by developing better approximations for the exchange-correlation potential. The local density approximation (LDA) was the first major step (Kohn and Sham 1965), which was followed by gradient corrected versions (the generalized gradient approximation, GGA) (Langreth and Perdew 1980; Langreth and Mehl 1983; Perdew 1985; Perdew and Wang 1986;

Becke 1988; Perdew et al. 1996). Systems that exhibit strong correlations among the electrons, which include actinide materials and nuclear fuels, often need additional model refinement to describe the physical properties correctly. Popular approaches include the Hubbard U method (adding Hubbard U and J terms to the standard Hamiltonian in order to capture electron localization) (Anisimov et al. 1997), hybrid functionals (incorporating a portion of exact exchange from Hartree-Fock theory) (Heyd et al. 2003), and dynamical mean field theory (DMFT) (Georges et al. 1996). Nuclear fuel performance properties are in most cases closely related to defects, which imply large system sizes (number of atoms) extending beyond the crystallographic unit cell. The added computational expense from having to consider strong correlations in nuclear fuels simulations is a major challenge, which favors the Hubbard U model, often labeled as DFT $+$ U, over other potentially more rigorous but computationally costly methods.

DFT and the application of periodic boundary conditions help to make the many-body electron problem tractable. Further efficiency gains are possible by replacing the explicit treatment of core electrons with a smooth pseudopotential (Vanderbilt 1990) or related ideas implemented in the projector augmented wave (PAW) method (Blöchl 1994; Kresse and Joubert 1999). This is important for nuclear fuels since uranium has 92 electrons. Typical DFT calculations for uranium only treat the outermost 14 valence electrons explicitly, which is a huge benefit since the computational expense scales as $\sim N^3$, where N is the number of electrons, and absolutely necessary in order to be able to study defects.

Compared to empirical or semiempirical force-field descriptions of the interaction between atoms, the main benefit of DFT is much better control of the accuracy and having a predictive capability without any need for fitting to experimental data. For UO_2, one important feature of DFT compared to most semiempirical potentials is the ability to treat varying charge states, that is the formation of U^{3+}, U^{4+}, U^{5+}, and U^{6+} ions. The improved accuracy, unfortunately, comes with a much higher computational cost, which limits the number of atoms that can be studied to somewhere between 100 and 1000 depending on the material and the particular flavor of DFT being applied. Even though fitting to experimental data is not needed in DFT, validation against experiments is key for reliable prediction of materials properties.

This chapter focuses on using DFT calculations to model nuclear fuels and in particular a few key properties that are critically important for the performance of nuclear fuels in reactor applications. The most common type of nuclear fuel in the current fleet of light water reactors (LWRs) is uranium dioxide, UO_2. It is a semiconductor with low thermal conductivity, which is undesirable, but it has excellent performance under irradiation and a high melting temperature. Other options include metallic fuels based on uranium with added alloying elements such as zirconium, which have higher thermal conductivity than UO_2 but a lower melting point. They also tend to be less radiation tolerant, which can lead to significant swelling. Metallic uranium reacts very rapidly with water and nuclear reactors that would use metallic fuel thus rely on a different coolant than standard light water reactors, for example, liquid sodium, in order to avoid uncontrolled reaction with

the coolant in case of a clad breach. UO_2 with zirconium cladding has been a very successful fuel in LWRs, and it has been optimized for performance, reliability, and safety. However, there are fundamental limitations that have motivated interest in alternative advanced fuels and reactor designs, which encompass the metal fuels mentioned above as well as silicon (U_3Si_2)-, nitrogen (UN)-, and carbon (UC)-based uranium compounds. These alternatives address the two major drawbacks of UO_2: low uranium density and poor thermal conductivity. The new fuel concepts and the associated reactor designs also aim at providing additional safety margins, leading to better accident tolerance.

The remainder of this chapter will review the role of DFT in modeling nuclear fuel performance and discuss the unique challenges with applying DFT to nuclear fuels, in particular the impact of strong correlations caused by the uranium 5f electron, followed by case studies of using DFT to investigate point defects, fission gas behavior, and thermal conductivity in nuclear fuels. The main focus of our discussion is on UO_2, but other fuels will also be examined.

2   Nuclear Fuel Performance Modeling, Multi-Scale Simulations, and Role of DFT Calculations

The design and choice of materials for nuclear fuels vary between reactor types, but in general fuel elements with fissile material are enclosed in a protective cladding or in some cases a coating in order to prevent release of radioactive materials to the coolant, with exception for certain molten salt reactors where the coolant itself contains the fuel. The coolant transfers the heat generated in the fuel element from the cladding or coating surface to either a steam generator or directly to a turbine for production of electricity. In light water reactors, the fuel is in the form of small UO_2 pellets stacked on top of each other, with cladding made of a zirconium alloy shaped in the form of a long tube (fuel rod), which are assembled in bundles and placed in the reactor vessel. The goal of nuclear fuel performance modeling is, in essence, to assess the margin to failure of the fuel rod (Rashid et al. 2011; Williamson et al. 2012). This analysis includes both the fuel pellet and the cladding separating the fuel from the coolant. Fuel performance simulations are used by the industry to develop fuel designs, optimize reactor operation, and evaluate accident scenarios. These simulations are also used extensively by regulatory authorities. Fuel performance modeling is performed at the finite element level and resolves the full pin dimensions, with legacy codes being 1D (radial) (Berna et al. 1997) or in some cases 2D (radial and axial) (Rashid et al. 2004) and modern codes, such as the Bison fuel performance code, having the capability to also perform full 3D simulations (Williamson et al. 2012).

Accurate models of material properties and the evolution of material properties as function time in the reactor (burnup) are critical for accomplishing predictive fuel performance simulations. The relation and interlinkage between properties and fuel performance is famously complex (Rashid et al. 2011; Lassmann 1980).

Historically, these models were fitted to reactor test data and they were empirical in nature, which limited their application to the range of conditions covered by the available test data. These models should ideally be mechanistic by capturing the microstructure evolution during reactor operation and the effect of the microstructure on the properties of the fuel (Tonks et al. 2017). The idea is that such models would possess a higher degree of predictive power. Due to the challenge and expense of performing irradiation testing, development and parametrization of said models would almost certainly entail a strong component of multi-scale modeling and simulations. This is especially the case for new advanced fuels that have not been through the same historical testing programs as UO_2. There are several efforts around the world working toward the goal of mechanistic fuel performance modeling supported by multi-scale materials modeling. For example, the approach of Tonks et al. (2017) aims at predicting the microstructure and chemical evolution of fuels under irradiation, as described by a set of state variables, and then connecting the microstructure and chemical state of the fuel to materials properties governing fuel performance at the macroscale. This is in contrast to current empirical models that, instead of using the microstructure as the reference state for material properties, correlate them to burnup. The latter is not a unique measure of the actual microstructure, because all burnups do not lead to the same microstructure state. The proposed state-variable approach requires a multi-scale simulation framework starting from the electronic or atomistic scale, then going to mesoscale simulations involving among others Monte-Carlo techniques, cluster dynamics, rate theory, and phase field simulations to finally inform continuum level finite element simulations of macroscale fuel performance (Tonks et al. 2017). To this date, the most important role of DFT calculations in this multi-scale framework has been to study thermodynamic and kinetic properties of point defects (Andersson et al. 2009, 2011; Dorado et al. 2009; Dorado et al. 2011; Dorado et al. 2012; Crocombette 2012; Vathonne et al. 2014) and fission gas/product atoms (Yun et al. 2008; Nerikar et al. 2009; Andersson et al. 2011, 2014, 2015; Thompson and Wolverton 2011; Thompson and Wolverton 2013; Vathonne et al. 2017) in the fuel as well as chemistry manifested by non-stoichiometry and phase evolution (Andersson et al. 2012, 2013; Yu et al. 2009; Geng et al. 2008; Brincat et al. 2015). Thermal conductivity has also been predicted from DFT (Pang et al. 2013), but so far effects of microstructure and defects on thermal conductivity have only been assessed by empirical potentials.

3   DFT Calculations for Nuclear Fuels

Nuclear fuels rely on fission of ^{235}U to produce heat. From a DFT perspective, uranium atoms require special attention since the 5f electrons are strongly correlated and must in many cases be treated with advanced exchange-correlation schemes to capture the properties correctly. For example, both LDA and GGA predict UO_2 to be a metal instead of a semiconductor. This can be corrected by applying, e.g., Hubbard

U (Dudarev et al. 1997), hybrid functional (Kudin et al. 2002), or DMFT (Yin and Savrasov 2008) models. Most existing studies on defects in UO_2 use the DFT + U methodology due to its higher computational efficiency. For UO_2, the values of the U and J parameters, representing the onsite Coulomb and exchange parameters, respectively, are taken from experiments (Dudarev et al. 1997). The DFT + U method is available in many different DFT codes. The Vienna ab initio simulation package (VASP) (Kresse and Furthmüller 1996) is the most popular choice in the literature. The DFT + U method has been shown to reproduce the measured band gap of UO_2 rather accurately, but, as expected, that does not necessarily imply that all thermodynamic and thermophysical properties are perfectly captured. As an example, the lattice parameter is pushed up above the experimental value by GGA + U (Dorado et al. 2009; Sanati et al. 2011), while LDA + U predicts a smaller lattice constant closer to the experimental value (Wang et al. 2013; Sanati et al. 2011) but instead slightly overestimates the elastic constants (Sanati et al. 2011). The tendency of LDA(+U) to overbind and GGA(+U) to push in the opposite direction is well established in DFT. The difference in the predicted lattice constant between GGA + U and LDA + U carries over to defect migration barriers, with GGA + U predicting lower barriers than LDA + U, which has been hypothesized to be a result of the increased space for the migrating ion due to the larger lattice constant predicted by GGA + U (Andersson et al. 2011; Dorado et al. 2012). Even though trends in thermodynamic properties are similar between LDA + U and GGA + U, there are certainly quantitative differences, and the agreement with experimental data is in general qualitative rather than quantitative.

UO_2 is antiferromagnetic below the Néel temperature of 30.8 K. The magnetic structure is non-collinear with a **3 k** pattern and can only be reproduced if spin-orbit coupling is included in the DFT + U calculations (Laskowski et al. 2004). This can be done for perfect UO_2, but it presents severe computational challenges for defect studies involving supercells. Consequently, it is common practice to approximate the ground-state **3 k** structure of UO_2 with a simpler **1 k** structure where the magnetic moments are antiferromagnetically aligned on the (100) planes of the fluorite structure. Of course, at temperatures of relevance to reactor applications, UO_2 is paramagnetic. This state can be approximated by, for example, applying the SQS method to randomly distribute the localized magnetic moments in a supercell (Dorado and Garcia 2013). However, it has been shown that the **1 k** AFM structure is a good approximation of the paramagnetic state with respective to defect properties and that assumption is implicit in a majority of UO_2 defect studies (Dorado and Garcia 2013).

One issue that was revealed in early studies on UO_2 employing the DFT + U method was the propensity to obtain metastable electronic solutions due to different orbital occupations for the uranium 5f electrons (Dorado et al. 2009). This complicated prediction of accurate defect properties and created a surprisingly large spread among defect energies reported in the literature. Several approaches have been developed to control the electronic solution and increase the likelihood of

reaching the lowest energy ground-state orbital configuration. The two most popular choices are probably the occupation matrix control (Dorado et al. 2009) and the U ramping methods (Meredig et al. 2010). The first relies on prescribing the initial orbital occupation matrix, which helps the minimization algorithm to find the correct solution. This requires a search over the full range of possible occupation matrices. For structures with low symmetry that can be a laborious task. Alternatively, the U ramping method relies on a slow increase of the U value from zero to the nominal value for UO_2, which has been shown to increase the chances of finding the correct solution. Even though this does not guarantee that the lowest energy solution is obtained, practical experience has shown that the method is quite reliable.

U_3Si_2 is a metal, which is captured by regular LDA/GGA. However, there is another important issue for U_3Si_2. Standard GGA predicts the ground-state U_3Si_2 crystal structure to be thermodynamically as well as dynamically unstable with respect to alternative phases identified by combining DFT calculations with a structure optimization algorithm (Noordhoek et al. 2016). None of the new phases have been observed in experiments and they are likely artifacts. This behavior can be rectified by introducing a small Hubbard U parameter, although this gives rise to ferromagnetism that is not reproduced in experiments (Noordhoek et al. 2016). However, existing studies have not fully explored the competition between ferromagnetism and paramagnetic structures based on disordered local moments. Even though metastable electronic solutions exist also in the U-Si system, the resulting variation in energy is much smaller than for UO_2, and existing studies do not apply any of the special methods developed for UO_2 to control the orbital occupation.

When used as a nuclear fuel, the high-temperature bcc γ phase of uranium is most relevant. It may also be stabilized by alloying. Metallic uranium exhibits complicated bonding with many allotropes as function of temperature. Most studies apply regular GGA for this material, and the need for schemes accounting for strong correlations is less obvious than for UO_2 and U_3Si_2. However, there are still challenges that complicate DFT studies of this material. Similar to the bcc phase for many transition metals, DFT predicts the bcc phase of uranium to be mechanically unstable due to a negative shear elastic constant at zero Kelvin (Beeler et al. 2010; Beeler et al. 2013). This implies that DFT cannot easily be used for studying the properties of the bcc phase, in particular studies of defects are problematic since they will induce sufficient symmetry breaking for the lattice to spontaneously relax into a new or severely distorted structure. The bcc phase is stabilized by anharmonicity at high temperature. Methods have been developed to account for this physics, mainly in transition metals (Souvatzis et al. 2008). The basic idea is to superimpose the phonons that stabilize the bcc phase at high temperature on the static structure and thus capture the anharmonic effects leading to stability at high temperature (Söderlind et al. 2012). Another option is to run molecular dynamics simulations at high temperature (Hellman et al. 2011), which automatically accounts for the anharmonicity and stabilizes the bcc phase.

4   Thermodynamic and Kinetic Properties of Point Defects in Nuclear Fuels and their Behavior under Irradiation

The behavior of point defects in nuclear fuels governs some of the most important fuel performance properties. First, radiation damage creates a cascade of interstitials and vacancies, some of which recombine with each other and some of which agglomerate into voids and interstitial loops. The latter causes fuel swelling and may lead to the fuel element coming into contact with the cladding, thus impacting mechanical performance. The presence of point defects also reduces the thermal conductivity of the fuel. Moreover, point defects govern diffusion and thus impact any diffusion-controlled phenomena in the fuel, such as creep, fission gas retention/release, and sintering. Consequently, it is essential to be able to predict the equilibrium concentration of point defects as well as their evolution under irradiation.

Prediction of non-stoichiometry and diffusion rates requires a point defect model, and the behavior under irradiation requires a model that handles defect creation and annihilation, such as rate theory or cluster dynamics. The main role for DFT calculations is to provide input to these higher-level models. There are examples of this work flow in the literature, most of them for UO_2 (Andersson et al. 2014, 2015). We refer to the literature for a discussion of the higher-level models and focus our review on the underlying DFT calculations.

4.1   Point Defects under Thermal Equilibrium

In thermal equilibrium the concentration of point defects is determined by the thermodynamic properties of vacancies, interstitials, and possibly anti-site defects (not important for UO_2, though). For semiconductors such as UO_2, it is also necessary to account for the charge state of each defect (Nerikar et al. 2009a; Andersson et al. 2011; Crocombette 2012), which for $UO_{2\pm x}$ corresponds to the number of bound holes and electrons, and ensure that overall charge neutrality is maintained. A thermodynamic model connects the defect properties to concentration. UO_2 can maintain significant non-stoichiometry and it should be expressed as $UO_{2\pm x}$ (Guéneau et al. 2002), with x ranging from slightly negative values to 0.25. The exact value of x, as governed by the oxygen chemical potential or partial pressure, is important since it directly couples to the concentration of oxygen and uranium defects. The range of non-stoichiometry is much smaller for UN and U_3Si_2.

DFT calculations have been used extensively to study properties governing the equilibrium thermodynamics in nuclear fuels, in particular for UO_2. The most straightforward quantities to calculate are defect formation energies and binding energies of small defect clusters. The typical approach applies a supercell setup based on at least a $2\times2\times2$ expansion of the fluorite UO_2 unit cell. Oxygen and uranium vacancies and interstitials are introduced into the lattice, and the structure is then allowed to relax in order to minimize the energy. Most calculations also

relax the volume and shape of the supercell, consistent with zero pressure boundary conditions. Adding an oxygen interstitial to a supercell would create two localized holes in order to maintain overall charge neutrality in the cell, because the oxygen interstitial forms an O^{2-} ion. However, in many cases we are more interested in the oxygen interstitial in itself without any bound holes, which corresponds to a charged defect. For example, the oxygen Frenkel (creation of one oxygen vacancy and interstitial) and Schottky (creation of two oxygen vacancies and one uranium vacancy) defect reactions involve nominally charged defects and should be calculated using charged supercell to avoid formation of holes and electrons. For an oxygen interstitial, the charged defect can be studied by adding two electrons to the supercell according to the standard approach of applying a compensating uniform background charge, which fills the two holes that exist in the neutral calculation. It is important to apply corrections for the long-range interaction between periodic images of the defect and to align the electrostatic potential between the reference defect-free structure and the charged supercell containing the defect. Approaches to handle these corrections have been discussed extensively in the literature on semiconductors (Lany and Zunger 2008; Taylor and Bruneval 2011; Freysoldt et al. 2009, 2014). The calculation of the image charge correction at the monopole level is well-defined, but there are still open questions about how to best apply the potential alignment correction, especially for defect structures that include volume relaxation (Bruneval et al. 2015). For UO_2 close to perfect stoichiometry, all defects are predicted to have formal charges, i.e., an oxygen interstitial has a charge of -2, but if the material deviates from the stoichiometric point or equivalently the Fermi level moves from the mid-gap position, the defects may take nonformal charge states (Vathonne et al. 2014). Other charged defects are studied following the same approach as outlined for oxygen interstitials above.

In agreement with experiments (Guéneau et al. 2002), DFT studies of the UO_2 point defect thermodynamics have shown it is much easier to oxidize (form UO_{2+x}) UO_2 than to reduce (form UO_{2-x}) it (Andersson et al. 2011; Andersson et al. 2014; Cooper et al. 2018). An extra complication for UO_2 is that many point defects, in particular oxygen interstitials in the UO_{2+x} range, have a strong tendency to form clusters, which culminates in the formation of ordered phases at the U_4O_{9-y} and U_3O_7 stoichiometries. These reactions have been investigated by DFT and also in experiments (Andersson et al. 2013; Desgranges et al. 2009, 2011). More work is needed to reconcile the detailed experimental observations with predictions by DFT. Even though oxygen defects are dominant in $UO_{2\pm x}$, U defects are very important for fuel performance since they diffuse slower and thus constitute the rate-limiting step for mass transport.

Defect energies can be obtained from static single-point supercell calculations, while entropies require calculation of phonons, which implies calculation of the dynamical matrix from forces on atoms displaced from their equilibrium positions or from perturbation theory. The finite displacement method has been used to calculate phonon dispersion in perfect UO_2 based on the GGA and GGA $+ U$ for the exchange-correlation potential (Sanati et al. 2011; Pang et al. 2013; Yin and Savrasov 2008; Wang et al. 2013). The predictions using GGA $+ U$ are in

good agreement with inelastic neutron experiments. The low symmetry of defect supercells requires many more displacements and force calculations to obtain the phonon dispersion. This added computational complexity together with the challenge of using DFT $+ U$ in phonon calculations has so far precluded defect entropies from being calculated. Existing studies of defect thermodynamics involving the full free energy have relied on a combination of DFT calculations and empirical potentials to access entropies (Andersson et al. 2014). The main conclusions from studies of the UO_2 point defect thermodynamics are that oxygen defects are more prevalent than uranium defects; that UO_2 is much easier to oxidize (UO_{2+x}) than to reduce (UO_{2-x}) (Cooper et al. 2018), which favors oxygen interstitials and uranium vacancies; and that the oxygen interstitials in UO_{2+x} has a strong tendency to form clusters (Andersson et al. 2013). Charge compensation for oxygen interstitials in UO_{2+x} is predicted to occur by U^{5+} ions (holes) (Cooper et al. 2018), and U^{6+} ions are only form in U_3O_8 and compounds with higher oxygen content (Andersson et al. 2013), which do not form the fluorite structure.

The discussion about point defects under thermal equilibrium conditions above refers to UO_2, but similar work has been performed for other fuels, including U_3Si_2 (Middleburgh et al. 2016), UN (Claisse et al. 2016a, b; Mei et al. 2013), and metal fuels (Beeler et al. 2013; Beeler et al. 2010). U_3Si_2 does not exhibit significant non-stoichiometry, which could be a drawback since the chemical evolution happening due to fission events may result in formation of new U-Si phases with different volume. The fact that UO_{2+x} stays in the fluorite structure with very little volume change is beneficial for fuel performance.

4.2 Point Defects under Irradiation

Under irradiation, defects (vacancies and interstitials) are created by damage events and may annihilate by recombining with each other or with various sinks, such as surfaces, voids, grain boundaries, and dislocations. The balance between defect sources and the reaction rate with sinks governs the irradiation-induced concentration of defects. The reaction rate is a function of the sink strength, which can be a complex function of several parameters of which concentration is always going to be important, and the diffusion rate of defects. At high temperatures the rate of diffusion is sufficiently fast to recover the thermal equilibrium concentrations of point defects. In order to understand the materials response and properties under irradiation below this temperature, the kinetic properties of point defects must be calculated.

DFT calculations are a valuable tool also for the kinetic problem. As for thermodynamics, a supercell setup is used to describe each point defect and the barrier is calculated by using the nudged elastic band method or a variation of this method (Millis et al. 1995; Henkelman and Jonsson 2000; Henkelman et al. 2000). Diffusion of oxygen defects is much faster than for uranium defects. The oxygen defect barriers are in the range of 0.5–1 eV (Andersson et al. 2009, 2012, Dorado et al. 2011), while those for uranium defects are roughly 4 eV or

higher (Dorado et al. 2012), with exception for some clusters of uranium vacancies (Andersson et al. 2014). The fast diffusion rate of oxygen defects implies that their concentrations will be close to thermodynamic equilibrium at reactor operating conditions, while the concentration of uranium defects is increased at all but the very highest temperatures. Interstitial diffusion of both oxygen and uranium ions occurs by interstitialcy mechanisms, which means that, rather than performing a direct jump to a vacant nearest neighbor site, the interstitial atom kicks out a lattice atom into a neighboring interstitial position. Diffusion of uranium vacancies follows a slightly curved path to a nearest neighbor site (Goyal et al. 2015). The curved path reduces the barrier significantly by extending the distance to nearest neighbor ions at the saddle point. The curved mechanism for uranium vacancies also means that clusters of two uranium vacancies may diffuse with a lower barrier than single vacancies, because in nuclear fuels a uranium ion in the saddle point position experiences less repulsion from the nearest neighbors when a second vacancy is nearby.

In addition to the barrier for migration, the diffusion rate includes a factor that corresponds to the attempt frequency, which is related to the ratio between the vibrational frequency for the starting and saddle points. As for the vibrational entropy, the attempt frequency for diffusion in UO_2 has to date only been obtained from empirical potentials (Andersson et al. 2014).

Self-diffusion of uranium and oxygen is determined by the concentration and mobility of point defects. The concentrations are given by the thermodynamic properties discussed in the previous section and the mobilities are obtained according to the procedure reviewed above. For UO_2, this results in uranium vacancies being responsible for diffusion in nearly stoichiometric UO_2 and hyper-stoichiometric UO_{2+x} (Dorado et al. 2011; Andersson et al. 2011), while uranium vacancies with bound oxygen vacancies dominate diffusion in slightly hypostoichiometric UO_{2-x} (Andersson et al. 2011). The concentration of uranium interstitials is too low according to DFT, but experiments have indicated that there could be a contribution for highly substoichiometric samples. Correspondingly, oxygen self-diffusion occurs by interstitials or clusters of interstitials in UO_{2+x} (Andersson et al. 2009, 2012; Dorado et al. 2011), while oxygen vacancies are dominant in UO_{2-x}. Both mechanisms contribute in nearly stoichiometric UO_2. It is interesting that even the large oxygen interstitial clusters can migrate with a low barrier and contribute to diffusion in UO_{2+x} (Andersson et al. 2012).

5   Fission Gas Diffusion in Nuclear Fuels

Fissioning of ^{235}U creates a number of fission gases and fission products, of which Xe is the most important from a fuel performance perspective. Xe atoms are not soluble in any nuclear fuel and thus want to escape from the lattice. This can occur by forming bubbles within the grains or by escaping to the grain boundaries and precipitating bubbles that decorate the boundaries. Finally, the gas may reach a free surface and be released from the fuel. This step typically occurs by the

concentration of gas at grain boundaries increasing until a bubble percolation threshold is reached. When this happens, the gas may reach an already open grain triple junction that vents to a crack or open surface, causing release. Bubbles within grains are usually limited to a few nanometers in size due to continuous resolution from fission fragments, while grain boundary bubbles can grow much larger. If the gas is retained in the fuel element as small intragranular bubbles or, in particular, large grain boundary bubbles, the fuel swells, and if it is released, the pressure increases in the plenum. If there is a clad breach, the gas may escape to the outside environment. Consequently, it is important to be able to predict the rate of gas release. This is a notoriously difficult problem due to the coupling to chemistry, defect dynamics, and microstructure evolution. It is one of the most uncertain and impactful parameters in nuclear fuel performance models. The models are most advanced for UO_2. Even though they are based on years of testing, there is room for improvements. The underlying diffusion mechanisms for Xe atoms in bulk UO_2 are still debated. Atomistic simulations and DFT calculations have been used to develop mechanistic release models for UO_2 (Andersson et al. 2014). For new advanced fuels, fission gas release/retention models are rudimentary because of the lack of test data. Simulations will play key role in the development of new gas release models (Miao et al. 2017; Miao et al. 2018).

The rate of fission gas release is controlled by the steps outlined above. Of these, the first step corresponding to diffusion of single gas atoms through the bulk grain to intragranular bubbles or to the grain boundaries lends itself best to investigation by DFT calculations, simply because the number of atoms required to describe grain boundaries with fission gas atoms in the second step is too large for handling in DFT. Since bulk diffusion of single gas atoms is the slowest step in the fission gas evolution process, this sets the timescale for fission gas release.

The diffusion rate of fission gas atoms is determined by the location of gas atoms in the lattice and how they interact with thermal- and irradiation-induced defects. DFT and empirical potentials have been used to investigate the preferred trap site of Xe atoms in the UO_2 lattice (Andersson et al. 2011, 2014; Ball and Grimes 1990; Grimes and Catlow 1991; Thompson and Wolverton 2011). The calculations are performed by adding a Xe atom to a vacant uranium or oxygen site (or a combination of uranium and oxygen vacancies) or to an interstitial site in a supercell. The stability is then assessed from the energy required to add the Xe atom to this supercell and the energy associated with creating the trap site (vacancies) that the Xe atom occupies. That is, it is the sum of the trap site formation energy and the incorporation energy of Xe into this site, which is referred to as the solution energy. Several studies employing DFT and empirical potentials have shown that large fission gas atoms such as Xe prefer uranium vacancy trap sites (Andersson et al. 2011, 2014; Ball and Grimes 1990; Grimes and Catlow 1991; Nerikar et al. 2009b). These vacancy trap sites may also be coordinated with oxygen vacancies. The number of oxygen vacancies bound to the trap site is a function of the total concentration of oxygen vacancies in the material, which is governed by the oxygen chemical potential or non-stoichiometry, represented as the x in $UO_{2\pm x}$. For nearly stoichiometric UO_2 DFT studies have come to the conclusion that the preferred

trap site is a divacancy (one uranium and one oxygen vacancy), while oxygen-poor conditions (UO_{2-x}) favor a bound Schottky defect (one uranium and two oxygen vacancies) and oxygen-rich conditions favor a single uranium vacancy as the trap site (Andersson et al. 2014). Because UO_2 is a semiconductor, the preferred charge state of each Xe trap site, or equivalently the number of bound holes and electrons, must be calculated. This is done by following the same methodology as for point defects described in the preceding section. For UO_{2-x} and UO_2, all trap sites are in their nominal charge states (no bound holes) at the temperatures of interest for nuclear fuel applications (Andersson et al. 2014), but a transition to partial charges (bound holes) may occur for oxygen-rich conditions (UO_{2+x}) (Andersson et al. 2014). This transition is consistent with the Fermi-level shifting from the top half of the band gap in UO_{2-x} close to the valence band edge in UO_{2+x}. A complete analysis of the preferred trap site for Xe atoms must involve both the energy and the entropy contributions, but just as for point defects, DFT calculations of trap site entropies have so far been deemed too costly or too difficult to pursue. Existing studies of the full free energy have relied on a combination of DFT calculations and calculations based on empirical potentials for the entropies (Andersson et al. 2014). As further discussed below, at low temperatures the high binding energies of a uranium vacancy to the single uranium vacancy trap sites for Xe cause a transition to the uranium divacancy (potentially with additional oxygen vacancies) as the preferred trap site (Andersson et al. 2014).

Diffusion of Xe in an interstitial trap site occurs with a low barrier by temporarily displacing a lattice oxygen ion into an interstitial site (Liu and Uberuaga 2011). However, the Xe interstitial position is a high-energy state compared to vacancy trap sites and that leads to a negligible contribution to diffusion under thermal equilibrium conditions and probably also under irradiation.

Diffusion involving vacancy trap sites occurs by binding a second assisting uranium vacancy (Andersson et al. 2011, 2014; Ball and Grimes 1990; Govers et al. 2008; Thompson and Wolverton 2013, Vathonne et al. 2017) and potentially additional uranium vacancies under irradiation. The binding energies are straightforward to calculate from DFT using supercells, but care must be applied to treat the charge state of each cluster correctly. The corresponding entropies are more challenging for DFT calculations and have so far only been investigated using calculations based on empirical potentials. The second assisting uranium vacancy has a negative binding energy (attractive) for all clusters and in many cases forms a very stable cluster with the original trap site (Andersson et al. 2011, 2014). Diffusion of these clusters involves two steps. In the first Xe moves between the two uranium vacancies constituting the mobile cluster, which is a low-barrier event and in most cases the Xe atom even occupies the central position of the cluster, in-between the two constituent uranium vacancies. The second step is rate-limiting and it involves migration of one of the vacancies to another nearest neighbor position. This step can either occur by a direct mechanism involving a single migration jump to another nearest neighbor site or by first jumping to a second nearest neighbor position and then returning to another nearest neighbor site (Thompson and Wolverton 2013; Andersson et al. 2014). The barriers are obtained from nudged elastic band

calculations. As for diffusion of point defects, the attempt frequencies have not yet been calculated from DFT but rather rely on relating the phonon frequencies at the saddle point and initial position obtained from empirical potentials. The resulting diffusivity can be expressed by an Arrhenius relation with an activation energy given by the sum of the effective vacancy formation energy, the binding energy to the trap site, and the cluster migration barrier. If the binding energy is very strong for a particular cluster and that cluster dominates over the corresponding trap site, the diffusivity will simply be given by the mobility of that cluster. This occurs in UO_2 at low temperatures. The total Xe diffusion rate is the sum of the individual cluster diffusivities weighted by their relative concentration in lattice.

The resulting Xe diffusivities increase going from UO_{2-x} to UO_2 and UO_{2+x} (Andersson et al. 2011, 2014; Miekeley and Felix 1972). This is a consequence of both an increase of the concentration of uranium vacancies and a reduction of the migration barrier of clusters involving fewer oxygen vacancies, though the latter effect is at least partially counteracted by a reduction in the binding energy of vacancies to the trap site.

It is challenging to measure the fission gas diffusion rate experimentally. The reasons are twofold. First, experiments primarily rely on measuring the gas release in postirradiation annealing experiments, which involves more uncertainty than, for example, tracer diffusion experiments, and, second, the diffusivity is very sensitive to non-stoichiometry and thus the experimental conditions and how the oxygen partial pressure is controlled in the experiment (Lawrence 1978). Xe diffusion studies on nominally stoichiometric UO_2 yield activation energies from 2.87 eV to 3.95 eV and pre-exponential factors from 5×10^{-4} m^2/s to 2.90×10^{-12} m^2/s (Andersson et al. 2014). Typically, higher activation energy is compensated by a higher pre-exponential factor, which is expected since the stoichiometry is maintained close to UO_2 for all cases. In order to systematically explore the variation of the diffusivity with non-stoichiometry, experiments have been performed under the same initial irradiation conditions for UO_{2-x}, UO_2, and UO_{2+x} samples (Miekeley and Felix 1972). These experiments established clear trends for the three ranges, which provide data suitable for validation of DFT and atomic-scale simulations. Calculations qualitatively capture the variation in the diffusivity as function of non-stoichiometry (Andersson et al. 2011, 2014), though there are still questions as to the quantitative agreement. The lack of quantitative agreement is at least partially explained by the approximations applied in the DFT methodology, e.g., the choice of exchange-correlation model and the assumption that properties acquired at zero kelvin can be extrapolated to high temperatures where experiments are performed.

In fission gas release models, the intrinsic diffusion coefficient discussed so far is only valid at high temperature (above approximately 1600 K) (Turnbull et al. 1982), where the effects of irradiation are completely annealed. At lower temperatures, the increased concentration of point defects must be accounted for. This gives rise to radiation-enhanced diffusion dominating over intrinsic diffusion in an intermediate temperature range (from about 1300 to 1600 K) (Turnbull et al. 1982). The

activation energy observed in experiments is much lower than in the intrinsic regime, and it has a very low pre-exponential factor. The mechanism responsible for this diffusion rate is presently not known. DFT or atomistic simulations based on empirical potentials are not able to reproduce this behavior, as the mobility predicted by DFT and empirical potential calculations for the Xe defect clusters involving up to two uranium vacancies is too low (Andersson et al. 2014). It is possible that this discrepancy may be a consequence of neglecting the mobility of extended Xe-vacancy clusters, i.e., clusters involving more than one bound uranium vacancy as well as additional oxygen vacancies or possibly Xe interstitials which are known to be highly mobile but also energetically very unfavorable. The hypothesis concerning extended Xe-vacancy clusters implies that, in order to develop accurate models of Xe diffusion under irradiation, it is critical to understand the interaction between Xe and vacancies leading to the formation of extended clusters with potentially increased mobility.

6   Thermal Conductivity of Nuclear Fuels

Thermal conductivity is one of the most important properties for nuclear fuel performance. The most challenging part of the problem is to predict the degradation as a function of damage and chemical evolution in the fuel. For an insulator or semiconductor like UO_2, this implies calculating phonons and phonon scattering parameters. DFT has been used to estimate the conductivity of pure UO_2 (Pang et al. 2013), which leads to a slight overestimation that is highest at low to intermediate temperatures. Phonon-phonon interaction is the main scattering mechanism according to these simulations. There are indications that the discrepancy between simulations and experiments for the thermal conductivity is due to the lack of a mechanism for phonons to be scattered by spins or electronic excitations in the DFT simulations (Gofryk et al. 2014). The importance of spin scattering is emphasized by comparing the experimental thermal conductivity of ThO_2 and UO_2 (Gofryk et al. 2014). Even though the DFT phonon calculations may include spins, capturing this mechanism would require solving the dynamic evolution of spin configurations coupled to the lattice dynamics. This problem has been addressed for a few materials by coupling molecular dynamics simulations based on empirical potentials with a spin Hamiltonian (Ma et al. 2008; Ma and Dudarev 2014), but this treatment has not been applied to UO_2 and extending it involves several additional challenges.

The thermal conductivity of U_3Si_2 and UN fuels is both metallic, and estimating the thermal conductivity from DFT entails solving the transport problem for electrons, rather than for phonons as in UO_2. This has not been attempted in the literature, but the theory for addressing the problem is in place, even though the f electrons in uranium may present some obstacles for the band structure calculations needed to solve the Boltzmann transport problem.

7   Summary and Outlook

We have reviewed applications of DFT calculations to study nuclear fuels and the role of DFT calculations in multi-scale modeling of nuclear fuel performance. UO_2 fuel for light water reactors was emphasized, because of the large body of work performed on this material. Advanced fuels such as U_3Si_2 and UN were also briefly discussed. The uranium 5f electrons are strongly correlated, which leads to regular GGA failing to capture the semiconducting nature of UO_2. This can be rectified by applying exchange-correlation schemes designed to treat this type of material. The Hubbard U model is the most popular choice for defect studies due to its computational efficiency. Other more cutting-edge approaches to treat strong correlations, for example, DMFT, will continue to evolve and be applied to UO_2 and other fuels but may be too expensive for the type of calculations needed to assess nuclear fuel performance properties. Examples of studying point defect thermodynamics and kinetics as well as the behavior of fission gas and thermal conductivity were given. Present DFT calculations of point defect properties only address the energy contribution to the free energies, and the entropies are obtained from empirical potentials. Future work should remove the reliance on empirical potentials for calculating defect entropies. We also expect DFT calculations to be applied or continue to be applied to new advanced fuels, including metal fuel, U_3Si_2 and UN. Further advancements are expected for the multi-scale modeling frameworks, which should increase the use for DFT calculations and thus their value. Experimental validation will be important to assess uncertainty in the calculations. Uncertainty quantification should enable evaluation of how the uncertainty at the electronic and atomistic levels translates through a multi-scale simulation framework to impact fuel performance simulations.

Abstract

The interatomic potential is a mathematical function that represents the potential energy of a collection of interacting atoms as a function of geometric variables, such as distance and angle. The potential provides the underpinning physical basis for molecular statics, molecular dynamics, and kinetic Monte Carlo simulations of radiation effects in materials. The validity of these simulations is governed by the fidelity of the potential. The functional form of the potential is chosen based on the type of interaction, e.g., metallic, covalent, or ionic. The

R. Devanathan (✉)
Energy and Environment Directorate, Pacific Northwest National Laboratory, Richland, WA, USA
e-mail: ram.devanathan@pnnl.gov

parameters of the function are optimized by fitting to properties of the system of interest obtained from experiment or density functional theory calculations. Caution should be exercised when applying interatomic potentials to conditions that are quite different from the ones used to fit the potential. Charge transfer processes, dissimilar material interfaces (e.g., metal-ceramic interfaces), and multicomponent alloys are challenging to represent using potentials. This chapter introduces potential functions, offers examples of the application of potentials to understand the primary damage state, and presents an assessment of potentials for studying the radiation response of materials.

1   Introduction

Atomistic computer simulation, when used in conjunction with experimental validation, can offer predictive understanding of the performance and degradation of nuclear materials. Simulations can shed light on the early stages of radiation damage, mechanical degradation, species diffusion, gas bubble formation, nucleation and growth of phases, chemical segregation, phase transformation, interface restructuring, corrosion, and fracture of materials under the combined effects of mechanical stress, corrosives, extremes of temperature and irradiation by energetic particles. Often, this information is challenging to obtain by experiment alone. Classical molecular dynamics (MD) and Monte Carlo (MC) simulations require a rigorous description of the potential energy of the system. The widely used MD simulation method involves the numerical integration of Newton's equations of motion for a system of interacting atoms given by Eq. (1).

$$m_i \frac{d^2 \vec{r}_l}{dt^2} = \cdot - \nabla_{\vec{r}_l} V \tag{1}$$

m_i is the mass of atom i, $\vec{r}_i$ is its position vector, t is time, and V is the potential energy, which is a function of geometric variables such as the interatomic distances and bond angles. The potential function consists of a sum of terms that represent different interactions relevant to the material system of interest. These interactions can involve one, two-, three-, or many-body terms. For computational efficiency, the interactions are often limited to a sphere around each atom with the radius being the interaction cutoff distance.

The predictive power of the simulation depends on the reliability of the interatomic potential. The parameters of the potential function are derived by fitting to known experimental properties, such as lattice constants and elastic constants. In addition, point defect properties calculated using density functional theory (DFT) can be used to optimize the potential parameters. The application of DFT to nuclear materials is discussed in detail by Andersson (▶ Chap. 86, "Density Functional Theory Calculations Applied to Nuclear Fuels") in this volume. There is no perfect potential for a material. In selecting functional forms and optimizing parameters to simulate materials phenomena of interest, trade-offs are made by balancing

accuracy, development time, computational cost, ability to represent problem of interest, and transferability to other problems. It is important to understand the limitations imposed by the choice of a function to avoid using potentials outside their range of applicability. In the following sections, we present commonly used functional forms and discuss the emerging trends in potential development.

2   Potential Functions

The functional form of the interatomic potential, also known as the force field, depends on the dominant type of interaction present in the material, e.g., metallic, covalent, or ionic. This function is chosen typically based on physical intuition about the nature of the interaction.

2.1   Intra-molecular Functions

Intra-molecular potentials operate between atoms in a molecule. They are commonly encountered in simulations of polymers and liquids, for instance, simulation of the interaction of water with nuclear waste glass. There are several well-known examples of these potentials, including OPLS (Jorgensen et al. 1996), AMBER (Wang et al. 2004), and DREIDING (Mayo et al. 1990).

Covalent bonds between adjacent atoms are represented by a bond potential that minimizes the energy at an experimentally determined bond distance, r_0. There are many functional forms for this bond potential. The most common one is the harmonic bond potential, where the bond energy V_B between atoms i and j is summed over all bonds in the system. k_{ij} is the force constant and r_{ij} is the bond length between atoms i and j.

$$V_B = k_{ij}(r_{ij} - r_0)^2 \tag{2}$$

Similarly, one can constrain the angle θ_{ijl} between bond vectors $\overrightarrow{r_{ij}}$ and $\overrightarrow{r_{il}}$, around a central atom i between atoms j and l to approach the experimentally determined bond angle θ_0. Here again, the harmonic form of the angle potential V_A with a force constant k_{ijl} is the most common form.

$$V_A = k_{ijl}(\theta_{ijl} - \theta_0)^2 \tag{3}$$

For four consecutive bonded atoms i, j, l, and m, the torsion around the jl bond can be constrained, typically using the cosine of the angle ϕ_{ijlm} between the plane containing the ij and jl bonds and the plane with the jl and lm bonds. This is called a dihedral or torsion potential, and it can also assume the harmonic form similar to Eq. (3). More complex intra-molecular interactions can also be included but will not be discussed here. These intramolecular functions are relevant to the simulation

of radiation effects in polymers (Polvi et al. 2012). The rest of the discussion will focus on intermolecular or interatomic interactions that are especially important for metals, semiconductors, and ceramics.

2.2 Simple Pair Potentials for Model Systems

The Lennard-Jones (LJ) potential (Lennard-Jones 1931) is one of the simplest interaction models. It is a summation of the energies of bonds between pairs of neutral entities (atoms or molecules). It is also known as the 12-6 potential because of its functional form shown in Eq. (4).

$$V_{LJ}\left(r_{ij}\right) = 4\varepsilon \left[\left(\frac{\sigma}{r_{ij}}\right)^{12} - \left(\frac{\sigma}{r_{ij}}\right)^{6} \right]^{-} \tag{4}$$

This energy is summed over all the bonds present in the system to get the potential energy. The potential has two adjustable parameters, σ representing the finite interatomic separation at which V_{LJ} becomes zero and ε representing the depth of the potential minimum that occurs at an interatomic distance r_{ij} of $2^{1/6}\sigma$. The first term in Eq. (4) represents Pauli repulsion and the second term represents van der Waals attraction. The LJ potential has been used to model noble gases and has the advantage of computational efficiency. The potential is too simple by itself to model the behavior of solid systems, especially those relevant to nuclear energy technology.

The repulsive part of the LJ potential was changed to an exponential term by Buckingham (Buckingham 1938) as shown in Eq. (5).

$$V_{Buck}\left(r_{ij}\right) = A_{ij}e^{-B_{ij}r_{ij}} - \frac{C_{ij}}{r_{ij}^{6}} \tag{5}$$

This potential lacks directionality and is spherically symmetric as the LJ potential. It includes 3 adjustable parameters, namely, A, B, and C. The repulsive term converges to A as r_{ij} approaches zero while the magnitude of the attractive term increases leading to unphysical attraction at small values of r_{ij}. This can make MD simulations using the Buckingham potential unstable. The repulsive part must be modified for use in simulations of energetic events, such as displacement cascades (Dong et al. 2016).

2.3 Potentials for Metals and Alloys

The summation of pairwise bond energies over all bonds present in the system is simplistic, because it assumes that a given bond is not influenced by the presence of other bonds in the system. In reality, when the coordination number is increased,

the new bond contributes a smaller value to the cohesive energy than the original bond. It is known that pairwise potentials satisfy the Cauchy relation for elastic constants ($C_{12} = C_{44}$), which is not true for most metals. Moreover, the vacancy formation energy is comparable to the cohesive energy for pair potentials and this does not hold for metals (Ercolessi et al. 1988). To overcome the deficiencies of pair potentials, effective medium potentials have been developed for metals under the Finnis-Sinclair (Finnis and Sinclair 1984) formalism or the embedded atom method (EAM) (Daw and Baskes 1984; Daw et al. 1993). The EAM potentials can be expressed as follows:

$$V_{EAM} = \sum_i F \left(\sum_i \rho_i \left(r_{ij} \right) \right) + \frac{1}{2} \sum_{i,j \ (i \neq j)} V_{rep} \left(r_{ij} \right) \qquad (6)$$

The first term is the attractive embedding energy, which is a functional that varies nonlinearly with the coordination number. It is a function of the electron density, ρ. This electron density is in turn expressed as a function of r_{ij}. The second term is the pairwise repulsive term. In a similar way, the Finnis-Sinclair potential energy is the sum of two terms, an attractive term that is proportional to the square root of the electron density and a pairwise repulsive potential. The square root form was inspired by the second moment approximation to the tight-binding density of states and may not necessarily have a physical significance. The EAM-type potentials have been successfully applied to simulate the behavior of several metals. The EAM method has been extended to covalent materials through the modified EAM (MEAM) approach, where angle-dependence was introduced into the density, ρ (Baskes 1987). MEAM potentials have been developed for C, Al, Si, Ti, V, Cr, Mn, Fe, Ni, Cu, Zr, Nb, Mo, Pd, Ag, Ta, W, Pt, Au, Pb, and various alloys of these elements (Lee et al. 2010).

For nuclear energy applications, we will consider three metals, namely Zr, U, and Fe. We pick these cases as illustrative examples from the large body of work on potentials for metals and alloys. Zr-based alloys are used as fuel cladding in nuclear reactors. Several potentials have been developed for Zr, but they do not reproduce the high stacking fault energy and phase transformations with increasing temperature. Mendelev and Ackland have developed a reliable MEAM potential for hexagonally close packed Zr by using defect formation energies and stacking fault energies from DFT in the fitting procedure (Mendelev and Ackland 2007). This work is interesting for three reasons. First, it links DFT and MD simulations by using DFT results to parameterize potentials. Second, it clearly illustrates the tradeoffs in potential development, by generating two potentials that reproduce different sets of properties. The authors emphasize the need for care in selection of properties to which the potential is fitted. Third, it raises questions about the ability of the EAM functional form to capture the full range of properties of metals. In a similar vein, a MEAM potential has been developed to represent the body centered cubic (bcc) phase of U-Zr alloys (Moore et al. 2015). Alloys of U and

Zr have potential applications as metallic fuel in advanced nuclear reactors. Defect formation energies from DFT calculations were used along with experimental values of the elemental elastic constants in the fitting.

One of the important advances in potential fitting is the Force-Matching method (Ercolessi and Adams 1994). This approach uses DFT to obtain forces for many atomic configurations of interest, including crystals, liquids, surfaces, and atomic clusters, and then fits potentials by matching these forces. An EAM potential for Fe has been developed using force-matching (Mendelev et al. 2003). The authors generated a simple model of liquid Fe at the known density and determined forces for this model using DFT. The EAM potential was fit to these forces, lattice constants of bcc and face centered cubic (fcc) Fe at 0 K, vacancy formation energy, and energy difference between bcc and fcc phases. The potential was found to reproduce properties such as the lattice constant, elastic constants, point defect energies, liquid density, and melting temperature better than existing potentials for Fe. Despite these advances, the empirical potential approach is severely limited for the simulation of a real alloy, such as stainless steel. This task requires potentials that describe the interactions of Fe, Cr, Ni, C, and minor alloying elements that contribute to precipitation hardening and solid solution strengthening. It is also challenging to develop a potential that stabilizes the fcc phase in the composition range of interest. Bonny et al. (2013) have developed an EAM-type potential for FeNiCr that may be a good starting point for modeling radiation damage in austenitic stainless steels. The potential stabilizes the fcc phase. It has been benchmarked against DFT data and experimental observations.

2.4   Potentials for Covalent Materials

The Stillinger-Weber (S-W) potential for Si presents another good example of going beyond the limitations of pair potentials (Stillinger and Weber 1985). In this case, the potential met a need to stabilize the diamond structure and reproduce the densification of Si and Ge on melting. The S-W potential is a sum of two-body and three-body terms as shown in Eq. (7). The latter introduces dependence on the angle between ij and ik bonds, θ_{ijk}.

$$V_{S-W} = \sum_i \sum_{j>i} V_2\left(r_{ij}\right) + \sum_i \sum_{j\neq i} \sum_{k>j} V_3\left(r_{ij}, r_{ik}, \theta_{ijk}\right) \qquad (7)$$

This potential has been applied to the study of Si, Ge, III-V, and II-VI compound semiconductors.

The Tersoff potential brings in the angular term in the form of bond order parameter, b_{ij} (Tersoff 1988). The idea is that the strength of a bond depends on its environment, namely, the number of bonds, bond lengths, and bond angles. This dependence is introduced through b_{ij}. The general form of the Tersoff potential can be written as follows.

$$V_{\text{Ters}} = \sum_i \sum_{j>i} V_{repulsive}\left(r_{ij}\right) + b_{ij} V_{attractive}\left(r_{ij}\right) \tag{8}$$

The Tersoff potential has been widely used to study radiation effects in covalently bonded materials, including Si and SiC. The latter is a component of TRISO nuclear fuel and is also a fusion reactor material. Brenner has developed bond order potentials that are especially tailored for carbon-based materials (Brenner 1990). This work has been developed further in the form of reactive empirical bond order potentials (REBO) that are well suited to model solid carbon-based materials (Brenner et al. 2002). Another key development in this area is the Environment Dependent Interatomic Potential (EDIP) that inverts cohesive energy curves obtained from first principles data to derive many-body potentials (Bazant et al. 1997). The bond order potentials can accommodate multiple bonding states but not changes in the charge state. To understand this issue, we will discuss ionic materials next.

2.5   Potentials for Ionic Materials

We have seen that the interatomic potential can be expressed as a sum of one-, two-, and many-body terms. Terms higher than three-body will be challenging to evaluate computationally. The three body terms are needed for covalent materials as discussed above. For ionic materials, many-body terms are implicitly incorporated into an effective pair potential, which is typically a sum of long-range Coulombic interaction between charges $\bar{q}_i$ and q_j separated by a distance r_{ij}, V_{LR}, and short-range interactions, V_{SR}.

$$V_{LR}\left(r_{ij}\right) = \frac{1}{4\pi\varepsilon_0} \frac{q_i q_j e^2}{r_{ij}} \tag{9}$$

ε_0 is the permittivity of vacuum.

$$V_{SR}\left(r_{ij}\right) = A_{ij} e^{-B_{ij} r_{ij}} - \frac{C_{ij}}{r_{ij}^6} + D_{ij}\left[e^{-2m_{ij}\left(r_{ij}-r_{ij}^0\right)} - 2e^{-m_{ij}\left(r_{ij}-r_{ij}^0\right)}\right] \tag{10}$$

The short-range potential in this case is the sum of the Buckingham potential in Eq. (5) and the Morse potential with 3 additional fitting parameters, D, m, and r_0.

The short-range potential can become attractive at close separations less than 0.1 nm. The Ziegler-Biersack-Littmark (ZBL) repulsive potential (Ziegler et al. 2010), V_{ZBL}, is based on a universal screening function and is often smoothly splined to the Buckingham potential for MD simulation of energetic recoils (Dong et al. 2016). The combined potential remains repulsive at very small values of r_{ij}.

$$V_{ZBL}\left(r_{ij}\right) = \frac{1}{4\pi\varepsilon_0} \frac{Z_i Z_j e^2}{r_{ij}} \varphi\left(\frac{r_{ij}}{a}\right) \tag{11}$$

$$\varphi(x) = 0.1818e^{-3.2x} + 0.5099e^{-0.9423x} + 0.2802e^{-0.4029x} + 0.02817\mathrm{e}^{-0.2016x} \tag{12}$$

$$a = \frac{0.8854a_0}{Z_i^{0.23} + Z_j^{0.23}} \tag{13}$$

Here, Z_i and Z_j are the charges of the nuclei of atoms i and j, respectively, and a_0 is the Bohr radius.

The potentials for ionic systems can include rigid-ion models or core-shell models (Dick and Overhauser 1958). The former treat ions as fixed point charges, which ignores polarization. The shell models treat ionic polarizability by considering ions as cores connected to shells (Lewis and Catlow 1985). Each ion is represented by two particles of opposite charge, namely, a core and a shell connected by a harmonic spring. The sum of the core and shell charges is the ion charge. The original core-shell model of Dick and Overhauser (1958) was based on massless shells. At each MD step, one needs to perform an optimization to restore the shells to their zero-force positions. This creates a significant computational overhead. Due to residual forces, there can be small energy drifts even after careful optimization of the shells.

In the dynamical core-shell model, the shells are treated as particles with very small mass compared to the mass of the corresponding core particle. The sum of the core and shell masses is equal to the atomic mass. The more massive core represents the nucleus and its inner electron shells, while the shell represents the valence electrons. The electrostatic interaction between ions i and j is made of four terms instead of one – core i-core j, core i-shell j, core j-shell i, and shell i-shell j terms. There is no electrostatic interaction between the core and shell of the same ion. The short-range potential acts only between the shells.

The shells are propagated concurrently with the cores during each MD time step. The movement of the lighter shell in response to changes in the electric field acting on the ion produces a dipole, which represents the polarization of the electron cloud by the external electric field. The extent of the core-shell motion limits the size of the MD time step. The core-shell model requires the use of a smaller MD time step compared to the rigid-ion model to ensure energy conservation and stability of the simulation.

MD simulations of energetic processes, such as recoil damage events, can become unstable if a shell model potential is used. In such simulations, dynamic processes can drive two ions to approach each other closely leading to a polarization catastrophe. At short separations, the strong Coulomb attraction between the core of one ion and the shell with opposite charge of a nearby ion can cause the simulated structure to collapse. This instability limits core-shell potentials to low-temperature simulations, and these models are not used in simulations of displacement cascades

and thermal spikes. For such simulations, rigid-ion potentials offer the advantages of lower computational intensity and greater stability. In rigid-ion models, the ions can be assigned formal charges ($+4$ for U and -2 for O) or partial charges based on fitting to experimental data. However, the shell models give a better representation of the equilibrium properties including the elastic constants in static calculations. The choice of rigid ion or shell model will be based on the phenomena of interest. These ionic potentials have the limitation that the charge of the ion is held fixed. The charge cannot be changed in response to changes in the local environment. This fixed charge model reduces the fidelity of the simulation and imposes restrictions on the types of materials or processes that can be simulated.

2.6   Charge Optimized Potentials and Reactive Force Fields

Reactive force fields are needed to model dissimilar material interfaces, for instance, to simulate corrosion of metals and alloys. In addition, materials used in nuclear technologies are composed of multiple phases, for instance, carbide precipitates in steel or oxide phases in oxide dispersion strengthened steel. In the last two decades, new approaches have been developed to treat these types of interfacial problems. There are two key concepts underlying these approaches. One of these concepts, bond order, has been presented in the previous section in the context of potentials developed by Tersoff and Brenner. The bond order can be used to self-consistently identify the type of interaction present in the simulation. The other concept is the self-consistent equilibration of charge (Phillpot and Sinnott 2009).

A series of charge optimized many-body (COMB) potentials have been developed by Phillpot, Sinnott, and coworkers (Liang et al. 2013) to simulate multiphase materials. The charge state of an ion is dynamically determined based on the local environment using the principle of electronegativity equalization. The charges are iteratively optimized, which imposes an order of magnitude higher computational cost than using fixed charge potentials. The fidelity and cost of simulations with such potentials lie somewhere between those of molecular dynamics with fixed charges and density functional theory. The potential energy in the COMB formalism is the sum of electrostatic, short-range, van der Waals, and correction terms as shown in Eq. (14).

$$V_{COMB}(q,r) = V_{electrostatic}(q,r) + V_{SR}(q,r) + V_{VDW}(r) + V_{correction}(r) \tag{14}$$

The first two terms depend on ionic charges q and positions r, while the last two depend only on positions. The electrostatic energy is a sum of the self-energy to form a charge, the charge-charge (qq) interaction energy, the charge-nucleus (qZ) interaction energy, and an energy related to polarizability.

$$V_{electrostatic}(q,r) = V_{self}(q,r) + V_{qq}(q,r) + V_{qZ}(q,r) + V_{polar}(q,r) \tag{15}$$

The short range term is a bond order potential that is charge dependent. The Van der Waals term has been discussed previously. The correction term is included to eliminate unphysical interactions and add new functionality. In addition, this term can be modified to reproduce experimentally determined lattice constants. COMB potentials have been used to simulate metal-oxide and semiconductor-oxide interfaces and the oxidation process at the surface of Cu.

The bond order formalism has been used by van Duin and coworkers (Senftle et al. 2016) to develop reactive force fields, ReaxFF, that allow for dynamic bond breaking and bond formation during the simulation. The potentials have a good degree of transferability, because a given element is treated the same way regardless of whether it is in the gas phase, liquid phase, or a dissimilar material interface. The ReaxFF potential energy is the sum of the following terms: bond energy, bond angle, torsion, over-coordination penalty, van der Waals, Coulomb interaction, and a specific energy term.

$$V_{Reax} = V_B + V_A + V_T + V_{over} + V_{VDW} + V_{Coulomb} + V_{specific} \qquad (16)$$

The first four terms are bond order dependent, and the next two terms are charge dependent.

ReaxFF started as a hydrocarbon potential but has been adapted to simulate many different classes of materials, including metals and ceramics. Over the years, different parameter sets have been developed for different materials families, and it is important to choose the set that is relevant to the problem at hand. Despite the previously mentioned transferability of ReaxFF, parameters developed to study O for a combustion chemistry problem may not be appropriate for O at a mineral-water interface. ReaxFF has been developed by chemists interested in reactive processes and may be a good choice to model catalysts. Elastic properties of interest to metallurgists have not been usually included in the force field fitting. However, there is nothing that precludes the use of elastic properties to reparameterize ReaxFF to study thermo-mechanical degradation of alloys for energy technology applications. Shin et al. (2012) have developed a ReaxFF parameterization for binary alloys in the Fe-Ni-Al system using data from first principles calculations. The fitting procedure considered elastic properties of various phases, surface energies, adatom binding energies, and diffusivities. Simulations performed with this force field have provided insights into segregation in Fe-Ni-Al alloys.

3 Application of Potentials to Simulate the Primary Damage State

There is a long history of using interatomic potentials to study the dynamics of radiation damage in materials (Gibson et al. 1960; Robinson and Torrens 1974; Guinan and Kinney 1981). This section presents recent examples of the use of interatomic potentials to study the primary damage state in a variety of materials mainly using MD simulations. Djurabekova and Nordlund

(► Chap. 88, "Molecular Dynamics Simulations of Non-equilibrium Systems") provide a detailed discussion of MD simulations of collision cascades and swift heavy ion damage elsewhere in this volume. Given that the radiation damage resistance of a crystalline material is dictated by the competing effect of short-range covalent and long-range ionic forces (Trachenko et al. 2005), it is evident that MD simulations of radiation damage will strongly depend on the choice of interatomic potential. In the last decade, there has been considerable interest in evaluating the fidelity of potentials for simulating radiation damage in a material, usually by comparing defect properties to DFT calculations or experimental data.

3.1   Defects in Metals and Alloys

There is a large database of DFT defect energies in α-Fe, and many potentials have been developed to simulate radiation damage in α-Fe (Malerba et al. 2010). This combination makes this material a good test bed for evaluating the effect of the features of a given interatomic potential on the ability to match defect energy data from DFT studies. Malerba et al. (2010) compared five semi-empirical potentials by studying point defect properties and defect cluster distributions. These included Mendelev-type potentials (Mendelev et al. 2003) as well as magnetic potentials that modify the embedding term in EAM using a combination of Stoner and Ginzburg-Landau models (Dudarev and Derlet 2005). They found that Mendelev-type potentials match DFT results most closely and thus are ideal for extending the scale of DFT calculations to simulate radiation damage. This finding is not surprising given that the fitting of the Mendelev potential was informed by DFT calculations. Gao et al. (2017) have simulated displacement cascades with energy up to 20 keV in α-Fe using three magnetic potentials and a Mendelev-type potential. For the same recoil energy, they found differences in defect production and cascade volume between these potentials. The magnetic potentials gave a larger interstitial formation energy than the Mendelev-type potential, which resulted in smaller self-interstitial clusters in the former. If the cluster size distribution is used as input in coarser grained simulations, the evolution of the radiation damage will be quite different for these potentials. Malerba et al. (2010) have concluded that none of the potentials they studied were satisfactory for describing self-interstitial clusters and dislocation interactions in Fe. There is a need to improve the fidelity of these potentials to make them more reliable for the study of radiation damage evolution. This conclusion is consistent with a recent finding of Klaver et al. (2016) based on a study of the FeCr system.

FeCr alloys are promising candidates for structural applications in nuclear reactors due to their radiation tolerance and corrosion resistance. The addition of Cr to Fe changes the radiation response. The combined effects of radiation, stress, and elevated temperature can accelerate the precipitation of a Cr-rich α' phase in FeCr alloys. Such precipitates have the potential to cause embrittlement of the material. The sign of the mixing enthalpy in this system changes with increasing Cr concentration (Malerba et al. 2008), which presents a challenge for EAM potentials.

Efforts have been made to refine the FeCr interaction and reproduce the change in the mixing enthalpy. These modifications include multiplying the repulsive term in q. (6) by a local concentration-dependent term and the introduction of two embedding terms – one for the *s* band and another for the *d* band. These potentials do not explicitly account for an important property of this system, namely, magnetism. The development of a spin-polarized potential will require a new functional form and a new algorithm to handle spin dynamics in MD simulations (Malerba et al. 2008).

Klaver et al. (2016) have evaluated the ability of four FeCr potentials to model interstitial formation and binding energies in FeCr alloys containing 8 at.% and 16 at.% Cr. The energies were compared to corresponding values from DFT calculations. Getting the defect energies correct is key to reliably simulating the primary damage state produced by energetic recoils. These recoils initiate atomic displacement cascades that displace many atoms within 1 ps followed by dynamic vacancy-interstitial recombination and defect clustering on the scale of tens of ps (Devanathan 2009). The size distributions of the resulting vacancy clusters and interstitial clusters are different, and their thermal evolution is also different due to differences in migration energies. These differences in cluster fractions, defect stability, segregation at interfaces, and cluster lifetime can lead to large differences in the numbers of freely migrating vacancies and interstitials known as defect production bias. This bias can influence the long-term evolution of radiation damage and observed properties such as swelling. The work of Klaver et al. (2016) shows inconsistencies between defect energies calculated using empirical potentials and DFT. This discrepancy raises questions about the ability to reliably model radiation damage in FeCr alloys with high Cr content using existing empirical potentials. While it is possible to refit potentials to improve the agreement with defect properties from DFT, there is practically no wiggle room for improving the fitting using current functional forms. One must look beyond the EAM formalism to model radiation effects in binary and multicomponent alloys.

3.2   Radiation Damage in a Covalent Material

SiC is a covalent material that has potential applications as a structural material in fusion reactors and a fuel cladding in advanced fission reactors. Crystalline SiC is known to be amorphized under energetic particle irradiation. Gao, Weber, and Devanathan (2002) have reviewed fundamental mechanisms of radiation damage accumulation in SiC based on the findings of MD simulations using bond-order potentials. In this material, the minimum energy needed to displace an atom from its lattice site, known as the displacement threshold energy (E_d), is quite different for Si and C regardless of the potential used. The threshold energy surface is also highly anisotropic. The E_d values serve as important input parameters for coarser-grained simulations of radiation damage. MD simulations with empirical potentials show that the defect production in SiC is dominated by C interstitials and vacancies. The damage produced by energetic recoils consists of a central vacancy-rich region and

an interstitial-rich periphery. The primary damage state consists of isolated interstitials and vacancies and small defect clusters. In contrast to the primary damage state in alloys with defect clusters containing tens of defects, in SiC defect clusters containing more than three defects were rarely seen. The amorphization of SiC proceeded by the gradual accumulation of clusters or the overlap of displacement cascades instead of direct amorphization within the cascade. The damage dose in displacements per atom for complete amorphization and the swelling behavior of the material showed good agreement with experiment, which provides validation for this bond-order potential. High-resolution transmission electron microscopy (HRTEM) images calculated from the MD simulation cells also showed agreement with corresponding experimental images of irradiated SiC and provided insights into atomic-level mechanisms behind the experimental observations.

Subsequent MD simulations showed that chemical short-range disorder (site exchange between Si and C) measured by the fraction of homonuclear (C-C) bonds may play an important role in the amorphization of SiC (Devanathan 2009). The increases in enthalpy and volume of the system with the introduction of atomic displacements or Si-C exchanges closely followed the increase in the C-C homonuclear bond ratio regardless of the sublattice in which displacement was introduced. Interestingly, the simulated amorphous states produced by radiation damage accumulation and melt quenching had slightly different densities and homonuclear bond ratios. This points to the existence of different amorphous or highly damaged states in SiC. Debelle et al. (2014) have used MD simulations with the Gao-Weber bond-order potential (2002) to shed light on recrystallization by swift heavy ion energy deposition in SiC with different levels of preexisting damage or amorphization. The simulated recrystallization behavior was quite different depending on the extent of amorphization and the findings were in agreement with experiment.

Recently, Samolyuk et al. (2015) have studied the migration barrier for carbon interstitials in SiC using three commonly used potentials and compared the results to DFT calculations. Two of the potentials yielded a migration barrier that was much higher than DFT results, while the third potential by Gao and Weber (2002) yielded a migration barrier closer to the DFT result. When 10 keV and 50 keV displacement cascades were simulated with these potentials, the Gao-Weber potential produced fewer defects in the primary damage state due to more effective damage annealing by the rapid migration of carbon interstitials. This study has identified the source of differences in the damage state produced in SiC with different potentials, by benchmarking defect energies from these potentials against DFT results.

3.3 Radiation Effects in Ionic Materials

Sickafus et al. (2000, 2007) have performed molecular statics calculations with a set of shell model potentials (Minervini et al. 2000) to shed light on the radiation tolerance of pyrochlore oxides. These potentials are transferable across a wide range of pyrochlore oxides, which makes it possible to evaluate trends in the

radiation response as A and B cations are varied in $A_2B_2O_7$ pyrochlore. Sickafus et al. (2007) concluded based on their calculations integrated with experiments that better radiation tolerance is expected in materials with inherently disordered phases with wide ranges of stoichiometry. Devanathan et al. (2010a) have used a rigid ion potential based on the Minervini potential to study radiation-induced defect accumulation in gadolinium zirconate and titanate pyrochlores. The study showed that cation Frenkel pair accumulation played a key role in the amorphization of $Gd_2Ti_2O_7$. The simulations also quantified the swelling accompanying the damage accumulation and amorphization. In contrast, when defects were introduced in $Gd_2Zr_2O_7$, there was efficient dynamic annealing and no amorphization. Zhang et al. (2010) integrated experimental swift heavy ion irradiation and HRTEM characterization of pyrochlores with MD simulation of thermal spike damage using these potentials. The morphology of individual ion tracks produced by 2.2 GeV Au ions in $Gd_2Ti_2O_7$, Gd_2TiZrO_7, and $Gd_2Zr_2O_7$ as revealed by HRTEM was reproduced by the thermal spike simulations in these materials. The simulations provided insights into the time evolution of ion tracks and revealed the phase transition pathways leading to the concentric track structures observed experimentally. In $Gd_2Ti_2O_7$, the simulations showed an amorphous core for the ion track core, which was surrounded by a concentric shell of defect fluorite, and an outermost shell of defective pyrochlore, consistent with the nanoscale core-shell structure seen in HRTEM images. In $Gd_2Zr_2O_7$, rapid recrystallization of the ion track prevented amorphization and instead led to a defect fluorite core consistent with experimental observation. The reproduction of the experimentally observed morphology by the simulation for three different compositions provides validation for the potential. At the same time, the simulation has revealed atomic-level mechanisms behind the different responses of these pyrochlore to the passage of swift heavy ions. These pyrochlores have potential applications as waste forms for immobilization of high-level nuclear waste.

Devanathan (2009) has used MD with a partial charge model and Buckingham-type potentials to simulate energetic recoils in zircon ($ZrSiO_4$), which is also a nuclear waste form. The simulations revealed that about 5000 atoms were displaced by 30 keV U recoils consistent with the findings of a nuclear magnetic resonance experiment (Farnan et al. 2007). The simulations showed that direct amorphization occurred in the cascade. The amorphous core was relatively enriched in Si, while the periphery of the cascade was enriched in Zr. The experimental study by Farnan et al. (2007) assumed that Si displacements were about one-sixth of total displacements according to stoichiometry. The simulations confirmed that this is indeed the case. The simulations also revealed the occurrence of Si-O-Si polymerization and under-coordination of Zr in the displacement cascade.

In contrast to the amorphization by direct impact in zircon and by damage accumulation in SiC, UO_2 and its fluorite structured surrogate CeO_2 are not amorphized by swift heavy ions. MD simulations of swift heavy ion damage in CeO_2, simulated using thermal spikes, showed that the primary damage state consisted of point defect clusters with no amorphization (Yablinsky et al. 2015). The results were consistent with experiments carried out by these authors. CeO_2

remained crystalline following irradiation with 940 keV Au gold ions. Experimental results suggested a small reduction in density at the center of the ion track. Simulation results showed a lower density track core and indicated the formation of interstitial loops at the periphery of the track consistent with experimental findings.

MD simulations of U recoils with energies in the range of 0.5–80 keV in UO_2 have been performed with rigid ion potentials (Devanathan et al. 2010b). Regardless of the recoil energy, there was no amorphous zone in the primary damage state of UO_2. Vacancies were preferentially created at the center of the cascade and interstitials at the periphery. The cluster size distribution was quite different for vacancies (large clusters) and interstitials (smaller clusters). In addition, swift heavy ion simulations in UO_2 (Devanathan et al. 2010b) have shown that the radiation response depends on the linear energy transfer (LET). Defects were not produced for LET less than 4 keV/nm. From 4 to 16 keV/nm, isolated point defects were produced. At much higher LET (66 keV/nm), dislocation loops were produced with Burger's vector along the <110> direction. When the simulations were extended to nanograined material, defect production was dominant near the grain boundaries. The boundaries also acted as a sink for point defects produced. The ability of MD simulations to reproduce the experimentally observed radiation response of different materials shows that the potentials are sensitive to the characteristic behavior of the material even though radiation response was not used to fit the potentials.

Govers et al. (2007) performed a comprehensive evaluation of 19 potentials for UO_2 by carrying out static calculations of elastic constants, lattice constants, and defect formation, migration, and binding energies. These values were benchmarked against experimental data or DFT results. The study considered core-shell potentials and rigid ion models. The potentials reproduced lattice constants and elastic constants well as they were fitted to these properties. The agreement with DFT data on defect energies and configurations was dependent on the type of defect considered. No single potential emerged as the best choice for simulating defects and radiation damage in UO_2 based on static calculations. The class of potential, the functional form, or the charges of the ions did not have a strong influence on the ability of the potential to reproduce defect properties. In a subsequent study, Govers et al. (2008) also studied the evolution of the lattice parameter, specific heat, bulk modulus, and Gruneisen parameter with temperature and calculated the bulk melting temperature for 16 UO_2 potentials. The study concluded that rigid ion potentials with nonformal charges provide the best agreement with experimental data but may be unsuitable for the study of charged defects.

Devanathan et al. (2009) performed MD simulations of the premelting transition, melting temperature, and defect production by 1 keV U recoils in UO_2 using five different rigid ion potentials. For all the potentials studied, the experimentally observed premelting transition was reproduced, dynamic defect annealing in the displacement cascade was highly effective, and anion sublattice replacements were dominant. The primary damage state included isolated Frenkel pairs and interstitial and vacancy clusters of various sizes. The average displacement energy varied by a

factor of three and the number of stable Frenkel pairs in the primary damage state was also different by a factor of three depending on the choice of potential. The vacancy and interstitial cluster sizes and their spatial distribution were significantly different for the potentials studied.

Interatomic potential development is an ongoing activity with tremendous intellectual effort devoted to developing new functional forms and parameter optimization methods. As computing power moves from the Petascale to the Exascale (10^{18} floating point operations per second), large scale DFT calculations will become more and more accessible. One can develop a large database of defect properties to be used in potential fitting or to evaluate the fidelity of the potentials. It will also be possible to use complex functional forms, such as ReaxFF, in large scale MD simulations of interfacial processes in multiphase materials. Recently, low-energy displacement cascades in graphite have been simulated using ReaxFF and the resulting defects have been compared to the findings of DFT calculations (Smith et al. 2017). Such reactive MD simulations are in the early stages. There is considerable room for improving potentials even in well-studied materials to make them suitable for simulation of defect processes initiated by radiation interactions with matter.

4   Summary and Outlook

Despite the tremendous progress that has been made in the last two decades in developing bond order and charge-optimized potentials, considerable work remains to be done in developing potentials for materials used in nuclear technologies. This wish list includes the UO_2/Zr interface, stainless steel, oxide dispersion strengthened alloys, Ni-based superalloys, and glasses for nuclear waste disposal. The challenges associated with potential development include generating a large database of relevant properties from experiments and DFT calculations, assigning a weight to each property of interest based on its significance (almost an art form), and painstakingly minimizing the weighted square of the difference between the simulated value and the target value (Martinez et al. 2013). Since the properties fitted are often static, dynamic simulations (e.g., heating to different temperatures and going beyond the melting point) are needed to ensure that the simulated system is stable and the phase transitions and defect properties from DFT calculations are reasonably reproduced. There is invariably a tradeoff due to balancing accuracy, transferability, computational intensity, and the effort needed to develop the potential. Increasingly the power of machine learning from massive DFT data sets is being put to use to identify new functional forms and parameters for interatomic potentials (Behler 2016). With such an approach, the force acting on an atom can be predicted by the machine-learning algorithm based on the training set or computed on-the-fly for unusual environments using an *ad hoc* DFT calculation. When the results of this calculation are added to the machine learning database, the need to call upon DFT decreases progressively as the simulation proceeds (Li et al. 2015). While this approach holds promise, there are questions about the physical

basis of functional forms chosen through machine learning and the transferability of potentials developed from a small training set. With ongoing advances in data analytics, machine learning, and computing power, there is cause for optimism that reliable and transferable potentials for studying radiation effects multiphase materials will be developed by combining the best of physical intuition-based approaches and machine learning methods.

Molecular Dynamics Simulations of Non-equilibrium Systems

88

Contents

Abstract

The materials in nuclear reactors are subject to several radiation damage mechanisms. High-energy neutrons can give high (keV) recoil energies to nuclei via elastic collisions, many different nuclear reactions can also lead to lower recoil energies to nuclei, and nuclear fission fragments can get MeV kinetic energies from the fission process. The nuclei with high kinetic energies can damage the material both via nuclear and electronic excitations. In this chapter, we first overview briefly the nuclear damage mechanisms and then discuss how

molecular dynamics methods can be used to model the ensuing damage, both in the nuclear and electronic collision regimes. Some examples of recent results from both the nuclear and electronic regime are provided in the end.

1   Introduction

Nuclear reactor systems involve a large number of non-equilibrium effects that can affect the materials in the reactors. The neutrons coming from a fission or fusion reactor can damage materials in many ways. When they have high (MeV) energies, they will occasionally collide strongly with nuclei in the materials and transfer a high amount of energy to these. The maximum energy can easily be estimated from the classical kinematics equation of energy transfer between particles of masses m_1 and m_2 in a head-on collision:

$$E_{transferred} = \frac{4m_1 m_2}{(m_1 + m_2)^2} E_{initial} \tag{1}$$

For a neutron energy of 2 MeV moving in Cu, this amounts to a maximum energy transfer of about 120 keV. More accurate calculations, considering that not all collisions are head-on, show that the typical transferred energies are lower but still tens of keV's (Averback and Diaz de la Rubia 1998). These energies are about four orders of magnitude higher than the cohesive energy of the material, making it clear that they can lead to considerable damage in the materials. The atomic collisions induced by such high-energy ions are known as collision cascades and the slowing down by these collisions as *nuclear stopping*.

Also neutrons at lower energies can lead to damage in the materials. Damage production by the direct collision mechanism is possible down to energies of the minimum threshold displacement energy (Nordlund et al. 2005) of the material, i.e., neutron energies of a few hundred eV. When the neutron is thermalized to even lower energies, it will eventually undergo a nuclear reaction. These reactions almost always lead to another recoil energy. For instance, in (n, γ) reactions, the emitted γ particle has enough momentum to give the nucleus a recoil energy of a few hundred eV, enough for damage production (Raman et al. 1994). Naturally, if the emitted particle has a mass, such as in (n, α) reactions, the energy transfer is even higher, and also the emitted massive particle can cause damage.

Finally, if the neutron causes a fission reaction, the fission fragments can have energies of hundreds of MeV's (note that this energy release is the origin of energy production in normal nuclear power plants). At these very high energies, the fission fragments slow down mainly by collisions with electrons, known as *electronic stopping* (Ziegler et al. 1985). On the other hand, the nuclear collision energy transfer is much reduced at these high energies, and hence the electronic stopping dominates the energy loss. Heavy ions that slow down mainly by the electronic stopping are commonly called swift heavy ions. This interaction excites a large number of electrons into the conduction band. Since the energy loss to electrons

does not alter the path of the ion appreciably, the swift heavy ions move in straight paths, and the damage they produced is in straight cylindrical regions called ion tracks (Lang et al. 2008). De-excitation of the excited electrons in the insulating materials takes place within the limited region around the ion track. The released energy can then be transferred to the atoms in the lattice, known as "electron-phonon" coupling, leading to damage production. This damage can be produced via different atomic-level mechanisms.

Naturally, both mechanisms of damage production either in collision cascades or by swift heavy ion (via nuclear or electronic stopping powers, respectively) are relevant also in other systems. Ion implantation is a routinely used approach to dope silicon in the semiconductor industry, and the ions induce collision cascades that produce damage with mechanisms very similar to the neutron-induced ones (Chason et al. 1997). Ion tracks, on the other hand, are also naturally present in many minerals, produced in these by fission fragments from radioactive decay. The density of these is used routinely as a dating technique (Gallagher et al. 1998). They can also be produced deliberately by high-energy particle accelerators and are a basis of many promising nanoscience applications (Apel 2003; Toimil-Molares 2012). Such very high-energy particles are also present in space and can be a serious issue for reliability of electronics in space (Fleetwood et al. 1994).

Experimentally, the radiation damage can be detected in many different ways, and we mention here only a few key methods. As collision cascades only exist for a few ps, the atom motion in them cannot be directly detected. However, there is a special nuclear approach that has been used to determine the lifetime of a cascade in Fe to be 6 ps (Stuchbery and Bezakova 1999). Transmission electron microscopy (TEM) observation of amorphous pockets in semiconductors (Ruault et al. 1984; Bench et al. 2000) and local phase transitions in ceramics (Meldrum et al. 1998) also provide compelling evidence of dense regions of collision associated with the nuclear stopping. Moreover, field ion microscopy experiments have shown that 20–30 keV heavy ion irradiation can lead to dense regions of vacancies in W (Current et al. 1983), and more recent transmission electron microscopy has shown that 150 keV W cascades can directly produce dislocation loops in this material (Yi et al. 2015).

Ion tracks can also be detected experimentally in many different ways. In initially crystalline materials, chemical etching can reveal the location and areal density of tracks, since the damage track core etches faster than perfect crystal (Skupinski et al. 2005). However, this method does not tell anything about the atomic structure of the tracks. Cross-sectional TEM can be used to image tracks on the atomic level, either from the sides or as a cross section. TEM experiments have shown that the core of a track is amorphous (Meftah et al. 1994; Toulemonde et al. 2006). Rather recently, small-angle x-ray scattering experiments have revealed that the core of an ion track is underdense (Kluth et al. 2008).

In this chapter, we focus on computational methods for collision cascades and ion tracks, with some emphasis on new developments during the last 10 years. We review the methods of atomistic simulations of such high-energy irradiation effects relevant in nuclear systems, both in the nuclear collision and swift heavy ion

regimes. In both cases, standard molecular dynamics simulation approaches will not work directly, since the high kinetic energies involved may lead to serious energy nonconservation issues.

2   Modeling Approaches

The computer simulation approaches, developed to simulate materials in out-of-equilibrium conditions, are similar to those used for thermodynamically equilibrated systems. The latter, however, must be adjusted to capture the physics of processes taking place under irradiation with energetic ions. Every energetic ion passing through the surface transfers the energy and the momentum to the atoms of the irradiated material in a cascade until all the energy, which was brought in by the ion, dissipates inside the material. A prolonged ion irradiation with a high fluence (number of ions arriving at a unit surface during the entire irradiation time) may cause appreciable damage; however, the experimental rates – ion fluxes given by the number of ions per unit surface per unit time – are usually very low. The actual time interval between two subsequent cascades is much longer than the duration of a single cascade, and hence, any temporal (and/or spatial) overlap of the cascades is routinely neglected. If the fluxes are very high, and the subsequent ion arrives at the surface while the previous cascade is still not extinguished, the temporal and spatial overlap of simultaneous multiple cascades may lead to strong nonlinear effects. This situation is common during arc plasma-surface interaction (Timkó et al. 2010; Djurabekova et al. 2012) and needs to be taken a special care by adjusting the size of the simulation box. However, in this chapter, we will not consider the dense ion fluxes, but rather focus on individual cascades, which can be simulated one at a time. Bearing in mind that the size of a single cascade depends on the energy of an ion, the size of the simulation box can also be selected by using a simple empirical expression:

$$N_{at} = 20 \cdot \frac{E_{kin}}{1 \, eV} \tag{2}$$

This expression guarantees that the energy can be absorbed by the simulation box and dissipated gradually in a quasi-microcanonical ensemble. The latter requires additional clarification.

If a system of atoms is in a thermodynamic equilibrium, the properties of such a system can be described as averages of different thermodynamic ensembles (Allen and Tildesley 1989), depending on the property of interest. By fixing different external conditions, one can consider the micro-canonical (*NVE*) ensemble of an isolated system with the fixed number of atoms, N, within the fixed volume, V; the canonical (*NVT*) ensemble, connected to a heat bath of temperature T; and the isobaric-isothermal ensemble (*NPT*), which is connected to the heat bath and the volume of the system is flexible to keep the pressure P at a given value.

The control of temperature or pressure affects the velocities of the atoms. If baro- and thermostats are used during irradiation event simulations, the atom trajectories are perturbed from the true ones. For a cascade to be simulated properly, one has to allow a natural evolution of energy exchange in the system. In reality, the heat generated in the system during the development of the cascade will dissipate through the heat conduction to the bulk outside the actual cascade region. However, as it was mentioned in the previous paragraph, the system to simulate a single cascade is not large enough to dissipate all the energy, and if applying a fully *NVE* ensemble in the simulations, the system will inevitably heat up. This is an artifact, which may affect the results of the cascade. To avoid it, an emulation of thermal conduction can be used, i.e., the side atoms outside of a cascade region can be connected to a heat bath, providing a channel for energy dissipation in a reasonable manner, removing the energy from the system, but not interfering with the atoms, which were directly involved in the cascade. We call such an ensemble quasi-microcanonical, since the energy is not fully conserved, although no scaling of the atom velocities is performed in the actual cascade simulation zone.

Thus far, two basic atomistic approaches have been used to simulate irradiation effects in large-scale systems with the considerable number of atoms, binary collision approximation (BCA), and molecular dynamics (MD). Both approaches employ the Born-Oppenheimer approximation, which allows separating nuclear and electronic subsystems and taking into consideration the large difference in the time and size domains of both subsystems. In this approximation, the equations of motion are applied only to the massive and heavy nuclei, while the electrons follow the former immediately. This simplifies the simulation task, and the atoms in this approximation can be considered as spherical objects interacting between themselves according to the forces. The latter are derived from potential functions, which are described in greater detail in Sect. 3.

Both BCA and MD were developed initially to simulate the materials in two different limits. The BCA approach describes the radiation effects in materials, i.e., it follows the trajectory of energetic projectile (either the ion, which entered the material, or the recoil atom, which received the energy in a cascade) and calculates collision of this projectile and the encountered atom of the material at each BCA step (see Fig. 1). BCA is designed to describe the short-range interactions, i.e., at the distances between the colliding particles which are too short to be affected by the other atoms in the material, so the collision is strictly binary and the interaction is only repulsive. Since the BCA calculates the collision between two particles at each simulation step, the simulations are very fast and do not require large computational capacity. There exist many codes developed by different groups, which either use a so-called magic formula replacing the exact solution of the collisional integral for the universal ZBL potential at every BCA step (Ziegler 2013; Pugacheva et al. 1998) or precalculate all the scattering angles for each projectile-atom pair in the system in advance and tabulate them as the function of impact parameter (Miyagawa et al. 2002). However, the BCA is not valid at low energies; already at the energies around 500 eV, the multi-body interactions between the atoms become important and determine the dynamics of defect formation. Also the BCA approach is working
Fig. 1 Illustration of collisions in the binary collision approximation. Note that the other atoms, which are located near the knocked-on atoms, are not taken into account

well for linear cascades: the interaction between a projectile (energetic particle) and the particle in rest. Strictly speaking, the particle in rest may be involved in thermal motion, which is much less intense compared to the motion of the projectile particle. In this case, it can be neglected at the moment of collision. In the dense cascades, when many atoms are involved in the energy dissipation process (dense materials, such as metals of heavy elements), the interaction may happen between both moving atoms which leads to nonlinear cascades or thermal spikes, where the application of BCA becomes questionable.

The MD method, on the other hand, was originally developed to describe the materials in thermodynamic ensembles. Generally speaking, the MD method solves the system of Newton equations, with the driving forces derived from the potential. In other words, the interatomic potential for the material of interest is the key function, which defines the accuracy of the MD simulations. Very careful attention is usually paid to develop a potential, which is able to reproduce certain properties, which the material exhibits in thermodynamic equilibrium conditions. If the potential is able to reproduce all or some properties of materials, such as crystal structure(s), lattice parameter, cohesive energy, melting and boiling temperatures, elastic moduli, Young's and shear moduli, etc., the MD simulation of this material in a specific thermodynamic ensemble gives very reasonable results. Unfortunately, under ion irradiation, the thermodynamic equilibrium condition does not hold. In the process of momentum and energy transfer, the colliding atoms can approach each other much closer, and the potential, which was fitted to reproduce the thermodynamically equilibrated parameters, has no information about the nature of interactions at these short distances. The best solution that can be used to circumvent this problem is to spline the interatomic potential and the ZBL potential to introduce strong repulsive interactions within MD.

The other feature of MD method, which also requires special attention, is the time step, which is used in the MD iteration loop. Usually it is selected to be rather short that the atom cannot advance too far during a single MD step. In the equilibrium simulations, when the energies of atoms are varying only insignificantly, using a fixed time step is reasonable. However, in the cascade simulations, a single particle may have very high energy, which would allow it to move too far within a fixed time

step, such that it would cause the nonconservation of energy and instability in MD calculations. If the time step is fixed to a very small value, then after the ballistic phase, the simulations will proceed very slowly, and the simulation time will be unreasonably long. This is why the adaptive time step is necessary to advance the time depending on the highest value of the energy in the system (Nordlund 1995).

3   Interatomic Potentials for Simulation of Non-equilibrium Effects

Both the BCA and MD simulations rely on interatomic potentials that are discussed in detail in the chapter on Interatomic Potentials in this volume. The solution of the scattering integral in BCA relies on a repulsive interatomic potential:

$$V_{highE,rep,ij}(r_{ij}),$$

and this part also dominates strong collisions (kinetic energy roughly $>10\,\text{eV}$) in MD. The procedures to obtain these are well established. Ziegler, Biersack, and Littmark have from an averaging procedure formulated a simple analytical "universal repulsive potential" for all atom pairs Z_1–Z_2, which is typically valid to within $\sim 5\%$ in the high-energy region of interest (Ziegler et al. 1985). An alternative universal analytical potential has more recently been developed by Zinoviev (2015). Quantum chemical calculations specific to a given Z_1–Z_2 pair can be used to calculate repulsive potential accurate to within $\sim 1\%$ (Nordlund et al. 1997) which is comparable to the accuracy of the best experiments (Zinoviev and Nordlund 2017).

A typical curve illustrating the ZBL potential is shown in Fig. 2, which also illustrates one of the quantum chemical potentials that also have an attractive part (corresponding to the bound state of a dimer molecule).

The equilibrium potential required for MD simulations is far less accurately known. For simulations of ion irradiation, it is crucial to use equilibrium potentials where chemical bonds can break. Hence in this chapter, we only consider so-called "reactive" potentials, i.e., potentials where all bonds between atoms can break and reform (contrary to the case of almost all molecular mechanics force fields (Leach 2001). In general, these can be written in the form

$$V_i = \sum_j V_{rep,ij}(r_{ij}) + \sum_{jk} V_{attr,ijk}(r_{ij}, r_{ik}, \Theta_{ijk}) \tag{3}$$

Here V_i denotes the energy of atom i and j and k indices of neighboring atoms. Typically, the equilibrium potentials are constructed for near-equilibrium properties and hence are not consistent with the high-energy repulsive part $V_{highE,rep,ij}(r_{ij})$. In MD simulations that involve also high-energy collision cascades, it is thus customary to join the $V_{highE,rep,ij}(r_{ij})$ and $V_{rep,ij}(r_{ij})$ smoothly, e.g., with fifth-order spline interpolation function or by summation with a function that goes smoothly from 1 to 0 in a narrow distance interval (Nordlund et al. 1996). Usually
Fig. 2 Interatomic potentials for a Si-Si pair. In the legend, ZBL is used to show the shape of the universal potential developed by Ziegler et al. (1985), and DFT shows the density functional theory potential from Nordlund et al. (1997). While ZBl potential predicts only repulsive interactions at all distances, the DFT calculations show that beyond a certain distance, the interactions become attractive

this joining is done just by finding a functional form that gives a smooth connection between the two parts. However, recently the effect of the joining on damage production has been examined systematically (Sand et al. 2016), and sometimes it is carefully adjusted via DFT calculations (Belko et al. 2002; Stoller et al. 2016).

The swift heavy ion track formation induced by the electronic excitations leads to kinetic energies of atoms of the order of 10 eV (although, as evident from the discussion above, the exact mechanism of energy transfer to the atoms remains unclear, the observations of destruction of even strong covalent crystals imply that at least some atoms do get energies clearly above the cohesive energies, which are of the order of 5 eV). Hence for swift heavy ion effects above the synergy regime, it is in principle sufficient to have a good equilibrium potential. In the remainder of this section, we discuss briefly some of the classes of interatomic potentials that have been used in collision cascade and track simulations, as a comprehensive review of the vast field of interatomic potential development is beyond the aims of this chapter. Metals can be well described with so-called embedded-atom method (EAM) potentials (Daw et al. 1993). These can, via effective-medium theory, be motivated from fully quantum mechanical density functional theory (Puska et al. 1981; Manninen 1986). Originally (Foiles et al. 1986), they were formulated in the form

$$V_i = \sum_j V_{rep,ij}(r_{ij}) + F_i(\sum_j \rho_j(r_{ij})) \tag{4}$$

Here ρ_j is the electron density from atom j, and F_i is the energy that the solid gains when the ion core (metal atom without free electrons) is embedded in this electron density. Originally the EAM potentials were constructed with actual electron densities; however most recent implementations use ρ_j as fitting function of arbitrary form. In many potentials, the functional form of F_i is simply the square root function, which can be well motivated from the second-moment approximation of tight-binding electron structure models (Finnis and Sinclair 1984; Brenner 1989; Cleri and Rosato 1993; Albe et al. 2002). Regardless of exact physical motivations, all potentials that share the basic functional form can be called *EAM-like potentials*.

Regarding ionic materials, it is natural to seek a description of them based on the Coulomb potential between two different atomic charges q_i and q_j. These give directly the V_{attr} attractive part as pair potentials, while the repulsive part V_{rep} can, e.g., be a simple exponential, similar to the EAM-like potentials. For highly ionic materials near equilibrium, such a simple pair potential description is well motivated physically. However, one has to bear in mind that under irradiation, atoms can come far away from their initial positions and, e.g., can start forming N gas bubbles in some nitrides (Kucheyev et al. 2001). For describing such processes, fixed-charge ionic potentials are completely inappropriate, as they predict that the N-N interaction is completely repulsive. To circumvent this, one can (at least in principle) use charge-transfer interatomic potentials, where the charge of atoms depends on the local neighborhood, e.g., via electronegativity descriptions (Alavi et al. 1992; Albe et al. 2009; Yu et al. 2007).

In materials where the bonding is a mixture of ionic and covalent bonding, a pure pair potential is not likely to give a good description of the material. A prototypical example of this is SiO_2, which, while having a fairly high degree of ionicity, has a complex low-symmetry crystal structure with tetrahedrally arranged O atoms around the Si atoms. Such a structure cannot be described with pure pair potentials. Instead, a combination of an angular three-body term and an ionic one has proven to be suitable for describing at least the basic tetrahedral fourfold bonding of the Si atoms (Feuston and Garofalini 1988).

Materials with predominantly covalent bonding such as C, Si, Ge, and organic structures like hydrocarbons have a strong directional character of the bonds, due to the quantum mechanical hybridization of the valence electrons into sp^2 and sp^3 configurations. This hybridization leads to a preferred angle between bonds ($120°$ for sp^2 and about $109.47°$ for sp^3), and hence it is natural to formulate potentials that depend on the angle between bonds Θ_{ijk} and give an energy minimum at the preferred angle.

One widely used potential that utilizes this approach is the Stillinger-Weber potential originally made for Si (Stillinger and Weber 1985). It has in principle the form

$$V_i = \sum_j V_{2,rep,ij}(r_{ij}) + \sum_{jk} V_{3,ijk}(r_{ij}, r_{ik}, \Theta_{ijk}) \qquad (5)$$

i.e., has separate two- and three-body terms, where the two-body term has both repulsive and attractive parts and the three-body term has an explicit minimum at

$\Theta_{ijk} = 109.47°$. Although relatively simple in form and formulated more than 30 years ago, it is still widely used and been found to describe fairly well properties far removed from its initial fitting database (Balamane et al. 1992; Sastry and Angell 2003; Holmström et al. 2010). It has also been extended for a wide range of other materials (Wang and Stroud 1988; Pailthorpe and Mahon 1990; Oligschleger et al. 1996; Ichimura 1996; Aichoune et al. 2000), including giving a nonionic but rather successful description of SiO2 (Ohta and Hamaguchi 2001; Watanabe et al. 2004; Samela et al. 2008; Kluth et al. 2008). While rather successful for Si, Ge, and tetrahedral compound semiconductors, the Stillinger-Weber potential clearly is not suitable for carbon, which has the peculiar feature that the sp^2 (the bonding type in graphite and graphene) and sp^3 (diamond) bonding environments are almost identical in energy, i.e., two different bonding angles should have almost equal energy. To be able to describe several different bonding environments, Abell (1985) and Tersoff (1988) developed a formalism based on Linus Pauling's theory of the chemical bond (Pauling 1939). This formalism takes into account the observation by Pauling that the energy/bond decreases with increasing coordination number and allows having local energy minima at several different bonding configurations – including the possibility to have the exact same energy for two of them. The potential is written to formally appear like a pair potential:

$$V_i = \sum_j V_{rep,ij}(r_{ij}) + \sum_j g_{ijk} V_{attr,ij}(r_{ij}). \tag{6}$$

However, the g_{ijk} term is constructed to also depend on the angle between bonds Θ_{ijk} and the coordination number of atom i. In effect, g_{ijk} modulates the strength of the attractive part in a manner consistent with the Pauling theory. This "Tersoff-like" general form, sometimes with slight variations in the functional form of the three-body term g_{ijk}, has been parameterized for a very wide range of materials (e.g., Ashu et al. 1995; de Brito Mota et al. 1998; Matsunaga et al. 2000; Humbird and Graves 2004; Juslin et al. 2005; Billeter et al. 2007; Powell et al. 2007; Munetoh et al. 2007 and interestingly has been shown to be with certain parameter choices consistent with the Finnis-Sinclair and tight-binding-motivated EAM-like potentials (Brenner 1989; Albe et al. 2002).

The Tersoff formalism has also been extended for hydrocarbons (Brenner 1990; Brenner et al. 2002), giving an interatomic potential that is fully reactive and can describe a wide range of carbon allotropes and hydrocarbon molecules. These potentials, variably called Brenner, REBO, or AIREBO potentials, have been later implemented to include long-range forces (Stuart et al. 2000) and also include oxygen, to enable simulation of carbohydrates (Ni et al. 2004). They have been used to model several different kinds of irradiation effects, such as plasma-wall interactions (Salonen et al. 2001; Träskelin et al. 2004; Marian et al. 2007) and low-energy recoil damage in polyethylene and cellulose (Polvi et al. 2012). The Brenner carbon potential, without the complex bond-conjugation terms, has also been found to be reasonably good in describing radiation effects in carbon nanotubes and graphene (for a review of the extensive works in this area, see Krasheninnikov and Nordlund 2010).

Studying swift heavy ion effects in organic materials is challenging, in part because it is likely that much of the damage is produced by electronic effects causing bond breaking and in part because the atomic potentials for organic materials (like the Brenner one) are rather slow. However, in many cases, organic materials can be described also well by so-called coarse-grained models, in which the basic object is not single atoms, but parts of, or a full molecule. The simplest variety of such models is describing compact molecules as spheres interacting with Lennard-Jones potentials. Such models have been used to get good insights into, e.g., laser ablation (Zhigilei et al. 1998; Schäfer et al. 2002) and swift heavy ion irradiation of organic materials (Bringa et al. 2002; Bringa 2003).

4   MD Simulation of Interaction of Energetic Ions with Materials

As mentioned earlier, incident ions interact with irradiated materials in two distinct ways, either via direct collisions with atoms of the material or via excitation of electronic subsystem, which are described by nuclear, S_n, and electronic, S_e, stopping powers, respectively. Typical S_n and S_e curves are shown in Fig. 3. As one can see, both regimes are well separated to large extent; however, the energy regions where both nuclear and electronic stopping powers are significant also exist. Atomic collisions in the regime of nuclear stopping power can be simulated directly; the interaction of ions with electronic subsystem in the electronic stopping power regime (>100 keV/amu) requires development of additional multiscale models to enable these effects within a classical MD. With exception of a few key details
Fig. 3 Nuclear (S_n) and electronic (S_e) stopping powers in Si as a function of Au ion energy as calculated by TRIM95 software (Ziegler 1995)

which need to be paid thorough attention in the simulations of energetic atomic cascades in MD, in this chapter, we will mostly focus on the electronic effects in materials, as this is a new area of application of atomistic simulations, where the methodology is still under development.

4.1   Collision Cascades: Nuclear Stopping Power

Unlike the BCA approach, the MD simulation cell must be constructed according to the crystal or amorphous structure of the material and thoroughly equilibrated in the suitable potential that all atoms assume the sites, which correspond to the lattice site in the chosen thermodynamic ensemble. The size of the cell must be sufficiently large to ensure that the core of the cascade is in the middle of the cell and sufficiently far from the borders of the simulation cell. Introducing an energetic particle into the cell can be done either from the outside of the cell (simulating the near-surface radiation effects) or by randomly selecting an atom of the cell and giving it a recoil energy in a random direction. The latter approach will emulate the evolution of a cascade inside the bulk. Bearing in mind a small size of the MD simulation box (a couple of hundred nanometers at most), these simulations can be thought as representative of a small box cut out from the real, very large bulk system.

4.2   Electronic Stopping Power

Electronic effects are not explicitly taken into account within the classical molecular dynamics simulations. Solving the time-dependent (TD) Schrödinger equations for the atomic system with a highly energetic particle moving through became possible recently (most commonly using a TD-DFT approach) (Pruneda et al. 2007; Correa et al. 2012; Zeb et al. 2012; Ojanperä et al. 2014). Hence solving time-dependent Schrödinger equation at every step between the collisions, as well as during the collision by MD, may provide an accurate answer on energy loss to the excitations in electronic subsystem; however, to date this approach is computationally very expensive.

Instead, simplified approximations can be used to take into account the energy loss due to electronic stopping power, which agree fairly well with experiments. Following the basic idea of BCA simulations, the electronic stopping power can be implemented also in MD as a so-called frictional force. The implementation of the friction force in MD is similar to the algorithm used in SRIM, namely, the moving atom loses the energy between the collisions proportional to its velocity. The function $-(\frac{dE}{dx})_e(v)$ is obtained, e.g., from the broad SRIM database, where the experimental measurements for different materials as well as theoretical estimations, if such measurements are not available, are collected (Ziegler 2013). This has been implemented in MD by several groups (Pronnecke et al. 1991;

Nordlund 1995; Nordlund et al. 1998; Cai et al. 1998; Hou et al. 2000; Duffy and Rutherford 2007; Duvenbeck et al. 2007; Sandoval and Urbassek 2009) and demonstrated to work well by comparisons of experimental and simulated ion range distributions (Sillanpää et al. 2001; Peltola et al. 2006).

This approach, however, does not allow taking into account the energy, which may be returned back to the lattice atoms via electron-phonon coupling mechanism (Flynn and Averback 1988; Koponen 1992). The first attempt to introduce an analytical expression for calculation of cooling of the heat released in a cascade in metals by electrons was made in Finnis et al. (1991). This approach was developed later by Hou et al. (2000), deriving the parameters for the electron-phonon coupling from the Sommerfeld model, giving a simple way to include the electron-phonon coupling on atoms as a frictional force. These approaches can give insight into the role of electron-phonon coupling on collision cascade development in the nuclear stopping regime (Pronnecke et al. 1991; Björkas and Nordlund 2009). However, they are not suitable for modeling swift heavy ions, where it is crucial to know how heat is transferred from an evolving hot electron system to atoms. For this purpose, models have been developed where the electronic heat conduction is modeled concurrently with the atomic dynamics by solving the heat conduction equations as a function of space and coupling the electronic and atomic heat locally (Duffy and Rutherford 2007; Vazquez et al. 2017).

4.3   Thermostats for Simulations of Radiation Effects in Materials

Nuclear and electronic stopping powers imply that the incident energy is deposited to the irradiated material partly as potential (multiple defects remaining in the structure after the irradiation) and partly as kinetic energy. While the former form of the deposited energy is of interest as a result of the simulation, the latter may result in artificial heating of the lattice. The heating of irradiated samples is also observed in experiments if the irradiation fluxes are high and the sample is not well coupled to the surrounding, and special care is taken to keep the irradiated sample under the same temperature condition. Analogously, in molecular dynamics simulations of collision cascades or swift heavy ions, it is important to ensure that the extra heat is removed from the finite simulation cell, not to introduce an artificial heating of the system.

The standard approach to achieve this is to remove heat from the system at the boundaries, far from the high-energy recoils or ion track. This can be done in several different ways: by linear scaling (Nordlund et al. 1994) of velocities or using the Langevin (Caturla et al. 1996) or Berendsen (Nordlund et al. 1998) thermostats. Although none of these approaches can perfectly damp the pressure wave emanating from cascades, system size and parametric scaling studies can be easily used to determine whether the actual damage production results are affected by the boundary scaling (Samela et al. 2005).

5   Modeling Radiation Damage Produced by Swift Heavy Ions

In the electronic stopping power-dominated swift heavy ion (energy $\gg 10$ keV/amu) regime, the probability of individual collisions with atoms is rather negligible. Instead, the intense electronic excitation produces a narrow trail of permanent damage along the ion path – the ion track (Fleischer et al. 1975). The complex nature of electronic stopping power is discussed in detail in several publications (Itoh and Stoneham 1998; Itoh et al. 2009; Duffy et al. 2012; Schiwietz and Grande 2011; Rethfeld et al. 2014); however, none of them suggests an accurate model free of fitting parameters, which can be directly implemented in atomistic simulations.

Different mechanisms of how electronic excitations may result in permanent damage in materials, which have been proposed thus far, are the following: (i) heating of a track core through electron-phonon coupling (a two-temperature model) (Toulemonde et al. 2006; Duffy et al. 2012); (ii) Coulomb explosion, which may be caused by many electrons being rapidly excited out of the core because of the passing ion (Bringa 2003); (iii) "cold melting," i.e., electrons being excited into antibonding states causing bond breaking (Gorbunov et al. 2014; Medvedev et al. 2015a, b); and, finally, (iv) plasma formation in the track core (Cherednikov et al. 2013a, b). All models are dramatically different, in that the model (i) explains everything by rapid heating of the track core into temperatures of the order of 100,000 K, while model (iii) states that the material can be damaged even if the temperature never exceeds the melting point of about 2000 K. The models (ii) and (iv) are more specific to certain materials, where the charge relaxation may delay by a few ps.

Historically, the Coulomb explosion mechanism was the first mechanism, which was suggested to explain formation of nuclear particle tracks in minerals to analyze the records of energetic radiation in lunar rocks (Fleischer et al. 1965, 1967). Already then, the authors admitted that this model describes best the track formation in polymers, which was clearly confirmed later by Schiwietz et al. in (2004). Bringa and Johnson (2002) showed that Coulomb explosion on the early stage in combination with thermal spike on a later stage is able to jointly explain high electronic sputtering yields in polymeric materials. In other materials, the Coulomb explosion mechanism has not been confirmed; however, we mention here the attempt to explain track formation in Pd_80Si_20 metallic glass, where the authors observe plastic flow in the wake of the projectile, which may have been caused by Coulomb explosion inducing metal polarization (Klaumünzer et al. 1986). However, it is generally accepted that in many solid materials, the charge neutralization time is too short to cause any significant displacement of atoms (Duffy et al. 2012).

The model (iii), known mostly as "cold melting" or also as "lattice destabilization," assumes the modification of interatomic interactions due to electronic excitations. The equilibrium state of bonds in non-excited system will be different from that in the system, where the atoms forming the bonds are excited. If the

excitation lasts sufficiently long time, it may cause strong displacements in vicinity of the excitation, leading to fast melting (at temperatures much below the melting point) known as athermal (or sometimes also nonthermal) melting. Although very interesting, this mechanism has inherent problem of implementation in atomistic simulations as it requires a modification of interatomic potential depending on the excited state of the atoms. Some attempts to take this process into account were performed by Rymzhanov et al. in (2016) using density functional theory calculations; however, the validity of such an approach is not fully justified.

Finally, there are also several attempts to explain the formation of ion tracks by using so-called thermal spike model. This model was proposed to quantify track formation mostly in insulators as it implies thermal heat exchange between electronic and atomic subsystems. Strictly speaking, a thermal spike does not explain how the energy was deposited to electrons but rather describes the system after an electronic temperature has reached locally a thermal equilibrium. The thermal spike could result from an initial Coulomb explosion (Bringa and Johnson 2002) or changes in the interatomic forces (Itoh et al. 2009). The thermal energy of electrons is transferred then to the atoms via electron-phonon coupling, heating the lattice to the temperatures, which may cause atomic disorder (e.g., melting or boiling). Knowing the electronic stopping power and assuming a Gaussian distribution of the energy deposition around the track core and that the temperature within the track must rise, at least, to the melting point, it was possible to deduce the radius of the disordered track (Szenes 2005). Toulemonde et al. proposed to deduce the melt radius by solving analytically a coupled system of heat equations written separately for electronic (T_e) and ionic (T_i) temperatures (Toulemonde et al. 2000):

$$\begin{cases} C_e \frac{\delta T_e}{\delta t} = \nabla(K_e \nabla T_e) - G(T_e - T_i) + B(r, t) \\ \rho C_i(T_i) \frac{\delta T_e}{\delta t} = \nabla(K_i(T_i) \nabla T_i) + G(T_e - T_i) \end{cases} \qquad (7)$$

Here, $T_{e,i}$, $C_{e,i}$, $K_{e,i}$ are local temperature, specific heat capacity, and heat conduction of electronic and ionic subsystems and G is the electron-phonon coupling parameter. The function $B(r, t)$ describes the energy density supplied to electronic system during the SHI path. Integrating this function over the time and space must result in the measured value of $\frac{dE}{dx}_e$. This model is mainly known as the inelastic thermal spike (*i*-TS) model (to distinguish it from a thermal spike developed in dense collision cascades). Since the model follows the evolution of two temperatures T_e and T_i, the model is also called the two-temperature model. This two-temperature approach is based on the model which was developed by Kaganov et al. (1957) and Lifshits et al. (1960) for metals, and then, it was applied to study laser (Fujimoto et al. 1984) and SHI-induced effects also in metals (Wang et al. 1994). Application of this model to insulators is not rigorously proven; however, using fitting parameters in the two-temperature equations, good agreement with experiments was shown also for different insulators (Toulemonde et al. 2006).

6   Modeling of SHI Impacts by Using MD Methods

Since electronic structure is not explicitly described in MD algorithm, it is not immediately clear and straightforward how a SHI impact can be modeled by using this method. One of the first attempt to simulate the SHI impact in MD was made by Urbassek et al. (1994). In these simulations, a cylindrical track of a given radius was instantaneously energized by giving a constant energy, E_0, to all atoms within this track. Similar approach was used also in later papers by Bringa et al. (2002), Bringa and Johnson (2002), and Bringa (2003). In the latter works, these and other authors used the value of the stopping power $\frac{dE}{dx}_e$ integrated over the length of the simulation cell to estimate the amount of energy, which can be given to the atoms in the track to simulate more realistic impacts (Lima et al. 2016; Lan et al. 2013; Jiang et al. 2013; Lang et al. 2015; Rivera et al. 2017). The profile in these simulations can be either flat or distributed as Gaussian with the standard deviation about 1–2 nm. Although rather primitive, this model of instantaneous energy deposition can already provide valuable insights on how the lattice can accommodate the energy in a restricted volume and what is the structure of the tracks inside. For instance, it was shown that track formation in different oxides is driven by competition of heat and mass transfer, fast quenching of the molten phase, and eventual recrystallization. However, what remains unclear is the size of the restricted region where this energy has to be deposited. Usually the radius of the track is left as the free parameter, and the simulations are made for a number of combinations of E_0 and r_{tr} with results compared to the experiment (Urbassek et al. 1994; Bringa and Johnson 2002).

It is also possible to benefit from existing i-TS model and develop a multiscale approach, where the Eqs. 7 are solved numerically until the heat is maximally transferred from electronic to ionic subsystem at time t_{max} (usually around 100 fs) and, then, translate the temperature profile $T_i(r, t_{max})$ into kinetic energies of atoms in the simulation cell (Kluth et al. 2008; Pakarinen et al. 2009; Leino et al. 2015). Since the i-TS model uses the parameters of the system obtained in thermal equilibrium, it is necessary to adjust the profile $T_i(r, t_{max})$ scaling it to the melting point given by the potential in use. As it was shown, the choice of the model how the energy is deposited to the simulation cell may affect significantly the simulation results (Mookerjee et al. 2008), where significant differences in the sputtering rates as predicted by the inelastic thermal spike deposition and the cylinder model were reported.

In all aforementioned methods, it is important to set correctly the boundary conditions. For instance, periodic boundary conditions can be used to mimic the bulk case (all directions periodic), and the surface can be simulated by leaving one direction to be open (nonperiodic). Despite the choice of the boundary, the limited size of the simulation cell (finite number of atoms) causes two simulation artifacts. First of all, a strong shock wave, which is generated in the cell after the energy was introduced in the center of the track only, will return back to the track passing through periodic boundary condition. Moreover, the heat that is introduced in the cylindrical center of the cell eventually will spread in the cell and thermalize at the

temperature, which is much higher than expected if heat conduction is assumed. Hence, a special attention must be paid to mimic heat conduction effect to the bulk and to dampen the pressure waves from the track. To achieve this goal, the velocities of the atoms near the boundaries of the simulation cell must be scaled by using, e.g., Berendsen thermostat. A more advanced method to cancel the pressure wave was introduced in Zhigilei and Garrison (1999).

6.1   Two-Temperature Molecular Dynamics Model

The two-temperature MD (2TMD) model follows the temperature evolution in electronic and ionic subsystems directly within MD simulations. It can be done by using a Langevin thermostat with the friction force added to the MD equations of motion of atoms:

$$m_i \mathbf{a}_i = \mathbf{F}_i(t) + \xi m_i \mathbf{v}_i \tag{8}$$

Here, m_i, $\mathbf{a}_i$, $\mathbf{F}_i$, and $\mathbf{v}_i$ are mass, acceleration, force, and velocity of a given atom i. The value ξ is estimated as

$$\xi = \frac{V G(T_r)(T_e - T_i)}{\Sigma_i m_i v_i^2} \tag{9}$$

In this model, the simulation cell is divided into smaller cells of equal volume V, where electronic and ionic temperatures are averaged separately (see Fig. 4). Within this geometry, the boundary condition can be set to the desired temperature to imitate the heat conduction to the bulk. Moreover, the size of the ionic and electronic structure does not need to be the same. By imposing a larger mesh for electronic subsystem, the electronic temperature can be converged to the desired bulk temperature in more gradual manner. This model was initially used to simulate
Fig. 4 Illustration of the 2TMD simulation cell. For clarity the grids of electronic and ionic subsystem are shown separately. In each cell of the grid, a local electronic and ionic temperature is defined. Dirichlet boundary condition is applied at the sides of the electronic temperature grid (light blue color). Size of the grid point should be sufficiently large to enable statistically meaningful values of local temperature

the short-pulse laser melting (Ivanov and Zhigilei 2003) but later on was extended to be used to simulate the electronic effects in radiation damage simulations (Duffy and Rutherford 2007).

6.2   Parameterization of the Inelastic Thermal Spike Model

Advantage of one implementation of the inelastic thermal spike model over the other, such as an instantaneously deposited energy or by a natural evolution within the 2TMD model, depends on the specific problem and the studied material. However, both implementations rely heavily on the parameters used in the model.

First of all, what remains ambiguous is how the energy is deposited to the electrons by a SHI. In the original model by Toulemonde et al., the initial distribution of energy is described by the expression suggested by Waligórski et al. (1986). This distribution is then scaled to give stopping power predicted by the SRIM software (Ziegler 2013).

There are more theoretical attempts to reproduce initial electronic cascades, especially in the short-pulse laser irradiation community (Rethfeld 2004), later on adopted for simulations of electronic effects during a SHI impact on materials by using Monte Carlo approach (Medvedev et al. 2010, 2015a, b). These types of simulations may provide a more realistic distribution of initial energy deposition, giving deeper insight on the energy distribution taken away from the track by fast δ-electrons.

Furthermore, it is not clear how to estimate parameters of electronic subsystem in such a far-from-equilibrium condition. Originally, in the Toulemonde's model (Toulemonde et al. 2000), the free-electron gas model is used to estimate the electronic heat capacity ($C_e = \frac{3}{2} N_e k_B$, where N_e is the electron density and $k_B b$ is the Boltzmann constant) and conductivity ($K_e = D_e C_e = (\frac{1}{3} l v_f C_e)$ with D_e being the electron diffusivity and l and v_f the electron mean free path and Fermi velocity, respectively.) The electron-phonon coupling constant remained in the Toulemonde's model as a free parameter adjusted to result in the track radius observed in experiments.

The free-electron gas model leads to severe underestimation of the C_e parameter, since the electronic temperature may rise during the SHI impact by several orders of magnitude. In the limit when the electronic temperature homogenized, but still $T_e \gg T_i$, the Eqs. 7 can be simply rewritten as

$$C_e \frac{\delta T_e}{\delta t} = G \cdot (T_e - T_i) \tag{10}$$

Solving this equation gives a clear relationship between G and C_e:

$$\tau = \frac{C_e}{G} \tag{11}$$
Fig. 5 Electronic temperature dependence of the specific heat capacity $C_e(T_e)$ as calculated with DFT. The dash-dotted line shows the commonly used C_e from the free-electron gas model assuming two excited electrons (Toulemonde et al. 2000). The left image shows the same data zoomed in at lower temperatures. (Reprinted with permission from Leino et al. (2015). Copyright (2018) by the EDP sciences)

where τ is the relaxation time, which can be obtained from pump-probe experiments by direct measurement of the electron temperature after laser pulse using angle-resolved photoemission spectroscopy (Johannsen et al. 2013).

Daraszewicz et al. (2014) suggested the recipe to calculate the electron-phonon coupling from the first principles for W. However, this is less straightforward, if the studied material is an insulator. In this case, the specific heat capacity still can be calculated from $C_e = \frac{\delta E}{\delta T_e}$, where modification of the internal energy E is found from the analysis of the electronic density of states (DOS) obtained in finite-temperature generalization of the density functional theory (DFT) using Quantum Espresso (Giannozzi et al. 2009). If the value of the relaxation time is known experimentally, the strength of electron-phonon coupling can be estimated from Eq. 11. Figure 5 shows the difference between the electronic specific heat capacity calculated by using Quantum Espresso and the free-electron gas model (temperature-independent), where it is clear that C_e at low temperature is strongly overestimated, while at high electronic temperature, it must be multifold higher.

7   Simulations of Track Formation in Bulk Materials

As described in Sect. 5, simulation methods, which exist to date to simulate SHI impacts on materials, are still under development. However, already initial attempts to simulate this complex phenomenon with the available tools have resulted in a few very valuable insights, and we review here briefly a few significant examples.

The first experimental measurements of tracks in amorphous materials, e.g., a-SiO$_2$, by using small-angle X-ray scattering spectroscopy (SAXS), indicated the existence of a core-shell structure. By then, it was clear that the nature of ion track damage ranges from small differences between track and the rest of material in amorphous structures (e.g., SiO$_2$ Klaumünzer 2004), formation of point defect and defect clusters in ionic crystals (Trautmann et al. 2000; Khalfaoui et al. 2005), to amorphization of crystalline materials (e.g., InP Kamarou et al. 2008; Klaumünzer 2004; Meftah et al. 1994). However, the new finding clearly showed that the subtle difference in densities appears even within a track region itself. Although it was clear that in the core of the track the density was different from that of a periphery, it was not obvious whether the ratio was toward the overdense shell and underdense core or the other way around. The insight on the track formation was possible through MD simulations. A few profiles obtained for different energy depositions with profiles calculated by using Toulemonde's *i-TS* model (7) are shown in comparison to the experimental profile reconstructed from the SAXS signals. It is clear that the ion track leaves a clear signature of an underdense core surrounded by the overdense shell (see Fig. 6). In the same figure, we demonstrate an excellent agreement between the size of the track obtained in crystalline quartz by MD simulations using the energy loss of 15.9 keV/nm and the TEM image of the same track, but using energy loss of 14 keV/nm (Meftah et al. 1994).

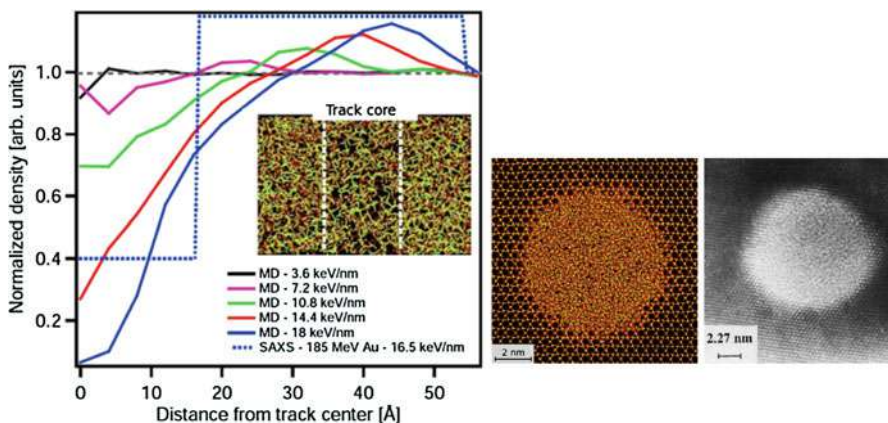
The mechanism revealed in these simulations can be summarized as shown in Fig. 7. The energy deposited to the electronic subsystem in a SHI impact is


Fig. 6 Left: Radial density profiles obtained in MD simulations for a-SiO$_2$ shown in arbitrary units. Unmodified density of the cell is shown with a dashed line at 1.0. The dotted line shows for comparison a density profile extracted from the SAXS measurements of the 185 MeV Au (Kluth et al. 2008). The inset shows a snapshot of MD simulations at the moment when the track has already cooled down to its final state. Right: Comparison of track sizes in crystalline quartz obtained in MD simulations with energy loss $S_e = 15.9$ eV/nm and in experimental TEM image with $S_e = 14$ keV/nm from Meftah et al. (1994). Fig. 7 Mechanism of track formation in amorphous materials. The track is heated in the narrow region around the swift heavy ion path. In the following few picoseconds, the pressure waves formed due to extremely high-temperature gradient that transport the material from the track core to the periphery of the track. The intense heat exchange with the infinite thermal bath of a surrounding material leads to the temperature quench, and the structure freezes in the density-alternating state

subsequently transferred to the lattice via the electron-phonon coupling. Large amount of energy deposited nearly instantaneously (within a few hundreds of femtoseconds) in a limited volume of an ion track leads to very fast phase transition within the track to a high-pressure vapor phase of the material, generating strong pressure waves, which transport the material from the track center. The cold material surrounding the track resists the wave propagation pressing the material to a higher density state. At the same time, the efficient heat exchange between the small volume of a heated track and cold, but infinitely large, surrounding bulk material dissipates the heat from the track freezing in the inhomogeneous density distribution around the track. Since a-SiO$_2$ is known to be highly viscous, the density variation remains as a permanent track after the impact region cooled down to the room temperature.

The combination of the *i*-TS model by Toulemonde (Eqs. 7) and MD simulations would lead to a monotonic increase of the track radius approximately as the square root function of the deposited energy, which can be intuitively expected. However, this was not confirmed in the experiments (Afra et al. 2013), where it was found that the track radius saturates and does not exceed a certain value for the given material. Intriguingly, in the other experiments for the same material, a-SiO$_2$, the saturation of the track radius with increase of the stopping power was not observed while using a different technique, the Rutherford backscattering (RBS) (Meftah et al. 1994). Having in mind that specific heat capacity $C_e = \frac{\delta E}{\delta T_e}$ depends on the electron density of states, which are different at different electronic temperatures, one can calculate $C_e(T_e)$ as shown in Fig. 5. Plugging in this function to the full 2TMD model, the results show that, indeed, the track radius saturates with increase of the stopping power. This is explained by rapid growth of the C_e at high electronic temperatures and thus the slower rise of the temperature in the track. Now, if we turn our sight to the defects, which are created out of the track radius, we see that the distance from the track center to the individual defects keeps increasing with increase of

the stopping power, although the track radius has already been saturated. Since the higher stopping power would produce higher-energy δ-electrons, the individual defects formed in the electronic cascades initiated by the δ-electrons may locate further away from the track. This can explain the discrepancy between the SAXS (Afra et al. 2013) and RBS (Meftah et al. 1994) experiments, since the former technique is sensitive to change of densities in the track but the latter measures the defects and disordered regions. In Fig. 8, the MD track radii measured by analyzing the density variations and the furthest defects found in the MD cell away from the center of the track are compared to the SAXS and RBS results. Although the MD track radii obtained by measuring the furthest defects are still somewhat smaller than the RBS signal, the growing trend is clear when it is compared to the saturated trend of the track radii obtained by measuring the density variation in the track.

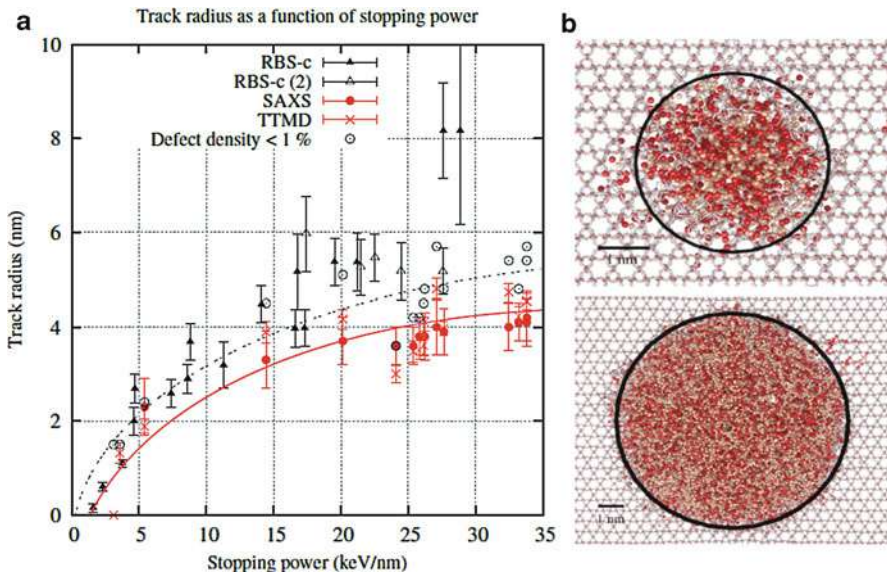
Effect of the parameterization of Eqs. 7 was also clearly observed in SrTiO$_3$ in Weber et al. (2014), where the reduction of the thermal conductivity of the electronic and ionic subsystems was associated with defects in a predamaged SrTiO$_3$ layer. By reducing these parameters by the order of magnitude, the authors found that track in the predamaged SrTiO$_3$ layer (with up to 1.5% of Frenkel pairs in the structure)


Fig. 8 (**a**) Track radius as a function of stopping power. The experimental data are from Meftah et al. (1994), Tombrello (1984), and Afra et al. (2013). The lines are polynomial fits to the simulation data points to guide the eye. The empty circles indicate a radius at which the defect concentration falls below 1% in the simulations; (**b**) Snapshots of tracks obtained with lower-energy ions (27 MeV Au, top) and at the saturation region (1.4 GeV Au, bottom). The circles are the track radii that are obtained by fitting density variation. Defected atoms are drawn as large spheres. (Reprinted with permission from Leino et al. (2015). Copyright (2018) by the EDP sciences)

was larger and compared much better to the tracks seen in the experiment. On the other hand, the SHI tracks were found to cause a healing effect in the predamaged SiC via the so-called SHIBIEC effect, which stands for swift heavy ion-induced epitaxial recrystallization (Debelle et al. 2012, 2014). In these experiments, the ideal zinc blende structure of 3C-SiC was predamaged by 100 keV Fe ions at room temperature with the fluences of 2×10^{14} cm^2 and 4×10^{14} cm^2 to achieve partial and full amorphization of a layer of the 3C-SiC sample. After introducing SHI tracks according to Eqs. 7 generated by 0.87 GeV Pb ions, the damage existed in 3C-SiC partially recovered due to temperature-induced recrystallization at the interface between crystal-amorphized phases of 3C-SiC. The lower the degree of amorphization, the stronger recovery was achieved in both experiments and simulations, as shown in Fig. 9.

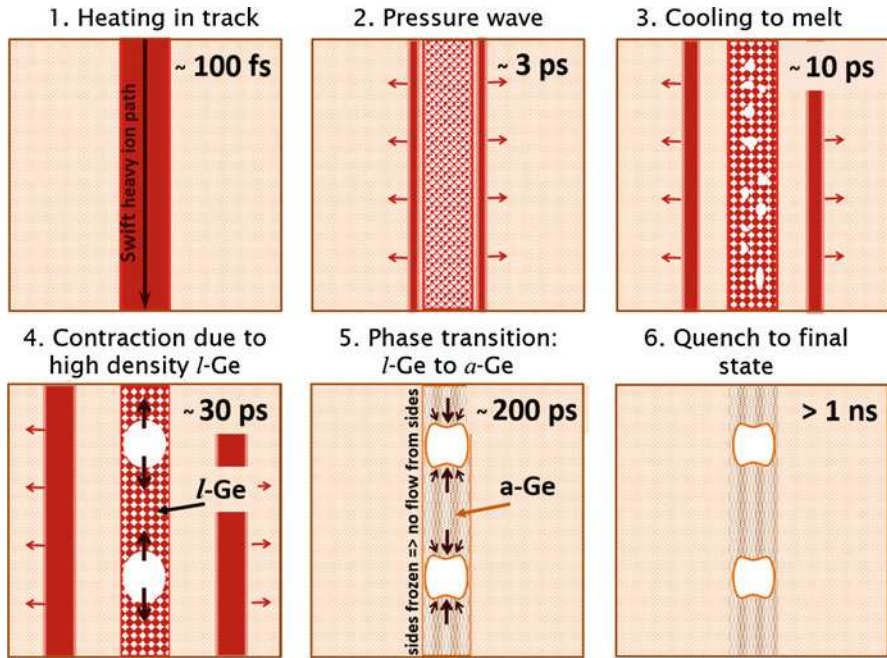
One more interesting phenomenon, which was explained by using MD simulations of ion tracks, was the formation of "bowtie"-shaped voids in amorphous germanium. In this material, the heating induced by a SHI track has led to a series of phase transitions within the track region (Ridgway et al. 2013; Hooda et al. 2017). Simulation of track evolution in amorphous germanium revealed the stages schematically illustrated in Fig. 10. First two stages are similar to track dynamics in other insulating materials: during the first 100 fs, the track core rapidly heats up, and the strong pressure waves transport the material away from the center of the track during the following 3 ps. While cooling down from a vapor to the liquid phase, a phase transition occurs: the hot low-density liquid germanium turns into much denser cooler liquid germanium phase. This transition creates empty space, and a multitude of small voids form along the track during another 10 ps. For more than 30 ps, the temperature in the track is sufficient to enable the coalescence of
Fig. 9 Simulated depth distributions of the damage in the 3C-SiC cells damaged by low-energy recoils and subsequently heat treated by a thermal spike caused by 0.87 GeV Pb ions Case of (**a**) fully amorphous and (**b**) partially amorphous. The corresponding images of the analysis of angular structure factors show atomistic image of the recovered buried layer of the predamaged 3C-SiC


Fig. 10 Illustration of the mechanism of formation of "bowtie" voids in amorphous germanium. Hot track vaporizing Ge atoms in a limited volume (stage 1), pressure waves are transporting material away from the track center (stage 2). In the stage 3, the hot low-density liquid germanium changes to high-density cold germanium melt, which leads to formation of small voids. The voids agglomerate in larger voids during the stage 4. Continuous cooling leads to another phase transition from high-density liquid to low-density amorphous phase. The frozen high-density shell prevents expansion of material outward, and the voids contract only along the track axis, where the temperature still allows the atom movement during the stage 5. At the last stage 6, the formed bowtie shape freezes in

small voids into larger ones, which gradually contract along the track axis due to expansion of the amorphous Ge after a reverse phase transition from the liquid to amorphous state, whose density is known to be lower. During this last transition, the void assumes the final "bowtie"-shape that remains unchanged longer than 1 ns. The comparison of the simulated void in amorphous Ge and the TEM image of the void obtained with the same irradiation condition are shown in Fig. 11.

8   Conclusions

In this chapter, we reviewed briefly the basics of physics of far-from-equilibrium processes, which take place during modification of materials by energetic ions or recoils in the wide range of ion energies. We also discuss how molecular dynamics methods can be modified to model realistically the ensuing damage, created by
Fig. 11 On the left, a TEM image of a bowtie-shaped void formed in amorphous Ge by swift heavy ion irradiation. On the right, the void simulated by using *i*-TS model in combination with classical MD simulations during the same radiation conditions. (Reprinted with permission from Ridgway et al. (2013). ions via nuclear collisions and the electronic excitation regime. Examples of recent insights, which became available owing to newly developed multiscale models based on classical MD methods, are also given at the end of the chapter. These examples are focused on damage generated by swift heavy ions via interactions with electronic subsystem of the irradiated materials.

Kinetic Monte Carlo Algorithms for Nuclear Materials Applications

89

Contents

Abstract

Microstructure evolution of irradiated materials is a complex phenomenon that involves time and length scales that can expand several orders of magnitude. Defects produced in the irradiation can interact with the existing microstructure, sometimes inducing changes in the mechanical, electrical, or even magnetic properties. The selection of the most adequate material for nuclear applications requires an understanding at a fundamental level of the evolution of these defects during the lifetime of the reactors. Therefore, very efficient simulation tools, with physical and accurate parameters must be used. In this review,

one of the computational methods that is commonly employed to study defect evolution, kinetic Monte Carlo, is described. The differences and similarities between three algorithms are explained: atomistic (or lattice), object, and event kinetic Monte Carlo. In order to reveal the applicability of these methods in the nuclear field, examples are given for the case of one of the candidates for first wall materials for both fusion and IV generation fission reactors: FeCr alloys. Finally, the limitations of the models to describe these systems and the current efforts to improve the predictive capabilities of this approach, as well as other developments in the field are discussed.

1   Introduction

The search for materials for nuclear applications, in both fusion and next generation fission reactors, requires reliable models capable of describing the production and evolution of defects produced during the irradiation and the interaction of these defects with the microstructure (Zinkle et al. 2009; Dudarev et al. 2009; Knaster et al. 2016). Due to the difficulties in performing neutron irradiation experiments, ion irradiation has become during the last years a commonly used method to obtain information about how defects are produced and how they interact. However, an extrapolation from ion irradiation conditions to neutron damage is needed, and in this task, simulations are a key component. With the use of accurate computer models, the large range of parameters in these experiments can be analyzed to understand their influence in microstructural changes. These parameters are temperature, dose rate, dose, irradiation energy, surface effects, dislocation density, or impurity content, among others. However, no single model is capable of describing the effects of irradiation from the time scale of defect production (a few picoseconds) to the lifetime of a reactor (years) or from the size of the collision cascade (a few nanometers) to sizes that can be compared to experimental characterization results.

Recently, multiscale modeling (Phillips 2001) has been quite successful in building validated models starting from first principles calculations (Heinisch 1990; Caturla et al. 2000; Domain et al. 2004; Fu et al. 2005; Malerba et al. 2008; Martínez et al. 2012, among others). Binary collision approximation models together with molecular dynamics can provide information about the initial defect distribution produced by the irradiation up to several picoseconds. The defect distribution, their character, type, and structure can be obtained from these models although, to this day, there is no experimental validation of these results at this short time scales and localized dimensions. However, this information can be used as input for other models such as rate theory (RT) or kinetic Monte Carlo (KMC). In fact, already in the early 1990s, the importance of the defect distribution at the picosecond time scale was revealed to explain phenomena such as void swelling using results obtained with molecular dynamics and rate theory models (Woo et al. 1991). Later, the relevance of the initial defect distribution on microstructure evolution has been

shown in different metals and irradiation conditions using kinetic Monte Carlo models (Heinisch 1990; Caturla et al. 2000; Domain et al. 2004).

One important point in the development of multiscale methods is the validation of the models with experiments. And in this validation, KMC plays a crucial role. As it was mentioned above, results obtained from molecular dynamics about damage produced from a collision cascade cannot be, to this day, directly compared to experiments. Similarly, results of defect migration that can be obtained with classical molecular dynamics or density functional theory (DFT) can only be compared with experiments with the aid of KMC or RT models. Irradiated materials characterization can be done using different techniques. Some of the most widely used are transmission electron microscopy (TEM), atom probe tomography (APT), small angle neutron scattering (SANS), and positron annihilation spectroscopy (PAS). Transmission electron microscopy, for example, can provide information about defect concentrations, sizes, character (vacancy or self-interstitial) (Jenkins et al. 1976), structure (e.g., orientation of dislocation loops), and, under some conditions, chemical composition. The resolution of this method has improved significantly during the last few years (Zinkle et al. 2009), but it is still limited to diameters of the order of 1 nm in most cases. Also, *in situ* TEM measurements during irradiation reveal the dynamic nature of defect production and evolution and can reveal processes that would be lost in a "postmortem" analysis of the irradiated sample (Yao et al. 2008). SANS or PAS can provide information about smaller defects than TEM, but they also have their limitations. PAS, for example, can only detect open defects such as vacancies or voids of all sizes (Kuriplach 2002); however, the interpretation of the results is not straightforward. APT (Miller 2000) is able to provide information about local chemical composition and therefore help in understanding phenomena such as irradiation-induced segregation of solutes and precipitation (Hornbogen and Glenn 1960; Miller et al. 2003).

Besides characterization techniques, there are also other experimental methods to obtain information about defects in irradiated metals. Resistivity recovery experiments, which consist of irradiating the sample at low temperatures and then annealing at increasing temperatures to observe the different stages of defect recombination, have proven to be particularly useful in identifying migration energies of point defects (Takaki et al. 1983; Matsui et al. 1988; Ullmaier 1991; Fu et al. 2005). In magnetic materials such as Fe and FeCr alloys, other methods can also be used to understand changes in magnetic properties after irradiation, such as polarized neutron reflectivity (Papamilhail et al. 2016a, 2016b). As mentioned above, comparing fundamental calculations of defect properties and defect distributions to these experimental results can only be done with the use of a kinetic model.

In this review, the kinetic Monte Carlo algorithms that are more widely used in nuclear applications are described, in particular, lattice (or atomistic) kinetic Monte Carlo (AKMC), object kinetic Monte Carlo (OKMC), and event kinetic Monte Carlo (EKMC). After the description of the methods in general terms and the parameters required, examples are provided for AKMC and OKMC. In nuclear applications, ferritic/martensitic steels are considered as good candidates for structural materials

both for fusion and generation IV fission reactors (Andreani et al. 2006; van der Schaaf et al. 2006) with Cr concentrations between 9 and 12% (Murty and Charit 2008; Mansur et al. 2004). These materials have been selected due to their resistance to void swelling as well as creep; however, they present problems of embrittlement as well as some concerns about phase stability under irradiation (Yamamoto et al. 2006). Therefore, the examples that will be given here are of FeCr alloys under irradiation for low and high Cr concentrations. One of the main limitations of the KMC and rate theory methods is that the relevant events to be included are selected a priori, and there is no unambiguous method for this selection; it is to the discretion of the modeler, who normally chooses these processes through an iterative comparison with selected experiments. In recent years, new methods have emerged to avoid this limitation. At the end of this chapter, the limitations of these techniques, the needs for nuclear materials applications, and the developments toward reaching these goals are discussed.

2 Methodology

Given the complexity of systems with many constituents and possible evolution pathways, predicting the dynamic evolution of such a system, which might be out of equilibrium, will require numerical methods. Hereby a stochastic approach to solve this problem is described, which consists in solving the single master equation of all possible reactions without dealing with it directly, since the latter equation is very difficult to solve even numerically. Despite the fact that this method was originally aimed to solve coupled chemical reaction systems, it is being also widely used to model radiation damage microstructure time evolution in nuclear materials.

2.1 The Kinetic Monte Carlo Algorithm

In a similar way to the Bortz-Kalos-Lebowitz (BKL) algorithm (Bortz et al. 1975), this time-dependent method for solving the master equation relies in random selection of possible physical events attending to their rate of occurrence (Gillespie 1976). The method assumes that each of the events experienced by the system are *memoryless* or Markovian, which means that the transition rate for event j, r_j, apart from being independent of time, only depends on the initial and final states. A common assumption in these methods from transition state theory (TST) is expressing the transition rates r_j in the Arrhenius form for simplicity. This way, the list of required parameters for such a rate is limited to the prefactor r_j^0 and the activation energy of the process, E_j:

$$r_j = r_j^0 \, exp \, \left(-E_j / k_B T \right) \tag{1}$$

A cumulative rate function R_N is defined as the sum of all the possible transitions that can occur during the many-body system dynamics. According to its definition,
Fig. 1 Representation of the cumulative function R_i as a step function

R_N is a monotonously growing step function, as illustrated in Fig. 1, whose value R_i is constant in the interval {i-1, i}:

$$R_N = \Sigma_{i=1}{}^N R_i \qquad (2)$$

where N is the total number of possible events in the system, thus identifying both the transition and the specific element in the system which undergoes such transition.

The selection of which event takes place during the dynamic evolution of the system using this algorithm is described as follows:

1. Calculation of the cumulative function R_N, as the sum of all the possible transition rates R_i for every element in the multibody system:

$$R_N = \Sigma_{i=1}{}^N \Sigma_{j=1}{}^i r_j \qquad (3)$$

2. Sample of a first random number $rand_1$ using a uniform random number generator in the unit interval.
3. Perform the transition i that corresponds to the cumulative rate R_i, considering $R_{i-1} < rand_1 R_N \leq R_i$ and as shown in Fig. 2.
Fig. 2 Selection of the transition i after a time step dt in the kinetic Monte Carlo algorithm

4. Sample of a second random number $rand_2$ as in step (2).
5. Increase of the "real" elapsed time by a time step dt calculated as:

$$dt = \ln(1/rand_2)/R_N \qquad (4)$$

6. Recalculation of the rates R_i affected by the executed transition and updating the value of the cumulative function R_N.
7. Return to step (2) until a simulation ending condition is reached (elapsed time, number of executed events, etc.).

This algorithm, as depicted above, is only taking care of the time evolution of the multibody system. Spatial dependencies can be integrated to the particular event (transition undergone by a particular element) and can be updated as desired. Several alternative applications of this method using different space managements are illustrated in the following sections.

2.2 AKMC: Atomistic Kinetic Monte Carlo

When the KMC method is applied to elements belonging to a rigid lattice structure, it is commonly referred as lattice KMC (LKMC) or atomistic KMC (AKMC). Elements in this system which experience the state transitions selected from the KMC algorithm are bonded to specific fixed positions given by the crystallographic structure of the material. This technique is widely used to simulate phase separation (or intermixing) of alloys assisted by the vacancy diffusion mechanism (Young and Elock 1966).

In general, the AKMC method can be used to simulate the migration of mobile point defects (I and V). This fact is of particular importance since materials studied applying this method are aimed to be used in nuclear power plants. The main consequence of the radiation damage produced in these materials is the formation of Frenkel Pairs; thus, concentrations of I and V will be present at all times in these materials. The migration of point defects affects the local composition after every migration jump, as concentration of I and V, i.e., C_I and C_V, respectively, is modified locally but also because the migration of V involves a bulk atom to fill the previous location of the vacancy. In case of alloys, the latter process can change the atomic distribution of solute and solvent, as it was mentioned earlier.

2.3   OKMC: Object Kinetic Monte Carlo

An alternative application of the KMC algorithm to study the microstructure evolution of defects is the object KMC (OKMC) or off-lattice KMC method. OKMC codes do not explicitly make use of a predefined lattice structure, but it can be taken into account in the migration steps of point defects, as the code is tracking the coordinates of every single defect in the simulations. The simulation domain in these algorithms is divided into a homogeneous mesh, as shown in Fig. 3. This feature allows the calculation of either point defects or solute concentrations to obtain information such as tracer diffusivities or energy of mixing in alloy materials.

Among other features, OKMC codes are not only able to handle all point defects and impurities but also point defect clusters, mixed clusters of different shapes and Burger vector directions, interaction with interfaces, and more. This is of great interest as these methods can be used to reproduce, and thus explain, for example, the formation of dislocation loops found in transmission electron microscopy characterization of irradiated materials.

Fig. 3 Schematic representation of the resulting mesh containing point defects, impurities, clusters, and interfaces. In this case each point represents a point defect; colors indicate different defect types
2.4   EKMC: Event Kinetic Monte Carlo

The two methods described above (OKMC and AKMC) use the BKL algorithm (Bortz et al. 1975) to evolve the time. The so-called event kinetic Monte Carlo (EKMC) and the first-passage kinetic Monte Carlo (FPKMC) methods use a different algorithm for advancing the simulation time. As in OKMC a list of events is required, but here the time delay for all the possible events is calculated first, and the event with the shortest time delay is the one picked. This event is then performed and all the new time delays calculated again for the next simulation step. The time advances by the delay time of the event picked. In the EKMC method, some approximations are made in order to calculate the delay time of events (Lanore 1974; Dalla Torre et al. 2005; Fu et al. 2005; Jourdan and Crocombette 2012; Becquart et al. 2010). A more general method was developed by Opplestrup et al. (2006, 2009), the FPKMC. Here a "protective domain" is defined to calculate the event rate, and if that event is selected, it is moved to the edge of its domain. This approximation makes the algorithm very efficient for low defect concentrations compared to OKMC; however, the efficiency decreases at high concentrations since the "protective domains" have to be calculated at each time scale (Donev et al. 2010).

3   AKMC Applied to Modeling Fe and FeCr Alloys

High chromium ferritic and martensitic steels are considered as essential materials for several concepts for next-generation fission reactors (Klueh and Nelson 2007) as well as for future fusion reactors (Zinkle and Busby 2009). The addition of Cr has a beneficial effect on mechanical, corrosion, and radiation resistance properties of the matrix: the study of the stability of Fe-Cr solid solutions versus the α-α' decomposition, which occurs below the domain of stability of the σ phase, is therefore of great technological importance. The thermodynamic and kinetic modeling of this demixing process is a challenging problem, even without irradiation, due to the specific properties of Fe-Cr alloys. This system exhibits a unique inversion between ordering and segregation tendencies at the Cr contents of technological interest (9–12%) (Mirebeau et al. 1984). This behavior is related to the magnetic properties of the Fe-Cr alloys, as it has been shown by recent ab initio studies (Klaver et al. 2006; Olsson et al. 2006). Fe-Cr alloys also present significant vibrational entropies (Swan-Wood et al. 2005). Magnetic and vibrational contributions to the entropy affect both the thermodynamic and diffusion properties of the system. The details of the thermodynamic and kinetic model used in the KMC calculations are described in Levesque et al. (2011), Martinez et al. (2011), and Senninger et al. (2014, 2016).

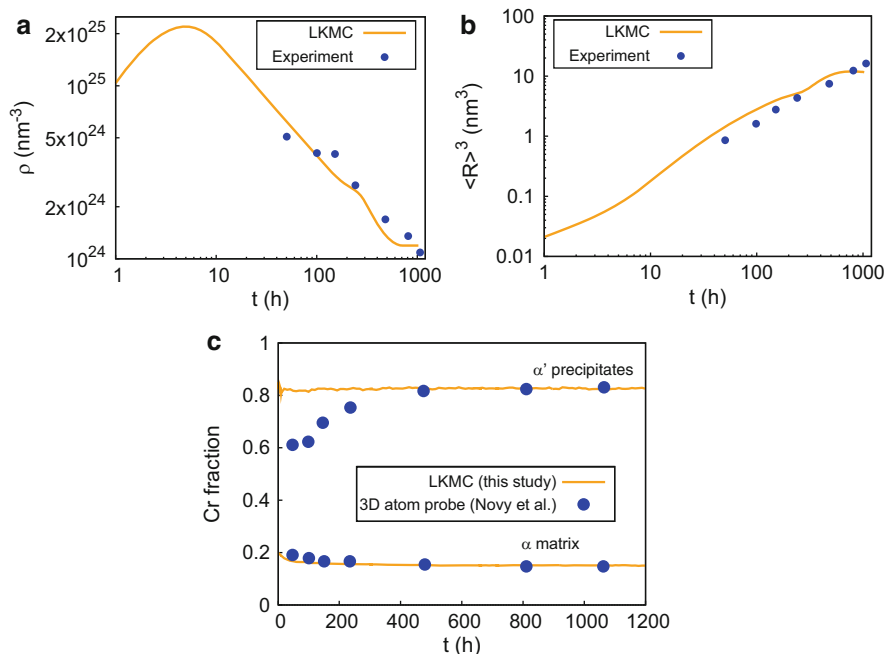
  LKMC has been used to study the precipitation kinetics of a Fe-20%Cr sample at 773 K, which are the same conditions used by Novy et al. (2009) in their 3D atom probe experiments. Transport has been considered through vacancy diffusion. The rate for vacancy hopping has been calculated using a harmonic transition state theory approximation. The migration barrier is obtained via a broken bond model


Fig. 4 Comparison between the LKMC simulations and 3DAP experiments (Novy et al. 2009) for a Fe-20%Cr sample (**a**) evolution of the density of α' precipitates during annealing, (**b**) evolution of the average radius of α' precipitates, and (**c**) evolution of the Cr fraction. Reprinted with permission from (Martinez et al. 2012) Copyright (2012) by the American Physical Society

with pair interactions fitted to ab initio data. Figure 4a and b show the evolution of the density and average radius, respectively, of the α' precipitates as given by both experiments and LKMC. We observe that simulations predict extremely well the experimental values for both the density and average radius although the average precipitate size seems slightly larger in the simulations.

Comparison of the evolution of the composition in the different phases, α and α', has also been performed. Results are shown in Fig. 4c, where it might be observed that the equilibrium compositions, after 500 h, predicted by the simulations are also in good agreement with 3DAP measurements. For shorter aging times however, the evolution of the composition appears much more rapid in the simulation than in the experiments of Novy et al., especially for the α' phase. It should be noticed that in the LKMC simulations, this evolution is found to depend on the criterion chosen to define the precipitates, but the previous conclusion remains qualitatively valid: the Cr concentration in the α' precipitates reaches its equilibrium value much faster in the simulations than in the experiments. It is well known that aberrations of ion trajectories and local magnification effects limit the spatial resolution of 3DAP. The composition of very small precipitates (below 2 nm) is thus subjected to significant statistical error (Vurpillot et al. 2000). The choice of parameters used for the identification of solute clusters may also induce additional uncertainties

(Hyde et al. 2011). It is worth noting that the size and density of precipitates, as well as the solute concentration of the matrix, are much less sensitive to such uncertainties. A typical case is copper precipitation in iron, where LKMC simulations (Soisson et al. 2010) usually predict almost pure Cu for precipitate radii as small as 1 nm, while 3DAP measurements overestimate the iron content (Morley et al. 2009).

Irradiation effects can also be taken into account in these models (Senninger et al. 2016; Martínez et al. 2018). For that end, self-interstitials have been modeled in the same way as vacancies, characterizing the formation and migration energies through DFT data. LKMC can be used to model radiation-induced segregation (RIS) near point defect sinks, going beyond the Wiedersich model. The LKMC simulations take into account the dependence of the transport coefficients on the local concentration and can treat precipitation. Figure 5 shows the steady-state concentration of defects and the Cr profile for a 10%Cr alloy at 650 K and 950 K with dose rate 10–6 dpa/s and 10–3 dpa/s. As predicted by the Wiedersich model, one observes Cr enrichment at 650 K and depletion at 950 K. The concentration of Cr at the ideal sink evolves very rapidly and reaches steady-state at low doses (a few 0.01 dpa). On the other hand, the total Cr segregated, defined as:

$$S^{Cr} = \int \left(X_{Cr}(z) - X_{Cr}(0) \right) dz \tag{5}$$

evolves much more gradually.
Fig. 5 Steady-state point defect and Cr concentration profiles in the vicinity of an ideal sink for an alloy at 10% Cr. Left, irradiated at 650 K and 10–6 dpa/s and, right, irradiated at 950 K and 10–3 dpa/s. Reprinted from (Senninger et al. 2016) Copyright (2016), with permission from Elsevier

4 OKMC Applied to Modeling Fe and FeCr Alloys

An advantage of working without a rigid lattice is the savings in memory use that allows for simulations with larger sizes. OKMC codes are specific for all of those objects of interest that can be found inside irradiated steels, such as point defects and impurities, and study their time evolution. Diffusion rate of mobile particles is a thermally activated process whose frequency can be described as:

$$\nu = \nu_0 \exp\left(-E_m/k_B T\right) \tag{6}$$

where ν_0 and E_m are the migration prefactor and activation energy, respectively. These parameters, among many others, are introduced in the simulator beforehand so it is important to find accurate values either from experimental data available in the literature or by numerical calculations methods such as density functional theory (DFT) and molecular dynamics (MD). In a three-dimensional movement, the diffusivity of impurities (C, etc.), point defects (I or V), and defect-driven lattice atoms (Fe or Cr) can be calculated as:

$$D = \nu \, \lambda^2/2d \tag{7}$$

where λ is the jump length and d is the dimension of the diffusion, often considered as three-dimensional although in metals, some types of defects move in one dimension. The frequency of migration, ν, introduced in this equation is straightforward for impurities and point defects from Eq. (15.1). Diffusivities of defect-driven lattice atoms in FeCr alloys can be also obtained through the simulation execution.

Migration of point defects and impurities eventually leads to their interaction with other objects of the same type but also with boundaries (interfaces) or clusters. Point defects can undergo recombination if they interact with the opposite defect or create more complex structures. The distance for which an object interacts with the surrounding defects/boundaries is given by its capture radius. This parameter is set as an input data for each mobile particle in the system; a default value for this parameter is the lattice parameter of the b.c.c. iron: 0.287 nm. In case of more complex structures such as voids, dislocation loops, etc., this parameter can be determined in different ways depending of the geometric description of the complex. Some OKMC codes use a capture sphere using a capture radius centered in the middle of the object (Caturla et al. 2000; Domain et al. 2004; Ortiz and Caturla 2007), while others use the envelope of the sum of capture radii of its constituents (Martin-Bragado et al. 2013). In the first description, clusters of defects are represented as a single point, located at the center of mass of the cluster, with the number of defects in that cluster and a capture radius that can depend on the number of defects and/or the cluster type. In the latter, the location of each point defect is actually kept in the simulation (Martin-Bragado et al. 2013).

There are also different ways when dealing with Cr in OKMC codes when modeling FeCr alloys. One option consists of considering Cr as an impurity that

can occupy substitutional sites in the lattice (Gámez et al. 2011), so it typically diffuses by paring itself with an I or V, until the latter point defect is emitted (Martin-Bragado et al. 2018). Another way consists of counting the number of both Fe and Cr atoms in each cell (hence allowing the calculation of their concentration in such cells when required), instead of recording individual positions for each Fe and Cr atoms (Dopico et al. 2015). The latter way treats global inhomogeneous alloys as discrete cells of homogeneous alloys, where the migration parameters of defects are modified depending on the concentration of solute in the cell they are contained. The mechanical properties of Fe-based and FeCr-based steels for nuclear applications are modified by the complex microstructures that are formed within them due to radiation. OKMC codes are able to model the formation and time evolution of these defects in order to reproduce actual transmission electron microscope observations of such irradiated steels and predict their behavior.

These complex structures (or clusters) of point defects and impurities can trap and/or emit its constituents attending to the energy barrier of the process. As it was previously mentioned, the capture radii of complex structures spatially determine the region where objects are allow to interact. In case of trapping a defect, the formation energies would be needed to compute the binding energy of such a defect to the cluster, while for detrapping (or emission) of defect constituents, the migration energy will be also required. Clusters can also experience other actions like transformation into another cluster, internal Frenkel pair recombinations of its constituents, and one- or three-dimensional migration in case it is a mobile defect. Some examples of these structures are three-dimensional vacancy clusters (voids), small clusters of self-interstitial atoms (SIA) with 3D migration, and dislocation loops of SIA with Burger's vectors along $\frac{1}{2}$ a_0 <111> and a_0 <100> directions. The latter defect has recently attracted scientific interest Marian et al. (2002), Marinica et al. (2012), Xu et al. (2013) and Granberg et al. (2017) to explain its formation since it is an immobile defect, commonly observed in TEM micrographs, that can act as defect sink in these steels, thus varying locally the mechanical behavior.

As mentioned in the introduction, information about migration energies of defects can be obtained from resistivity recovery experiments where first the sample is exposed to irradiation and then it is annealed with increasing temperature. In this process, different activation mechanisms are revealed as the temperature increases, which show as peaks when representing the derivative of the resistivity curve with temperature. Each one of these peaks is due to one (or several) recombination processes that result in the decrease of the resistivity of the sample due to defect annihilation (e.g., recombination between a single self-interstitial and a single vacancy). Therefore, each one of these peaks is normally related to the activation of an event such as the migration of a defect. The interpretation of these curves, and the association of each peak to a particular defect, is not straightforward. The use of combined DFT calculations and KMC simulations has proven to be very useful in the interpretation of these experiments (Fu et al. 2005; Gámez et al. 2011). Here, an example for pure Fe and FeCr in the dilute limit irradiated with electrons is presented. For more details of this calculation, see Gámez et al. (2011).

Table 1 Migration and dissociation energies for defects in pure Fe. Data from Fu et al. (2005)

Species	Migration energy (eV)	Dissociation energy (eV)
I	0.34	
I2	0.43	1.14
I3	0.43	1.26
I4	0.40	1.98
In	Immobile	
V	0.67	
V2	0.62	0.97
V3	0.35	1.04
V4	0.48	1.29
Vn	Immobile	

Table 2 Migration and dissociation energies for Cr in pure Fe

Species	Migration energy (eV)	Dissociation energy (eV)		Reference
ICr	0.23	$Cr + I$	0.42	(Olsson et al. 2007, Olsson 2009, Ortiz et al. 2011)
ICr2	0.30	$Cr + ICr$	0.31	(Olsson et al. 2007, Ortiz et al. 2011)
		$Cr_2 + I$	0.73	
I2Cr	Immobile	$ICr + I$	0.88	(Olsson et al. 2007, Ortiz et al. 2011)
		$Cr + I_2$	0.45	
I2Cr2	Immobile	$Cr + I_2Cr$	0.36	(Olsson et al. 2007, Ortiz et al. 2011)
		$Cr_2 + I_2$	0.75	
		$ICr + ICr$	0.86	
		$ICr_2 + I$	0.97	

The resistivity recovery curve can be modeled using information about migration energies of defects from DFT or from empirical potentials (for those clusters too large to study with DFT). In this case the migration energies of the different types of defects, vacancies, and self-interstitials are those given in Table 1 for the case of pure Fe, while Table 2 gives the values for defects containing Cr. Besides migration energies, it is also necessary to have information about the dissociation energy needed to detach a defect from a cluster. This requires knowledge of the binding energy as a function of number of defects in the cluster for all sizes and for all defect types. From the formation energy of clusters as a function of size, the binding energy of a single defect to a cluster can be calculated as:

$$E_b(n) = E_f(n) + E_f(1) - E_f(n+1) \tag{8}$$

Typically, values for small clusters can be obtained from DFT calculations (Fu et al. 2005). For larger cluster sizes, calculations with empirical potentials

that have been fitted to DFT are normally used. This information is then used to obtain a curve for all cluster sizes by fitting the data from the atomistic simulations. Tables 1 and 2 show the values for the example presented here. The prefactor for defect migration and dissociation is also another parameter in these simulations, and the most common procedure is to consider the vibration frequency of the lattice. The dissociation energy is calculated as the sum of the binding energy of the defect to the cluster plus the migration energy of the defect. For large clusters (in the calculations presented here, for clusters with more than four defects), the binding energy of a cluster with n defects is calculated as:

$$E_b(n) = E_f + \frac{\left(E_b(2) - E_f\right)\left(n^{2/3} - (n-1)^{2/3}\right)}{2^{2/3} - 1} \qquad (9)$$

with $E_f{}^V = 2.07$ eV and $E_f{}^I = 3.77$ eV, after (Fu et al. 2005). Therefore, the dissociation energy of a point defect from a cluster with n defects is $E_d(n) = E_b(n) + E_m$, where E_m is the migration energy of the point defect.

As mentioned above, there are also interaction rules that have to be taken into consideration in an off-lattice kinetic Monte Carlo calculation. On one hand, defect reactions must be defined for all types of defects and all defect sizes. For example, the recombination between self-interstitials (I) and vacancies (V), not just for single defects but for all cluster sizes, must be specified. That is, $V_n + I_m \rightarrow V_{n-m}$ (if $n > m$) or $\rightarrow I_{m-n}$ (if $m > n$). And the same for the interaction between clusters of the same type: $V_n + V_m \rightarrow V_{n+m}$, $I_n + I_m \rightarrow I_{n+m}$. In the example presented here, the calculations were done with the code Bigmac, developed at LLNL (Johnson et al. 1998) where clusters are represented by the number of defects and a capture radius. The capture radius for a cluster is often calculated as:

$$r_n = Z.\left(\frac{3n\Omega}{4\pi}\right)^{1/3} + r_0 \qquad (10)$$

where $r_0 = 3.3$ Å and obtained such that the distance between V and I is 3.3 a_0 (Fu et al. 2005), with $a_0 = 0.287$ nm, n is the number of defects, and Ω is the atomic volume of Z is the bias factor, taken as 1.15 for interstitials and 1 for vacancies.

The description above is for the simplest calculation of a metal under irradiation, only vacancies and self-interstitials are considered, and, moreover, only one type of vacancy clusters or self-interstitial clusters for each size is taken into account. However, in some metals different types of clusters of the same type can be observed after irradiation. For example, in Fe 1/2 <111> loops and <100> loops are often observed after ion irradiation (Yao et al. 2008), and their concentration, size, and ratios depend strongly on parameters such as irradiation energy, impurity concentration, proximity to surfaces, or irradiation type (electron, ion, or neutron). Introducing these details in the calculation imply extending the values of Table 1 for all the different clusters as well as all the different interactions. The same must be done when the effects of impurities such as carbon must be included.

When considering an alloy, different approaches can be used. If it is a diluted alloy, considering diluted as a concentration lower that 0.1%, the alloy element can be introduced in the same way as an impurity, that is, all the positions of the alloying atoms can be explicitly included in the calculation. In this case, the relevant migration and dissociation energies and reactions that involve the alloying atom and all the defects must be specified. For the case of FeCr in the dilute limit, the parameters in Table 2 have been considered in the calculation. These parameters, like in the case of pure Fe (Table 1), come mostly from DFT calculations. For the case of high concentration, this approach in not efficient if large system sizes have to be considered and other methods can be used such as those based on using concentration cells within the simulation box, as explained above (Dopico et al. 2015).

Possibly the simplest calculation of an irradiated metal using OKMC that can be directly compared to experiments is that of the resistivity recovery curve after electron irradiation. In this case defects are produced as Frenkel pairs, distributed randomly in the irradiated area and with a dose rate given by the electron irradiation rate. Results are presented here that follow the conditions in the experiments by Abe and Kuramoto (Abe and Kuramoto 1999) for three different FeCr alloys with concentrations between 0.01 and 0.1%. The initial condition in these simulations are pairs of vacancies and self-interstitials distributed randomly in the simulation box, which was a cube with a volume of $(287 \text{ nm})^3$. Cr atoms are also distributed randomly in the simulation box with the appropriate concentration, depending on the experimental conditions. Table 3 includes the number of Frenkel pairs considered for each calculation, obtained from the experimental initial resistivity of each sample and considering a resistivity per Frenkel pair of 30 $\mu\Omega$.cm/at% (12). An isochronal annealing is then performed, starting at 77 K and increasing the temperature 3 K every 3 minutes, following the experimental conditions in Abe and Kuramoto (1999).

Figure 6 shows the derivative with temperature of the total number of defects normalized to the initial number of Frenkel pairs obtained for the temperature range studied (80 K up to 150 K). Figure 6a shows the results for pure Fe and for three FeCr concentrations (0.019 at%, 0.047 at%, and 0.095 at%) which are those in the experiments by Abe and Kuramoto. The first peak is called the ID2 peak and it corresponds to the recombination between self-interstitials and vacancies that belong to the same Frenkel pair, which is known as correlated recombination. The second peak, IE, corresponds to recombinations between self-interstitials and vacancies after a longer migration of the self-interstitial. For the case of Fe, this peak is located at around 140 K and it has a smaller amplitude than the first peak. The first interesting feature of adding Cr is the shift of the IE peak toward lower temperatures, and the shift increases as the Cr concentration increases, as can be seen in Fig. 4a, and as observed experimentally (Abe and Kuramoto 1999; Maury et al. 1987). The reason for this shift is the formation of mixed dumbbells, that is, Fe-Cr self-interstitials that, as given in Table 2, have a lower migration energy than pure Fe dumbbells. However, they also have a low binding energy and therefore a low dissociation energy (see Table 2). At low temperatures, where the IE peak is located, these interstitials can perform several jumps before dissociating.
Fig. 6 Derivative of the number of defects as a function of temperature. (**a**) For the case of pure Fe and three FeCr concentrations. (**b**) For FeCr 0.019 at% and different values of the capture radius for I + Cr compared to the case of pure Fe

In these simulations, one parameter that played an important role was the capture radius between the substitutional Cr and self-interstitials. If a capture radius of 0.95 nm is used, like in the case of the interaction between a pure Fe self-interstitial and a vacancy, the IE peak almost disappears, as shown in Fig. 4b, while the best agreement with the experimental data is obtained for a recombination radius of 0.28 nm, that is, the second nearest neighbors distance. This short-range interaction between Cr and a self-interstitial atom can be interpreted as an effective value since according to DFT, not all orientations of these two defects will result into an attractive interaction, in some cases it is repulsive (Olsson et al. 2007; Terentyev et al. 2008).

As an example of the type of information that can be obtained from OKMC, the evolution of defects with temperature for the case of FeCr 0.019 at% is presented in Fig. 7: single vacancies (V), single self-interstitials (I), mixed dumbbells (ICr), vacancy clusters (Vclus), self-interstitial clusters (Iclus), and the different mixed clusters considered in these simulations (ICr2, Cr2I2, and CrI2).

This figure shows how at around 100 K, the number of single vacancies and single self-interstitials starts decreasing. This gives rise to the first recovery peak, ID2. At the same time, the number of interstitial clusters (Iclus) increases, while the number of vacancy clusters (Vclus) decreases. This implies that the species migrating are self-interstitials and not vacancies, which occurs at higher temperatures. The concentration of ICr dumbbells is always very low due to the fact that their dissociation energy is low (0.42 eV). However, they also have a low migration energy, lower than the self-interstitial dumbbell (0.23 eV and 0.34 eV, respectively); therefore, it can perform several jumps before dissociating giving rise to the shift of the IE peak with respect to pure Fe (see Fig. 4a). The low migration of the mixed dumbbell is also responsible for an enhanced recombination
Fig. 7 Evolution of defects with temperature for the case of FeCr 0.019 at%

between vacancies and self-interstitials with respect to pure Fe. ICr can also interact with other ICr, with self-interstitials or with substitutional Cr to form higher order clusters. In this model only those clusters given in Table 2 are included, that is, Cr2I2, I2Cr, and CrI2. For more details on the contribution of these clusters to the recovery stages, see Gámez et al. (2011).

5   Conclusions

As shown above, KMC models have the advantage that the location of every defect (or cluster) in three dimensions is preserved, unlike in rate theory models (RT), where in most applications only the defect concentration is followed. However, KMC is computationally more expensive than RT models. For certain applications, the three-dimensional character of KMC is needed, since spatial correlations must be accounted for to be able to describe some of the features observed experimentally. This is the case of resistivity recovery experiments of irradiated Fe at very low temperature, where the first peaks measured in these experiments can only be explained with the use of KMC models. KMC, however, has the limitation of the system size that can be modeled for the time scales relevant for nuclear applications. Typical OKMC calculations have sizes of a few hundred of nanometers per side on a cubic lattice. In metals, one of the factors that limits the size (or time scale) of the OKMC calculations is the wide disparity of rates between different events. Both in b.c.c. and f.c.c. metals, there are self-interstitial clusters that migrate, according to molecular dynamics simulations, almost athermally, that is, their migration energies are very low (~ 0.1 eV). Moreover, these defects migrate in one-dimension which, for low doses, implies that these defects can travel over long distances without

interacting with other defects, therefore, slowing down the calculation. In these cases, EKMC and FPKMC approaches are more efficient, since defects can jump in one single simulation step several lattice distances.

The efficiency of these algorithms can also be improved by the use of parallel algorithms. Parallelization is relatively simple in an EKMC or FPKMC approach, and there are also algorithms for the case of OKMC such as the synchronous parallel algorithm of Martinez et al. (2008) or parallelization using GPUs (Jimenez and Ortiz 2016).

One of the key issues in KMC models is the accuracy of the parameters used. This is particularly important in the OKMC and EKMC/FPKMC algorithms, trying to avoid the "ad hoc" selection of the possible events included in the calculation. The on-the-fly kinetic Monte Carlo methods, for example, compute the rates of the specific processes at the same time as the algorithm is evolving so that event rates are not tabulated. There are different implementations of the on-the-fly KMC, one of the first ones due to Henkelman and Jonsson (2001). The self-evolving atomistic kinetic Monte Carlo (SEAKMC) developed by Xu et al. (2011), SEAKMC, is able to achieve long simulation times by defining "active volumes" around the defect of interest (Xu et al. 2012, 2015). When the systems to be studied are very complex, such as in defect evolution in concentrated alloys, special methods have been developed to produce the catalogue of transition rates in a more efficient way. One such method consists of using artificial neural networks to predict the values of the energy barriers (Castin and Malerba 2010).

There are still challenges in the development of KMC models such as the implementation of strain fields in a general form, although there are some recent advances (Mason et al. 2014).

Rate Theory of Radiation Damage

Contents

Abstract

The theoretical foundations of rate theory applied to radiation damage are presented here. A general stochastic framework for the evolution of atomic clusters within the context of death-and-birth processes is first given. This leads to the well-known master equation, which, in the limiting case of a Poisson process, tends in the macroscopic limit to the mean-field approximation. The background of classical nucleation theory is given, pointing out some of the difficulties and challenges. When atomic clusters grow or shrink by the absorption of single atomic defects, a continuum Fokker-Planck approximation can be derived. This is followed by the mean-field theory of void growth that has been widely used to study the phenomena of swelling and creep. In materials with

high generation rates of helium gas, the more fundamental approach of "cluster dynamics" is developed, and under certain approximations shown to describe continuous nucleation and growth of helium bubbles. Some aspects of spatial behavior of clustering are discussed, particularly the role of cluster motion and fluctuations that lead to spatial self-organization and pattern formation.

1   Introduction and the Physics of Radiation-Generated Defects

Clustering of defects in materials is a process that embodies a rich variety of physical mechanisms and which has significant implications to a wide range of material technologies. Strong deviations from thermodynamic equilibrium conditions drive atomic-size defects into agglomeration, as an attempt to reduce the system's free energy. In nuclear energy applications (both fission and fusion), materials used as nuclear fuels, structural materials, the pressure vessel, as well as instrumentation materials are all subjected to the generation of non-equilibrium concentrations of atomic defects. Energetic neutron collisions with lattice atoms produce intrinsic lattice defects, as well as extrinsic impurities or insoluble gas atoms. This leads to the formation of pure vacancy clusters (voids), clusters of vacancies and gas atoms (bubbles), small interstitial-type and vacancy-type loops, and stacking fault tetrahedra (SFTs).

The generation of point defects in materials stems from two primary types of neutron interactions with bulk materials, known as elastic and inelastic interactions. These are caused by fundamentally different processes and lead to the production of different types of defects within materials. Elastic interactions occur when incoming neutrons transfer their kinetic energy to a host lattice atom. If the energy transferred by the neutron in this collision is greater than the displacement threshold energy, E_{th}, of the lattice atom, then the atom will be ejected from its lattice site. This initial ejected atom is called the primary knock-on atom (PKA). This process leads to the production of a vacancy and a self-interstitial atom (SIA) within the host lattice. Upon ejection from its lattice site, if the PKA still carries greater kinetic energy than E_{th}, it will lead to the ejection of a secondary knock-on atom and so on. This successive chain of elastic collisions and scattering is referred to as cascade damage and has been studied extensively both experimentally and computationally. Inelastic interactions occur under high-energy irradiation conditions leading to (n, He) and (n, p) transmutation reactions within the host lattice. These interactions lead to the production of significant quantities of solute gas atoms within the bulk, namely, helium and hydrogen. Helium is highly insoluble in metals and therefore highly mobile inside matrix materials.

The physics of point defects has been a topic of numerous studies within the field of radiation damage for some time. It is well known that both vacancies and self-interstitial atoms (SIAs) agglomerate into clusters of various sizes. Vacancies combine to form three-dimensional (3-D) voids in the vicinity of the primary damage site, while SIAs typically combine to form 2-D glissile or sessile dislocation

loops on the periphery. Studies have shown that glissile loops are highly mobile and perform 1-D random motion in their slip direction. The production of Frenkel pairs and resulting clusters are known to lead to hardening, swelling, and creep phenomena in irradiated metals. In irradiated materials, point defects and small defect clusters are produced by collision cascades initiated by primary knock-on atoms (PKAs). Following this event, point defects agglomerate, and their rates of agglomeration are determined by fundamental energies of migration, formation, and binding. In this chapter, a systematic presentation of the rate theory of atomic clustering, is given proceeding from the general framework of cluster dynamics to the specific methods of solutions under a variety of approximations.

2   Theory of Cluster Dynamics

Let $C(n, t)$ represent the number of clusters of size n that exist in the system at time t per unit volume. Generally, n can be a composition of various species, such as vacancies and helium atoms with a bubble or several species that cluster together in a precipitate. Let's assume first that n is for one single species (e.g., vacancies forming a void). We will now develop *master equation* to determine $C(n, t)$. A master equation is a set of first-order differential equations describing the time evolution of the probability of a system to occupy each one of a discrete set of states. In the context of atomic clustering, if the total number of atoms is fixed, the probability of finding a defect cluster containing n atoms is proportional to its volumetric concentration.

   We would like to know how many of the clusters will change size so that they will move into the size range ω. Let $W(n; n', \Delta t)$ be the probability that a cluster of size n' will grow to be size n in the time interval between t and $t + \Delta t$. The number of clusters per unit volume growing into the interval ω can be called N^+ and is defined as follows:

$$N^+ = \int_\omega dn \int_\Omega C(n', t)W(n; n', \Delta t)dn' \tag{1}$$

The number of clusters leaving the size interval ω is N^- and is given by:

$$N^- = \int_\omega C(n, t)dn \int_\Omega W(n'; n, \Delta t)dn' \tag{2}$$

In the limit $\Delta t \to 0$, we have $W(n'; n, \Delta t) \to R(n'|n)\Delta t$, and $W(n; n', \Delta t) \to R(n|n')\Delta t$. The net rate of change in the concentration of clusters is thus:

$$\lim_{\Delta t \to 0} \frac{N^+ - N^-}{\Delta t} = \omega \frac{\partial C}{\partial t} = \int_\omega dn \int C(n', t)R(n|n')dn' - \int_\omega dnC(n, t) \int R(n'|n)dn' \tag{3}$$

In the limit of $\omega \to 0$

$$\frac{\partial C(n, t)}{\partial t} = \int_1^\infty [C(n', t) R(n|n') - C(n, t) R(n'|n)] dn' \qquad (4)$$

Equation 4 is the basis for all efforts to find the concentration of defects in irradiated materials and is now commonly known as *cluster dynamics*. In other literature, this is also known as the Smoluchowski-Chapman-Kolmogorov equation (SCK) in probability theory. In its raw form given by Eq. 4, the cluster dynamics equation is not solvable! The reason is that we need to determine transition rates between clusters of arbitrary size, containing possibly several atomic species and existing in widely separated spatial locations within a structure. The number of combinations involved would be overwhelming and would result in an astronomical number of coupled rate equations. For these practical reasons, a variety of approximations have been developed over the years to cast simplified and computable forms of Eq. 4 with varying degrees of approximations. We outline some of the key developments below.

3 Nucleation Theory

3.1 Classical Theory

We will now turn our attention to the specific application of the SCK equation to the nucleation of atomic clusters in a general environment, for example, agglomeration in the gas, liquid, or solid state of small atomic clusters (Katz and Wiedersich 1971; Russell 1971). To this end, we follow a development of *classical nucleation theory*. The basic assumptions of this theory are (1) atomic clusters originate when two atoms come together. (2) These clusters are in equilibrium with the surroundings and can grow or shrink by the addition or removal of single atoms. (3) Most clusters will break up into single atoms, but there is a finite probability that a cluster will grow large enough (i.e., to the *critical size*) that the number of atoms that leave the cluster will just equal those that come to it. (4) If the cluster grows larger than this critical size, it will not shrink but will grow to a macroscopic size. We would expect that the probability of an atom leaving the cluster to decrease, as the cluster grows bigger. Qualitatively this can be seen from considerations of the surface curvature. As the cluster grows, the curvature of the surface will decrease resulting in an increase in the number of nearest neighbors for each surface atom. The more nearest neighbor bonds that have to be broken to free the particle, the less likely it is to break away. This is the origin of the *Gibbs-Thompson effect*. At a point in the growth, the probability that an atom will hit the cluster will just be equal to the probability that one will break away. Once the cluster has grown larger than this size, there will only be a small probability that it will decrease in size, since fewer atoms will leave the cluster than will hit it.

3.1.1   The Becker-Döring Formulation

Richard Becker and Werner Döring constructed a widely used theory of nucleation in the context of ferromagnetism (Becker and Döring 2013). This formulation, now known as classical nucleation theory, has been widely applied in many fields (Ball et al. 1986). In this theory, the transition probabilities (i.e., the Rs) can be calculated in terms of two parameters – the *impingement frequency* β and the *evaporation frequency* α. The transition probability $R(n + 1|n) = \beta A'(n)$ where $A'(n)$ is the area of space around the cluster which will hold an impinging monomer. Similarly, $R(n - 1|n) = \alpha A'(n - 1)$. We can now write for the transition probabilities in the clustering dynamics Eq. 4 as:

$$R(n'|n) = \quad \beta A'(n)\delta(n' - (n + 1)) + \alpha A'(n - 1)\delta(n' - (n - 1))$$
$$R(n|n') = \quad \beta A'(n')\delta(n - (n' + 1)) + \alpha A'(n' - 1)\delta(n - (n' - 1))$$
$$(5)$$

where δ is the Dirac delta function, and we only consider first-order growth (or shrinkage) terms. Substituting these probabilities into Eq. 4, and utilizing the sifting property of the Dirac delta function, results in:

$$\frac{\partial C}{\partial t} = \beta A'(n-1)C(n-1, t) + \alpha A'(n)C(n+1, t) - \beta A'(n)C(n, t) - \alpha A'(n-1)C(n, t)$$
$$(6)$$

This procedure is called *detailed balancing*. At equilibrium, $\frac{\partial C}{\partial t} = 0$ and C can be called the *constrained distribution function*, $C_\circ$. Thus, at equilibrium, we would have:

$$\beta A'(n-1)C_\circ(n-1) + \alpha A'(n)C_\circ(n+1) = \beta A'(n)C_\circ(n) + \alpha A'(n-1)C_\circ(n) \quad (7)$$

If there is no steady growth of clusters through the size classes (i.e., for steady-state conditions), the Eq. (7) can be made more restrictive and would have the form:

$$\beta A'(n - 1)C_\circ(n - 1) = \alpha A'(n - 1)C_\circ(n) \quad (8)$$

or, $\alpha = \beta \frac{C_\circ(n-1)}{C_\circ(n)}$. It should be noted that by using an equilibrium condition, α has been determined by invoking the principle of thermodynamic reversibility. This principle requires that, at equilibrium, every microscopic process takes place at the same rate as its reverse. While α has been found for an equilibrium condition, it is assumed to have the same value under non-equilibrium conditions. Substituting for α in the rate equation (Eq. (6)), we obtain:

$$\frac{\partial C}{\partial t} = \beta A'(n)C_\circ(n)\left[\frac{C(n + 1, t)}{C_\circ(n + 1)} - \frac{C(n, t)}{C_\circ(n)}\right]$$
$$- \beta A'(n - 1)C_\circ(n - 1)\left[\frac{C(n, t)}{C_\circ(n)} - \frac{C(n - 1, t)}{C_\circ(n - 1)}\right] \quad (9)$$

The above equation is a difference-differential equation for nucleation. This equation can be greatly simplified if we assume that $C/C_\circ$ and $DC_\circ$, defined below, vary slowly with n and if we disregard terms of higher than second order. To proceed, we define:

$$D(n) \equiv \beta A'(n) \simeq \beta A(n) \tag{10}$$

Now, expand in a Taylor series about n the following functions (note that the time dependence is implied): $\frac{C(n+1)}{C_\circ(n+1)}$; $\frac{C(n-1)}{C_\circ(n-1)}$; and $D(n-1)C_\circ(n-1)$. Let's perform the first expansion, and one can easily do the other two in a similar fashion.

$$\frac{C(n+1)}{C_\circ(n+1)} = \frac{C(n)}{C_\circ(n)} + \left[\frac{\partial \frac{C(n+1)}{C_\circ(n+1)}}{\partial n}\right]_{n+1=n} (n+1-n) + \frac{1}{2}\left[\frac{\partial^2 \frac{C(n+1)}{C_\circ(n+1)}}{\partial n^2}\right]_{n+1=n} (n+1-n)^2$$

Substituting these expansions into the difference-differential equation yields:

$$\frac{\partial C}{\partial t} = \frac{\partial}{\partial n}\left[D(n)C_\circ(n)\frac{\partial(\frac{C(n)}{C_\circ(n)})}{\partial n}\right] \tag{11}$$

The above is known as the *isothermal nucleation equation* and has the form of Fick's second law of diffusion in a force field with a variable diffusion coefficient. This observation is consistent with the view that nucleation is a random-walk process through cluster size space. We can now rewrite the nucleation equation as an equation of continuity in *size space*, as follows:

$$\frac{\partial C}{\partial t} + \frac{\partial J(n)}{\partial n} = 0 \tag{12}$$

if we let $J(n) = -DC_\circ \frac{\partial}{\partial n}(C/C_\circ)$, where $J(n)$ is then the cluster current in size space, which is the net number of clusters growing from size n to $n+1$ per unit time, the "nucleation current $J(n)$ can also be written as:

$$J(n) = -D\frac{\partial C}{\partial n} + uC \tag{13}$$

$$= (\text{random walk term}) + (\text{drift velocity, } u, \text{ term})$$

with the "velocity" u given by: $u = D\frac{1}{C_\circ}\frac{\partial C_\circ}{\partial n} = D\frac{\partial}{\partial n}\ln C_\circ$ In principle, we can generalize the above procedure to derive a governing equation for the nucleation of atomic clusters, which contain atomic species α, β, γ, etc., as a continuity equation in an n-dimensional size space, given by:

$$\frac{\partial C(\mathbf{n}, t)}{\partial t} + \nabla \cdot \mathbf{J}(\mathbf{n}) = 0 \tag{14}$$

where $\mathbf{J}$ is the generalized cluster flux in size space, as a function of the vector $\mathbf{n} = \{x_1, x_2, \ldots\}$, which is composed of x_1 of the α-species, x_2 of the β-species, etc.

3.1.2   The Steady State

We now consider the possibility that a steady current of clusters exists without any change in C (i.e., $\partial C/\partial t = 0$). In order to produce such a situation, we must continuously supply monomers to keep $C(1)$ constant and remove all the clusters equal to or larger than a certain size, $\hat{n}$, so that size will not go to infinity (Becker and Doring 1935). Using the equation for the nucleation rate, we have:

$$J_S = -DC_\circ \frac{\partial}{\partial n}(C_S/C_\circ) \tag{15}$$

where the subscript S indicates steady state. Also, from the steady-state model, we can write:

$$(C_S/C_\circ)_{n=1} = 1 \quad \text{and} \quad (C_S/C_\circ)_{n=\hat{n}} = 0 \tag{16}$$

Integrating Eq. (15) for J_S yields: $\int\limits_{n=1}^{n=\hat{n}} -\frac{J_S}{DC_\circ} dn = \int\limits_{1}^{\hat{n}} d\frac{C_S}{C_\circ} = -1$. Or, the steady-state nucleation current is simply given by:

$$J_S = \left[\int\limits_{1}^{\hat{n}} \frac{dn}{DC_\circ} \right]^{-1} \tag{17}$$

In general, we can show that the steady-state *constrained* distribution function is given by:

$$C_\circ(n) = C(1) \exp[-\Delta G(n)/kT] \tag{18}$$

where $C(1)$ is the number of monomers and $\Delta G(n)$ is the free energy to form an atomic cluster of size n. $C_\circ$ has a sharp minimum when ΔG is maximized or when the cluster reaches its *critical size*, $n = n_C$. Thus, we can set $D = D_C$ and approximate $C_\circ$ by expanding $\Delta G(n)$ about the critical size n_C to the second order to get:

$$J_S = D_C C_\circ(n_C) \left[\left(\frac{1}{2\pi k_B T} \right) \frac{\partial^2 \Delta G(n_C)}{\partial n^2} \right]^{1/2} = D_C C_\circ(n_c) \mathcal{Z} \tag{19}$$

where

$$\mathcal{Z} = \left[\left(\frac{1}{2\pi k_B T} \right) \frac{\partial^2 \Delta G(n_C)}{\partial n^2} \right]^{1/2} = \left[\frac{-1}{2\pi} \left(\frac{\partial^2 \ln C_\circ(n_C)}{\partial n^2} \right) \right]^{1/2} \qquad (20)$$

$\mathcal{Z}$ is generally called the *Zeldovich factor* (Zeldovich 1943).

3.1.3   Time Lag

We have not yet made any statements about the speed with which the process of nucleation takes place. In order to make such estimates, we must examine the variation of C and $C_\circ$ with cluster size and introduce a new concept, a critical region of size Δ. The region around $n_C \, \partial C_\circ / \partial n$ will be very small and that J will be dependent mostly upon the random walk term. The first problem is to determine a reasonable width, Δ, for this region, i.e., how far can we go from n_C in cluster size before the increasing drift term begins to have a dominant effect on the direction of cluster growth. A reasonable estimate for Δ can be made by reexamining the nucleation equation as follows:

$$\frac{\partial C}{\partial t} = \frac{\partial}{\partial n} \left[D C_\circ \frac{\partial C / C_\circ}{\partial n} \right] = \frac{\partial}{\partial n} \left[D \frac{\partial C}{\partial n} - D \frac{C}{C_\circ} \frac{\partial C_\circ}{\partial n} \right] \qquad (21)$$

In the vicinity of n_C, we have $\frac{\partial C_\circ}{\partial n} \cong \left. \frac{\partial C_\circ}{\partial n} \right|_{n_C} + (n - n_C) \frac{\partial}{\partial n} \left. \frac{\partial C_\circ}{\partial n} \right|_{n_C}$, $C_\circ = C(1) \exp [-\Delta G / k_B T]$, and $\ln C_\circ = \ln C(1) - \Delta G / k_B T$. Therefore, $k_B T \frac{\partial^2 \ln C_\circ}{\partial n^2} = -\frac{\partial^2 \Delta G}{\partial n^2}$. However, $\frac{\partial^2 \ln C_\circ}{\partial n^2} = -\frac{1}{C_\circ^2} \left(\frac{\partial C_\circ}{\partial n} \right)^2 + \frac{1}{C_\circ} \left(\frac{\partial^2 C_\circ}{\partial n^2} \right)$. And at $n = n_C$, we have: $\frac{\partial^2 C_\circ}{\partial n^2} = C_\circ \frac{\partial^2 \ln C_\circ}{\partial n^2}$. Thus, $\frac{\partial C_\circ}{\partial n} = (n - n_C) 2\pi \mathcal{Z}^2 C_\circ$ If we set $D = D_C$, the nucleation equation becomes:

$$\frac{\partial C}{\partial t} = D_C \frac{\partial^2 C}{\partial x^2} - u \frac{\partial C}{\partial x}. \qquad (22)$$

where $u = 2\pi D_C \mathcal{Z}^2 x$ and $x = n - n_C$. The nucleation Eq. 22 can now be used to see how the random walk and drift terms interact. Consider what happens to a group of clusters placed at size $n_C + \Delta / 2$. From diffusion theory, the random walk term will cause a spread of clusters in the form of a Gaussian distribution. The drift term, on the other hand, will have the effect of moving the whole distribution to higher value of x. We can see these movements quantitatively if we assume that u is $\approx$ constant and solve the nucleation equation for C.

$$C = \frac{1}{\sqrt{4\pi D_C t}} \exp \left[\frac{-(x - ut - \Delta / 2)^2}{4 D_C t} \right] \qquad (23)$$

A measure of the amount of spread of the clusters is given by the root mean square deviation of x, i.e., $d = (\overline{x^2} - \overline{x}^2)^{1/2} = \sqrt{2D_C t}$, where $\overline{x^2} = \int_{-\infty}^{+\infty} x^2 C(x,t) dx$ to express this quantitatively let $u \cong \pi D_C \mathcal{Z}^2 \Delta =$ constant. Then if we have the correct $\Delta/2$; $\Delta/2 > \sqrt{2D_C t} - ut$. Since $\sqrt{2D_C t} - ut$ will have a maximum at $t = \tau_{\Delta/2}$:

$$\frac{d}{dt}(\sqrt{2D_C t} - ut)\bigg|_{t=\tau_{\Delta/2}} = 0 \qquad \text{or} \qquad \tau_{\Delta/2} = D_c/2u^2 \qquad (24)$$

$\tau_{\Delta/2}$ is thus the time at which the maximum number of clusters have crossed n_C. The inequality then becomes:

$$\frac{\Delta}{2} > \frac{D_C}{u} - \frac{D_C}{2u} = \frac{D_C}{(2\pi D_C \mathcal{Z}^2 \Delta)} \qquad (25)$$

$$\frac{\Delta}{2} > \frac{1}{2\mathcal{Z}\sqrt{\pi}} \qquad (26)$$

The same procedure could be used to find $n_C - \Delta/2$. Thus we may define the critical region as being of width Δ and centered on n_C. Those clusters which are smaller than $n_C - \Delta/2$ will be affected mostly by the drift term and dissolve. Likewise, those clusters larger than $n_C + \Delta/2$ will tend to grow, and those between $n_C - \Delta/2$ and $n_C + \Delta/2$ will tend to be governed by random walk. For completeness, we should mention the usual approach to defining Δ. Consider $\Delta G(n)$ as given in the equation for $C_\circ(n)$, i.e.:

$$C_\circ(n) = C(1) \exp[-\Delta G(n)/k_B T] \qquad (27)$$

The dependence of $\Delta G(n)$ on n is schematically shown in Fig. 1. If a cluster reaches a size which has an energy closer than $k_B T$ to $\Delta G(n_C)$, then there is a good probability that it will move over the free energy *hill*. Thus, we define Δ by the following equation:

$$\Delta G(n_C + \Delta/2) - \Delta G(n_C) = k_B T \qquad (28)$$

Expanding $\Delta G(n_C + \Delta/2)$ about n_C, we get:

$$\Delta G(n_C + \frac{\Delta}{2}) - \Delta G(n_C) = \frac{\Delta}{2} \frac{\partial \Delta G(n_C)}{\partial n}\bigg|_{n_C} + \frac{\Delta^2}{8} \frac{\partial^2 \Delta G(n_C)}{\partial n^2}\bigg|_{n_C} \qquad (29)$$

or $\Delta/2 = \frac{1}{2\mathcal{Z}\sqrt{\pi}}$. This value of Δ is very close to the one we found before. The advantage of the previous treatment was that we obtained a value for the time, $\tau_{\Delta/2}$, which we cannot get from the last procedure. We can now postulate that $C_S/C_\circ$ is approximated by:

$$C_S/C_\circ = \qquad 1 \qquad \text{when} \qquad n < (n_C - \Delta/2)$$

$$C_S/C_\circ = \qquad 0 \qquad \text{when} \qquad n > (n_C + \Delta/2) \qquad (30)$$
$$\frac{\partial}{\partial n}(C_S/C_\circ) = \quad -\frac{1}{\Delta} \quad \text{when} \qquad (n_C - \Delta/2) < n < (n_C + \Delta/2)$$

Thus using the steady-state equation we get:

$$J_S = -D_C C_\circ(n_C)(-\frac{1}{\Delta}) = D_C C_\circ(n_C)/\Delta \qquad (31)$$

If we then accept as a reasonable value of Δ, $\Delta = 1/\mathscr{Z}$, we get the same result for J_S as we had for the Zeldovich treatment (Eq. 19). We have not directly examined the length of time that would exist between a rapid change in supersaturation and the appearance of visible clusters, but we have all of the information that we need to calculate this delay time. It can be divided into three parts: (1) The time τ_N to nucleate to a size $n_C - \Delta/2$, (2) the time τ_Δ to grow from $(n_C - \Delta/2)$ to $(n_C + \Delta/2)$, and (3) the time τ_G to grow from $(n_C + \Delta/2)$ to visible size. The times τ_N and τ_G will be related to the drift velocity which we have already derived, and the time τ_Δ will be related to $\tau_{\Delta/2}$. Examining τ_Δ first, we remember that $\tau_{\Delta/2}$ was the time for 16% of the clusters to grow from $(n_C + \Delta/2)$ to less than n_C. No more than this number would ever be smaller than n_C because of the effect of the drift velocity to larger sizes.

By symmetry, we see that the same arguments could be applied to clusters growing from $(n_C - \Delta/2)$ to n_C. Therefore, if a particular cluster grows from $(n_C - \Delta/2)$ to n_C, and then on to $(n_C + \Delta/2)$, the total time for this growth will be $2\tau_{\Delta/2}$. Note we have used here the principle of time reversibility, i.e., if a cluster shrinks from $(n_C + \Delta/2)$ to n_C in time $\tau_{\Delta/2}$; the reverse process will take the same amount of time. In summary, we have $\tau_\Delta = D_C/u^2 = \frac{1}{\pi D_C \mathscr{Z}^2}$. We can proceed to find τ_N from the drift velocity, u. By definition, $u(n) = dn/dt$. Therefore, we

have $\int\limits_{0}^{\tau_N} dt = \int\limits_{1}^{(n_C-\Delta/2)} \frac{dn}{-u(n)}$. Here, we use the growth velocity $-u$ or alternatively reverse the time axis and consider the time to dissolve a cluster of size $(n_C - \Delta/2)$. In the same manner, we can calculate $\tau_G = \int\limits_{n_C+\Delta/2}^{n_V} dn/u(n)$. From these times, we can also estimate the time τ_S to reach a steady-state distribution of clusters (of sizes up to $n_C + \Delta/2$). Thus, $\tau_S = \tau_G + \tau_\Delta$.

3.2 Extension to Radiation Damage

Interest in the application of classical nucleation theory to radiation damage grew rapidly in the early 1970s. The first such undertakings were accomplished by Katz and Wiedersich (1971) and Russell (1980) in 1971. These studies extended the classical theory to materials in an irradiation field. This development required consideration of two species (vacancies and interstitials) that are continuously produced as voids nucleate. We start by writing and expression for the Gibb's free energy (GFE) of a system containing a concentration distribution, $N^{eq}(m)$, of clusters of sizes m, can be expressed as

$$G = G_0 + \sum_m N^{eq}(m)g_m - kT \sum_m \ln W_m, \qquad (32)$$

where G_0 is the free energy of the perfect lattice, g_m is the GFE required to form a void of size m, and the last term is the absolute temperature multiplied by the configurational entropy. We note that g_m is typically estimated as the void formation energy (E_m^f) under the assumption of negligible volume and entropy changes in the formation process. Also, W_m represents the number of possible ways in which a void of size m can be distributed in the lattice, which can be shown to be

$$W_m = \frac{m^{N^{eq}(m)}(\frac{1}{m\Omega})!}{[(\frac{1}{m\Omega} - N^{eq}(m)]![N^{eq}(m)]!}. \qquad (33)$$

The chemical potential of a void of size m, volume $m\Omega$, where Ω is the atomic volume, can be defined as the partial derivative of G with respect to the equilibrium concentration of size m voids, or:

$$\mu_m = \frac{\partial G}{\partial N^{eq}(m)} = E_m^f + kT \ln\left[\Omega N^{eq}(m)\right]. \qquad (34)$$

The chemical potential of a single vacancy can therefore be taken as $\mu_v = E_v^f + kT \ln[\Omega C_v]$, where the vacancy formation energy can be substituted from the equilibrium vacancy concentration, given as $C_v^{eq} = \Omega^{-1} \exp\left(-\frac{E_v^f}{kT}\right)$. The vacancy chemical potential can therefore be expressed as:

$$\mu_v = kT \ln \left[\frac{1}{\Omega C_v^{eq}} \right] + kT \ln [\Omega C_v] = kT \ln S_v. \tag{35}$$

where $S_v = C_v/C_v^{eq}$ is the vacancy supersaturation in the lattice. For the vacancies and voids to be in chemical equilibrium, the chemical potential of voids of size m must be equal to m times the chemical potential of an individual vacancy. Therefore, the equilibrium void distribution function can be solved for from (34) and (35) as:

$$N^{eq}(m) = \Omega^{-1} \exp(m \ln S_v - \frac{E_m^f}{kT}). \tag{36}$$

Under non-equilibrium conditions, we can define the nucleation current (in the phase space of cluster size) as the rate at which clusters of size m grow to $m + 1$. This can be expressed as:

$$I = \beta_v(m)N(m) - \alpha_v(m+1)N(m+1) - \beta_i(m+1)N(m+1). \tag{37}$$

Here, the emission of interstitials as a void growth process is neglected due to the large formation energy of interstitials. By the condition of thermodynamic reversibility, the rate of capture of vacancies to clusters of size m should equal the rate of emission of vacancies of clusters of size $m + 1$, and therefore α_v can be solved for, with $C_0(m)$ replaced with $N^{eq}(m)$. Plugging this back into Eq. 37, we obtain:

$$I = -\beta_v(m)h(m) \left[\frac{N(m+1)}{h(m+1)} - \frac{N(m)}{h(m)} \right], \tag{38}$$

where the function $h(m)$ is defined in:

$$\frac{h(m)}{h(m+1)} = \frac{N^{eq}(m)}{N^{eq}(m+1)} + \frac{\beta_i}{\beta_v}. \tag{39}$$

The ratio of impingement frequencies β_i/β_v is referred to as the arrival-rate ratio and plays a large role in determining the critical void size, m_c, which occurs at the minimum of $h(m)$. Approximating the difference in the brackets of (38) as the differential $d(N/h)/dm$, the resulting differential equation can be solved under the boundary conditions that $N/h \to 1$ and 0 as m goes to 1 and ∞, respectively. The nucleation current can then be calculated as:

$$I = \left[\frac{1}{2\pi} \left(\frac{d^2 \ln h}{dm^2} \right)_{m_c} \right]^{1/2} \beta_v(m_c)h(m_c). \tag{40}$$

where the first term on the right-hand side is called the Zeldovich factor and corrects for the fact a fraction of clusters which have grown past the critical size will still shrink to smaller sizes.

The extension of the theory to include the effects of gas atoms resulting from transmutation reactions was also accomplished by Wiedersich et al. (1974) and Russell (1978). The derivation of these heterogeneous nucleation models follows the same structure as the preceding model, under the assumption that gas atoms are static nucleation sites for voids. The number of clusters with j gas atoms per unit volume is taken as M_j, making the total concentration of gas atoms, M, equal to $\sum\limits_{j=1} jM_j$. The Gibb's free energy expression takes the modified form:

$$G = G_0 + \sum_j \sum_m \left[N_j^{eq}(m) g_{mj} - kT \sum_m \ln W_{mj} \right], \tag{41}$$

where N_j^{eq} is the equilibrium distribution of gas-vacancy clusters per unit volume containing m vacancies and j gas atoms. The configurational term can be calculated as:

$$W_{mj} = \frac{M_j!}{[M_j - N_j^{eq}(m)]![N_j^{eq}(m)]!}. \tag{42}$$

The presence of gas atoms in voids leads to an internal pressure that aids in stabilizing voids against dissociation. This has the effect of leading to smaller values of the critical size, as the pressure reduces the effect of surface tension against collapse. Thus, the reversible work of formation g_{mj} will contain a positive contribution due to surface tension and a negative contribution due to the gas pressure. Assuming the gas atoms in the matrix are at an effective pressure p^{eq}, corresponding to the temperature and their concentration, the reversible work of adding gas atoms to a cluster at pressure p is $jkT \ln(p^{eq}/p)$. Assuming the ideal gas law holds, the pressure can be determined from $pV = jkT$, where $V = m\Omega$. Estimates for p^{eq} can be obtained from statistical mechanics models. The reversible work of cluster formation can then be expressed as $g_{mj} = 4\pi R^2 \gamma - jkT \ln\left(\frac{p_{eq}}{p}\right)$, where γ is the surface energy and the cluster radius R can be taken as $(3m\Omega/4\pi)^{1/3}$. For chemical equilibrium to be satisfied, the condition $m\mu_v = \mu_{mj}$ must be satisfied, where the chemical potential of gas-filled clusters is:

$$\mu_{mj} = \frac{\partial G}{\partial N_j^{eq}(m)} = g_{mj} + kT \ln\left[\frac{N_j^{eq}(m)}{M_j} \right]. \tag{43}$$

Using Eq. (35) and assuming chemical equilibrium, the equilibrium distribution of gas atoms in voids can be solved for as:

$$N_j^{eq}(m) = M_j \exp(m\ln S_v - \xi m^{2/3} + j\ln(p^{eq}/p)). \tag{44}$$

where $\xi = (4\pi/kT)(3\Omega/4\pi)^{2/3}\gamma$. The exponential term represents the free energy of cluster formation. Whereas in the homogeneous void nucleation case, this was a function of m alone, this term represents an energy surface dependent on both m and j. Solution of the nucleation current I_j follows (40), with the critical cluster size now a function of j. Following a similar procedure as the homogeneous case, it can be expressed as:

$$I_j = \left[\frac{1}{2\pi}\left(\frac{d^2 \ln h_j}{dm^2}\right)_{m_{cj}}\right]^{1/2} \beta_v(m_{cj})h_j(m_{cj}). \tag{45}$$

where the function h_j is defined in (39) with j subscripts added to $h(m)$ and $N^{eq}(m)$.

4   Mean-Field Theory of Void Growth

The aim of the previous treatment of defect cluster nucleation is to predict the *nucleation rate* of voids or bubbles of a critical size but does not attempt to follow the size distribution to the growth regime. The basic assumption of void growth theory is that a discrete array of point defect sinks can be approximated by a continuous distribution of an absorbing medium into which an *average* void or bubble is placed. This is the key idea of the "mean-field approximation," which we will follow here (Brailsford and Bullough 1972).

In this approach, all sinks are homogenized in an effective medium (that includes, voids, precipitates, bubbles, dislocations, grain boundaries, etc.). The absolute loss rate of interstitials and vacancies within this effective medium is written as $(D_i c_i k_i^2)$ and $(D_v c_v k_v^2)$, respectively, where the D's are diffusion coefficients and the C's are fractional concentrations. The quantities (k_i^{-1}) and (k_v^{-1}) are the mean fee path distance an interstitial or vacancy moves in the medium before getting absorbed. The objective of the theory is to determine the sink strengths (the k's) for each type of sink independently and then add those together is an effective loss rate. Each considered sink is surrounded by a region free of sinks and then enclosed within an effective medium, and a boundary value problem is solved. We follow this approach for a single void of a mean size, but the method has been generalized for all other sinks (see Brailsford and Bullough 1972 for details).

The neutral void sink is assumed to be a small sphere of radius r_{s1} at the center of a larger spherical region of radius R_1 that is free of all other sinks. Voids do not have a preferential attraction toward interstitials over vacancies (unlike dislocations), and hence we will assume that the fractional concentration of each is c. If the defect generation rate is K (displacements per atom per second), then the steady-state concentration c of defects in the sink free region is:

$$\frac{D}{r^2}\frac{d}{dr}\left(r^2\frac{dc}{dr}\right) + K = 0, \quad r_{s1} \leq r \leq R_1 \tag{46}$$

with the boundary condition: $D\frac{dc}{dr} = \bar{K}(c - \bar{c}_1)$ at $r = r_{s1}$. $\bar{K}$ is the transfer velocity across the matrix-void interface. Since K is the jump rate into the sink per available site, the jump rate out (i.e., thermal emission) is $\bar{K}\bar{c}_1$, where $\bar{c}_1 = c^e \exp(F_1\Omega/kT)$. c^e is the thermal equilibrium concentration of defects, and $F_1\Omega$ is the change in energy of the void (volume V and surface area A), and Ω is the atomic volume. $F_1 = \pm\partial(V\delta P + \gamma A)/\partial V = \pm(\delta P + 2\gamma/r_{s1})$. where γ is the surface tension and δP is the excess internal pressure in the void due to any enclosed gas. The $\pm$ sign relates to interstitial and vacancy emission, respectively. At $r = R_1$, the concentration c and its first derivative are continuous with the steady-state concentration in the medium ($r > R_1$). If we assume that n type of sinks simultaneously exist, then $k^2 = k_1^2 + k_2^2 + k_3^2 + \ldots = k_1^2 + k_n^2$, where Dck_1^2 is the loss rate of point defects due to voids. Far away from the void, and neglecting point defect recombination, Eq. 46 now takes the form:

$$\frac{D}{r^2}\frac{d}{dr}\left(r^2\frac{dc}{dr}\right) + K' - DCk^2 = 0, \quad r \geq R_1. \tag{47}$$

The effective defect generation rate in the medium, K_1, is the increased rate due to emission from the neutral sinks, and K_n is the additional increase due to emission from the other $(n-1)$ sink types. Thus, $K' = K + K_1 + K_n$. The solution to Eq. 46 in the boundary layer and Eq. 47 in the lossy medium outside the region R for a dilute sink concentration (i.e., neglecting (r_{s1}/R) compared to unity) is given by (Brailsford and Bullough 1972):

$$c = \mu - \lambda\left(\frac{r_{s1}}{r}\right) - \frac{Kr^2}{6D}, \quad r_{s1} \leq r \leq R_1 \tag{48}$$

$$c = \frac{K'}{Dk^2} + \frac{AR_1}{r}\exp[-k(r - R_1)], \quad r \geq R_1 \tag{49}$$

where μ, A, and λ are given by:

$$\mu = \frac{KR_1^2(3 + kR_1)}{6(1 + kR_1)D} + \frac{K'}{Dk^2}, \quad A = \frac{KR^2}{3D}, \tag{50}$$

$$\lambda = \left[\left(\frac{K'}{Dk^2} - \bar{c}_1\right) + \frac{KR_1^2}{6D}\frac{(3 + kR_1)}{(1 + kR_1)}\right] \tag{51}$$

If C_s is the average concentration of neutral sinks (e.g., voids) in the medium, the flux of point defects can be calculated and from which the "sink strength" of neutral sinks is obtained. The sink strength k_1^2 and the thermal emission rate K_1 from neutral sinks are given by (Brailsford and Bullough 1972):

$$k_1^2 = 4\pi r_{s1}C_{s1}; \quad K_1 = 4\pi r_{s1}C_{s1}D\bar{c}_1. \tag{52}$$

Following similar treatments, the sink strengths of other types of microstructures (e.g., dislocations and precipitates) have been derived for both vacancies and for interstitials. Dislocations are found to attract more interstitials than vacancies, hence creating an imbalance in point defect flows to other features, notably voids. The sinks strengths are shown to be (Brailsford and Bullough 1972):

$$k_i^2 = Z_i \rho_d + 4\pi r_s C_s + Y_i 4\pi r_p C_p \tag{53}$$

$$k_v^2 = Z_v \rho_d + 4\pi r_s C_s + Y_v 4\pi r_p C_p \tag{54}$$

where r_s is the radius of neutral sinks at a concentration of C_s and r_p is the radius of the coherent sinks (precipitates) at a concentration of C_p, and $Y_v = 1$, $Y_i = 1 + (Z_i - Z_v)\rho_d/(Z_v\rho_d + 4\pi r_s C_s)$, $Z_v = 1$, and $1.02 \le Z_i \le 1.08$. The effective defect generation rate from all sinks (K') is obtained by summing all thermal emission terms, thus $K_i' - K = 0$ and $K_v' - K = D_v \left[Z_v\{\rho_d^L \bar{c}_{vl} + \rho_d^N c_v^e\} + 4\pi r_s C_s \bar{c}_{vs} \right]$. The superscripts L and N are for irradiation-induced dislocation loops and network, respectively. Incorporating mutual recombination between vacancies and interstitials with the rate constant α, the steady-state point defect concentrations in the medium (average or mean-field) are given by:

$$K - D_i c_i k_i^2 - \alpha c_i c_v = 0 \tag{55}$$

$$K - D_v c_v k_v^2 - \alpha c_i c_v = 0 \tag{56}$$

Solution of these two equations leads to:

$$c_i = (D_v k_v^2/2\alpha)[-1(1 + \mu) + \{(1 + \mu)^2 + \eta\}^{\frac{1}{2}}], \tag{57}$$

$$c_v = (D_i k_i^2/2\alpha)[-1(1 - \mu) + \{(1 + \mu)^2 + \eta\}^{\frac{1}{2}}] \tag{58}$$

where $\eta = 4\alpha K / D_i D_v k_i^2 k_v^2$ and $\mu = (K' - K)\eta/4K$.

Now, one calculates the excess accumulation rate of vacancies at neutral sinks (voids), which would be given by $\{D_v c_v - D_i c_i - D_v \bar{c}_{vs}\}4\pi r_s C_s$. This is also the volume swelling rate, $\frac{d}{dt}\frac{\Delta V}{V}$. After some algebra, we find $\frac{d}{dt}(\frac{\Delta V}{V}) = \left[\frac{d}{dt}(\frac{\Delta V}{V})\right]_0 F(\eta)$, where:

$$\left[\frac{d}{dt}(\frac{\Delta V}{V})\right]_0 = K(Z_i - Z_v)\rho_d 4\pi r_s C_s (Z_v\rho_d + 4\pi r_s C_s)^{-1/2}$$

$$\times \left\{ Z_i\rho_d + 4\pi r_s C_s + 4\pi r_p C_p \left[1 + \frac{(Z_i - Z_v)\rho_d}{Z_v\rho_d + 4\pi r_s C_s} \right] \right\}^{-1} \tag{59}$$

is the volume swelling rate in the absence of recombination and thermal emission:

$$F(\eta) = (2/\eta)[-(1 + \mu) + \{(1 + \mu)^2 + \eta\}^{1/2} - \zeta\eta], \tag{60}$$
Fig. 2 Variation of the function F with temperature for 316 stainless steel parameters: $C_p = 0$, $\rho_d^L = 10^{-2} \rho_d = 10^9$ cm^{-2}, $Z_i = 1.01$, $Z_v = 1.0$, $4\pi r_s C_s = 10^{11}$ cm^{-2}, $\alpha/D_i = 10^{17}$ cm^{-2}, $D_v = 0.6 \exp(-1.4\,eV/kT)$ cm^{-2} sec^{-1}. (Figure from Brailsford and Bullough 1972)

and

$$\zeta(T) = \frac{D_v(Z_v\rho_d + 4\pi r_s C_s)\{Z_i\rho_d + 4\pi(r_s C_s + r_p C_p)\}}{2K(Z_i - Z_v)\rho_d\{Z_v\rho_d + 4\pi(r_s C_s + r_p C_p)\}} \tag{61}$$

Equation 4 is further approximated with a simple linear time dependence for $[\frac{\Delta V}{V}]_0$, such that:

$$\left(\frac{\Delta V}{V}\right)_0 \approx \frac{K(t - t_0)(Z_i - Z_v)\rho_d 4\pi r_s C_s}{(\rho_d + 4\pi r_s C_s)(\rho_d + 4\pi r_s C_s + 4\pi r_p C_p)} \tag{62}$$

where Kt_0 is an incubation dose (1–10 displacements per atom (dpa)), and is obtained from experiments, and Kt is the current dose in dpa. The main role that the function $F(\eta)$ plays is the temperature dependence of swelling. Calculations of the temperature dependence of the function $F(\eta)$ at two different dose rates are displayed in Fig. 2, taken from reference (Brailsford and Bullough 1972).

5   Coupled Nucleation-Growth Rate Theory

Classical nucleation theory tends to be inadequate for modeling cluster growth because of its high sensitivity to physical parameters, which are typically not known to a high degree of accuracy. This aspect renders it virtually non-predictive. In addition, the theory calculates nucleation rates but does not predict defect cluster density nor size as function of irradiation dose. On the other hand, the mean-field void growth theory presented above assumes that defect clusters (e.g., voids,

bubbles, and dislocation loops) have already nucleated and that their concentrations are constant, independent of dose and spatial location within the material. To remedy these deficiencies and at the same time have a tractable system of cluster dynamics equations, Ghoniem et al. (1985) developed a minimal set of cluster dynamics equations, where assumptions can be made about nucleation of bubbles under high rates of gas production due to nuclear reactions. In this method, a list of coupled rate equations for the concentrations of species is developed. Each equation represents a mass balance equation for a particular defect cluster species as the sum of all production and loss rates of the species to be equal to its concentration rate of change. Under the mean-field approximation, where statistical variations in time and space are averaged, these equations are only time-dependent. The general structure of the cluster dynamics equations reads:

$$\partial_t C_{ij} + \nabla \cdot \mathbf{J}_{ij} = S_{ij} - L_{ij} \tag{63}$$

The volumetric concentration of a cluster containing i Frenkel pairs (negative i for interstitials, and positive i for vacancies) and j helium atoms is C_{ij}; its flux $\mathbf{J}_{ij}$ is composed of two terms: a diffusive flux $-D_{ij}\nabla C_{ij}$ and a convective flux $\mathbf{V}_{ij}C_{ij}$, where the velocity $\mathbf{V}_{ij}$ is proportional to a configurational force $\mathbf{F}_{ij} = -\nabla E_{ij}$ where E_{ij} is an elastic interaction energy and the proportionality parameter (mobility) is $M_{ij} = \frac{D_{ij}}{kT}$. The source and loss terms S_{ij} and L_{ij} can include the processes of absorption, coalescence, and emission. The system of clustering equations represented by Eq. 63 is very generic and cannot be solved without specific details. In practice, however, self-interstitial atom clusters (SIAs) do not associate with helium atoms (energetically unfavorable), and thus negative values of i result in separate equations for SIAs. For positive values of i (i.e., vacancies), they agglomerate with helium atoms j to produce helium-filled bubbles. The practical combination of i and j is determined by the nucleation condition for a stable bubble nucleus, which can be quite large if there is not enough gas atoms to stabilize bubbles. However, when the gas generation rate is high (as in fusion energy neutron spectrum), a critical stable bubble nucleus can have only 1 vacancy and 2–3 helium gas atoms bound to it. Divacancies may likewise bind several gas atoms to form stable bubble nuclei. Because the concentration of single vacancies is always much higher than that of di- or tri-vacancies, an assumption can be made that the bubble nucleus size contains only 1 vacancy and 2–3 gas atoms. Once a critical bubble is formed, the *mean-field* or average bubble can be described by a growth equation similar to our previous discussion of void growth, and there would not be need to determine the concentrations of various size helium-vacancy clusters within the spirit of this description.

Following Ghoniem et al. (1985), rate equations for the concentrations of vacancies ($C_{10} = C_v$), self-interstitials ($C_{\bar{1}0} = C_i$), helium interstitials ($C_{01} = C_g$), helium substitutional atoms ($C_{11} = C_g v$), di-helium interstitials ($C_{02} = C_{2g}$), di-helium mono-vacancy ($C_{12} = C_{2g}v$), the critical nucleus (C^*), the bubble density (C_b), the number of helium atoms in a bubble (m), and the average bubble radius (R) can be expressed as rate equations. Cluster mobility is a very strong

function of its size, and as such only single vacancies, interstitials, and helium gas atoms are assumed to be mobile. The *reduced* set of rate equations derived by Ghoniem et al. (1985) are:

$$\frac{\partial C_v}{\partial t} = D_v \nabla^2 C_v + fG + (\beta e_1 + \delta)C_{gv} - \left[\alpha C_i + \beta C_g + \gamma \left(C_s^v + C_{gv} + 2C_{2g} \right. \right.$$
$$\left. \left. + 2C_{2gv} + 3C^* \right) \right] C_v$$

$$\frac{\partial C_i}{\partial t} = D_i \nabla^2 C_i + fG - \alpha C_i \left(C_v + C_{gv} + 2C_{2gv} + 3C^* + C_s^i \right)$$

$$\frac{\partial C_g}{\partial t} = D_g \nabla^2 C_g + G_{He} + \beta \left(e_1 C_{gv} + e_2 C_{2gv} + 2e_5 C_{2g} \right) + \delta \left(C_{gv} + 2C_{2gv} \right.$$
$$+ 2(2C_{2g}) + 3C^* + m_1 C_b \right)$$
$$+ \alpha C_i \left(C_{gv} + 3C^* \right) - \beta C_g \left(C_v + 4C_g + C_{gv} + 2C_{2gv} \right.$$
$$+ 2C_{2g} + 3C^* + \epsilon C_b \right)$$

$$\frac{\partial C_{gv}}{\partial t} = \beta e_2 C_{2gv} + 2\delta C_{2gv} + \beta C_g C_v + 2\gamma C_v C_{2gv} - C_{gv}(\beta e_1 + \delta + \gamma C_v$$
$$+ \alpha C_i + \beta C_v)$$

$$\frac{\partial C_{2gv}}{\partial t} = 3\delta C^* + \beta C_g C_{gv} + 2\gamma C_v C_{2g} - C_{2gv}(\beta e_2 + 2\delta + 2\beta C_v + 2\alpha C_i + 2\gamma C_v)$$

$$\frac{\partial C_{2g}}{\partial t} = 2\alpha C_i C_{2gv} + 2\beta C_g^2 - C_{2g}(\beta e_5 + 2\delta + 2\gamma C_v + 2\beta C_g)$$

$$\frac{\partial C^*}{\partial t} = 2\beta C_g \left(C_{2gv} + C_{2g} \right) - 3C^* \left(\delta + \alpha C_i + \beta C_g + \gamma C_v \right)$$

$$\frac{\partial C_b}{\partial t} = \frac{4}{m} \left(3\beta C_g C^* \right) + \frac{3}{m} \left(3\gamma C_v C^* \right)$$

$$\frac{\partial m}{\partial t} = \epsilon \beta C_g - \delta m$$

$$\frac{\partial R}{\partial t} = \frac{1}{R} \left(\frac{a_0^2}{48} \right) (\gamma C_v - \alpha C_i - \gamma (e_3 - e_4))$$

$$(64)$$

A constraint on the solution of the reduced set of rate equations above is that the total helium gas concentration must be conserved. Therefore, the total volumetric concentration of helium gas, M should be equal to that produced by irradiation $G_{He} \times t$, that is, $M = G_{He} \times t = (C_g + C_{gv} + 2C_{2gv} + 3C^* + mC_b)$.

Accurate numerical solution of the reduced mean-field rate equations should satisfy this constraint at all times. In solving this system of equations, other microstructure features (e.g., network dislocations, grain boundaries, and precipitates) are assumed to be distributed, and their interaction rates with point defect and helium-vacancy clusters is taken from the mean-field approximation

of rate theory. Expressions for the concentration of helium atoms at precipitates (M_{ppt}) and grain boundaries (M_{GB}) are given as:

$$dM_{ppt}/dt = \varepsilon_{ppt}\beta C_{ppt}C_g - \delta M_{ppt}, \quad dM_{GB}/dt = \beta C_{GB}C_g - \delta M_{GB}.$$

The reaction frequencies of self-interstitials (α), helium (β), and vacancies (γ) and the thermal emission probabilities of vacancies (e_1, e_2) in the above equations are given as $\alpha = 48\nu_i \exp(-E_i^m/kT)$, $\beta = 48\nu_g \exp(-E_g^m/kT)$, $\gamma = 48\nu_v \exp(-E_v^m/kT)$, $e_1 = \exp(-E_{v,g}^b/kT)$, $e_2 = \exp(-E_{v,2g}^b/kT)$, and $\delta = bG$, where the factor of 48 is the assumed combinatorial number, ν is the atomic jump frequency, and E^m and E^b represent migration and binding energies, respectively.

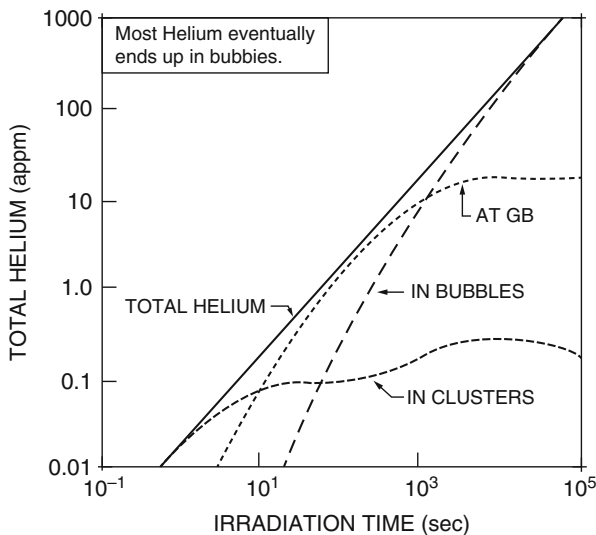
The factor δ is called the re-solution frequency and represents the probability per displacement for dissolving a helium atom back into the matrix (b) times the displacement damage rate (G). Descriptions of the remaining symbols are given in the following nomenclature. The fraction of surviving Frenkel pairs per displacement is f, the displacement damage rate G, the helium production rate G_H, the equivalent matrix-distributed sink density for interstitials C_s^i, the equivalent matrix-distributed sink density for vacancies C_s^v, the equivalent grain boundary sink concentration C_{GB}, the precipitate cavity combinatorial number ε_{ppt}, the equivalent precipitate sink concentration C_{ppt}, and the average number of helium atoms per cavity m. More details of numerical calculations are found in reference Ghoniem et al. (1985). Figure 3 shows the distribution of helium in clusters, bubbles, and grain


Fig. 3 Distribution of helium gas in the matrix among microstructure features. The irradiation conditions are for 316 stainless steel at 625 °C at a dose rate of 3×10^{-3} dpa/s and a helium/dpa ratio of 5 appm He/dpa (Ghoniem et al. 1985)

boundaries as a function of time. Since the helium injection rate is constant, the total amount of helium is linear in time. During early irradiation times (<0.01 dpa), most of injected helium resides in small helium-vacancy clusters. These are converted to bubbles at a higher dose. The largest proportion of helium ends up in matrix bubbles at doses greater than about 10 dpa. It is observed that during the early stages of irradiation, helium is contained in small clusters. Later, a large proportion goes to grain boundaries.

6 Defect Cluster Size Distribution

Beyond the mean-field theory of nucleation and growth, additional information on defect cluster size or spatial distributions may be necessary. Several approaches to determine the size distribution of SIA (Ghoniem 1989; Kiritani 1973; Hayns 1976) and gas-filled bubbles (Ghoniem and Sharafat 1980; Golubov et al. 2001) have been developed. These approaches are all attempts to develop numerical solutions of the SCK cluster dynamics Eq. 4. We follow here an approach that emphasizes the observation that transitions in cluster size are more often small, either by absorption/emission of single defects or by small size fluctuations resulting from nearby collision cascades. Under these assumptions, the SCK Eq. 4 is approximated as a continuous Fokker-Planck (FP) equation that can be solved numerically. We follow the work of Ghoniem and Sharafat (1980) here.

Let the concentration of clusters containing h helium atoms and u vacancies at time t is given by $C(h, v, t)dhdv = C_{tot}(t)P(h, v, t)dhdv$, where $P(h, v, t)dhdv$ is the probability of finding a cluster in the size interval ($h, u \rightarrow h + dh, v + dv$). The time evolution of the probability function in terms of all possible transitions in the helium-vacancy phase space is given by writing Eq. 4 as:

$$\partial_t P = \sum_k W\{[(h - \Delta h_k), (v - \Delta v_k)] \rightarrow (h, v)\}P[(h - \Delta h_k), (v - \Delta v_k), t]$$

$$= \sum_k W\{(h, v) \rightarrow [(h + \Delta h_k), (v + \Delta v_k)]\}P(h, v, t) \qquad (65)$$

Here Δh_k and Δv_k are fluctuations in the helium and vacancy contents, respectively, which are caused by a stochastic process, k. The transition probability, W, and the cluster probability density, P, can both be expanded around the point (h, v), similar to the procedure that we developed in Sect. 3 to obtain the 2D FP equation given by:

$$\partial_t P + \nabla \cdot (\boldsymbol{F} - \boldsymbol{D} \cdot \nabla)P = 0 \qquad (66)$$

where $\boldsymbol{F}$ and $\boldsymbol{D}$ are drift vector and diffusion coefficient tensor (in size space), respectively. The components of $\boldsymbol{F}$ and $\boldsymbol{D}$ represent first and second moments of the transition probability, respectively, and are given by (Ghoniem and Sharafat 1980).

$$\boldsymbol{F} = \begin{bmatrix} a_{1h} \\ a_{1v} \end{bmatrix}, \quad \text{and} \quad \boldsymbol{D} = \begin{bmatrix} a_{2hv} & a_{2hh} \\ a_{2vv} & a_{2vh} \end{bmatrix} \qquad (67)$$

It is noted, however, that while cascade-induced fluctuations do not influence the magnitudes of the first moments (a_{1h}, a_{1v}), they increase the magnitudes of the second moments (a_{2hh}, a_{2vv}). Numerical solution of Eq. 66 on an infinite quarter phase plane is given in Ghoniem and Sharafat (1980), where a two-moment solution is presented for the specific case that size transitions are only single-step (i.e., no large fluctuations due to cascades). Under these conditions, the rates of helium (k^{gc}), vacancy (k^{vc}) and interstitial (k^{ic}) capture, helium replacement (k^{gr}), and vacancy emission (k^{ve}) can be used to compute the elements of $\boldsymbol{F}$ and $\boldsymbol{D}$. These are given by:

$$a_{1h} = k^{gc} - (k^{ge} + k^{gr}), \tag{68}$$

$$a_{1v} = k^{vc} - (k^{ic+ve} + k^{gr}), \tag{69}$$

$$a_{2hh} = \frac{1}{2}[k^{ge} + k^{gr} + k^{ge}], \tag{70}$$

$$a_{2vv} = \frac{1}{2}[k^{ic+ve} + k^{gr} + k^{vc}], \tag{71}$$

$$a_{2hv} = a_{2vh} = k^{gr} \tag{72}$$

A numerical solution to the FP equation, Eq. 66, has been developed by Ghoniem and Sharafat (1980). Denoting the cluster size by the vector $\boldsymbol{x}$, such that $\boldsymbol{X} = h\boldsymbol{i} + v\boldsymbol{j}$, where $\boldsymbol{i}$ and $\boldsymbol{j}$ are unit vectors along the h and v directions in cluster size space. Taking the first moment of Eq. 66, we obtain $d < \boldsymbol{X} > /dt = < F(\boldsymbol{X}) >$, where the right-hand side represents the drift vector averaged over the probability distribution function. The symbol $< \quad >$ is used to denote this average. This equation is not a closed because we do not know the probability distribution function P a priori. However, to lowest order, one can approximate this equation as:

$$\frac{d < \boldsymbol{X} >}{dt} = F(< \boldsymbol{X} >) \tag{73}$$

The integration of Eq. 73 gives the trajectory of the average cluster in the growth regime of the flow field in vacancy-helium size space. Let us define the variance matrix by (Ghoniem 1989):

$$< \delta X_i \delta X_j > = < X_i X_j > - < X_i >< X_j >, \quad i, j = h, v. \tag{74}$$

Kinetic equations for the variance matrix have been developed in reference Ghoniem (1989) and are given by:

$$\frac{d < \delta X_i \delta X_j >}{dt} = < a_{1j} X_i > - < X_i >< a_{1j} > + < a_{1i} X_j >$$
$$- < X_j >< a_{1i} > + < a_{2,ij} > . \tag{75}$$

Equation 75 is again not closed, and expansions of the parameters around their values at the average trajectory, (x) would result in an open-ended set of moment equations. Although it is possible to develop coupled equations for higher order moments (see Ghoniem 1989), it is sufficient here to develop a lowest order expansion of Eq. 75:

$$\frac{d < \delta X_i \delta X_j >}{dt} \approx a_{2,ij}(< \boldsymbol{X} >). \tag{76}$$

Equation 76 is the lowest order evolution equation for the variance matrix. The second moments of the transition probabilities, $a_{2,ij}$, are the components of the diffusion tensor (68) and are to be evaluated at the average trajectory, $< \boldsymbol{X} >$. We can reconstruct the probability distribution function from its zeroth, first, and second moments. The simplest reconstruction procedure can be based on Gaussian functions, i.e.:

$$P(h, v, t) \approx \left(\delta X_h \delta X_v \sqrt{2\pi} \right)^{-1} \exp\left(-y^2/2 \right),$$

$$\text{where} \quad y = \left[\left(\frac{h - < h >}{\delta X_h} \right)^2 + \left(\frac{v - < v >}{\delta X_v} \right)^2 \right]^{\frac{1}{2}} \tag{77}$$

This FP formulation permits study of the effects of simultaneous helium generation and cascade-induced point defect fluctuations on cavity evolution. This is certainly useful for extrapolating existing radiation damage data to anticipated fusion conditions where the primary differences in damage parameters are the helium generation rate and the cascade size. Cascade effects on the cavity size distribution are included through the second moments of the transition probabilities in the Fokker-Planck equation. Cascades induce fluctuations in point defect concentrations. Since the RMS value of fluctuations depends on the cascade size, we must determine a spectrally averaged value for the variances δX_v, and δX_h,.

The FP model has been applied to the study of interstitial loop size distribution in irradiated materials and has been compared directly to experiments. Figure 4 shows the evolution of the interstitial loop size distribution at various irradiation doses (a) and the effects of stochastic cascade fluctuations on the size distribution in (b). It is clear that collision cascades have a dramatic effect on the broadening of the size distribution as compared to single-step events by point defect absorption/emission.

7   Instabilities and Pattern Formation

Experimental observations have demonstrated the existence of fully or partially ordered (patterned) void, bubble, and dislocation loop microstructure in irradiated materials. These experimental observations are particularly striking for the spatial ordering of bubble and void microstructure in irradiated materials (Sass and Eyre
Fig. 4 (**a**) Evolution of the interstitial loop size distribution for single-step point defect absorption/emission. (**b**) Influence of collision cascades on the spread of the size distribution and comparison with the experiments of Hall and Potter (1979)

1973; Johnson et al. 1983; Evans 1971; Mazey and Evans 1986; Kulcinski and Brimhall 1973; Wiffen 1972). An important characteristic of void and bubble lattices is their spatial orientation along crystallographic directions, at least for the three main crystal structures (FCC, BCC, and HCP). Concepts on the behavior of dynamical system have been successfully applied to the problem of microstructure evolution in irradiated materials. Self-organization of irradiated microstructures can thus be viewed as one of the few examples where patterning can be directly linked to the collective dynamical behavior of defects. The void lattice parameter is typically about two orders of magnitude larger than the atomic lattice parameter and about

four times larger than the void diameter in fully developed void superlattices. The void lattice parameter has been reported to initially decrease with increasing dose as the superlattice is being formed (Loomis et al. 1977) and then attains a constant value once the superlattice is fully developed (Evans 1979; Arsenault 1973; Loomis et al. 1977).

Murphy described the coupled evolution of point defects and vacancy loops in the framework of a one-dimensional rate theory dynamical model (Murphy 1987). In this description, point defects are the only mobile species, which diffuse in space. They may annihilate by recombination or through absorption by network dislocations and vacancy loops, which are immobile and are supposed to be created instantaneously by cascade effects.

$$\partial_t c_i = K - \alpha c_i c_v + D_i \partial_x^2 c_i - D_i c_i (Z_{iN} \rho_N + Z_{iV} \rho_V)$$

$$\partial_t c_v = K(1 - \epsilon) - \alpha c_i c_v + D_v \partial_x^2 c_v$$
$$- D_v (Z_{vN}(c_v - \bar{c}_{vN})\rho_N + Z_{vV}(c_v - \bar{c}_{vV})\rho_V)$$

$$\partial_t \rho_V = \frac{1}{|\vec{b}| r_V^0}[\epsilon K - \rho_V (D_i Z_{iV} c_i - D_v Z_{vV}(c_v - \bar{c}_{vV}))] \tag{78}$$

where K is the displacement damage rate of point defects, ϵ the cascade collapse efficiency, responsible for the trapping of part of the vacancies in dislocation loops. ρ_N is the line density of network dislocations, and ρ_V is the line density of vacancy loops, given by $\rho_V = 2\pi r_V N_V$, where r_V and N_V are the mean radius and number density of loops, respectively. The mean loop radius is approximately constant and equal to $r_V^0/2$, where r_V^0 is the initial loop radius. b is the Burgers vector and $Z_{vr} \simeq 1$ and $Z_{ir} \simeq 1 + B$. Furthermore, the network dislocation density is assumed to be uniform and constant in time.

The system (78) admits uniform steady-state solutions c_i^0, c_v^0 and ρ_V^0. Their linear stability analysis has been performed on defining the spatial fluctuations of defect densities through $c_r(x, t) = c_r^0(1 + \bar{c}_r(x, t))$ and $\rho_V(x, t) = \rho_V^0(1 + \bar{\rho}_V(x, t))$ (Murphy 1987). The linear evolution matrix for a Fourier mode of wavenumber k of these fluctuations is given by:

$$\mathbf{M} = \begin{pmatrix} -\bar{K}/c_v^0 - k^2 D_v & -\alpha c_i^0 & -D_v Z_{vV}(c_v^0 - \bar{c}_{vV})\rho_V^0/c_v^0 \\ -\alpha c_v^0 & -K/c_i^0 - k^2 D_i & -D_i Z_{iV} rho_V^0 \\ \dfrac{D_v Z_{vV} c_v^0}{|\vec{b}| r_V^0} & -\dfrac{D_i Z_{iV} c_i^0}{|\vec{b}| r_V^0} & -\dfrac{\epsilon K}{|\vec{b}| r_V^0 \rho_V^0} \end{pmatrix} \tag{79}$$

where $\bar{K} = K(1 - \epsilon) + D_v(Z_{vN} \rho_N \bar{c}_{vN} + Z_{ivV} \rho_V^0 \bar{c}_{vV})$.

If at least one eigenvalue of this matrix has positive real part at finite k, the corresponding eigenmode will grow and destabilize uniform solutions by giving rise to spatial oscillations. The determination of the eigenvalues of this matrix implies the resolution of a cubic characteristic equation. However, since the response of vacancy and interstitial densities to small perturbations are much more rapid

than the response of vacancy loop densities, this characteristic equation may be reduced to a linear one giving the linear growth rate of linear perturbations. This linear growth rate has been computed numerically (Murphy 1987) for parameter values corresponding to 316 stainless steel (Foreman and Makin 1979). It has been found positive for wavelengths in the micron range and network dislocation densities lower than some critical value. An interesting aspect of this analysis is also the temperature dependence of the wavelength of the fastest growing perturbations. For network dislocation densities in the range 10^{12}–$10^{13} \mathrm{m}^{-2}$, this wavelength is slightly increasing with temperature for temperatures less than 500 °C and strongly increasing for temperatures larger than 500 °C, in agreement with experimental results obtained in similar materials (Murphy 1987). It may also be shown that the wavelength decreases with increasing displacement rate. Similar calculations have also been made for neutron-irradiated copper at 250 °C, where, for a network dislocation density of $10^{11} \mathrm{m}^{-2}$, instability was found for a wavelength of approximately 3.4 μm, in agreement with experimental observations (Muncie et al. 1985). Hence, it has been shown here that rate theory is able to predict an instability in the dislocation structure of irradiated materials.

8   Conclusions

Classical nucleation theory has provided easy concepts for understanding the clustering physics of point defects in irradiated materials. However, even with extensions to describe point defect supersaturation and the presence of helium gas in under irradiation, it is not adequately predictive. A more phenomenological treatment of void growth using a mean-field approximation has resulted in qualitative comparisons with many experiments, although such an approach is also limited in its fundamental reach. Coupling nucleation and growth in one single model has also been successful in overcoming the traditional limitations of separate nucleation and growth theories. However, the approach relies on specific assumptions on the critical nucleus size of a bubble being small enough that tractable computations can be performed. Cavity evolution under conditions of cascade damage and high helium generation, which are typical of fusion reactor conditions, is shown to be a continuous process which cannot be easily separated into the classical nucleation and growth regimes. It is also emphasized that the rate of helium transport, which is described as an effective helium mobility, has a strong dependence on bubble evolution. The long transient, associated with high helium mobility, is a result of the concentration buildup of small bubbles clusters which act as the primary traps for migrating helium. However, the quasi-steady-state mobility can be understood in terms of three simple mechanisms: radiation displacement at low temperatures, interstitial replacement at intermediate temperatures, and thermal desorption at high temperatures. The displacement of helium by cascades from bubbles results in significant effects on cavity evolution. First, this displacement process provides for an internal source of helium production which, in turn, causes continuous cavity nucleation. Second, the resulting fine distribution of helium nuclei in the

matrix is associated with slower growth rates for helium-filled cavities. Finally, the stochastic framework represented by Fokker-Planck theory is shown to be a convenient approach to the analysis of interstitial loop and bubble evolution under neutron and ion irradiation conditions.

Abstract

Neutron irradiation can severely impact the mechanical behavior of nuclear structural materials. Irradiation introduces a high density of nanometric defects that block dislocation motion and result in hardening and a loss of ductility often associated with the onset of localized plastic flow in a highly heterogeneous manner. In our hierarchy of numerical methods used to understand and quantify mechanical property degradation under irradiation, discrete dislocation dynamics (DD) provides a window into the time and length scales where critical interactions between dislocations and defects occur. In the present chapter, we discuss the current state of the art of DD simulations applied to irradiation scenarios, introducing the theoretical models devised to deal with dislocation-defect interactions, crystal structure particularities, and the most salient aspects of several highlighted applications. We also discuss current limitations and what new understanding has been gained vis-a-vis serviceable nuclear materials using these techniques.

1   Introduction

Irradiation hardening is a complex phenomenon involving the interplay between a material's microstructure and irradiation-generated defects, and its effects on mechanical behavior. This complexity is generally owed to the existence of nontrivial dependencies between the mechanical response of a material and a relatively large number of internal (temperature, chemical composition, internal microstructure, etc.) and external (dose rate, dose, external stress, etc.) variables, which are often correlated with one another. The reader is referred to reviews of the evolution in our understanding of radiation damage processes and mechanical properties that exist on the topic for more details (Matzke 1992; Sickafus et al. 1999; Odette and Lucas 2001; Ackland 2010).

Before the advent of large-scale simulations and high-performance computing, the prevalent thinking in irradiation hardening of materials was dominated by two main models. The first one is commonly known as the *dispersed barrier hardening* (DBH) model, originally proposed by Seeger in the 1950s (Seeger 1958). The main idea behind the DBH model is that dislocation loops and vacancy clusters produced directly within displacement cascades act as barriers to gliding dislocations, resulting in hardening (defect production in the cascade region is also the main premise behind other irradiation damage theories such as the *production bias model* and swelling). Seeger's approach is substantially equivalent to the well-known Orowan mechanism for hardening due to precipitates and dispersed particles (Singh et al. 1997; Lambrecht et al. 2010) applied to irradiated materials. Consequently, the yield strength increase from irradiation is then determined from the bowing stress required to overcome the irradiation obstacles. The second model used to explain irradiation hardening is known as the *loop decoration hardening* model, which assumes the formation of defect "clouds" around the cores of ingrown

dislocations (i.e., dislocations present in the material before irradiation) (Blewitt et al. 1960). These dislocations cannot then act as dislocation sources until they can pull away or free themselves from the clouds of defects (Young 1962; Holmes 1964). In such way, the stress necessary to unlock these dislocations so that they can act as dislocation sources again is then likely to determine the yield strength of the irradiated crystals. This mechanism of radiation hardening is commonly known as "source" hardening and is conceptually equivalent to the formation of Cottrell atmospheres around dislocations by solute atoms during plastic flow (Cottrell and Bilby 1949).

With the emergence of large-scale molecular dynamics (MD) simulations, it was soon established that dense cascades in metals result in damage in the form of self-interstitial atom (SIA) clusters (Marian et al. 2003; Bacon et al. 2006; Terentyev et al. 2008, 2010) and various forms of vacancy-type clusters ranging – depending on the material and the cascade energy – from small nanovoids, stacking fault tetrahedra (SFT) (Wirth et al. 2002; Osetsky et al. 2005, 2006; Zinkle 2012), and vacancy loops (Diaz de La Rubia et al. 1989; Calder and Bacon 1993; Phythian et al. 1995). Moreover SIA clusters can evolve into dislocation loops displaying one-dimensional migration, while vacancy-type clusters typically display little or no mobility. Among others, these observations led to the adoption of the combined *dislocation* and *production* bias models as the most successful theories to explain irradiation damage accumulation that we have today (Woo and Goesele 1983; Woo and Singh 1990; Golubov et al. 2000). While information from MD cascade simulations has helped inform our understanding of irradiation hardening, it has not settled the question as to what is the prevalent mechanism behind yield strength increases. In addition, experimental observations have clearly established the existence of a sharp and prominent yield drop both in irradiated face- and body-centered cubic (FCC, BCC) metals, associated with the onset of plastic flow localization via narrow "defect-free" dislocation channels above a certain dose (cf. Sect. 4.2). These channels concentrate all deformation in a highly heterogeneous way leading to a plastic instability that is seen to severely compromise irradiated materials' ductility. This instability is also observed in polycrystalline metals and alloys in the form of the absence of work hardening. While some of these features are a priori incompatible with a DBH interpretation, irradiation can also result in sub-thermodynamic precipitation and/or the formation of gas bubbles, which are perfectly consistent with the DBH model.

In any case, irradiation hardening and flow localization are collective plastic phenomena that cannot be approached solely from an atomistic simulation point of view. Kinetic methods such as kinetic Monte Carlo (KMC) and cluster dynamics can push the time- and length-scale envelope beyond those attainable atomistically, although often at the expense of physical accuracy (see corresponding chapters on KMC and rate theory methods in this Volume. Ideally, the simulation tool of choice should capture long-range elastic interactions between dislocations and local (short-range) effects describing defect-dislocation interactions. Dislocation dynamics (DD) is such a technique, designed as an accurate method to calculate strain hardening and collective dislocation processes. From their original inception

in the late 1980s, the last two decades have seen tremendous improvements in the development of efficient DD algorithms applied to all kinds of different scenarios. Indeed, DD suggests itself as the ideal technique to study irradiation hardening, as it naturally captures both long- and short-range interactions mentioned above. The purpose of this chapter is to introduce the technique, discuss its theoretical underpinning, and review the most notable applications within the realm of irradiated materials.

Notwithstanding earlier advances in the development of closed-form expressions for the stress fields of arbitrary dislocation segments, the method of discrete dislocation dynamics was originally introduced in the late 1980s/early 1990s independently by researchers in France and the United States, first as a 2D method (Lépinoux and Kubin 1987; Ghoniem and Amodeo 1988; Gulluoglu et al. 1989), quickly followed by extensions to three dimensions (Amodeo and Ghoniem 1990; Kubin and Canova 1992; Kubin et al. 1992). The technique enjoyed early success fueled by a wide range of applications and improvements in computational power and was picked up by multiple groups worldwide who have used it and made notable contributions to our understanding of, among others, dislocation junction formation, strain hardening, plasticity in confined volumes, patterning, etc. For more information, the reader is referred to the chapter on dislocation dynamics simulations in the accompanying volume to this series on multiscale modeling of materials.

In terms of the use of DD for the simulation of irradiation hardening in materials, the early works started around the late 1990s and relied heavily on MD simulations of dislocation-obstacle interactions to provide the physical nexus between cascade defects and gliding dislocations. Therefore, the evolution of the DD technique as it relates to nuclear material applications is strongly linked to the availability of reliable descriptions of the interactions between dislocations and irradiation obstacles, which have been typically simulated atomistically. Currently, there are examples in the literature of simulations including point defects, dislocation loops, stacking fault tetrahedra, voids, precipitates, and grain boundaries, as well as demonstrations of the formation of defect-free channels following the hardening peak. This is the object of Sects. 3 and 4 in this chapter.

2 Brief Overview of DD Theory and Its Implementation

Discrete dislocation dynamics is a method intended for the study of the collective evolution of ensembles of crystal dislocations under applied loads. In DD, macroscopic system properties (e.g., stress-strain response) are computed directly from the evolution of the dislocation microstructure, therefore establishing a direct link between microstructure and properties. In contrast to atomistic methods where the degrees of freedom of the system are individual atomic positions, in DD, the degrees of freedom are the positions of line defects (dislocations) in three-dimensional space (two-dimensional implementations of DD are not considered in this chapter). The main objective of the DD method is to evolve the discrete dislocation configuration

in time. Typically it is assumed that dislocation motion is overdamped, so that it is possible to define the dislocation velocity of an elementary line segment as a function of local quantities such as stress σ and line orientation ξ and possibly other parameters like Burgers vector $\boldsymbol{b}$, slip plane normal $\boldsymbol{n}$, and temperature T:

$$\boldsymbol{v} = \hat{\boldsymbol{v}}(\sigma, \xi, \boldsymbol{b}, \boldsymbol{n}, T) . \tag{1}$$

The function $\hat{\boldsymbol{v}}$ is known as the *mobility law*. The stress field is composed of the stress field exerted by the dislocation network and either a uniform "external" stress associated with elastic deformation of the supercell in periodic simulations or the elastic "correction" field which accounts for mechanical boundary conditions in finite-volume simulations. In irradiated materials, irradiation-induced defects such as voids and precipitates may also contribute to the local stress field.

The dislocation stress is computed from the *static* elastic theory of dislocations; hence rendering DD is a quasistatic method, despite its name. The elastic fields engendered by a dislocation loop $\mathscr{L}$ can be derived in the infinitesimal-deformation eigendistortion theory of Mura (1987). For an infinite isotropic medium, the displacement and stress fields generated by the loop are, respectively,

$$\boldsymbol{u}^{\infty}(\boldsymbol{x}) = -\frac{\boldsymbol{b}\Omega}{4\pi} - \frac{1}{8\pi(1-v)} \oint_{\mathscr{L}} \frac{1}{R} \left\{ (1-2v)\,\boldsymbol{b} \times \hat{\boldsymbol{\xi}}' + \left[\hat{\boldsymbol{R}} \cdot \left(\boldsymbol{b} \times \hat{\boldsymbol{\xi}}' \right) \right] \hat{\boldsymbol{R}} \right\} d\ell' \tag{2}$$

$$\begin{aligned} \boldsymbol{\sigma}^{\infty}(\boldsymbol{x}) = {} & \frac{\mu}{4\pi(1-v)} \oint_{\mathscr{L}} \frac{1}{R^2} \left\{ (1-v) \left[\hat{\boldsymbol{\xi}}' \otimes (\boldsymbol{b} \times \hat{\boldsymbol{R}}) + (\boldsymbol{b} \times \hat{\boldsymbol{R}}) \otimes \hat{\boldsymbol{\xi}}' \right] \right. \\ & + \left[(\boldsymbol{\xi}' \times \boldsymbol{b}) \otimes \hat{\boldsymbol{R}} + \hat{\boldsymbol{R}} \otimes (\boldsymbol{\xi}' \times \boldsymbol{b}) \right] \\ & \left. + \hat{\boldsymbol{R}} \cdot (\boldsymbol{b} \times \hat{\boldsymbol{\xi}}') \left[3\hat{\boldsymbol{R}} \otimes \hat{\boldsymbol{R}} + \boldsymbol{I} \right] \right\} d\ell' . \end{aligned} \tag{3}$$

In Eqs. (2) and (3), $\boldsymbol{b}$ is the Burgers vector, μ is the shear modulus, and v the Poisson ratio. Moreover, $\boldsymbol{R} = \boldsymbol{x} - \boldsymbol{x}'$, $R = \|\boldsymbol{R}\|$, $\hat{\boldsymbol{R}} = \boldsymbol{R}/R$, and $\Omega = \int_{\mathscr{S}} R_j/R^3 \, dA'_j$ is the solid angle subtended by the loop. Note that these fields are singular when computed at any point of the dislocation line itself ($\boldsymbol{R} = 0$) and regularization methods are necessary (Cai et al. 2006; Po et al. 2014a, 2017).

The mobility law, Eq. (1), defines the velocity point-wise along a dislocation line. However, because the line is a flexible object with a potentially infinite number of degrees of freedom, the numerical solution of the loop evolution equation requires that a discretization procedure be introduced to reduce the number of degrees of freedom to a finite set. To this end, an arbitrary dislocation configuration is discretized in line elements having constant Burgers vector, called *segments*, connected at *nodes*. Conservation of the Burgers vector requires that the vectorial sum of the Burgers vector vanishes for each node. Different discretization methods and evolution strategies have been implemented, and we distinguish the following three methods.

1. *Segment-based DD*. In the segment-based implementation, the dislocation network is composed of piecewise linear segments. Within a certain glide plane, segment orientation varies discretely among a predetermined set, which includes edge, screw, and junction orientations (Devincre et al. 2011). This pre-defined set of segment orientations is used to tabulate and speed up the calculation of the stress field which each segment generates. For each segment, the sum of the external stress field and the stress field due to nearby segments is computed at one point along the segment, typically the midpoint. This midpoint stress is then used to compute the segment velocity based on material-specific mobility laws, which in general can be expressed as Eq. (1). The midpoint velocity is then used to advance the position of each segment, and finally nodes are reconnected taking advantage of the discrete set of segment orientations, as illustrated in Fig. 1a.

2. *Node-based DD*. The starting point of the nodal DD method (Weygand et al. 2002; Arsenlis et al. 2007) is the equation expressing the condition of force equilibrium for an elementary dislocation line. If we assume that the drag force exerted by the lattice is proportional to the velocity $\boldsymbol{v}$, then the condition of force equilibrium reads

$$\boldsymbol{B}(\boldsymbol{\xi}, \boldsymbol{n}, T)\boldsymbol{v} = \boldsymbol{\sigma b} \times \boldsymbol{\xi} \tag{4}$$

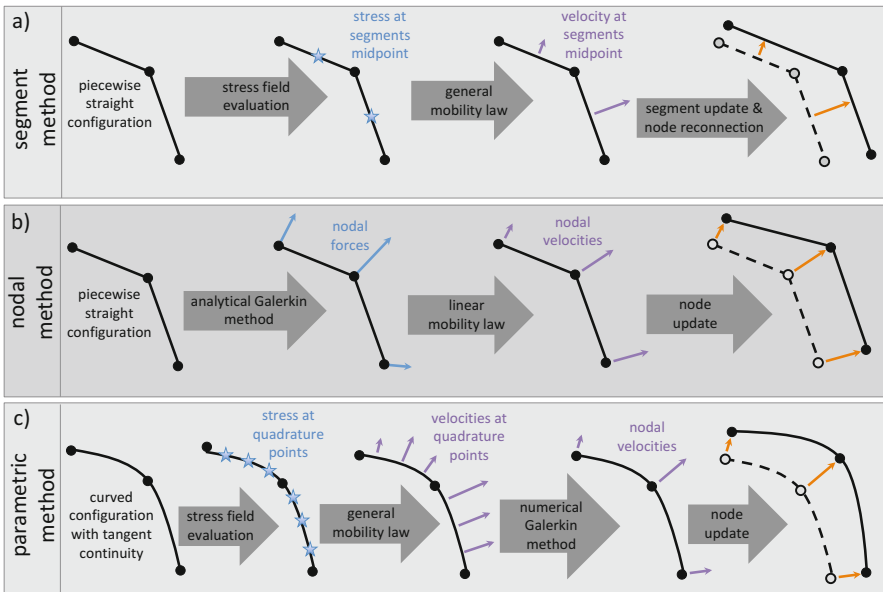
where $\boldsymbol{B}(\boldsymbol{\xi}, \boldsymbol{n}, T)$ is a drag coefficient possibly dependent on slip system, line orientation, and temperature and $\boldsymbol{f}^{PK} = \boldsymbol{\sigma b} \times \boldsymbol{\xi}$ is the mechanical force exerted by the stress field on the dislocation (Peach-Koehler force). Clearly the


Fig. 1 Comparison between (**a**) segment, (**b**) nodal, and (**c**) parametric DD methods

condition (4) can be regarded as a special case of the mobility law (1) if we take $\hat{\boldsymbol{v}}(\boldsymbol{\sigma}, \boldsymbol{\xi}, \boldsymbol{b}, \boldsymbol{n}, T) = \boldsymbol{B}^{-1}(\boldsymbol{\sigma}\boldsymbol{b} \times \boldsymbol{\xi})$. In order to solve (4) numerically, the dislocation network is discretized into piecewise straight segments with constant Burgers vector meeting at nodes. Equation (4) is then assembled as a discrete system of equations for the nodal velocities:

$$\mathbb{B}\boldsymbol{V} = \boldsymbol{F} \tag{5}$$

which can be solved via discrete numerical methods such as finite elements. The mobility matrix $\mathbb{B}$ is sometimes approximated by its diagonal in order to speed up the computation of the nodal velocities (Arsenlis et al. 2007). The nodal method is sketched in Fig. 1b.

3. *Parametric DD*. The parametric DD uses the Galerkin finite element method to obtain nodal velocities (Ghoniem et al. 2000; Po and Ghoniem 2014; Po et al. 2014b). In general, however, the weak form is constructed from the general mobility law (1) instead of the linear law (4). The parametric method allows for spline segments with tangent continuity across nodes, which in general require a smaller number of nodal degrees of freedom to approximate curved loops compared to linear segments. The use of nonlinear mobility laws is particularly important in BCC metals, where non-Schmid stress components influence the mobility of screw dislocations.

The above methods are discretization strategies suited to obtain time-marching schemes for the degrees of freedom describing the dislocation network configuration. In addition to the time-marching scheme, a typical DD timestep comprises several discrete events which are now briefly summarized.

- *Network re-discretization*. The length of individual dislocation segments may change drastically during the course of a simulation. Dedicated algorithms are therefore necessary to locally increase or decrease the network discretization by local addition or removal of nodes and segments.
- *Cross-slip*. Screw dislocation segments can change their glide plane by a mechanism called *cross-slip*. Cross-slip is one of the most important length multiplication and obstacle avoidance mechanisms available to gliding dislocations. In FCC metals, cross-slip may require recombination of the Shockley partial dislocations and is typically implemented as a thermally activated phenomenon (Kubin 2013).
- *Junction formation and breaking*. When pairs of attractive dislocation segments collide, it is numerically advantageous to replace the original segments with a new segment having Burgers vector equal to the vectorial sum of the original Burgers vectors. This operation requires the implementation of both efficient collision detection algorithms between segments and topological operations that change the connectivity of the network. Dislocation junctions are passively released by unzipping of the junction segments or actively by dedicated algorithms.

2.1   Considerations Related to Boundary Conditions

2.1.1   Using Periodic Boundary Conditions for Strain Hardening Simulations

From its original limitations as a 2D method or a 3D method consisting only of closed dislocation loops, DD has been successfully extended to study bulk representative volumes by the use of periodic boundary conditions (PBC) (Fivel and Canova 1999; Bulatov et al. 2000; Madec et al. 2004). Dislocation configurations compatible with the use of periodic boundary conditions must result in net zero integral over the primary box of the so-called dislocation density or Nye's tensor. Although dislocation structures that satisfy this condition are not unique, calculations have shown that the degree of arbitrariness introduced in periodic reconstructions is small for large-scale DD simulations (Bulatov et al. 2000). The general idea is to use closed loops or infinite dipoles that ensure the translational periodicity along each spatial dimension. Using PBC, however, introduces an artifact in the form of self-annihilation of dislocation lines. Nevertheless, by setting the values of the self-annihilation distances and ensuring that the resulting dislocation mean free path is physical, one can mitigate the implications of this effect (Madec et al. 2004), and indeed highly accurate DD simulations using PBC are now commonplace in the literature.

2.1.2   Coupling to Finite Elements for Simulations of Confined Volumes

The dislocation stress and displacement fields $\boldsymbol{u}^{\infty}(\boldsymbol{x})$ and $\boldsymbol{\sigma}^{\infty}(\boldsymbol{x})$ given in (2) and (3) are valid for an infinite medium. In the case of a finite domain $\mathscr{B}$, the state of internal stress driving dislocation motion is the superposition of the stress $\boldsymbol{\sigma}^{\infty}(\boldsymbol{x})$ and a "correction" stress $\boldsymbol{\sigma}^{c}(\boldsymbol{x})$ which results from the solution of an elastic boundary value problem (BVP) (Eshelby 1979; Van der Giessen and Needleman 1995; Deng et al. 2008; Weygand et al. 2002; Po et al. 2014b). The BVP solves for the displacement field $\boldsymbol{u}^{c}(\boldsymbol{x})$ which satisfies

$$\begin{cases} \sigma_{ij}^{c} = c_{ijkl}u_{k,l}^{c} & \text{in } \mathscr{B} \\ \sigma_{ij,j}^{c} = 0 & \text{in } \mathscr{B} \\ \sigma_{ij}^{c}\hat{n}_{j} = p_{i} - \sigma_{ij}^{\infty}\hat{n}_{j} & \text{on } \partial_{N}\mathscr{B} \\ u_{i}^{c} = \bar{u}_{i} - u_{i}^{\infty} & \text{on } \partial_{D}\mathscr{B} \end{cases} \tag{6}$$

In (6) $\partial_{N}\mathscr{B}$ is the portion of the boundary over which the external traction p_{i} is applied, while $\partial_{D}\mathscr{B}$ is the portion of the boundary over which a displacement boundary condition $\bar{u}$ is prescribed. Once the solution of this BVP is found, the displacement field and stress field in the crystal are computed as $u_{i} = u_{i}^{\infty} + u_{i}^{c}$ and $\sigma_{ij} = \sigma_{ij}^{\infty} + \sigma_{ij}^{c}$, respectively. The BVP (6) is typically implemented using the Galerkin FEM. It can be shown that the total solution is independent of virtual loops
Fig. 2 Construction used for the solution of the BVP (6). For each dislocation segment on the domain boundary, a loop with the same Burgers vector and opposite line direction is constructed outside the integration domain and encloses the virtual slip surface β^{P*}. One portion of the external loop coincides with the boundary segment, and the opposite side is pushed to infinity in the direction of the boundary normal

added outside the domain. This fact can be used to cancel the stress field of internal segments deposited on the boundary, at the cost of virtual segments extending away from the boundary, as sketched in Fig. 2.

2.1.3   Anisotropic Elasticity

The majority of DD implementations use the isotropic elasticity approximation, due to the considerable technical simplification it affords. Real materials, however, are generally anisotropic to some extent, and for some applications, this cannot be ignored. As well as leading to quantitative differences in mechanical response, large elastic anisotropy allows certain unique phenomena to emerge, in particular dislocation instabilities, leading to sharp corners on the dislocation network, and enhance dislocation multiplication due to weakened Frank-Read sources. For a comprehensive introduction to anisotropic elasticity, the reader is referred to Balluffi (2016) and Bacon et al. (1980), and for its implementation in DD simulations, see Bacon et al. (1980), Han et al. (2003), Rhee et al. (2001), Fitzgerald and Aubry (2010), Yin et al. (2012), and Aubry and Arsenlis (2013).

One of the most notable examples where elastic anisotropy effects are most important in the context of nuclear materials is the behavior of Fe alloys at high temperature. In prismatic loops generated under irradiation, the lowest-energy shape does not necessarily correspond to a circular loop. Figure 3 (top) shows the anisotropic elastic line tension, Γ, vs. orientation for two situations of interest: $\langle 111 \rangle$ loops at 400°C and $\langle 100 \rangle$ loops at 500°C in iron (Dudarev et al. 2008). Although far from the constant value isotropy predicts, Γ remains positive for the former case, and no sharp corners appear. A barely discernable flattening of the circle toward a hexagon is present. For the second case, Γ dips below zero, and

Fig. 3 Top: line tension vs. orientation for ⟨111⟩ loops at 400 °C and ⟨100⟩ loops at 500 °C. Bottom: TEM micrographs confirming the predicted loop shapes
corners emerge. TEM micrographs confirm the prediction. The anisotropic elastic calculation reproduces the hexagonal and square symmetries of the ⟨111⟩ and ⟨100⟩ orientations, respectively.

A special case worth mentioning is that of hexagonal close-packed (HCP) metals, where the absence of cubic symmetry calls for the consideration of elastic anisotropy as an intrinsic lattice feature. A number of DD implementations that capture this aspect of HCP plasticity have been proposed (Monnet et al. 2004; Drouet et al. 2014; Aubry et al. 2016), although the application of DD to irradiated hexagonal metals is much more scant (cf. Sect. 4.1.3).

The effects of elastic anisotropy can be striking and are non-negligible in many metals of interest to radiation materials science. In particular, α-Fe (and also ferritic steels) become highly anisotropic at high temperature. This leads to different types

of prismatic loops appearing and sharp corners emerging on dislocation networks. This in turn significantly reduces the stress required to operate certain orientations of Frank-Read sources, enabling the onset of plasticity at much lower applied stresses than the isotropic approximation would suggest (Fitzgerald 2010; Fitzgerald et al. 2012).

2.2   Direct Consideration of Dislocation Partials for DD Simulations of FCC Metals

The dissociation of perfect dislocations into partials is a principal feature of close-packed lattices such as FCC and HCP structures. The importance of this dissociation is typically predicated upon a single parameter, the stacking fault energy, which is known to control critical features of plastic deformation in FCC metals such as the stability of dislocation junctions (and, by association, stage II hardening), cross-slip (and, by association, recovery), etc. Dislocation partials also enable the formation of structures of particular importance in irradiation scenarios such as stacking fault tetrahedra (SFT), which form from the collapse of vacancy platelets condensed during the cooling of the thermal spike of displacement cascades. These SFT are known to be sources of considerable hardening in irradiated FCC metals and therefore attracted significant amounts of research from both experimental and simulation points of view. However, while experimental advances have provided unique insights into the interaction mechanisms between network dislocations and SFT, a detailed step-by-step sequence of dislocation reactions has remained elusive, and the venerable "Kimura-Maddin" mechanism (Kimura et al. 1963) has remained the accepted interaction mechanism up to the development of reliable simulation techniques. One key feature of SFT is that they are dislocation structures themselves and thus amenable to study by MD and DD simulations. However, the explicit consideration of dislocation partials in DD simulations of FCC crystals was not considered a priority in the DD community up until very recently, and before that, the interaction between dislocations and SFT was only captured in an effective manner, informed by MD simulation results.

The first comprehensive effort to include dislocation partials in DD simulations of FCC crystals was done by Shenoy et al. (2000). However, a comprehensive model of dissociated dislocation dynamics and its application to irradiated materials was subsequently developed by Martinez, Arsenlis, and Marian in a series of papers where the isotropic elasticity-based DD technique was effectively generalized to any crystal lattice (Martinez et al. 2008a, b; Marian et al. 2009). The splitting of perfect dislocations into partials at physical nodes is achieved by considering the following additional vector conservation rule:

$$\sum_i \vec{n}_i = 0 \tag{7}$$

where $\vec{n}_i$ is a unit vector representing planes where dislocations partials are glissile, e.g., for Shockley partials, $\vec{n}_{\mathrm{Sh}} \equiv \langle 1/\sqrt{3}, 1/\sqrt{3}, 1/\sqrt{3} \rangle$. Note that for certain types of partials, $\vec{n}$ represents planes that are not lattice planes, and therefore the associated dislocation is sessile (e.g., a *stair rod* dislocation). As well, the model includes an additional force acting on partial dislocation segments:

$$\vec{f}_i = \vec{\xi}_i \times \gamma \vec{n}_i \tag{8}$$

where γ is the stacking fault energy. Choosing the correct sense for the $\vec{n}$ vectors ensures that this force is always attractive between partials. The inclusion of the above two expressions into the standard elastic DD formulation has been shown to suffice to predict the most important dislocation partials in the FCC lattice (Martinez et al. 2008a). By way of example, Fig. 4a shows the unfaulting of a triangular Frank loop into a stacking fault tetrahedron by the decomposition of Frank dislocation segments into Shockley and stair rod partials, such as the following reaction (in Thompson notation ($\mathrm{A}\alpha : \frac{1}{3}\left[\bar{1}1\bar{1}\right]$, $\mathrm{A}\delta : \frac{1}{6}\left[\bar{1}2\bar{1}\right]$, $\delta\alpha : \frac{1}{6}\left[\bar{1}0\bar{1}\right]$.)):

$$\mathrm{A}\alpha \rightarrow \mathrm{A}\delta + \delta\alpha$$

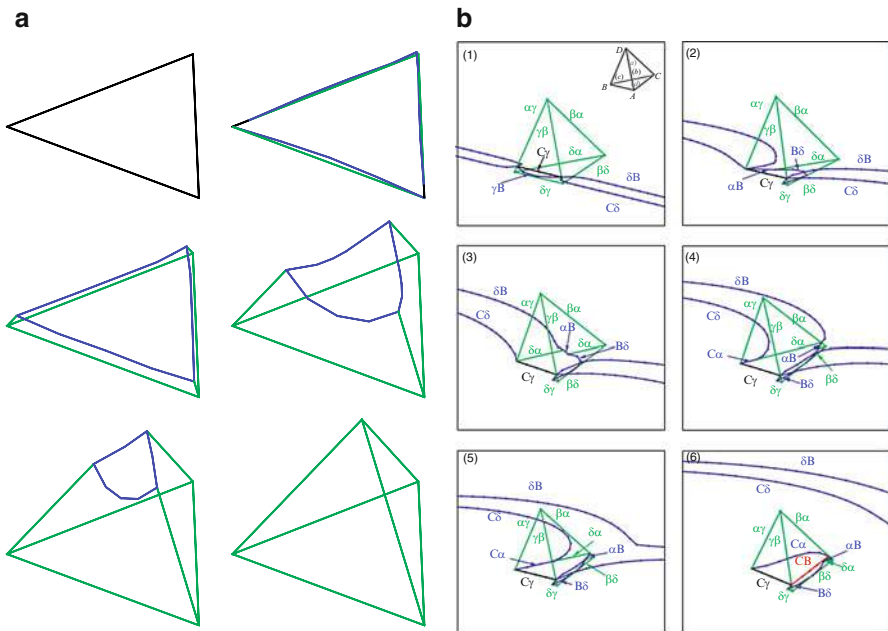
where it has been assumed that the dissociation takes place on the (111) (d) plane. Equivalent reactions can be written for the other planes.


Fig. 4 (**a**) Unfaulting of a triangular Frank loop into a stacking fault tetrahedron. (From Martinez et al. 2008a). (**b**) Sequence of simulation snapshots of the interaction between a 60° dislocation with a 4.7-nm SFT. (From Martinez et al. 2008b)

The technique allows for detailed studies of dislocation-SFT interactions, an example of which is shown in Fig. 4b as a sequence of simulation snapshots of the interaction between a 60° mixed dislocation with a 4.7-nm SFT (from Martinez et al. 2008b). The quantitative implications of these studies will be discussed in Sect. 3.2.

3 Dislocation Interactions with Irradiation Obstacles

In general, irradiation-induced defect clusters constitute obstacles for gliding dislocations, but the fate and strength of the interaction depend on specific atomic mechanisms, which are best revealed by MD simulations. These mechanisms have been reviewed and classified by Bacon and Osetsky (2005) and Bacon et al. (2009). However, sometimes MD cannot capture the details of the interaction mechanisms, particularly those that emerge at low strain rates and quasistatic conditions or those involving many-body effects. In such cases, DD itself can provide information about the process, and here we review some of the most important examples.

3.1 Prismatic Loops

Despite their complexity, recent studies have shown that the reaction pathway between gliding dislocations and prismatic loops is well represented within DD simulations, hence indicating that these reactions are governed by elastic interactions. For example, Shi et al. (2015) have considered all possible reactions between a $1/2\langle 111\rangle\{110\}$ edge dislocation and a square $\langle 100\rangle\{100\}$ interstitial loop in α-Fe and compared their result to corresponding MD simulations carried out by Terentyev et al. (2008). It was found that DD simulations are able to reproduce the reaction pathways observed in the atomistic simulations. Examples of such reaction pathways are shown in Fig. 5. Similar conclusions were reached by Cui et al. (2017), who considered DD simulations of $1/2\langle 111\rangle\{110\}$ edge and screw dislocations interacting with $1/2\langle 111\rangle\{111\}$ prismatic loops in comparison to the MD results of Liu and Biner (2008).

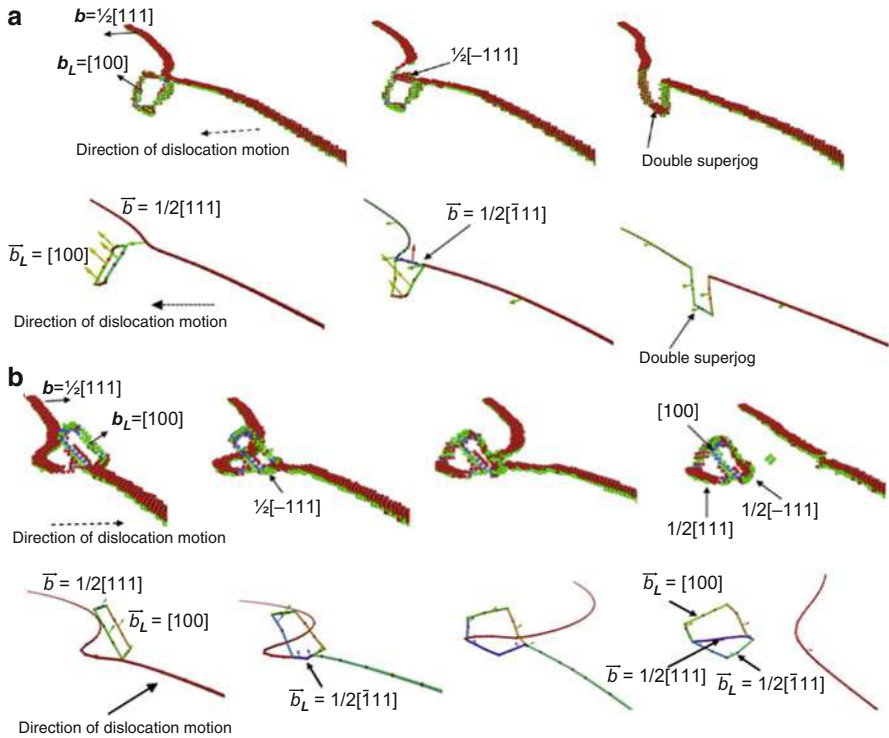
DD simulations of bulk α-Fe deformation (Arsenlis et al. 2012), confined grain deformation (Gururaj et al. 2015b), and micropillar compression (Cui et al. 2017) have considered different populations of the two types of prismatic dislocation loops typically observed in irradiated Fe. In these simulations, prismatic loops are resolved individually, with typical loop densities in the range $10^{20} \sim 10^{22}$ m^{-3}. These models do not require any particular assumptions, and therefore they are well-suited to predict the collective behavior of dislocation-obstacle interactions at the microscale. However, the discrete representation of loops limits their scope of applicability because of the high computational cost associated with the increased number of elastic segments. Higher defect densities and larger simulation time and spatial scales can be achieved if the discrete representation is replaced by a phenomenological description of obstacle-dislocation interaction, with parameters determined


Fig. 5 Examples of corresponding reaction pathways in DD and MD simulations between a $1/2\langle111\rangle\{110\}$ edge dislocations and a square $\langle100\rangle\{100\}$ interstitial loop in α-iron (Shi et al. 2015). (**a**) Prismatic loop incorporated into the mobile edge dislocation in the form of a double super-jog. (**b**) Pinning-reaction-unpinning of the glissile dislocation, with transformation of the prismatic loop

from lower-scale simulations. For example, Ghoniem et al. (2001) performed early DD simulations to capture the strength of the interaction between dislocations and arrays of dipolar loops. Terentyev et al. (2013) have used simple DD calculations to extract the parameters necessary to describe $1/2\langle111\rangle$ dislocation loops in Fe as stochastic thermally activated obstacles to be used in larger-scale simulations. Along the same lines, Cui et al. (2018) have extracted the parameters that govern the SIA loop density evolution in Fe and have turned the dislocation-defect interaction into a continuum field problem coupled to DD simulations.

3.2   Stacking Fault Tetrahedra

The implementation of the model described in Sect. 2.2 has enabled the study of dislocation-SFT interactions as the building block for irradiation hardening in metals with moderate-to-low stacking fault energies. While several of these
Fig. 6 Examples of DD simulations accounting for partial dislocations explicitly. Comparison of quasistatic atomistic simulations and DD simulations described in Sect. 2.2. Atomistic simulations from Marian et al. (2009)

simulations have been verified by dedicated MD simulations (Marian et al. 2009), as shown in Fig. 6, DD allows for a more efficient exploration of the relevant parametric space, to which – in addition to dislocation character, line length, temperature, stress, and obstacle size – one must add the surface of the area intersected by the glide plane on the SFT. As well, using the FCC/DD model gives access to strain rates not captured by MD simulations, thus providing an extra window into the dynamics of irradiation hardening in FCC metals. One of the most interesting physical insights gained from FCC/DD simulations was that the strength of SFT does not depend on their size but only on the intersected triangular area, such that equal areas in two tetrahedra of different sizes would give rise to the same response (Marian et al. 2009). This is also discussed in Sect. 4.1.1.

Unfortunately, the timesteps achievable by explicit integration of the equations of motion in the FCC/DD system drop to values that preclude the direct use of the technique to simulate strain hardening in a statistically representative manner. Until these issues are resolved, the explicit consideration of partials is likely to be limited to the study of unit mechanisms.

3.3   Voids and Precipitates

The mechanisms of interaction between dislocations and voids or precipitates have been explored by MD simulations by Osetsky and Bacon (2003) and Osetsky and Bacon (2010). For α-Fe, it was found that small coherent precipitates ($d < 2$ nm) can be sheared by moving dislocations, while larger precipitates and voids are overcome by more complex mechanisms, which may include dislocation climb, jog formation, and phase change of the precipitates. Although dislocations do not leave Orowan loops behind voids and sufficiently large coherent precipitates, the strengthening effects of these strong obstacles are compatible with the

Bacon-Kocks-Scattergood (BKS) strengthening model (see Sobie et al. (2015) for a comparison between strengthening models) (Bacon et al. 1973). This model predicts an obstacle resistance:

$$\tau_c = \frac{\mu b}{2\pi L} \left[\ln \left(D^{-1} + L^{-1} \right)^{-1} + B \right], \tag{9}$$

where D and L are the obstacle spacing and diameter, respectively, and B is an obstacle-specific fitting constant. Figure 7 shows the agreement of Eq. (9) in the case of voids and coherent Cu precipitates in α-Fe. Small precipitates offer a weaker resistance because obstacle shearing allows for large breakaway angles, which are inconsistent with Eq. (9). The situation is somewhat more complicated in FCC metals, because partials interact individually with voids when their spacing is larger than the obstacle size. In addition, the dissociated core prevents climb over voids by vacancy absorption, ultimately resulting in a larger deviation of the obstacle strength from Eq. 9 (Bacon and Osetsky 2005; Lehtinen et al. 2018). Moreover, obstacle strength decreases with temperature, because local energy fluctuations assist dislocation unpinning from obstacles (Monnet et al. 2010).

DD simulations carried out by Haghighat et al. (2009) have shown that elastic calculations predict a behavior of dislocations in the proximity of a void which is consistent with MD results when the image forces due to the void are taken into account. In large-scale calculations, however, accurate image force calculations cannot be performed for every void, and atomistically informed phenomenological interaction laws are once again more feasible. For example, Queyreau et al. (2011) considered the temperature dependence of void strengthening in DD simulations with a void density of $2 \times 10^{23} \mathrm{m}^{-3}$ in α-iron. Voids were assumed to be pinning points within the simulation domain, and they were released based on a probability following an Arrhenius-type law with activation energy dependent on the local stress and parameters extracted from MD simulations.

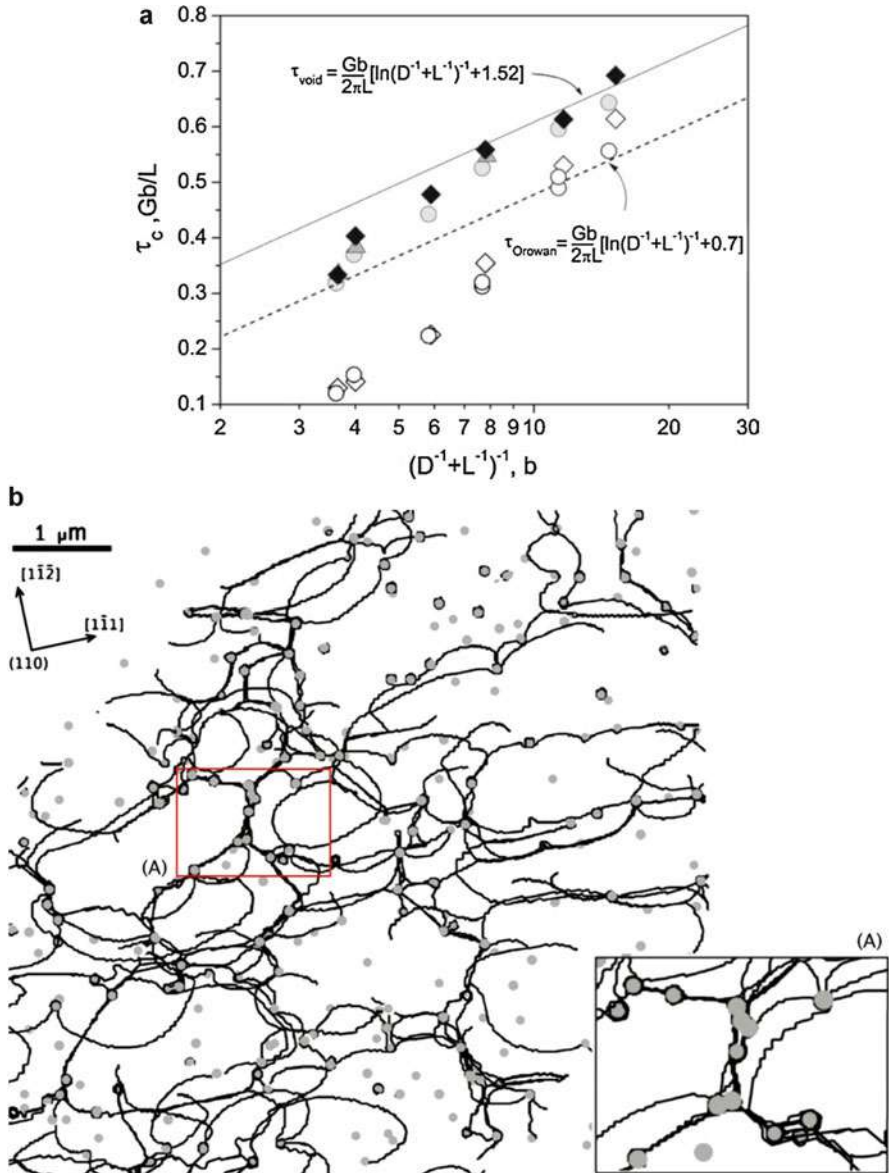
Also in the case of precipitates, accurate elastic calculations which account for image forces were performed to study the parameters governing the strength of both impenetrable (Shin et al. 2003) and penetrable (Takahashi and Ghoniem 2008) particles. A variety of techniques to account for impenetrable particles in larger-scale DD simulations have been proposed (Mohles 2001, 2004; Monnet 2006; Monnet et al. 2011; Ringdalen et al. 2017). Queyreau et al. (2010) have analyzed the effects of combined forest hardening and Orowan strengthening due to non-coherent carbides in reactor pressure vessel (RPV) steels. In this simulation, spherical carbide precipitates with average density of 3×10^{19} m^{-3} and mean precipitate diameter of $0.1\,\mu\mathrm{m}$ are regarded as volumes impenetrable to dislocations, and they can only be overcome by the formation of Orowan loops (Fig. 7b). It was found that although precipitate hardening is well described by the BKS model, when precipitate hardening is combined to forest hardening, the overall strengthening effect is best described by a quadratic rule of mixing between the two effects.


Fig. 7 (**a**) Strengthening effects of voids (full symbols) and coherent Cu precipitates (hollow symbols) in α-Fe as a function of the harmonic average between their diameter D and spacing L (Osetsky and Bacon 2003). (**b**) Snapshot of DD simulations of combined forest hardening and Orowan strengthening due to non-coherent carbides in RPV steels (Queyreau et al. 2010)

4   Applications

4.1   Homogeneous Irradiation Hardening

Here we discuss simulations in FCC Cu and BCC Fe as representative of each of their own material classes in terms of irradiation hardening.

4.1.1   Simulations in Irradiated Cu

One of the main advantages of DD simulations over atomistic simulations is the in principle much higher computational efficiency of the former, which allows for rapid exploration of the parametric space of the dislocation-defect interaction process. Variables such as defect size, dislocation length, dislocation character, defect orientation, stress, temperature, etc. create a many-dimensional landscape that is very difficult to probe using just atomistic simulations. With dislocation dynamics, one can explore these dependencies more extensively and enable a deeper understanding of the key variables affecting the process. By way of example, Fig. 8 shows the strength of SFT in Cu as a function of several key parameters as obtained with DD simulations methods such as that described in Sect. 2.2 (Marian et al. 2009).

Moreover, higher-scale models such as parametric or stochastic dislocation dynamics or crystal plasticity can be informed with multidimensional correlations, further reducing the computational overhead and reach larger scales. For example, one of the things that we have learned from DD simulations in Cu is that the strength of SFT does not directly depend on SFT size but on the area intersected by the dislocation glide plane and the defect, such that equal areas on SFT of different sizes give rise to the same response (Marian et al. 2009). This has enabled the development of universal laws that can be used in the coarser models, thus
Fig. 8 Strength of stacking fault tetrahedra in Cu to dislocation glide as a function of the intersection point between the defect and the glide plane, dislocation character, and SFT orientation

eliminating the need to simulate individual dislocation-SFT interactions directly and quantifying bulk hardening on experimental scales (Arsenlis et al. 2004; Robertson et al. 2005; Barton et al. 2013).

4.1.2   Simulations in Fe

DD simulations of bulk hardening in Fe can be used to investigate the dichotomy existing in the irradiation hardening community which distinguishes between dispersed-barrier hardening and dislocation decoration (cf. Sect. 1). This has motivated significant work recently (Gururaj and Robertson 2011; Arsenlis et al. 2012; Gururaj et al. 2015b), from which some interesting conclusions have emerged. First, the hardening levels calculated using various defect densities are consistent with a DBH approach, whereby $\Delta \tau = \alpha \mu b \sqrt{d \rho_d}$, where d and ρ_d are the defect average size and number density, respectively (Arsenlis et al. 2012; Gururaj et al. 2015b). From these simulations, it is clear that the source hardening (dislocation decoration) model results in more elevated hardening levels than the DBH model for a given irradiation dose and, consequently, can trigger flow-localized behavior earlier (Gururaj et al. 2015b) (this is the object of the next subsection). Simulations including a combination of oxide-dispersed particles and irradiation defects have also revealed that particles can actually delay flow localization by holding the uniformity of the dislocation substructure against spatial fluctuations in the strain brought about by fine-scale irradiation defect distributions (Gururaj and Robertson 2011).

   As well, the well-known phenomenon of loop coarsening and "raft" formation can be simulated by enabling climb processes for dislocation segments (Keralavarma et al. 2012; Bakó et al. 2011).

4.1.3   Simulations in Zr

Although the volume of work is considerably smaller, there have been DD studies of irradiated Zr, which is the basis of Zircaloys used in nuclear fuel cladding. Drouet et al. (2014) have studied several configurations involving dislocations and irradiation loops as a function of loop geometry, glide plane orientation, and dislocation character. Their simulations have shown various interaction mechanisms between both objects including formation of double super-jogs, formation of helical turns, or sweeping of a loop by a gliding dislocation. They have also shown that the clearing of loops is more favorable when the dislocation glides in the basal plane than in the prismatic plane, consistent with observations of dislocation channeling in the basal plane observed after neutron irradiation by transmission electron microscopy.

4.2   Strain Localization

Strain localization is one of the main detrimental effects associated with high-dose irradiation in nuclear materials, as it has been extensively documented in the literature (Victoria et al. 2000; Hashimoto et al. 2004, 2006; Yao et al. 2004; Byun

and Farrell 2004; Byun et al. 2004, 2006b, a; Zinkle and Singh 2006; McMurtrey et al. 2014). Above a critical defect density, plastic flow in many materials is seen to occur along "defect-free" dislocation channels that result in a highly spatially heterogeneous deformation usually accompanied by a severe decrease in total elongation. These channels are seen to typically range between 150 and 250 nm in width and are generally oriented along {111} and {100} crystallographic orientations in FCC metals and {112} and {110} in BCC (Hashimoto et al. 2006; Zinkle and Singh 2006). Modeling this particular type of deformation presents many challenges as several phenomena taking place at sharply different time and length scales must be considered, including channel initiation, channel growth and propagation, etc.

The first efforts at modeling dislocation channeling using dislocation dynamics were conducted for irradiated Cu, assuming SFT removal mechanisms observed in MD simulations (Diaz de la Rubia et al. 2000; Sun et al. 2000; Khraishi et al. 2002). These simulations were effective in demonstrating that channel initiation results as a consequence of spatial fluctuations that trigger an instability characterized by a post-yield softening. However, the removal of objects by dislocations was based on effective contact rules based on MD simulations performed under strikingly different conditions than those of DD (Crosby et al. 2014). This introduces an incompatibility that questions the physical fidelity of the simulations. These physical models have eventually been extended in more recent DD works that treat dislocation-SFT interactions as true dislocation reactions (Martinez et al. 2008b, c) (cf. Sect. 2.2).

The other type of primary irradiation defect considered is dislocation loops. Being dislocation structures themselves, loops can be naturally captured within the linear elastic framework of DD, which allows for a direct treatment of dislocation-loop interactions (Nogaret et al. 2008; Arsenlis et al. 2012; Gururaj et al. 2015a). While the global mechanism that leads to plastic flow localization is fundamentally the same – i.e., local removal of irradiation defects either by absorption into the dislocation line or elastic repulsion – this type of simulations allows for a more detailed investigation of the channel nucleation and propagation mechanism. For example, for the case of 25-nm dislocation loops in Fe, it has been seen that the channel size is governed by the formation of a local curved dislocation source in the vicinity of a defect-depleted region grown by the absorption of and coalescence with irradiation defects (Arsenlis et al. 2012). This source can be activated at stresses significantly lower than the yield stress set by a homogeneous distribution of defects, resulting in softening and localized deformation in the vicinity of the source. The system behaves in an unstable manner in the sense that, as the source propagates throughout the simulation box, it triggers the absorption of more defects, which in turn makes the source segment grow and the required activation stress decrease. Some other works suggest that it is the level of defect hardening – rather than the defect density per se – that determines the onset of subsequent plastic localization (Gururaj et al. 2015b). In any case, channel initiation is a *rare* event, and large computational cells must be deformed to plastic strains above approximately 1% for channels to be incubated. This often requires massively parallel simulations and data analysis. Figure 9 shows the dislocation microstructure in an iron single crystal

Fig. 9 Dislocation microstructure in an iron single crystal after deformation with a defect density of 1.6×10^{22} m^{-3} loops, clearly showing the existence of a defect-free dislocation channel. (From Arsenlis et al. 2012)
populated with a density of 1.6×10^{22} m^{-3} dislocation loops. The width of the channel is approximately 150 nm, and its orientation is along the [211] direction (Arsenlis et al. 2012).

While much work remains to be done to improve the meaningfulness of DD simulations to continue studying plastic flow localization in irradiated materials, existing models have been capable of offering useful information of the process such as the observation that channels can be and are nucleated in bulk grains, not just at grain boundaries (McMurtrey et al. 2014). This can be important to understand important phenomena such as irradiation-assisted stress corrosion cracking initiation.

4.3 Irradiated Thin Films

The foils used in transmission electron microscopy for irradiation studies may be as thin as 40 nm, and hence dislocations and other defects within it can be strongly influenced by elastic image forces due to the free surfaces. These fictitious image forces arise due to the zero traction boundary condition ($\boldsymbol{\sigma} \cdot \hat{\boldsymbol{n}} = 0$) imposed at the free surface. While such a scenario is perfectly well-captured within the method for finite geometries described in Sect. 2.1.2, the high symmetry of the thin film geometry allows for a more direct approach that results in significant computational gains over the finite element model (Weinberger et al. 2009). The equilibrium problem for the displacement vector on a flat infinite surface can be solved analytically in Fourier space (Weinberger et al. 2009; Ferroni et al. 2014), giving a solution that decays exponentially along the direction normal to the free surface. The resulting image stresses can then be straightforwardly calculated and added to DD nodal force contributions via the Peach-Koehler formula like any other stress. The exploitation of the analytical Fourier solutions yields a significant

computational cost saving over the general FEM approach but can only be used for domains with sufficiently high symmetry that such an analytical solution exists.

Complications arise when dislocation segments reach the free surfaces, an issue that can be solved by extending terminating segments out of the crystal to infinity by defining *virtual segments* (Weinberger et al. 2009). The stress fields of the virtual segments must be included when computing nodal forces on the real segments inside the crystal, but they themselves do not move dynamically and are simply redefined at each timestep (Tang et al. 2006; Yoffe 1961). Ferroni et al. (2014) used this approach to perform DD simulations of irradiated thin films in Fe. The simulations concluded that radiation damage loops interact strongly with the surface when they approach to within $3\times$ the linear size of the loop. For situations where climb is negligible, e.g., low temperatures, free surfaces play a dominant role in the evolution of thin film dislocation structures. When climb was present however, many small prismatic loops had self-annealed or coalesced into larger loops before reaching the surface.

4.4   Irradiated Micropillars

Micro-mechanical testing is an emerging area of investigation in the field for irradiated materials, which prospects the benefit of a reduced amount of radioactive material that needs to be handled during experiments (Hosemann 2018). *In situ* mechanical tests such as nanoindentation, micro tension/compression, and micro bending also have the ability to directly observe isolated changes in the defect microstructure in relation to the applied load. Experimental micro-mechanics is therefore expected to provide new insights on the mechanics of plastic deformation and failure of irradiated materials. Moreover, because these experiments are typically conducted at length scales amenable by DD simulations, they also provide specialized data useful to advance materials modeling.

Cui et al. (2017) considered the problem of intermittent plastic flow in irradiated micropillars and performed a comprehensive DD study of the phenomenon as a function of material type (BCC Fe vs. FCC Cu), loading mode (strain vs. stress control), and irradiation dose. In these simulations, irradiation-induced defects were represented explicitly as dislocation debris within the simulation volume, namely, SFT for Cu and interstitial dislocation loops for Fe. The elastic BVP correction method described in Sect. 2.1.2 was applied to obtain uniaxial compression in both strain and stress control modes. It was found that, in general, defects hinder dislocation motion because they decrease the dislocation mean free path by participating in junctions. In stress control mode, where no stress relaxation takes place during the burst, the burst's size tends to decrease with dose. In strain control, however, the burst size is controlled by the difference between the burst stress, which increases with dose, and the deactivation stress of the active source. Therefore irradiation may result in larger dislocation bursts under strain control conditions, as shown in Fig. 10.

5   Summary and Future Directions

This chapter attempts to present an overview of the most salient developments concerning the use and application of discrete dislocation dynamics for irradiated materials. While the progress achieved over the last two decades has been remarkable, there are still several aspects of irradiation hardening lacking to be studied. By way of example, we give here a non-exhaustive list of issues needing to be resolved:

- Pushing the time-/length-scale horizon to achieve usable strains $>5\%$ and realistic strain rates ($<10^{-1}$ per second).
- Simulations considering complex precipitate geometries (needle shaped, elongated, faceted, etc.), as well as in nano-layered materials, have not yet been the focus of substantial work Ringdalen et al. (2017).
- Implementation of realistic models of irradiation-assisted dislocation climb.
- Except for some noted efforts Geantil et al. (2013), dislocation dynamics has been generally unsuccessful in predicting the formation of dislocation substructures at high deformations. More work in this area would be a welcome addition.
- Simulations of shock deformation using DD must be done including time-dependent displacement fields (in 3D in addition to 2D (Gurrutxaga-Lerma et al. 2013)) and accounting for inertial effects on dislocation motion.

Beyond these and other aspects meriting more study, we believe that DD has been extremely successful in providing critical insights into fundamental defect-dislocation processes with high relevance in nuclear materials.
