We wish to dedicate this book to the memory of Walter Kohn and Aneesur Rahman, founders of the modern approach to the physics and chemistry of real materials, both theoretical and computational. While their contributions will forever stand as milestones in the progress of science, we wish to commemorate their courage and vision in proposing new methods that would be fully implemented only decades later. We – and everyone who has known them personally – continue to remember them also for their tireless enthusiasm for science, their generous sharing of ideas, their unique kindness, and their charisma. As their articles start to disappear from citation lists in the same way as those of the founders of quantum mechanics, it is both humbling and comforting to know that any present and future development rests on the work of two wonderful people who have truly embodied the values of science.

Wanda Andreoni and Sidney Yip

Preface to *HMM2*

The *Handbook of Materials Modeling*, published in 2005, was the first reference work of its kind, providing a comprehensive description of an emerging field of research and helping to grow a community at the intersection of *Computational Science* and *Materials Science and Technology* through the development of the theory, modeling, and simulation of materials across the disciplines of physics, chemistry, and engineering. In producing the first edition, the editors were guided by a simple vision – target students, young researchers, and nonspecialists as the primary audience, introduce the concept and practice of linking materials research at different resolution levels (from the atomic to the meso- to the macroscale), and stimulate exploration and applications. The e-book version became available two years later.

The *Handbook of Materials Modeling Second Edition* (*HMM2*) follows its predecessor in serving the broad community of *Computational Science* and *Materials Science and Technology*. Its goal is to update the current state of the art of materials modeling and simulation in two complementary ways:

- *Strengthen* the foundations of materials theory, modeling, and simulation
- *Broaden* the scope to include challenges and opportunities of interdisciplinary interest

In both objectives, *HMM2* strives to promote open discussion of the capabilities and limitations of current methodologies and applications. The Second Edition is composed of two companion sets: *Handbook of Materials Modeling – Methods: Theory and Modeling*, and *Handbook of Materials Modeling – Applications: Current and Emerging Materials*. These will be abbreviated as *MTM* and *ACE*, respectively. Each set is a stand-alone publication with its own Table of Contents and individual chapters that are grouped under a number of parts. Both *MTM* and *ACE* are three-volume sets. There are 11 parts in *MTM* containing, beyond the Introduction, 10 sections with 88 chapters and 16 parts in *ACE* containing, beyond the Introduction, 15 sections with 120 chapters. The chapters which constitute the primary scientific content of the handbook are organized by the section editors in each set, working in coordination with the editors in chief. The section editors also provide an introductory overview of their own section, thus facilitating access to the following chapters.

Logistical issues aside, we think it is important to emphasize the holistic aspects of materials modeling and simulation, as an evolving discipline across science and technology and the complementarity of the two sets. As the community grows in scope and relevance, learning "in depth" with the aim of mastering the relevant theoretical and computational algorithms becomes more and more important. Equally, it becomes important to be able to discern unresolved materials issues for which information from simulations could "make a difference" and to properly apply and critically assess the chosen models and methods. Thus *all readers* should recognize the beneficial overlap of the two sets. In the respective introductions we will elaborate further on this point.

An undertaking of this magnitude can only succeed as a collective effort. The *Handbook of Materials Modeling Second Edition* would not be a reality without the dedicated efforts of former Springer Editor *Maria Bellantone*, to whom we are especially indebted. She brought us together and provided us with essential logistical support. We thank *Lydia Mueller* for her early guidance. Our deepest gratitude goes to *Juby George* and *Sunaina Dadhwal* for their invaluable editorial assistance, efficient communication with authors and editors, and efficient management of the Springer platform *Meteor*. Their assistance made it possible to complete the project on an admittedly ambitious schedule. That 200 plus chapters could be commissioned, manuscripts collected, revisions, etc., be undertaken and published in less than four years is an accomplishment for which the credit properly should go to the section editors and their authors. We would like to think all participants will take pride in what we have achieved together. This is a journey that will continue. We trust the community will be diligent in upholding standards and maintaining respect and collegiality among all stakeholders.

February 2020   Wanda Andreoni
                                                                                                   Sidney Yip
                                                                                                    Editors

About the Editors

Wanda Andreoni
Institute of Physics
Swiss Federal Institute
of Technology – Lausanne
Lausanne, Switzerland

Wanda Andreoni is Emeritus Professor of Physics at the Swiss Federal Institute of Technology of Lausanne (EPFL). She has been involved in Computational Materials Science since the early days of her research activity, in both academic and industrial institutions, covering also teaching, organizational, and research managing positions. She is a Fellow of the American Physical Society. She was Zernike Professor at the Groningen University (NL) (2011) and CECAM Director (2009–2012). Regarding editorial work, she was Coeditor of *Europhysics Letters* (1990–1993) and Editor of *The Chemical Physics of Fullerenes 10 (and 5) Years Later*, NATO ASI Series E: Applied Sciences, Vol. 316 (Kluwer, 1996), and of *The Physics of Fullerene-Based and Fullerene-Related Materials*, Series on the Physics and Chemistry of Materials with Low-Dimensional Structures, Vol. 23 (Kluwer, 2000).

Sidney Yip
Department of Nuclear Science
and Engineering
Department of Materials Science
and Engineering
Massachusetts Institute of Technology
Cambridge, MA, USA

Sidney Yip immigrated to the USA from China in 1950 at age 14. After receiving degrees in Mechanical Engineering and Nuclear Engineering from the University of Michigan and spending two postdoctoral years at Cornell University, he joined the Nuclear Engineering Faculty at MIT in 1965. From early research in theoretical studies of particle and fluid transport, he became broadly involved in atomistic modeling and simulation of materials. He edited the first edition of the *Handbook of Materials Modeling* as well as *Spectroscopy in Biology and Chemistry: Neutron, X-Ray, Laser* (1974) and *Materials Interfaces: Atomic-Level Structure and Properties* (1993). Other books include the monographs, *Foundations of Neutron Transport Theory* (1967), *Neutron Molecular Spectroscopy* (1968), and *Molecular Hydrodynamics* (1980), and a text, *Nuclear Radiation Interactions* (2014). He received Guggenheim Fellowship, US Senior Scientist Prize of the Alexander von Humboldt Foundation, Distinguished Alumnus Award of the University of Michigan, and the Robert Cahn Award. A Fellow of the American Physical Society, he became Professor Emeritus in 2009.

Part I
Introduction

Applications of Materials Modeling and Simulation: An Introduction

1

Wanda Andreoni and Sidney Yip

Contents

Abstract

The ultimate goals of research on materials are to improve on their properties and control processes such as chemical degradation or mechanical failure as well as to design new materials and processing routes. The *Handbook of Materials Modeling*, in its former and present editions, aims to clarify how modeling and virtual experiments contribute to this effort and to monitor their development over the years. In particular, the set *Handbook of Materials Modeling: Applications – Current and Emerging Materials* (*ACE*) offers an ample description of recent achievements in several areas of materials science and technology. It covers research on systems – such as catalysts or magnetic materials or complex oxides – on which modeling and simulations have traditionally focused, and especially on a few "discovered" during the last 15 years or so, such as 2D materials or novel photovoltaics or bio-inspired hierarchical systems. The former studies can be considered to be an update of those reported in the 2005 edition

e-mail: syip@mit.edu

of the *Handbook of Materials Modeling* (*HMM*). Therefore, by comparison, *ACE* provides the reader with a view of how computational materials science has developed since then. On the other hand, the articles on emergent materials show how critical the role of computations has been as an aid to experiment in tackling the (often unprecedented) related scientific and technological issues. Here we briefly introduce the 15 parts of *ACE* and emphasize the importance of topics treated therein and of the major findings. Several chapters provide a brief assessment of the applied methodologies by reporting on both achievements and failures. We shall underline what one can learn from these results and also point out connections between *ACE* and the companion handbook (*MTM*), which is devoted to the methods.

1   Introduction and Connection with *MTM*

Recent progress in technology has largely been related to the use of new materials of unprecedented complexity whose understanding appears to require the use of advanced modeling and simulation. Indeed, during the past decade or so, the realm of applications of computational materials science has broadened remarkably, their protocols have changed from the use of single to multiple methods for a more comprehensive understanding, and their objectives have gradually moved toward the requirements of rational design. Many are the challenges, however, that are still open so as to render the paradigms of virtual experiment essential companions to real experiment and thus help further progress in technology and fundamental understanding.

The *Handbook of Materials: Applications – Current and Emerging Materials* (*ACE*) gives an account of the various steps, successes, and failures in this endeavor to date. While we do not pretend that the scenario presented is complete, we are confident it gives a broad view of the diverse branches of materials science in which computations play a significant role.

ACE is the companion publication (set) to the *Handbook of Materials Modeling: Methods – Theory and Modeling* (*MTM*). Together these two stand-alone, multivolume publications constitute the *Handbook of Materials Modeling – Second Edition*. There is necessarily considerable overlap both amongst the parts in each set and amongst the individual chapters in each section. However this overlap is deliberate and intended to aid the reader. To access all the information available from the handbook, it would be advisable to examine the Table of Contents (*TOC*) for each set, along with consulting the present chapter (and its counterpart for *MTM*) for an overall introduction.

To aid readers relatively new to the handbook, we start by providing a brief description of the contents of the set *ACE*. As shown in the *Table of Contents*, the set consists of 15 parts and a total of 120 chapters. In analogy with the Introduction chapter to *MTM* (Table 1), we consider a list of keyword descriptors as a way of concisely characterizing the contents of *ACE*. This is shown in Table 1. Comparison

Table 1 List of keywords describing the topical themes of each of the 15 parts in *ACE*. For full section titles and the individual chapters in each section, see the *Table of Contents*

Plenary topics
Photovoltaics
Magnetism and spintronics
Low-dimensional materials
Nanoscale thermal transport
Electrochemical oxides
Surface catalysis
Nanomechanics
Hierarchical materials
Complex soft matter
Predictive modeling of glasses
Nuclear materials
Radiation damage
Human disease modeling
Crystal structure predictions

with the counterpart for *MTM* clarifies the commonalities and distinctions between the two sets of the handbook, if one simply notes the different contexts, namely frontier applications for *ACE* and fundamental methods for *MTM*.

Obviously method development is ahead of application: even when appreciation of new algorithms comes soon after their proposal, efficient implementation in computational codes is rarely fast, and a relevant application takes even longer. Therefore most of the results discussed in *ACE* can be considered a test of methods that are by now commonly used. *ACE* shows that computational materials scientists are setting increasingly more ambitious goals for their research that are often beyond the reach of available tools. On the other hand, *MTM* reports not only on methods that have been establishing themselves during the last decade but also on very recent highly promising developments. The latter clearly appear to be in line with the demand arising from the research work described in *ACE*.

2   A Brief Guide to the Parts of *ACE*

Here we will briefly introduce the topics addressed in *ACE* and highlight the relevance of each of them as well as methodological problems which seem to be common to diverse applications. For a more extensive and specific discussion, we refer the reader to the overviews by the section editors. In particular, they provide a global outlook of the current status of modeling and simulations and clarify both short- and long-term challenges.

Before focusing on each section separately, we note that, in each of them, particular attention is paid to the need to go beyond the understanding of a phenomenon obtained through the application of certain models and calculations and to translate it into suggestions for improvement or innovation. In fact, this drive toward the

practical use of the results of computational approaches has been developing over the last 10–15 years, certainly motivated by the increased and widespread need for "better" materials in current technologies. Simultaneously, computational scientists have become increasingly aware of the complexity of real materials. This implies, on the one hand, the need to acquire a global understanding of their behavior, e.g., concerning the interplay of chemical and mechanical properties in determining thermodynamic stability or concerning the performance of a given compound in real devices at operating conditions, and, on the other hand, the need to learn and make use of diverse theories and computational tools. Common concerns about the limitations of the latter can also be identified across the sections, e.g., about the lack of accuracy of standard approximations in DFT-based calculations, and the need for algorithms capable of bridging the description of a system at different length scales so as to unravel, for example, the influence that the interatomic processes have on the behavior at the mesoscale. Moreover, as we will see in the following, machine learning techniques have already started to be employed in the search for new materials in several areas.

In analogy with *MTM*, *ACE* opens with a collection of articles on subjects which we expect will be of special interest to the reader ("Plenary Topics," Editors: Andreoni and Yip). As shown in our section overview, some of these chapters can be easily connected to more than one of the following topical sections, thus providing further information and new perspectives. Others deal with additional very interesting topics that did not fit into the specific classification of Table 1.

The first topical part, "Photovoltaics: First Principles Modeling" (Editors: Bernardi and Grossman), is focused on ab initio approaches to the study of "modern" photovoltaics, namely, organic-inorganic halide perovskites (prototype $CH_3NH_3PbI_3$) and ultrathin group 6 metal chalcogenides such as WS_2. Both classes of materials have emerged in the last decade as highly promising alternatives to amorphous silicon (see, e.g., Editorial 2019). In an attempt to understand their characteristics and help design better performing devices, one is faced with a number of basic questions that cannot all be treated with current first-principle methods. These issues are pointed out in the overview by the section editors. However, as thoroughly discussed in the chapter by Filip, Volonakis, and Giustino for the case of perovskites (▶ Chap. 14, "Hybrid Halide Perovskites: Fundamental Theory and Materials Design") current ab initio methods have been successful in predicting – not just reproducing – several optoelectronic properties and have been of invaluable support to experimental research from the early days to date, also in the quest for more stable and nontoxic alternatives to lead compounds. As an example, we direct the reader to a related patent for the synthesis and utilization of nontoxic double perovskites, which were identified by the mentioned calculations (Snaith et al 2018).

The next part entitled "Modeling Applications to Magnetism, Magnetic Materials and Spintronics" (Editor: Sanvito) is well connected to the companion section in *MTM* (Editor: Sanvito) describing state-of-the-art theoretical and computational methods for the investigation of different aspects of magnetism and spintronics. The applications presented here involve the description of macroscopic magnetization

dynamics and of the interaction between electrical currents and spins at the atomic level. Moreover, a chapter is included on the search for novel magnetic materials using combined machine learning strategies and high-throughput data from electronic structure calculations. (For a general perspective, see the part on "Materials Informatics" in *MTM*.)

The part on "Low-dimensional Materials at the Nanoscale" (Editor: Chelikowsky) records successful applications of computations – mainly DFT-based – of the structural and electronic properties of 2D materials, nanoclusters, nanowires, and graphene nanoribbons. For example, these calculations clarify the interplay between limited dimensionality and quantum confinement and their influence on doping which is crucial for material functionalization. They also allow one to understand the evolution of physical properties with increasing system size and thus to predict how certain characteristics of the bulk such as the energy gap establish themselves.

The part "Thermal Transport" (Editor: Donadio) provides a broad view of the ongoing efforts to unravel multiple issues related to thermal transport in realistic systems and obtain reliable modeling tools and simulations. On the one hand, a few chapters describe in detail recent advances made in theoretical algorithms and computational schemes and point out the remaining challenges for method development. On the other hand, application of current approaches to a variety of systems, from polymers to metal alloys to nanostructured materials, clarifies the complexity of the problems that simulations should tackle in the near future.

The part "Challenges and Opportunities in Modeling Oxides for Energy and Information Devices" (Editors: Franchini and Yildiz) introduces the reader to a vast research arena, namely that of electrochemical materials, mainly complex metal oxides. The great interest in (complex) metal oxides stems from their versatile applications, as part of energy conversion and storage devices as well as of logic and memory systems. The articles presented in this section tackle fundamental issues that are critical for the performance of the mentioned devices. In particular, there are concerns mainly about the nature and role of point defects, surfaces, and interfaces, their effects on the ion or electron transport, and also about the limitations of currently available calculations to provide quantitative information.

We note that one of the chapters focuses on perovskite oxides and their use as electro-catalysts in fuel cells. In particular, it points out the lack of knowledge of the catalyst surface, for which modeling and simulations could be relevant. Electro-catalysis is actually one of the subjects more extensively treated in the next section, which is specifically dedicated to surface catalysis. In conclusion, we remark that, besides the use of traditional computational methods that are critically discussed in this section, also machine learning strategies have started to be applied for the optimization of the characteristics of electromagnetic oxides (see, e.g., Min et al. 2018).

The part on "Surface Catalysis" (Editors: Reuter and Metiu) also relates to a vast area of research. It suffices to realize that catalytic reactions are ubiquitous in our life and in industrial processes and that tremendous effort has been ongoing for decades in the search for "optimum" catalysts. The set of articles collected here

introduce relevant sub-topics and especially illustrate how current computational methods – from ab initio calculations to microkinetic models to computational fluid dynamics to multiscale approaches – have been applied during the last 10–15 years. In particular, the change of paradigm of modeling and simulations that we have mentioned above towards in silico design is clearly shown. Indeed, besides the mechanisms of specific chemical reactions and the nature of possible active sites and point defects, issues of major interest that have recently been tackled regard numerous factors that affect the performance and lifetime of the catalyst. For example, current investigation focuses on the interaction of the catalyst with its environment, e.g., heterointerfaces, other chemical species introduced in the reactor as either promoters or inhibitors of catalytic activity, and the solvent (in the case of electro-catalysis) or concentrates on the dynamical restructuring of the catalyst under operating conditions.

The huge amount of available data on catalytic processes calls for the use of artificial intelligence procedures in catalyst design. In addition to some references provided in the overview by the section editors to emerging applications of machine learning techniques, we direct the reader to an interesting discussion of recent progress in machine learning in the field of catalysis and on several severe challenges (Li et al 2018). We also suggest for further reading a recent general review on inverse design approaches to catalysis (Freeze et al 2019).

The next two sections illustrate how state-of-the-art modeling at various length scales can be applied to "everyday" materials with complex structures to study their fundamental properties. Understanding the connection of the mechanical properties to the structural characteristics is certainly a primary goal of this research. We note that dynamics simulations at the molecular or nanoscale level – namely, the first step in the chain of models leading to a more comprehensive representation of these systems – rely either on well-established coarse-grained schemes or on simple interatomic potentials. For methodological issues and an extensive perspective, we refer the reader to *MTM* and especially to the part "Soft Matter/Polymers Simulations" (Editor: Kremer).

The part "Multiscale Modeling of Structural Materials: Chemistry and Mechanical Performance" (Editors: Buehler and Martin-Martinez) mainly focuses on hierarchical natural materials such as silk, wood, and bamboo and on infrastructure composites such as asphalt and concrete. It also includes a chapter about silica aerogels, namely, nanostructures with an unusual structural organization. The part "Modeling the Structural Development and Mechanics of Complex Soft Materials" (Editors: Del Gado and Pellenq) is devoted to another fascinating class of "soft materials" and in particular reports on modeling and simulations for soft gels, cement, and clay. We remark that both the above sections also serve as an introduction to the rich phenomenology of the broad class of materials treated therein and to the achievements of experimental investigation.

Mechanical behavior is also the focus of the next part entitled "Nanomechanics of Materials: Structure and Deformation" (Editor: Zhu). Nanomechanics covers a large variety of nanoscale materials, such as nanowires, nanotubes, nanomembranes,

nanomotors, and low-dimensional materials in general. Size reduction has strong and peculiar effects on the mechanical properties of a material relative to those of the bulk and often leads to a remarkable enhancement in strength and toughness. Also unusual mechanisms have emerged as responsible for deformation and fracture. Some examples are given in the selected chapters. Most computational studies discussed therein are based on classical molecular dynamics. These simulations provide insights into, e.g., the nature and role of predominant defects or the mechanism leading to deformation in nano-twinned materials or the auxetic behavior of 2D materials. The limitations of this approach are also underlined, especially in terms of length and timescale of the simulations. For a more comprehensive understanding of "nanomechanics," we suggest further reading, e.g., the chapters included in the section "Recent Advances in Crystal Plasticity Modeling" (Editors: Cai and Ghosh) in *MTM* and also a recent review (Taloni et al. 2018) describing the failure behavior of materials at different size scales. We also point out a connection with the previous *ACE* section on "Low-dimensional Materials at the Nanoscale" (Editor: Chelikowsky) dealing with different aspects, mainly electronic properties, of nanostructures and 2D materials.

The section "Glass Science and Technology: Predictive Modeling" (Editors: Mauro and Onbasli) shows how constitutive models are commonly utilized for practical engineering purposes, with specific reference to the glass industry. This choice is certainly due to the ubiquitous presence of functional glasses in areas as diverse as construction, transport, automotive, or photovoltaic applications. Indeed modeling has proven to be crucial for the optimization and design of a large variety of functional properties of glasses. For example, the manufacturing of glasses is required to ensure unique stable attributes, such as high optical transparency, high mechanical strength, and high sound transmission loss. Moreover, as the extensive overview provided by the section editors points out, the current development of predictive schemes in the glass industry is moving toward a multiscale and physically based approach.

The next two parts, "Nuclear Materials" (Editors: Marian and Devanathan) and "Radiation Damage" (Editors: Short and Nordlund), are connected to a large extent, because, although distinct, they treat similar problems requiring the same computational approaches. The former reports on studies of the fundamental properties of nuclear fissile fuels, e.g., uranium dioxide, and structural materials, e.g., zirconium alloys, as well as on the detrimental effects of neutron irradiation on the performance and lifetime of nuclear reactors. The latter considers both neutron and ion irradiation effects and also materials other than nuclear. Both parts provide a comprehensive description of the various modeling strategies and simulations in use, from the atomic level to the continuum level. However, it is fair to say that, despite the advances in theory, modeling, and simulation, and experiments made over 50 years, formidable challenges still remain. For further specific discussions, readers should consult major reference works dedicated to this topic (Cacuci 2010; Konings 2012; IAEA 2018).

We also remark that damage induced by ionizing radiation in biological matter, say DNA or proteins, is not considered in this handbook.

The part "Multiscale Modeling of Diseases" (Editors: Dao and Karnidakis) provides an introduction to the emerging field of experimental and computational modeling of human diseases. It is a field of biophysical and biomedical research driven principally during the past 10 years by the developments along three directions, advanced multiscale modeling capabilities, new mechanobiology experimental techniques, and interdisciplinary collaboration among modeling scientists, experimentalists, and clinicians in the targeted specialties. The chapters discuss various computational methods developed for modeling at the meso-scale (particle-based) and continuum levels and specific studies on the human red blood cell (relevant to malaria) and sickle cell anemia.

The *ACE* set of the handbook closes with a section entitled "Computational Crystal Structure: Prediction and Materials Discovery" (Editors: Wang and Wolverton) providing another interesting topic of materials development. Applications of a variety of methods for the prediction of crystalline structures are presented for materials of given chemical compositions. The development of the basic algorithms, based on the exploration of the potential energy surface and energy minimization procedures, dates back more than 20 years. However, several new and more accurate procedures have been put in place only in the last decade so as to increase the ability to predict low-energy structures for complex compounds and discover unforeseen polymorphs. In particular, we emphasize extensions and adaptations of the genetic algorithm and particle swarm optimization techniques. Moreover, we point out the advent of an original methodology that combines results obtained both from the analysis of X-ray diffraction (Rietveld refinement) and from ab initio (DFT) calculations.

3   Conclusion

ACE provides an overview of several areas of materials science in which computations at different levels of sophistication have been extensively applied during the last 10–15 years. The role of computational materials science is now established.

However, it is clear that further progress is needed for physically based modeling and simulation to become essential components in the design of either new complex materials with prescribed properties or new procedures for material process control and synthesis. To meet these ambitious objectives, an intensive exchange between academia and industry and society will be necessary.

While we may very possibly have overlooked some topics of interest to the reader, we trust that he/she will find other very interesting and timely articles and particularly instructive perspectives on foreseeable future applications of computational methods. Indeed, after comparing the needs for more robust and far-reaching algorithms as clarified in *ACE* and the ongoing as well as expected method developments discussed in *MTM*, we can safely conclude by repeating Leibniz's famous sentence: "The present is pregnant with the future."

Wanda Andreoni and Sidney Yip

Contents

Abstract

This section is meant to complement the already extensive collection of articles classified in the following topical sections. In particular, additional applications of computational methods are discussed, which we believe will be of general interest to readers. They focus on different materials – ranging from graphene to titanium oxide to novel superconductors to cement to titanium alloys to glassy oxides and polymers – and/or critical material processes such as defect diffusion and fracture propagation, leading to degradation and failure. We will point out that some chapters can be related to several others across the sections of this part of the handbook (*ACE*) and add new information and perspectives. Connections with those of the companion set (*MTM*) will also be pointed out.

1   Introduction

This is a brief overview of contributions collected in a special *ACE* section that – as its counterpart in *MTM* – is intended to complement the others, each focused on one specific theme, and also offer additional perspectives.

Most of the plenary topics, it is hoped, will be of general interest to the reader. For example, some chapters deal with materials, such as titanium alloys, cement, titania, and graphene, which are of outstanding relevance for a variety of applications. In particular, the importance of graphene has emerged during the last 15 years (see, e.g., Geim and Novoselov 2007) and thus was not part of the first issue of this handbook. Others focus on topics that did not fit into one of the following sections, for example, superconducting materials. Also in this case, reliable computational approaches have become available only in the last decade or so.

2   Brief Chapter Overviews

This section opens with Payne's view of materials modeling in/for industry, in particular in the UK (Payne, ▶ Chap. 3, "The Industrial Impact of Materials Modelling"). A report is given of recent initiatives in Europe to connect the academic community of computational physicists in the field of materials science to industrial partners. The problems responsible for the fact that materials modeling has so far played a minor role (if any) in industry are clarified. Nevertheless its use has increased over the years at all length and time scales. We refer the reader to a chapter in this same section (Xu et al., ▶ Chap. 7, "Titanium Alloys: From Properties Prediction to Performance Optimization") for a thorough description of how several different approaches can be relevant to the various stages of product design in industry. Payne also provides a thoughtful discussion of the needs that industries will nevertheless continue to have for modeling results, (acquisition of) expertise, and/or tools, depending, in particular, on the size of the company.

One should remark that many academy-industry collaborations exist worldwide – although not systematically – and also that research centers at IBM and at chemical industries such as BASF have constantly supported the development of advanced computational methods as well as their application in various domains of materials science, thus generating several patents (for the impact of ab initio simulations see, e.g., Andreoni et al. 2006, 2012, Afyfy et al. 2013, Laino and Weber 2019).

The two following chapters discuss materials of primary importance in contemporary technology: titanium dioxide (titania) and graphene. In both cases, several examples show how computer simulations have been able to complement and aid in understanding and also predicting the results of experimental investigation.

The chapter on titanium oxide (Selloni, ▶ Chap. 4, "Titania and Its Outstanding Properties: Insights from First Principles Calculations") illustrates how a series of ab initio calculations have been able to elucidate the complex nature of TiO_2 surfaces. For example, their physical properties and chemical reactivity depend on

the specific polymorph, on the specific surface and its structure, on the unavoidable presence of point defects such as oxygen vacancies, and on the exposure to water. It is also clear that the ab initio approach to different situations is not "standard" but special attention must be paid to the methodology to be applied. Indeed real-world applications primarily refer to reduced TiO_2. Thus, modeling imposes the need to go beyond the generalized gradient approximation (GGA) to the DFT exchange-correlation functional so as to reduce its intrinsic self-interaction error. Therefore PBE-DFT was augmented either with a (semiempirical) Hubbard (U) term or with a fraction of exact-exchange term as in the hybrid PBE0 exchange-correlation functional.

The chapter on graphene (Yazyev, ▶ Chap. 5, "Modeling Disordered and Nanostructured Graphene") focuses on the modeling of its peculiar characteristics and the calculation of their effects on a variety of physical properties that are crucial for any of the diverse applications of this material. In particular, an outstanding achievement of computations was the prediction of the structure of topological defects (dislocations and grain boundaries) prior to experiment that has confirmed those results. Key ingredients were the construction of ingenious structural models and subsequent ab initio calculations for the investigation of the electronic properties as well as for the determination of the most energetically favorable defect configurations. Calculations have also revealed the dependence of the electronic properties of nanostructured graphene on the nature of the edges, i.e., armchair or zigzag or chiral. We note that a complementary account of computational studies – also linked to experiment – of graphene nanoribbons can be found in ▶ Chap. 31, "Electronic Structure of Atomically Precise Graphene Nanoribbons," by Talirz and Pignedoli.

One of the greatest challenges for electronic structure calculations has long been that of approaching the physics of superconductors and determining in particular the critical temperature T_c. This "dream" has become reality – within the framework of density functional theory – only recently, after the seminal paper by Lüders et al. (2005). Boeri, ▶ Chap. 6, "Understanding Novel Superconductors with Ab Initio Calculations," guides the reader through the main steps leading to this achievement and subsequent successes of theory and computations for conventional superconductors. State-of-the-art calculations are not only able to contribute to the understanding of mechanisms leading to superconductivity but also to quantitatively characterize superconductive phases and predict the transition temperature. On the other hand, the case of unconventional superconductors like the high-T_c cuprates is not approachable yet with available methods.

The next chapter (Xu et al., ▶ Chap. 7, "Titanium Alloys: From Properties Prediction to Performance Optimization") presents an exhaustive and detailed review of the application of computational tools to the design and optimization of titanium-based alloys. The specific role of different methods at different length scales in this complex process is elucidated. They comprise electronic structure calculations and atomistic simulations for an early screening of fundamental material properties, mesoscale approaches for an understanding of microstructure evolution under specific processing and operational conditions, as well as finite element methods

for the simulation of various manufacturing processes and the final optimization of the material performance. Not only successful applications of the above protocol are described, but also difficulties are pointed out as well as important challenges for future progress. In particular, the aid of artificial intelligence strategies based on "big data" is called for. Connections of this chapter are evident with the *MTM* set of this handbook covering all the above-mentioned methodologies. Moreover, we remark that the example of titanium alloys is extremely interesting in view of their relevance in diverse industries and applications. Namely, depending on their composition, they are used in aerospace, marine, and biomedical applications.

The following articles are concerned with the study of specific and critical material processes via modeling at multiple scales.

The next chapter (Kamrin, ▶ Chap. 8, "Quantitative Rheological Model for Granular Materials: The Importance of Particle Size") deals with a class of complex systems – dense granular flows – whose understanding is still limited. This chapter provides an overview of granular material modeling at diverse levels and especially an insightful analysis of the constitutive behavior of dense granular matter through the development of a nonlocal continuum model of fluidity (the nonlocal granular fluidity (NGF) model). Several applications demonstrate, in particular, the importance of grain size effects on the flow properties. We remark that dense granular flows are common in countless natural processes (e.g., rock avalanches) and industrial applications (e.g., in the pharmaceutical and agricultural sectors). In the effort to describe, predict, and thus control their behavior, modeling and numerical approaches play a special role.

The section proceeds with a chapter (Masoero, ▶ Chap. 9, "Mesoscale Mechanisms of Cement Hydration: BNG Model and Particle Simulations") focused on cement – the most widely used man-made material in the world and in particular on the formation of its fundamental constitutive unit, calcium-silicate-hydrate (C-S-H). Linking the kinetics of the evolution of this process to the chemical (microscopic) characteristics of the original compounds, and eventually to the structural properties and mechanical behavior of the material, is one of the most critical and still largely open issues. This part of the handbook (*ACE*) dedicates specific chapters to the physical, chemical, and mechanical properties of cement, describing the results of computational methods and their performance relative to experiment (Ioannidou, ▶ Chaps. 71, "Mesoscale Structure and Mechanics of C-S-H"; Qomi et al., and ▶ 72, "Nanoscale Composition-Texture-Property Relation in Calcium-Silicate-Hydrates"). Masoero's plenary topic article can be considered a complement to those chapters. It deals with a relatively simple and very instructive scheme, the model of boundary nucleation and growth (BNG). It is an attempt to provide an approximate description of the early controlling step of hydration that is physically based and amenable to quantitative analysis. In particular, it shows how kinetic Monte Carlo simulations of nanoparticle aggregation can be exploited to improve on the parameters governing the BNG model and especially to provide an insight into their physical meaning.

The next chapter (Ciccotti and George, ▶ Chap. 10, "In Situ AFM Investigations and Fracture Mechanics Modeling of Slow Fracture Propagation in Oxide and Polymer Glasses") constitutes an exception because it mainly describes experimental

techniques and observations. It offers an insightful account of how slow fracture propagation can be quantitatively studied using the combination of in situ atomic force microscopy and phenomenological multiscale modeling. While it is focused on oxide and polymer glasses, the results discussed therein have significant and general implications for all time-dependent deformation processes in brittle materials. This detailed and extensive description of the experimental results should be seen as a source of inspiration for the development of computational methods for the simulation of fracture propagation and also other multiscale phenomena. We remark that the use of inserts to explain various key concepts in the subject matter offline from the main text is effective and it is hoped will be helpful to the reader.

Extended defects such as dislocations are ubiquitous in real crystalline materials and influence a variety of physical properties. Diverse examples of modeling and multiscale simulations are currently helping to understand, e.g., the origin of a dislocation or the way it propagates and affects the mechanical properties of a given material (see, e.g., the *MTM* section on "Crystal Plasticity: From the Atomic Scale to the Macroscale" – Editors: Cai and Ghosh). The next chapter (Fan and Cao, ▶ Chap. 11, "Long Time-Scale Atomistic Modeling and Simulation of Deformation and Flow in Solids") is concerned with the onset and propagation of dislocation-driven deformation and flow in crystals (specifically bcc metals) and glasses. These are processes that involve time scales well beyond the reach of classical molecular dynamics of atomistic models. In the *MTM* set of this handbook, we have presented methods allowing to access longer time scales, both those using direct acceleration techniques (see the section "Long Time-Scale Simulation Methods," Editors: Perez and Uberuaga) and those circumventing the time constraints with the aid of advanced enhanced sampling approaches (see the section "Atomistic Simulations," Editors: Andreoni and Yip). Application of the latter is not possible yet, given the complexity and size scale of the systems under investigation. A simpler but efficient alternative is applied instead, the autonomous basin climbing (ABC) algorithm, which allows one to explore and characterize the potential energy surface of a given system by coupling minimum energy pathway methods, kinetic Monte Carlo and transition state theory. We remark that the ABC method was originally employed to investigate viscous flows and the origin of the glass transition in supercooled liquids (Kushima et al. 2009). Note also that related issues are discussed in one of the chapters of the "Plenary Topics" part in *MTM* (Rizzo, Chap. 9, "Critical Phenomena in Glasses").

Dislocations are known to influence not only the mechanical response of a given material but also many other characteristics and functionalities. Understanding and predicting the effects of a dislocation on, e.g., electronic, optical, magnetic, or thermoelectric properties requires a quantum-based approach. To this end, a completely new full quantum theoretical framework has very recently been introduced by Li et al. (in a series of articles starting in 2017) and constitutes the subject of the last chapter of this section (Li et al., ▶ Chap. 12, "Quantized Dislocations for Functional and Quantum Materials"). In this theory a dislocation is quantized ("dislon" is the name of the basic quantum). Starting from a 1D approach to describe quantized single dislocations, these authors have shown that an extended (3D) scheme can be used to describe the electron and phonon interactions with multiple dislocations.

Several examples are presented. Benefits of this framework are claimed also for explicit calculations. Moreover, other implications can be envisaged.

3   Conclusions

A plenary topic is expected to be of general interest to a varied audience of readers. We think that each chapter of this section deserves to be classified in this way. In fact, for example, as we have pointed out, most of the chapters can be related to others across the parts of *MTM* or *ACE* and/or refer to themes (materials or processes) of very particular relevance.

The main messages arising from a careful reading concern, on the one hand, the value that state-of-the-art modeling and simulations have in tackling complex problems related to real materials and, on the other hand, the need to extend their reach through the development of multiscale methods and their integration in the design and optimization process.

In this respect, we underline Payne's contribution that is explicitly concerned with the possible impact of materials modeling in the realm of industry. Beyond that, we wish to call attention to the existence of a natural, cultural gap between the scientific community in the role of "producers" of modeling and simulation tools and society at large in the role of "users" of the science and technology. Bridging this gap is a long-standing challenge to both sides. The most promising solution is bound to involve hands-on collaboration among all the stakeholders. Still, we can conclude that – as illustrated also in this section – in the last decade, many opportunities have flourished for computational materials science to contribute at least to the understanding of problems of relevance to technology and societal needs.

The Industrial Impact of Materials Modelling

3

Mike Payne

Contents

Abstract

It has been estimated that \$1Billion per year is spent on academic research on materials modelling. At the same time, there is increasing pressure on academics to realize and/or demonstrate the socioeconomic impact of their research. Naively, in attempting to reconcile these two facts, one might assume that there was a demonstrable economic impact of materials modelling amounting to multiple \$Billions per year. However, as will be discussed here, the situation is rather more complex than this naïve picture suggests and there are significant challenges to realizing the benefits of materials modelling.

1 Introduction

Academics tend to focus on the impact of their research in terms of the quantity of papers and the quality of the journals they publish in and the number of citations their work receives. In terms of the first metric, the annual output of papers based

M. Payne (✉)
Theory of Condensed Matter Group, Cavendish Laboratory, University of Cambridge, Cambridge, UK
e-mail: mcp1@cam.ac.uk

on Density Functional Theory (DFT) is so large that it has to be measured in kilopapers per year. In terms of the last metric, as Professor Nicola Marzari pointed out in 2013, DFT and electronic structure also reigns supreme with 18 the top 20 highest cited papers published by the American Physical Society. Therefore, there is little doubt about the academic impact of this field. However, here we focus on the economic impact of materials modelling, and so, from this point on in this chapter, "impact" will be used to refer exclusively to economic impact. Professor Marzari has estimated the global cost of academic research in materials involving DFT to be of the order of $1 Billion per year. This is based on an estimate of 10,000 for the number of DFT papers published per year which focus on materials and an estimate of $100,000 for the cost of the staff and computational resources required to generate each paper. If this is the case, then one would have expected that there would be a demonstrable economic impact of DFT modelling of many times this sum.

There are, of course, many simple and routinely used methods that academics have perfected to distract any detailed scrutiny of the wider impact of their work. One of the most common ones is to simply assert that the return on investment (RoI) on money spent on academic research is 19, sometimes this is even presented as the return on investment each year. It is a commonly quoted figure, and the methodology and, indeed, the time at which this figure was calculated are somewhat unclear. Nevertheless, this figure is widely used to justify investment in academic research. Notwithstanding any concerns about the figure itself, the obvious issue is that this result cannot extend to all levels of investment in academic research. If a country decides to spend its entire GDP on research 1 year, I find it doubtful that the research will generate 19 times that sum in total future economic benefits, let alone every year. If this were the case, then all the world's economic problems could be trivially solved by investing vast sums of money in academic research.

Over the last two decades, the UK has become increasingly focussed on the socioeconomic benefits of the research it funds. Initially, in the case of research grant applications to UK Research Councils, this involved little more than asking academics to consider whether their work might have impact. This question was usually addressed by including a completely unjustified statement about the £millions of economic benefit that the research would generate. Over the years, this requirement to consider impact has become more demanding and now every grant application to UK Research Councils has to include a (maximum) two page "Pathways to Impact" document explaining how the impact of the research will be realized. However, there are a significant number of weaknesses in the current UK system. For a start, the vast majority of these grant applications are refereed by other UK academics who may have limited, if any, experience of generating socioeconomic impact. However, the most significant flaw in the system is that it is entirely focused on the "input" side – the grant application – and there is currently no monitoring to see whether the claimed long-term socioeconomic impact has been achieved, let alone applying any sanctions on people who serially fail to deliver their promised socioeconomic benefit. Perhaps not surprisingly, there is a very varied level of engagement in generating impact within the UK research community.

The solution to the challenge of generating impact is, of course, trivial. It can be achieved simply by focussing on the "output" side of research and rewarding researchers who genuinely generate impact. If the easiest way to get the funding for a postdoctoral researcher is by generating impact, then I can guarantee that virtually every academic would focus on this challenge. If other countries wish to follow UK down this direction of expecting socioeconomic benefit from academic research, they are advised to create an output-based mechanism for ensuring this.

The importance of impact in the UK has now extended considerably beyond research grant applications. About once every 7 years, there is an assessment of the quality of all UK university research. Initially, if somewhat unimaginatively, this process was called the Research Assessment Exercise (RAE). During this era, it focused almost exclusively on academic measures of the quality of research. The RAE has now been replaced by the Research Excellence Framework (REF), and the first operation of REF took place in 2014. Under REF, the socioeconomic impact of research determines how £200 million of annual government funding is distributed to English universities by HEFCE (Higher Education Funding Council for England – similar mechanisms operate in the rest of the UK). The mechanism for evaluating impact under REF is through so-called Impact Case Studies, examples of which can be found at http://impact.ref.ac.uk/CaseStudies/. In addition to directly rewarding successful examples of impact, which is laudable, it should be noted that the last REF exercise only required one Impact Case Study for every ten academics entered into REF – thus recognizing that not every academic could be expected to generate socioeconomic benefit from their work during every REF reporting period. REF demanded high levels of auditable evidence of socioeconomic impact. For instance – though it does not relate to the current subject area – if a historian had made or contributed to a major television program – which one might have thought would have been an excellent example of social impact – an Impact Case Study would only have been admissible if there was auditable data for the size of the audience. Thus, many examples of academic research that have had significant socioeconomic benefit are not eligible for REF, and it is easy to envisage such examples in the field of materials modelling. If someone from industry finds the solution to a problem in the scientific literature, it is very unlikely that the consequent economic benefit would be associated with the original academic research as, in most cases, the academic would not be aware of this benefit.

Another example of impact playing a larger role in the funding of UK universities is provided by the change over the years in the mechanism for providing government funding for infrastructure. In the past, large amounts of infrastructure funding, say for buildings or major research facilities, were provided based on purely academic arguments. Now these schemes have been replaced by the UK Research Partnership Investment Fund (http://www.hefce.ac.uk/rsrch/ukrpif/). The UKRPIF provides significant investments into UK universities but only *after* those universities have brought in at least twice that amount of money in industrial (or other non-government) funding.

While these examples are taken exclusively from the UK, it does seem that discussions about the importance of generating socioeconomic impact from publicly

funded research are becoming widespread. The materials modelling community has, at least in part, justified its research funding for decades on the basis that this was an investment that would give us the ability to design materials which would obviously provide significant impact. However, while many industries have moved to "virtual" (i.e., entirely computational) design for all or some of their operations, the materials community is faced with the reality that virtual materials design is a long way from becoming the entirety of the product design cycle. This is not to say that the various materials modelling methods described in this handbook will not have a role in virtual materials design. It is just a statement of the fact that, whatever information we can determine about a material, we cannot currently guarantee, based on modelling alone, that the material will not deteriorate or fail over the lifetime of a product. As a community, we know that materials are complex on many levels, in their compositions, microstructures, and properties, and that materials properties range over enormous ranges of lenthscales and timescales. It is not clear that funders will continue to be sympathetic to these issues and may increasingly ask our community the question "If I can design a car or an airplane on the computer and go away and make it without creating a prototype, why can't I design a material on the computer and then go away and make it in exactly the same way." The first step of this process, namely, designing a material on the computer, has been an active research field for many years with numerous examples, such as the numerous predictions of superhard materials (see for instance, Mattesini and Matar 2001). These are materials that have elastic moduli that are larger than those of diamond. However, none of the predicted superhard materials have been developed into real-world products. There can be many reasons for this. One common problem is the failure to fabricate a material with the same composition and structure as the theoretically designed material. In the case of superhard materials, there may be failure mechanisms operating on larger lengthscales that cause the material to fail under loads that are smaller than the ones that can be accommodated by diamond so that the material is harder than diamond on the atomic scale but weaker on longer lengthscales. While we may struggle to point to examples of purely computational design of materials, materials modelling methods have been used by many companies for decades, so, presumably, there must be some benefit gained from their use. It is, however, quite difficult to determine this benefit as companies tend not to be very forthcoming about their use of materials modelling methods. Swenson et al. researched this issue for a report entitled "Modeling and Simulation: The Return on Investment in Materials Science" published by International Data Corporation (IDC) in 2004. More recently, Gerhard Goldbeck of Goldbeck Consulting has published a series of extensive reports on this topic (Goldbeck 2012, 2014; Goldbeck and Court 2016) and readers who wish to gain a deep understanding of the impact of materials modelling should read these reports. The remainder of this chapter will provide a summary of the most important findings presented in these reports interspersed with the author's own experiences and other people's accounts of their experiences of the impact of materials modelling – a number of these were covered in an E-CAM Industry Workshop on materials design "From the Atom to the Material".

2   Industrial Requirements for Materials Modelling

The first thing that needs to be appreciated by any academic who wishes to engage with industry is the enormous variation in expertise, work practices, and requirements for materials modelling from one company to the next. At the E-CAM Workshop, this was summed up by the phrase "There is no such thing as industry!" The talks and comments from industry-based participants reflected this broad range of requirements from industry for materials modelling, in terms of types of material, properties of interest, and, interestingly, the level of accuracy required. This ranged from one extreme of a requirement for quantitatively accurate predictive simulations to, in the middle, not being worried about the absolute value of a predicted quantity but only about trends under change of composition to the other extreme of only using modelling and simulation to provide insight into complex physical problems without requiring quantitative accuracy. It became apparent that in most cases, even in large companies, materials modelling is a very small-scale activity at present, and in many companies, it does not exist at all. It is also not unusual to have no company-wide view of modelling activities, so that there is no information exchange between different divisions of the same organization. A further important conclusion from the E-CAM Workshop was that the value of materials modelling was often only realized when these tools were integrated into the entire product design process. Materials operate in systems and any benefit in a material property is only realized in the real world if it can be incorporated into a product. Hence, the one story universally heard from industry is that materials modelling plays a role in product development but only a role – and the failure to address the rest of the ecosystem will usually prevent successful deployment of a material. This was clearly demonstrated in Ford's Virtual Aluminum Casting project (Allison et al. 2006) and it is referred to as Integrated Computational Materials Engineering (ICME, Pollack et al. 2008). Goldbeck (2016) provides further examples of ICME generating significant RoI including:

GE Aviation utilized an ICME approach to achieve a reduction in the amount of rhenium (a rare and expensive element) in superalloys for aircraft engine turbine airfoil components which resulted in the introduction of a new alloy in 2 years rather than the typical 6 years historically required.
QuesTek Innovations led a project that resulted in the development of the corrosion-resistant Ferrium S53 advanced high-strength steel alloy for landing gear and other applications. The ICME approach led to significant reductions in alloy development time and an estimated development cost savings of nearly $50 M.

ICME is something that academics cannot do alone, and, hence, there is a significant challenge to making a real economic impact from academic research unless it leaves the academic sphere. The level of investment needed to implement ICME represents a barrier to adoption which can make it extremely difficult to persuade a company of the potential benefits of materials modelling. Furthermore, to be incorporated into ICME, modelling methods need to be easy to use and

not dependent on high levels of expertise and experience. It should be noted that the VAC project outsourced a significant fraction of its materials modelling requirements to academia and this does provide a mechanism for circumventing this problem of accessibility. Interestingly, Goldbeck (2014) identifies a similar phenomenon among the network of Psi-k researchers (http://psi-k.net/), many of whom were found to have industry connections.

The various impact reports point to the high level of trust and, hence, widespread adoption of density functional theory methods by industry compared to the lower level of trust and, hence, more restricted adoption of empirical and coarse-grained methods. Golbeck (2016) emphasizes industry demands for improved guidance to help assess the accuracy of any computational method for a particular materials problem. As discussed earlier, industries may not be too worried about a high level of accuracy in any particular case but do need guidance about the expected level of error in any prediction of a materials property.

3 The Role of the Translator and the Level of Materials Modelling Activity

Many of us will know people or may even be the person who has an uncanny ability to relate a complex materials process to accessible atomic scale calculations. The E-CAM Industry Workshop highlighted their importance as every example of materials modelling significantly driving forward progress in an industrial process involved such an individual. Indeed, software vendors in the materials space probably spend as much time carrying out this task as developing their software. Given the importance of this task, it is encouraging that the European Materials Modelling Council has recognized this role and given it the title of "translator" – the individual who can connect (in both directions) a complex product challenge to a set of feasible materials modelling tasks. There is also direct numerical evidence in the IDC report that increasing levels of experience and expertise produce a greater level of impact of materials modelling – essentially, the more materials modelling a company carries out, the higher the rate of return on investment. Disappointingly, it seems that neither the IDC report nor, in many cases, a company's own experience of the value of materials modelling have led to increases in the amount of materials modelling a company does.

4 What Materials Modelling Can Do for Industry

Once one moves away from the academic aspiration of designing materials entirely on the computer to the real-world industrial use of materials modelling, perhaps as a component of ICME, then there are many ways that modelling can add value to a project. These include:

More efficient experimentation – for instance, using modelling to determine which direction to move in composition space to create a material with better properties.

Broader exploration and deeper understanding – in the case where modelling is cheaper than experiment and accurate enough using modelling to perform a more extensive parameter search than could have been afforded using experiment alone.

Saving a product development project and/or accelerated product development – for instance, modelling providing a solution to a problem that had not been solved using the tools previously available for development.

Risk management through safety testing.

It should be noted that none of these ways involve the entire design of a material but instead are contributions that modelling can make to the materials design process. In their IDC report, Swenson et al. developed quantitative models to illustrate the potential RoI of each scenario. These models were reanalyzed with updated financial figures in Goldbeck (2012). These analyses suggest a more credible value for the RoI for materials modelling in the range of 3 to 9 – with the higher value associated with a higher use of modelling suggesting that the more resource a company invests in materials modelling, the higher their rate of return on this investment.

5 Materials Modelling Marketplaces

The traditional model of operation of software companies creates a significant barrier to adoption of materials modelling methods, particularly for small- and medium-sized companies – usually referred to as "small and medium enterprises" (SMEs). The traditional model for software companies is selling licenses for software products which allow the software to be installed and used on the client's hardware. This model works well in the case of large companies who have suitable computer hardware and IT expertise to support the necessary hardware and software. However, SMEs often do not possess large computational resources or significant levels of IT support, In this case, a move into materials modelling may require substantial investment in computer hardware and increased levels of IT support in addition to the cost of the software license. Without an absolute guarantee of a successful outcome from the materials modelling and a consequent economic benefit to the company, one can understand why many companies are cautious about setting up a substantial materials modelling effort. This concern could be allayed if there were more information generally available about the successes of materials modelling, but there is an understandable reluctance for companies to reveal such information as their competitive advantage gained from the modelling could be revealed to their competitors. Sometimes this information is eventually divulged but usually only after a significant period of time so that the competitive advantage has elapsed and disclosure no longer risks the competitive advantage. Furthermore, the cost of software licenses is predicated on the assumption that they

are used continuously. For many SMEs, this is not a realistic model as it is likely that only a small fraction of staff time could be expended on materials modelling. The high start-up cost represents a significant barrier to entry for materials modelling. In various other market sectors, this issue has been addressed by moving to a "Cloud" model of computing and a charge per use approach to software – usually referred to as "Software as a Service." The US nanoHUB (https://nanohub.org/) provides an excellent example of a Cloud-based materials modelling service which provides hundreds of modelling tools and has over a million users who do not have to pay to use the resources provided by the site – even the computational resources needed to run the software. This clearly limits the range of software provided as this model precludes the participation of materials modelling software vendors and hence the lack of particular tools and techniques. Interestingly, the European Materials Modelling Council (EMMC https://emmc.info/) is creating a materials modelling marketplace that, in principle, could address this problem as it would allow any user to access both free and commercial modelling tools and purchase the necessary computational resources to for the calculations they wish to carry out – paying on a per-use basis for the actual work done rather than requiring a large initial investment. It will be interesting to see how this initiative develops in the longer term. I hope that it will lead to a much wider adoption of the "Software as a Service" model for materials modelling which will be crucial for the materials modelling community to see widespread use of its methods across industry.

Titania and Its Outstanding Properties: Insights from First Principles Calculations

4

Annabella Selloni

Contents

Abstract

Titanium dioxide (TiO$_2$) is one of the most widely used photocatalytic materials due its abundance, non-toxicity, and high stability in different environments and conditions. TiO$_2$ is also considered a prototypical metal oxide and a model system for experimental and theoretical studies of materials properties and surface reactions. TiO$_2$ has several polymorphs, rutile and anatase being the most common ones. Rutile is the thermodynamically most stable bulk phase; anatase is stable in nanoparticles and shows higher activity in many photocatalytic reactions, making it the most interesting phase for use in high surface area photocatalytic and photovoltaic devices. While insulating when stoichiometric, TiO$_2$ is most frequently reduced and electrically conducting due to the presence of intrinsic defects and their induced excess electrons, which transform it into an *n*-type semiconductor with many technologically relevant properties. As surfaces have a prominent role in most of TiO$_2$'s applications, intense efforts

A. Selloni (✉)
Department of Chemistry, Princeton University, Princeton, NJ, USA
e-mail: aselloni@princeton.edu

have been devoted to the characterization of TiO_2 surfaces and their interactions with various molecular species and environments. In this chapter, we present an overview of recent theoretical/computational studies on TiO_2, focusing mainly on reduced anatase surfaces and their interactions with molecular oxygen and water, which have a central role in various fields, from photocatalysis and nanomaterial synthesis to geochemistry and environmental chemistry. These studies highlight the effectiveness of combined experimental and theoretical approaches as well as the important role of simulations in bridging the gap between experiments under vacuum conditions and in realistic environments.

1   Introduction

Titania (TiO_2) is one of the most chemically stable, environmentally compatible, and functionally versatile oxide materials. While huge amounts ($\sim$7 million tons) of TiO_2 are produced every year for use as a white pigment in paints and many other common products, TiO_2 is also a prime material for advanced applications such as solar energy harvesting and hydrogen generation from water (Chen et al. 2010), photocatalytic decomposition and synthesis of organic chemicals (Schneider et al. 2014), environmental remediation (Hoffmann et al. 1995), reduction of CO_2 to chemical fuels (Ma et al. 2014), electron conductor in dye-sensitized solar cells (Hagfeldt et al. 2010), rechargeable batteries, super-capacitors, sensors (Bai and Zhou 2014), and biomedical devices (Rajh et al. 2014). In fact, TiO_2 is currently almost the only material that is suitable for photocatalytic applications on the industrial scale.

A fundamental characteristic of TiO_2 of great importance in photocatalysis is the energy of its valence band maximum (VBM) and conduction band minimum (CBM) (Graetzel 2001). Figure 1 shows the band edges of various photocatalysts, including TiO_2, compared to the water oxidation and reduction potentials. A photoexcited electron (e^-) can be transferred to an acceptor molecule (A) if the CBM of the material is higher than the reduction potential of A. Similarly, a photoexcited hole (h^+) can be filled by donor (D) electrons if the VBM of the material is located lower than the oxidation potential of D. TiO_2 has the appropriate band alignments for water splitting, which is one of the main reasons of the scientific interest in this material for over 40 years. The low energy of TiO_2's VBM is an additional favorable feature, which can largely explain why TiO_2 is an efficient photocatalyst for the oxidative degradation of organic pollutants.

TiO_2 has several crystalline forms, rutile and anatase being the most common ones. Rutile is the thermodynamically most stable bulk phase, while anatase is very common and stable in nanomaterials, due to the relatively low formation energies of its surfaces (Zhang and Banfield 1998). The anatase phase shows also the highest photocatalytic activity, which makes it the most interesting phase for use in high surface area photocatalytic and photovoltaic devices (Kavan et al. 1996). The structures of these two TiO_2 polymorphs are shown in Fig. 2. Both rutile (tetragonal, P_{42}/mnm, $a = b = 4.594$ Å, $c = 2.959$ Å) and anatase (tetragonal,

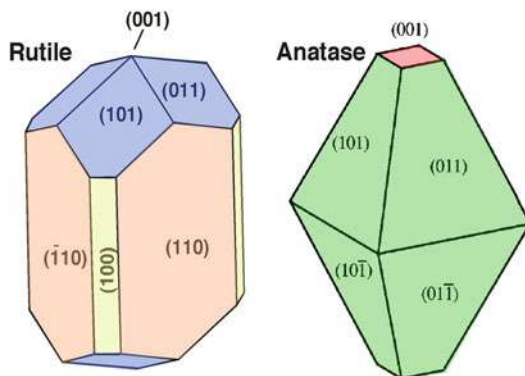
Fig. 2 Bulk structures of (**a**) anatase and (**b**) rutile. The tetragonal unit cell of rutile has dimensions $a = b = 4.587$ Å, $c = 2.957$ Å, and the one of anatase $a = b = 3.782$ Å, $c = 9.502$ Å
$I4_1/\text{amd}$, $a = b = 3.782$ Å, $c = 9.502$ Å) are built from chains of distorted TiO_6 octahedra, with Ti atoms coordinated by six oxygens and each oxygen atom surrounded by three planar Ti atoms. The distortion of the octahedral field is small in rutile, where the two apical Ti-O bonds are $\sim$1.98 Å and the four equatorial Ti-O bonds form a square with bond length $\sim$1.95 Å. The distortion is more pronounced in anatase, where the mirror plane symmetry perpendicular to the apical

bonds ($\sim$1.973 Å) is lost, and the four equatorial Ti-O bonds ($\sim$1.93 Å) are not in a plane. Interestingly, first principles electronic structure calculations have for long time been unable to reproduce the experimentally observed higher stability of rutile relative to anatase. Only very recently highly accurate quantum Monte Carlo calculations have shown that the energetic contribution arising from thermal nuclear motion is crucial in determining the phase stability of these two TiO_2 polymorphs (Trail et al. 2017).

Because surfaces play a major role in virtually all TiO_2 applications, it is of great interest to understand the effect of surface structure on various TiO_2's functional properties. Therefore, intense efforts have been devoted to characterizing the atomic geometries, electronic structures, and reactivities of different anatase and rutile surface terminations (Diebold 2003; Pang et al. 2013; De Angelis et al. 2014). Figure 3 shows the equilibrium crystal shapes of rutile and anatase derived from first principles calculations of the surface energies for different terminations. For rutile, the computed Wulff shape is mainly terminated by (110) and (011)/(101) surfaces (Ramamoorthy et al. 1994), whereas for anatase it consists of a truncated tetragonal bipyramid exposing majority (101) and minority (001) facets (Lazzeri et al. 2001). It is quite remarkable that these shapes, obtained assuming perfectly clean, stoichiometric, and defect-free bulk-terminated surfaces, agree well with the typical shapes of many synthetic and natural samples, which actually contain a large variety of imperfections, defects, and adsorbates.

In this Chapter, we present an overview of recent investigations on TiO_2, with particular focus on theoretical studies based on first principles total energy calculations and molecular dynamics simulations. The aim is to highlight the new physical/chemical insights provided by these studies as well as the advances that can be made by a combined theoretical and experimental approach. Most theoretical studies on TiO_2 are based on density functional theory (DFT), which has generally proven quite successful at predicting TiO_2 properties and explaining experimental observations over the last 20 years (De Angelis et al. 2014). However, the standard local density approximation (LDA) and generalized gradient approximation (GGA) of DFT fail in describing excited state properties as well as the behavior of the excess

Fig. 3 Equilibrium shapes of rutile (left) and anatase (right) obtained using the Wulff construction and the surface energies computed in Ramamoorthy et al. (1994) and Lazzeri et al. (2001), respectively


electrons of reduced TiO_2 (see below) (Di Valentin et al. 2009). This limitation originates from the self-interaction error (Cohen et al. 2008), causing problems such as the underestimation of the band gap and the over-delocalization of electrons in defects or impurity states. Green's function-based methods (Onida et al. 2002) are in general of great value to deal with problems such as calculations of excitation and ionization energies, transition matrix elements, absorption coefficients, and so on but are extremely expensive for studying systems of large size, such as surfaces and interfaces. In practice, more pragmatic approaches, notably the DFT+U method (Anisimov et al. 1991), explicitly penalizing the electron delocalization, and hybrid DFT functionals (Becke 1993; Perdew et al. 1996), including a fraction of Hartree-Fock exact exchange, are typically used to mitigate the self-interaction error. However, both methods are rather arbitrary in the amount of "correction" they include. As a result, the U value or fraction of exchange that works well for a particular application often does not produce similarly good results for another. Hence, much care is needed not only in applying these methods but also in comparing their results to experiment.

2   Reduced TiO_2

In stoichiometric form, rutile and anatase TiO_2 are insulators with band gaps of ~3.05 and 3.20 eV and formal oxidation states O^{2-} and Ti^{4+} for the oxygen and titanium ions, respectively. Most frequently, however, TiO_2 samples are reduced (i.e., substoichiometric with a reduced oxygen content) and electrically conducting, due to the presence of intrinsic defects, notably oxygen vacancies (V_O's) and titanium interstitials (Ti_{int}'s) (Di Valentin et al. 2009). These defects induce excess electrons, e.g., the removal of a neutral oxygen atom leaves two excess electrons in the lattice, thus transforming TiO_2 into an *n*-type semiconductor.

TiO_2's reduction is also associated with the formation of Ti^{3+} species, for which there are various experimental evidences, such as a g-tensor typical of a Ti $3d^1$ state measured in electron paramagnetic resonance (EPR) experiments (Berger et al. 2005; Livraghi et al. 2011, 2014), and the presence of a gap state at ≈ 2 eV above the valence band maximum and ≈ 1 eV below the conduction band minimum, which is observed by photoelectron spectroscopy (PES) and electron energy loss spectroscopy (EELS) (Diebold 2003; Thomas et al. 2007). This deep level indicates that V_O's excess electrons occupy well-localized states characteristic of small polaron behavior. At the same time, however, the occurrence of *n*-type conductivity suggests that these defects behave as shallow donors (Forro et al. 1994). For anatase, this behavior was confirmed by ARPES measurements (Moser et al. 2013), which showed a shallow donor level, ~40 meV below the CB, in samples containing a large concentration of O-vacancies.

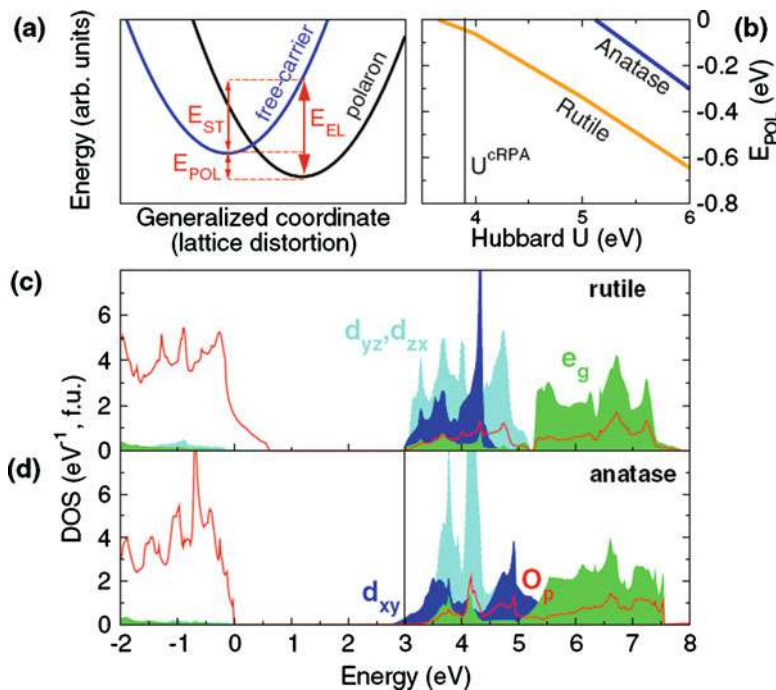
These seemingly conflicting results have motivated numerous investigations of intrinsic defects and their excess electrons in reduced TiO_2 in the last decades, and several general features of their states have now become clearer. In particular, there is now convincing evidence that excess electrons in bulk rutile tend to form


Fig. 4 (**a**) Schematic configuration coordinate diagram showing the polaronic formation energy (E_{POL}), lattice deformation energy (E_{ST}), and electronic localization energy (E_{EL}) as a function of lattice distortion for the polaronic and delocalized states. E_{POL} and E_{EL} represent the adiabatic and vertical excitation energies of the electron from the localized polaronic state to the "free" conduction band state and can be probed experimentally by, e.g., transport measurements and PES, respectively. (**b**) E_{POL} as a function of Hubbard U in bulk rutile (orange) and anatase (blue) shows that electron localization is "easier" (i.e., requires a smaller U value) in rutile than in anatase. The vertical line indicates the value U^{cRPA} determined using advanced RPA calculations. small polarons largely localized at single Ti lattice sites, whereas electrons prefer to form large polarons in anatase (Setvin et al. 2014b) (Fig. 4). Electron transport thus occurs mainly via hopping in rutile (Deskins and Dupuis 2007), while a band-like mechanism becomes accessible at relatively low temperature in anatase.

Another well-known characteristic of reduced TiO_2 is its blue color, whose intensity increases with the degree of reduction (Fig. 5). It was proposed earlier on that electronic $d \rightarrow d$ transitions originating from the Ti^{3+}- induced states in the band gap are responsible for the blue color (Khomenko et al. 1998), but the final states of these transitions were not known in detail. More recently, two-photon photoemission (2PPE) measurements identified an excited resonant state centered at ~ 2.5 eV above the Fermi energy (E_F) associated with Ti^{3+} species in reduced TiO_2 (Onda et al. 2004; Argondizzo et al. 2015; Wang et al. 2015; Zhang et al. 2015).
DFT calculations showed that this excited state is closely related to the band gap state, as they both result from the Jahn-Teller-induced splitting of the $3d$ orbitals of Ti^{3+} ions (Wang et al. 2015). The $d \rightarrow d$ transitions from the Ti^{3+} related occupied band gap state at $\sim$ -(0.8–1.0) eV to the empty excited state at $\sim$2.5 eV increase the photoabsorption in the ultraviolet (UV) region. At the same time, the wide distribution of these two states can extend the absorbance to the visible range. This extended photoabsorption together with the near infrared absorption produces an absorption minimum in the blue, which is the reason why reduced TiO_2 samples appear as blue.

3   Structure and Reactivity of Anatase TiO_2 Surfaces

While surface science studies of rutile date back to the late 1970s (Henrich et al. 1976), experimental characterization of well-defined anatase surfaces has been for long time challenging due to difficulties in growing sufficiently large single crystals for surface science measurements. For this reason, a great deal of information on anatase surfaces has initially come from theoretical studies (De Angelis et al. 2014). Anatase crystals most frequently expose (101) and (100)/(010) surfaces, with a smaller contribution of (001) facets (Fig. 3). The atomic geometries of (101) and (001) surfaces are shown in Fig. 6. From low energy electron diffraction (LEED) experiments, it is known that the majority (101) surface has the same (1×1) periodicity of the bulk termination. This surface is quite corrugated and exposes both undercoordinated fivefold Ti (Ti_{5c}) and twofold O (O_{2c}) atoms, as well as fully coordinated sixfold Ti (Ti_{6c}) and threefold O (O_{3c}) atoms (Fig. 6a). DFT studies have provided a detailed picture of the atomic relaxations on this surface, and the computed pattern has been found to agree well with the results of surface X-ray diffraction (SXRD) measurements in a recent study (Treacy et al. 2017).
Fig. 6 Ball and stick models (side views) of (**a**) anatase TiO_2 (101); (**b**) relaxed anatase TiO_2 (001) – (1 × 1); (**c**) reconstructed anatase TiO_2 (001) – (1 × 4) according to the ADM model (Lazzeri and Selloni 2001)

Unlike anatase (101), the bulk-terminated anatase TiO_2(001) surface exposes only coordinatively unsaturated Ti atoms (Ti_{5c}) together with O_{2c} and O_{3c} atoms (Fig. 6b). However, this structure is only metastable, and experiments have revealed that the anatase (001) surface is actually reconstructed with a (1 × 4) periodicity with respect to the bulk (Herman et al. 2000). The model that is widely accepted to represent the structure of the (1 × 4) reconstructed surface is the so-called "ad-molecule" (ADM) model (Fig. 6c), which was originally proposed on the basis of DFT calculations (Lazzeri and Selloni 2001). The ADM model is constructed by periodically replacing [100] rows of bridging O_{2c} atoms of the unreconstructed 1 × 1 surface with rows of TiO_3 species. This results in "ridges" on which the Ti atoms are fourfold coordinated. The computed surface energy of the 1 × 4 ADM structure is nearly half that of the unreconstructed surface, indicating that this reconstruction stabilizes the surface quite effectively. The primary mechanism of this stabilization is the relief of the surface stress (Lazzeri and Selloni 2001). On the bulk-terminated surface, the large Ti_{5c}-O_{2c}-Ti_{5c} bond angles (∼156°) and Ti_{5c}-O_{2c} bond lengths (1.96 Å) give rise to a significant tensile surface stress. In the 1 × 4 ADM structure, the insertion of an extra TiO_2 row causes a compression which

makes the surface bonds shorter, 1.80–1.85 Å, and the bond angles smaller, $\sim 120°$; as a result, the tensile stress is also strongly reduced.

3.1 Reduced Anatase TiO$_2$(101) Surface

A well-known result of surface science studies on TiO$_2$ is that the rutile TiO$_2$(110) surface exhibits a large (5–10%) concentration of surface oxygen vacancies under the typical preparation conditions used for those experiments (Diebold 2003). In contrast, STM measurements on a freshly cleaved anatase TiO$_2$(101) sample revealed an almost perfect surface with very few subsurface impurities and adsorbates and no oxygen vacancies (He et al. 2009a). DFT calculations showed that oxygen vacancies have indeed lower formation energy in the subsurface and deeper layers than at the very surface (Cheng and Selloni 2009a). DFT studies also predicted that an O-vacancy could easily migrate from the surface to the subsurface with a barrier of about 0.75 eV (Cheng and Selloni 2009a). Experimentally, surface oxygen vacancies are not naturally present on anatase (101) but could be induced by electron bombardment and found to migrate to subsurface sites at temperature larger than 200 K, in agreement with the theoretical prediction (Scheiber et al. 2012).

The different characteristics of oxygen vacancies and their accompanying excess electrons on the rutile TiO$_2$ (110) and anatase TiO$_2$ (101) surfaces are illustrated in Fig. 7. On rutile, V$_O$s prefer to form at surface bridging oxygen sites,

(a)   (b)
Fig. 7 Spatial distribution of the two excess electrons from an oxygen vacancy at the reduced rutile (110) and anatase (101) surfaces. (**a**) Surface V$_O$ in reduced rutile TiO$_2$ (110) (Deskins et al. 2011) and (**b**) subsurface V$_O$ in reduced anatase TiO$_2$ (101) (Selçuk and Selloni 2014), both from DFT+U calculations

and their excess electrons are mainly located away from the vacant site in the subsurface, where they form small polarons (Ti^{3+} species) that can hop rapidly among different sites (Deskins et al. 2011) (Fig. 7a). While the distribution of the excess electrons of a subsurface V_O on anatase (101) is not known as well as in the case of a surface V_O on rutile (110), several theoretical studies have predicted a distribution with one of the two electrons localized at a subsurface Ti site close to the vacancy and the other more or less (depending on the U value) delocalized on surface Ti sites (Selçuk and Selloni 2014); an example where both electrons form two well-localized Ti^{3+} species is shown in Fig. 7b.

3.2 The Interaction of Molecular Oxygen with Reduced Anatase $TiO_2(101)$

The interaction of molecular oxygen with TiO_2 surfaces plays a key role in many technologically important processes such as catalytic oxidation reactions, chemical sensing, and photocatalysis. For example, O_2 adsorbed on TiO_2 surfaces acts as an electron scavenger and is often used to suppress electron-hole recombination, which increases the lifetime of the excited state and thus the yield of the photocatalytic reaction (Berger et al. 2005). Molecular oxygen does not adsorb on stoichiometric TiO_2; excess electrons, i.e., reduced surfaces, are required. In fact, oxygen adsorption involves the transfer of one or more of these excess electrons from the TiO_2 surface to the O_2 molecule. Oxygen adsorption is also the first step toward oxygen incorporation, a fundamental reaction that strongly affects the chemical properties and charge-carrier densities, as it can transform the material from an *n*-type semiconductor to a poor electronic conductor.

An important aspect of the interaction of O_2 with reduced anatase TiO_2 concerns the charge state of adsorbed O_2. While DFT calculations generally predict that O_2 adsorbs as a peroxide (O_2^{2-}) (Aschauer et al. 2010), EPR measurements on anatase powders have identified stable superoxide (O_2^-) species (Berger et al. 2005). This difficulty has motivated hybrid functional calculations of the charge transfer reaction between reduced anatase (101) and molecular O_2 (Li and Selloni 2013). It was found that although the peroxo O_2^{2-} species is energetically more stable than O_2^-, there is a significant barrier, $\sim$0.3–0.4 eV, that must be overcome to transfer a second electron to the adsorbed O_2^- (whose formation is barrierless) and transform it to a peroxide. The existence of this barrier can thus explain why experimentally superoxo species are often observed.

Although O-vacancies are located subsurface on anatase (101), they can actively take part in the reaction with molecular O_2. In FPMD simulations it was indeed observed that an O_2 molecule adsorbed at a surface Ti_{5c} site close to a subsurface V_O can further react with the subsurface V_O according to the sequence **b-e** shown in Fig. 8 (Setvin et al. 2013). In the resulting structure, denoted $(O_2)_O$, the O_2 takes the position of a twofold coordinated O (O_{2c}) atom in a bridging configuration.
Fig. 8 Potential energy profile and selected structure snapshots along the pathway leading from an adsorbed O_2 atop a subsurface oxygen vacancy to the bridging dimer state at the anatase TiO_2 (101) surface. (Adapted from Setvin et al. 2013)

The $(O_2)_O$ retains a bond length of 1.46 Å, characteristic of peroxide. This species (often referred to as "interstitial" or "bridging" O_2) had been previously proposed to be an important intermediate in the photocatalytic splitting of H_2O on anatase (101) (Li et al. 2010).

Experiments were performed to verify whether such an $(O_2)_O$ species really exists (Setvin et al. 2013). Since $(O_2)_O$ should also form when an O_2 directly reacts with a surface V_O, surface V_O's were created on anatase (101) via electron bombardment and subsequently the surface was dosed with O_2. STM measurements showed that some of the V_O's were replaced by double spots located at O_{2c} sites, whose appearance agrees well with calculated STM images of the $(O_2)_O$ configuration. Without such artificially created surface V_O's, the same $(O_2)_O$ were observed quite rarely, most likely because O_2 does not often adsorb just on top of a subsurface oxygen vacancy.

4   Structure of TiO$_2$ Aqueous Interfaces

The structure of the TiO_2 – water interface – is relevant to a wide range of applications, from photocatalysis and biocompatible devices to more traditional applications like pigments and coatings (Sun et al. 2010). It was shown theoretically (Vittadini et al. 1998), and later confirmed by STM measurements (He et al. 2009a), that isolated water molecules adsorb in undissociated form on the anatase TiO_2 (101) surface, with the water oxygen (O_w) forming a dative bond with the Ti_{5c}, and the water hydrogen atoms (H_w) forming H-bonds with two O_{2c} atoms on the two adjacent rows (Fig. 9). The absence of water dissociation indicates that the (101) surface is little reactive, as one generally expects for very stable (i.e., low energy) surfaces. Molecular adsorption was theoretically predicted to remain favorable also at high water coverages, e.g., for one, two, and three adsorbed water monolayers (Tilocca and Selloni 2004), in accord with temperature-programmed desorption (TPD) experiments (Herman et al. 2003).

Several first principles molecular dynamics (FPMD) simulations have examined the structure of the interface between anatase (101) and liquid water (Cheng and Selloni 2010; Sumita et al. 2010; Hosseinpour et al. 2017). A first layer of water molecules adsorbed molecularly at Ti_{5c} sites and a second layer forming strong H-bonds with the O_{2c} surface atoms characterize the structure of this interface. At variance with the case of submonolayer water adsorption, the water hydrogen atoms of the molecules adsorbed at Ti_{5c} sites form H-bonds with the molecules of the second layer rather than with surface O_{2c} atoms. These two layers form a stable bilayer due to the presence of short H-bonds between first and second layer water molecules (Fig. 10a).

Only a few studies have examined the interface of water with anatase $TiO_2(001)$, and it is still unclear whether this surface maintains the (1×4) structure found in UHV when in contact with water. For both the bulk-terminated and reconstructed
Fig. 9 Water on anatase TiO$_2$ (101): (**a**) computed adsorption geometry of an isolated molecule, showing the H-bonds formed by the water hydrogens with the surface bridging oxygen atoms; (**b**) simulated constant density image, determined from the integrated local density of states in an energy window of 2.75 eV from the conduction band minimum; the image is periodically repeated. (**c**) Experimental empty state STM image taken at a sample temperature of 190 K (He et al. 2009b). The green and black arrows indicate ordered water clusters. Note that the image of a single water molecule extends over five lattice sites

surfaces, however, theoretical studies have predicted that water adsorbs dissociatively in the dilute limit and in mixed molecular-dissociative mode at high coverage, the fraction of dissociated molecules being of the order 25–30% (Selçuk and Selloni 2013). A similar amount of dissociated water molecules has been reported in first principles molecular dynamics simulations of the aqueous (001) interface (Fig. 10b) (Sumita et al. 2010). When one water molecule dissociates, one of the two Ti-O$_{2c}$ bonds of the Ti binding site breaks, causing a significant local restructuring.

Another well-studied aqueous interface is that with rutile TiO$_2$(011). This is the second most frequent surface in the equilibrium shape of rutile crystals (Fig. 3) and has attracted attention because its photocatalytic activity was reported to be significantly different from that of the most stable rutile (110) surface (Ohno et al. 2002). After surface science experiments discovered that the rutile TiO$_2$(011) surface is reconstructed with a (2 × 1) periodicity (Beck et al. 2004), extensive search based on DFT calculations identified a structural model with much lower surface energy in comparison to the bulk-truncated surface (Gong et al. 2009), which could also well reproduce the results of surface X-ray diffraction (SXRD)(Torrelles et al. 2008) and voltage-dependent STM measurements (Gong et al. 2009) (Fig. 11a).

To understand what happens when the rutile TiO$_2$ (011) surface structure observed under vacuum conditions is put in contact with the aqueous environment typical of TiO$_2$ photocatalysis, it is useful to first investigate the interaction of the surface with both isolated water molecules and a water monolayer. Using DFT calculations, it was found that the adsorption energy of an isolated water molecule on the non-reconstructed (1 × 1) surface is about three times larger than on the
Fig. 10 Snapshots from FPMD simulations of the interface of bulk water with (**a**) anatase TiO_2 (101) and (**b**) anatase TiO_2 (001). Water molecules or hydroxyl groups with green oxygen atoms adsorb onto five-coordinated Ti (Ti_{5c}). Water molecules with blue oxygen adsorb onto surface two-coordinated O_{2c} or adsorbed water molecules via strong H-bonds (red dashed lines). Water molecules with yellow oxygen adsorb to H_2O or OH that are already adsorbed onto Ti_{5c} via weak H-bonds (green dashed lines). Cyan dashed lines show ordinary H-bonds. (From Sumita et al. 2010)

reconstructed one, i.e., $E_{ads} = -1.27$ vs -0.42 eV (Aschauer and Selloni 2011). In other words, the bulk-terminated surface is much more reactive than the reconstructed one, consistent with its higher surface energy. Similarly, the adsorption of one water monolayer was found to be highly favorable ($E_{ads} = -1.04$ eV per molecule) on the non-reconstructed surface, whereas only a half-monolayer of water could bind directly to the surface Ti sites on the reconstructed surface (Aschauer and Selloni 2011). The formation of a tightly bound monolayer of adsorbed water molecules strongly stabilizes the non-reconstructed surface with respect to the reconstructed one, thus suggesting that the latter may switch back to
Fig. 11 Computed structures (top and side views) and STM images of (**a**) the reconstructed rutile TiO$_2$ (011), (2 × 1) surface; (**b**) the bulk-terminated rutile TiO$_2$ (011), (1x1) surface with two dissociatively adsorbed water molecules per (2 × 1) unit cell. Oxygen atoms belonging to terminal OH groups are highlighted in orange, and the white rectangle in the STM images shows the unit cell used for the calculations. Constant-density STM images are computed for a 0.5 eV bias from the conduction band minimum and are obtained by averaging images of snapshots taken from a FPMD simulation at 300 K (Balajka et al. 2017)

the bulk-terminated structure (i.e., deconstruct) when put in contact with an aqueous environment.

Recently experiments were carried out to verify this suggestion (Balajka et al. 2017). After exposure of the (2 × 1)-reconstructed surface to liquid water, the sample was transferred back to UHV where an overlayer with an apparent "c(2 × 1)" symmetry was observed in scanning tunneling microscopy (STM) images. On the basis of STM analysis and DFT calculations, this overlayer could be attributed to dissociated water on top of the unreconstructed (1 × 1) surface, confirming that the (2×1) reconstruction of the UHV-prepared surface is lifted when the surface is in contact with liquid water, as theoretically predicted. The deconstruction is achieved by rearranging only the surface atoms, and there is no mass transport involved. After evacuation of the liquid water, dissociated water hydroxyls remain adsorbed on undercoordinated Ti$_{5c}$ atoms of the (1 × 1) surface, forming an ordered overlayer with (2 × 1) symmetry and two hydroxyl groups per unit cell (Fig. 11b).

5   Excess and Photoexcited Electrons at Anatase TiO$_2$ Surfaces and Aqueous Interfaces

As for excess electrons in reduced TiO$_2$, the picture of photoexcited electrons in anatase is based on the polaron model, where the electron forms a localized state that is stabilized by an accompanying lattice distortion (the EPR signal of photoexcited electrons in anatase is indeed very similar to that of excess electrons from intrinsic defects or donor impurities). An important question to ask at this point concerns the degree of localization of the polaronic state.

As mentioned in Sect. 2, some experimental studies have identified large polaronic states formed by excess electrons in reduced and *n*-doped anatase. In particular, evidence of large polaronic states has been provided by angle-resolved PES (ARPES) measurements, which show a shallow dispersive quasiparticle band at about 40 meV below the CBM in reduced anatase (001) films (Moser et al. 2013). However, different results were obtained in other experiments. A prominent gap state 1 eV below the Fermi level was observed in PES experiments on single crystal anatase (101), whereas the same feature was drastically less pronounced on the anatase (001) surface (Thomas et al. 2007). The deep gap level on anatase (101) is similar to that observed on the rutile (110) surface, for which the formation of small polarons is well established. Finally, both deep and shallow polaronic states on anatase (101) were observed by Setvin et al. (2014), who used an STM tip to create V$_O$s on the surface (normally devoid of V$_O$s) and probed the local density of states around both these vacancies and subsurface impurities using scanning tunneling spectroscopy (STS).

In addition to the above studies carried out on well-defined surfaces under vacuum conditions, experiments on disperse anatase samples have revealed a remarkable dependence of the photocatalytic activity of anatase on the crystal surface, with oxidation and reduction reactions occurring preferentially on {001} and {101} facets, respectively (Tachikawa et al. 2011; Yu et al. 2014). Since these reactions involve photoexcited carriers, it is relevant to ask whether the facet dependence of the photocatalytic activity is related to the diverse behaviors of excess electrons observed in the surface science experiments or is rather due to the different reactivity of the two surfaces. Answering this question requires understanding how the behavior of excess electrons that is observed under vacuum conditions is modified in a humid or aqueous environment, as typically used in photocatalysis. This understanding is not yet available from experiment, yet interesting insights could be obtained from theory and simulations.

A recent study examined the behavior of excess electrons in proximity of the three most important (101), (001), and (100) anatase surfaces (denoted a-101, a-001, and a-100, respectively) and their aqueous interfaces, using both DFT+U static calculations and DFT+U-based first principles molecular dynamics (FPMD) simulations (Selcuk and Selloni 2016). The investigated slab models contained a single photoexcited electron or an excess electron provided either by an adsorbed H at a surface undercoordinated oxygen resulting in a surface bridging hydroxyl (O$_{br}$H) or by a bulk dopant, such as an interstitial H atom or a Nb impurity substituting a Ti atom inside the slab.

Results for a-101 and a-100 show that electron trapping does not occur on and near the *defect-free* surfaces, but can be induced by a surface hydroxyl, and possibly other types of defects. The stability of the $O_{br}H$ complex is at the origin of an interesting and rather unexpected effect that is electron-induced water dissociation. The typical mechanism of water dissociation involves two water molecules: one of the two molecules transfers a H to the O_{br}, and the other transfers a H to the first water before being adsorbed as a OH on a Ti_{5c} (Fig. 12).

To further explore the effects of the water environment on the localization of the excess electron, H-doped and Nb-doped (101) slab models were considered, in which the positively charged impurity, acting as an attractive potential for the electron, was located in the innermost layers of the slab, thus reducing the tendency of the electron to migrate to the surface. The simulations show that the excess electron is very mobile and spreads over several Ti sites when the slab is in vacuo, whereas it can rapidly reach the surface and becomes trapped in the form of a Ti^{3+} species close to an $O_{br}H$ when the system is solvated. Clearly, the stabilization provided by the formation of the Ti^{3+}-$O_{br}H$ complex makes the surface much more favorable for the electron in water/humid environment than in vacuo, despite the competition of water for the occupation of the surface Ti_{5c} sites.

A very different behavior is observed for excess electrons near the a-001 surface (Fig. 13). Unlike on a-101, FPMD simulations show that the excess electron avoids the a-001 surface and remains in the subsurface and inner layers throughout the simulation. At each instant, the electron forms a two-dimensional state in a (001) plane, but switches easily from one plane to another, which could be the reason of the three-dimensional dispersion observed in experiment. Due to the limited size of the model, the two-dimensional state appears as completely delocalized rather than a large polaron, whose radius is estimated to be around 10–20 Å (Moser et al. 2013).

A simple explanation of the reason why the electron tends to avoid the surface layers is given by the layer-resolved density of states (LRDOS) of an a-001 slab in the absence of excess electrons (Fig. 13d). While all inner layers of the slab contribute similarly to the DOS, both the conduction and valence band edges of the outermost layer are shifted upward by about 0.5 eV in comparison to the other layers. Since the 3d orbitals of the surface Ti_{5c} atoms are located at a higher energy compared to those in the subsurface and bulk layers, excess electrons prefer to remain inside the slab rather than at the surface. By contrast, holes will likely prefer to move to the surface, where they can be readily available for oxidation reactions.

Besides showing clear differences in the behaviors of electrons at the a-101 and a-001 terminations, the results of this study (Selcuk and Selloni 2016) further illustrate the crucial role of the environment on the structure and reactivity of TiO_2 surfaces. Whereas no trapping of electrons occurs on the a-101 surface in vacuum, an excess electron at the aqueous a-101 interface tends to become trapped into a stable Ti^{3+}-$O_{br}H$ complex through dissociation of an adsorbed water molecule or reaction with an aqueous proton. This trapping favors the interaction of electrons with adsorbates, so that reduction reactions should be facilitated on the (101) surface. On the other hand, the a-001 surface is strongly repulsive for electrons and attractive for holes and is thus predicted to have a significant activity for oxidation reactions. This difference between the two most common terminations of anatase agrees well with
Fig. 12 Typical mechanism of water dissociation induced by a localized electron at the anatase (101) – water interface; the sequence of four snapshots has a duration of ∼0.1 ps. Images are obtained from the simulation of a photoexcited electron using DFT+U with U = 3.9 eV. In the absence of the excess electron, H^+ of $O_{br}H$ and the solvated OH^- in the second snapshot recombine very rapidly

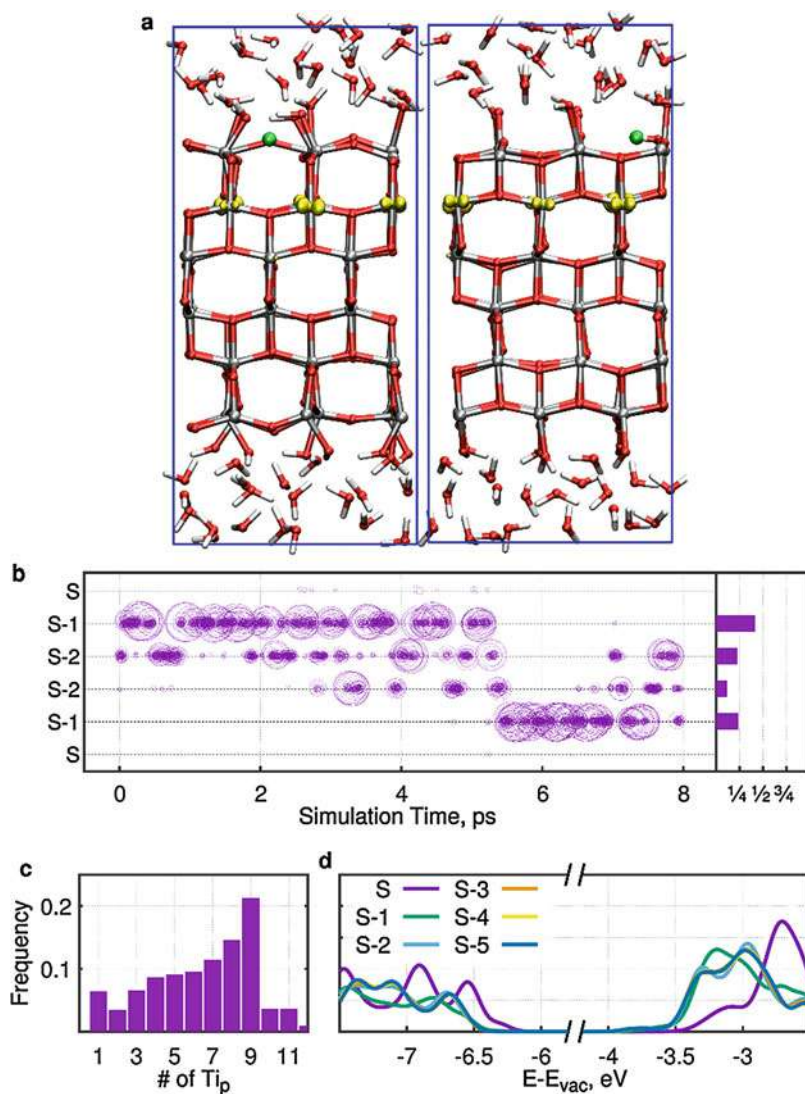
photoemission spectroscopy experiments, explains the observed facet dependence of photocatalytic reactions on TiO_2, and supports the suggestion that optimization of the ratio of a-101 and a-001 facets could provide a way to enhance the photocatalytic activity of anatase.


Fig. 13 (**a**) Side views of a six-layer hydroxylated (001) slab in water, from two different perspectives. The hydrogen on the bridging hydroxyl is shown in green. (**b**) Location of the e^-_{ex} in the direction perpendicular to the surface during a simulation with U = 3.9 eV and T = 400 K and corresponding distribution. The e^-_{ex} clearly avoids the (001) surface but switches frequently between different bulk layers. (**c**) Probability distribution of the number of Ti_p sites; note that the number of Ti atoms in each (001) layer of the slab is 9. (**d**) Layer-resolved density of states for an 11-layer a-001 slab. The labels S, S-1, S-2, etc. indicate the surface layer and the subsequent layers below the surface. Both the VB and the CB edges are shifted to significantly higher energies at the surface layer in comparison to the inner layers. The computed CB edge is located at −4.03 eV below the vacuum level, and the band gap is 2.09 eV. (From Selcuk and Selloni 2016)

6   Summary and Outlook

Despite its relatively low efficiency, TiO_2 remains one of the most widely used materials in photocatalysis as well as a benchmark for the development of new functional materials and a model system for the study of reaction mechanisms. At the same time, new applications as well as new areas of fundamental research on TiO_2 are emerging, which keep the interest in this material very lively. For example, TiO_2 is considered the most promising material for use as a thin film protective coating of semiconducting photoelectrodes in solar-fuel generators (Hu et al. 2015), while the study of 2D electron gas behavior at the anatase surface (Rödel et al. 2015) is an exciting new direction that has also the potential of novel interesting applications in electronic devices.

Theoretical studies and simulations have contributed substantially to the understanding of the fundamental physical and chemical properties of TiO_2 and related metal oxide materials over the last decades. In this chapter, we have presented an overview of a number of these contributions, ranging from the bulk electronic and optical properties to the polaronic character of defect states and charge carriers, the surface reactivity, the structure of the aqueous interface, and the behavior of electrons at this interface. Besides providing insight into existing experimental result, theory and simulations have proven capable to predict new properties subsequently verified by experiments and also to bridge the gap between experiments under carefully controlled conditions and experiments in more realistic environments.

Contents

Abstract

Being isolated for the first time in 2004, graphene has started an entire new field of two-dimensional (2D) materials driven by novel properties and phenomena observed in these materials as well as their potential technological applications. Due to their low-dimensional nature, the effects of lattice disorder and boundaries in 2D materials are enhanced in comparison to bulk materials. This chapter covers the most important contributions of computational modeling to predict the structure and properties of lattice imperfections in graphene, namely, the point defects, topological defects, and edges, and draws connections to the subsequent experimental works confirming these predictions.

1   Introduction

The first isolation of *graphene*, a single layer of carbon atoms obtained by micromechanical cleavage of graphite (Novoselov et al. 2004, 2005; Zhang et al.

O. V. Yazyev (✉)

Institute of Physics, Ecole Polytechnique Fédérale de Lausanne (EPFL), Lausanne, Switzerland
e-mail: oleg.yazyev@epfl.ch

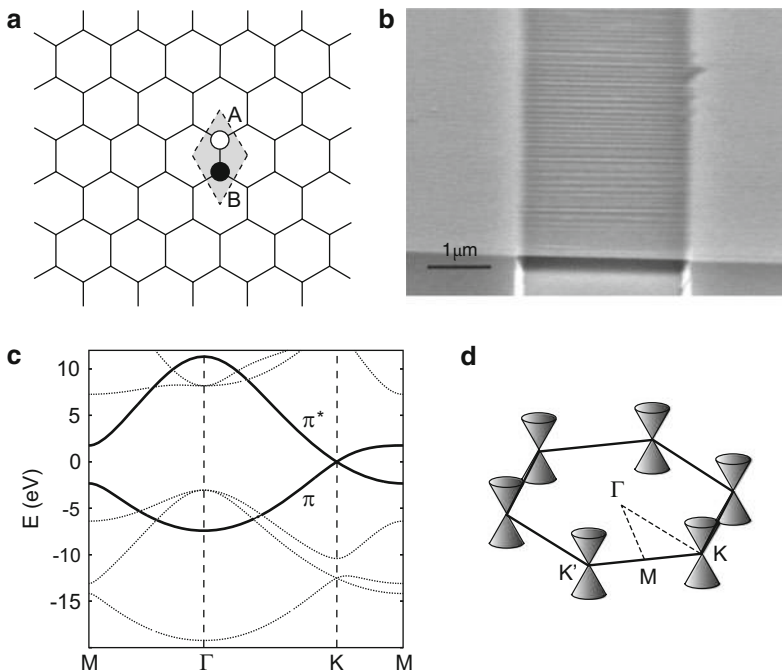
2005), started an entire new direction of research into two-dimensional (2D) materials extending from condensed matter physics to numerous other disciplines and promising novel technological applications. One particularly striking quality of graphene is its simplicity. The crystal structure of this material represents the bipartite honeycomb lattice with two equivalent carbon atoms per unit cell in sp^2 hybridization (Fig. 1a). The low-energy electronic properties of this material are dominated by the two π symmetry bands formed by the p_z atomic orbitals of carbon atoms (Fig. 1c). The bands form two conical intersection features in the corners of the Brillouin zone (points K and K′; Fig. 1d). These peculiar band dispersions called Dirac cones are responsible for many extraordinary electronic properties discovered in graphene (Castro Neto et al. 2009). Even the simplest theoretical descriptions, such as the one-orbital tight-binding model with only nearest-neighbor hopping integrals, are able to describe this feature accurately. Even though numerous other 2D materials have been discovered by now, graphene remains the most intriguing member of the family.


Fig. 1 (**a**) Two-dimensional honeycomb lattice of graphene showing the unit cell with two carbon atoms belonging to sublattices A and B. (**b**) Scanning electron microscopy (SEM) image of graphene bilayer freely suspended over a 2-micrometer-wide trench (Bao et al. 2009). (**c**) Band structure of graphene plotted along a high-symmetry k point path with the π symmetry bands highlighted. (**d**) Schematic representation of the band structure showing only the Dirac cone features in the corners of the Brillouin zone (points K and K′)

Despite the basic statistical physics arguments forbidding long-range crystalline order in two dimensions (Mermin 1968), relatively large samples of graphene can nevertheless be handled using basic laboratory equipment (Fig. 1b). Yet, reduced dimensionality of this material implies that structural imperfections, as well boundaries, have particularly strong effects on its physical properties. Furthermore, modern experimental techniques, in particular transmission electron microscopy (TEM) and scanning tunneling microscopy (STM), not only enabled the direct observation of structure and dynamics of defects in graphene at atomic resolution but also allowed their versatile creation and manipulation. Surprisingly, being a material with very simple crystal structure, graphene revealed an astonishing diversity of defects.

The purpose of this chapter is to give a brief overview of the most important contributions of computational modeling to predict the structure and properties of defects and boundaries in graphene that were consequently confirmed by the experiments. Without going into details of computational methods as such, we will consider the models of point defects, topological defects, and edges in graphene and draw a connection with the experiments.

2   Point Defects

Point defects in graphite, the bulk parent material of graphene, have been the subject of considerable research interest well before the first experimental isolation of this 2D material. Numerous modeling works have been performed in the context of understanding point defects that are created upon irradiation of graphite that is used as a moderator material in nuclear reactors. Even though graphite is an elemental material with a relative simple crystal structure, a very diverse family of point defects was proposed. These point defects include interstitials and vacancies as primary defects created upon radiation damage, their aggregates, metastable interstitial-vacancy pairs (Frenkel pairs) (Telling et al. 2003; Ewels et al. 2003; Akhmerov and Beenakker 2008), as well as defects produced by the rearrangement of carbon-carbon bonds within individual graphene layers (for an overview see Li et al. 2005). Further research interest was stimulated by the experimental observations of room-temperature ferromagnetism in graphite irradiated by high-energy protons (Esquinazi et al. 2003). It was suggested that defects play a crucial role in the induced magnetic ordering. This observation promised the possibility of creating novel magnetic materials based on light elements belonging to the *sp* block of the periodic table.

In atomically thin graphene, many predicted defects were directly observed using transmission electron microscopy (TEM). Not only this experimental tool allowed studying the structure of these defects at atomic resolution but it also allowed creating these defects and studying their transformations and migration in out-of-equilibrium conditions. Figure 2 reproduces TEM images of representative point defects in monolayer graphene (Kotakoski et al. 2011). The two primary defects induced by high-energy electrons in the TEM conditions are the Stone-Wales
Fig. 2 Experimental observations of point defects in graphene. (**a**) Transmission electron microscopy (TEM) image of pristine graphene lattice. (**b**, **c**) TEM images of simplest point defects in graphene – the Stone-Wales defect (**c**) and the single-atom vacancy (**c**). (**d**) Double vacancy in graphene and (**e**, **f**) more complex defects derived from it by means of in-plane bond rotations. The red dashed lines outline the defect structures (Kotakoski et al. 2011)

defects (Fig. 2b) and the single-atom vacancies (Fig. 2c). The Stone-Wales defect is produced by means of a 90° in-plane rotation of a pair of carbon atoms followed by the reconnection of covalent bonds (Stone and Wales 1986). This results in a structure composed of two pentagons and two heptagons, while the coordination environment of each carbon atom remains unaffected. The calculations show that the formation energy of the Stone-Wales defect is 5 eV, while the energy barrier of bond rotation is approximately 10 eV (Li et al. 2005). Sputtering a single carbon atom creates a vacancy defect which reconstructs by forming a new covalent bond, while one carbon atom remains undercoordinated in agreement with theoretical predictions (El-Barbary et al. 2003). The formation energy of single-atom vacancy defect was predicted to be 7.5 eV. The double vacancy defect produced by removing two neighboring carbon atoms allows a reconstruction involving two new covalent bonds (Fig. 2d). Such a defect structure composed of two pentagons and an octagon has no undercoordinated atoms. The calculated formation energy of this defect is 8 eV, comparable to the one of the single-atom vacancy (Krasheninnikov et al. 2006). However, the formation energy per removed carbon atom is significantly lower for the double vacancy defect, which reflects the tendency of vacancy aggregation in graphene. The energy of this defect can be further lowered by a series of in-plane bond rotations leading to more complex defect structures composed of pentagons and heptagons. Calculations show that the observed point defects in Fig. 2e, f both have lower formation energies than the initial double vacancy defect (Lee et al. 2005; Kotakoski et al. 2011).

The single-atom vacancy defect in graphene deserves to be discussed in more detail. It was shown by means of first-principles calculations that the dangling bond of the undercoordinated carbon atom at the vacancy defect carries a local magnetic moment due to an unpaired σ electron (Lehtinen et al. 2004). This could account for the observed ferromagnetic ordering in irradiated graphite if sufficiently strong magnetic exchange coupling between such localized magnetic moments exists. Even more interesting are the so-called quasilocalized electronic states induced by single-atom vacancies. These resonant non-bonding states result from the local breaking of the bipartite symmetry of graphene lattice (Pereira et al. 2006). The vacancy defect removes a carbon atom from one of the sublattices, and this gives rise to a localized π-electron state in the complementary sublattice. Such quasilocalized states have been observed in STM images as very distinct triangular features around point defect on the surface of graphite (Mizes and Foster 1989), while the corresponding dI/dV measurements exhibit at sharp peak at the Fermi level (Ugeda et al. 2010). First-principles calculations show that these states indeed form a narrow band at the Fermi level that undergoes spin polarization in order to relieve the electronic instability associated with high density of states at the Fermi level (Yazyev and Helm 2007). This suggests a novel mechanism of itinerant-like magnetism induced by disorder in graphene-based materials. Interestingly, the coupling between quasilocalized in the same sublattice is ferromagnetic, while it is antiferromagnetic between the opposite sublattices (Yazyev 2008). This points at a possibility of tailoring the type of magnetic ordering in disordered graphene by controlling the distribution of defects in the two sublattices.

A closely related imperfection in graphene is the hydrogen chemisorption defect. A hydrogen atom binds covalently to one carbon atom of graphene lattice causing its transformation from the sp^2 to sp^3 hybridization. The latter is no longer able to provide a p_z atomic orbital to the π-electron system of graphene and hence is equivalent to a single-atom vacancy. For the reasons described above, hydrogen chemisorption defects also induce quasilocalized states. However, these simple defects are free of symmetry-breaking reconstructions and can be easily introduced to or removed from graphene. These properties established the hydrogen chemisorption defect as the reference disorder in graphene. A number of recent studies modeled the effect of such defects on the electronic transport properties of graphene (Wehling et al. 2010; Gargiulo et al. 2014). Similar to the vacancies, hydrogen chemisorption defects induce magnetic ordering with a clear physical picture (Yazyev and Helm 2007). Figure 3a shows the characteristic triangle-shaped distribution of spin density around a hydrogen chemisorption defect with a nominal magnetic moment of 1 Bohr magneton. Figure 3b reproduces the density of states for spin-up and spin-down channels that clearly illustrates the fully spin-split narrow band at the Fermi level. Experimentally, the quasilocalized states due to hydrogen chemisorption defects in graphene have recently been investigated using STM revealing the presence of sharp resonances (Fig. 3c) and their splitting consistent with the predicted spin polarization (Fig. 3d; González-Herrero et al. 2016).

3 Topological Defects

Topological defects are distinct from point defects as these types of disorder are characterized by certain quantities defined nonlocally and hence do not change upon a local modification of the atomic structure of such defects. These quantities are further referred to as the structural topological invariants. An example of a topological defect is the *dislocation*, and the corresponding topological invariant is its Burgers vector. The nonlocality of a dislocation stems from the fact that the Burgers vector can be defined on an arbitrarily large contour encircling the dislocation core; therefore any local structural modification to it would not change the Burgers vector. Another relevant type of topological defects is the *grain boundary*, the interface between two single-crystalline domains of same material.

Orientation of the crystalline lattice changes across the grain boundary giving rise to the notion of misorientation angle, the corresponding topological invariant. Grain boundaries are the defects inherent to polycrystalline materials. Both dislocations and grain boundaries in bulk materials are extensively covered in practically all materials science textbooks.

As already mentioned above, 2D materials in general and graphene in particular are very susceptible to wide range of structural disorder. Hence, one can expect that obtaining large single crystals of 2D materials would be a challenging task, while polycrystalline morphologies of 2D materials should be abundant. In addition, the space of topological invariants of the corresponding defects in 2D materials is "narrower" than in the case of bulk, three-dimensional materials. For instance, the Burgers vector of a dislocation is constrained to lie in the plane of 2D crystalline lattice; hence only edge dislocations are possible in 2D materials. Similarly, only tilt grain boundaries exist in 2D materials. Dislocations and grain boundaries in 2D materials can be regarded as point-like and one-dimensional objects, respectively.

In order to proceed with the construction of dislocations and grain boundaries in graphene, we will borrow from soft matter community a third type of topological defect called the disclination (Seung and Nelson 1988). A disclination is the result of either removing from or adding to the ideal lattice a semi-infinite wedge of material. The corresponding topological invariant is the disclination strength s, which measures the wedge angle. Wedge removal results in positive ($s > 0$) disclinations while wedge introduction – in negative ($s < 0$). The particular cases of $s = 60°$ and $s = -60°$ disclinations in graphene appear as pentagons and heptagons embedded in the array of hexagons forming the honeycomb lattice as shown in Fig. 4.

The result of combining two complementary disclinations is the dislocation (Seung and Nelson 1988), and its Burgers vector depends on the distance between the pentagon and the heptagon. Two examples of dislocations in graphene are shown in Fig. 4. The pentagon-heptagon pair sharing an edge is the dislocation with the smallest Burgers vector $b = (1, 0)$ equal to the lattice constant of graphene (2.46 Å). Above, we defined the Burgers vectors as a pair of integers in terms of lattice vectors, similar to the chirality indices of carbon nanotubes. The second example shown in Fig. 4 corresponds to the second smallest Burgers vector $b = (1, 1)$ (or 4.26 Å) (Yazyev and Louie 2010a).

Finally, grain boundaries can be viewed as arrays of dislocations following the model introduced by Read and Shockley (1950). The misorientation angle θ is related to the Burgers vector of constituent dislocations and the distance between them. Two examples of symmetric grain boundaries in graphene are shown in Fig. 4. These two grain boundaries are formed by particularly dense arrangements of $b = (1, 0)$ dislocations and correspond to misorientation angles $\theta = 21.8°$ and $\theta = 32.3°$, respectively (Yazyev and Louie 2010a).

Interestingly, dislocations characterized by all allowed Burgers vectors and grain boundaries spanning the entire range of misorientation angles $0° < \theta < 60°$ can be constructed starting from pentagons and heptagons only. All carbon atoms in defect structures built following the described approach maintain their original threefold
Fig. 4 Three hierarchically related types of topological defects in graphene: disclinations, disloca-
tions, and grain boundaries. The definitions of the corresponding structural topological invariants
(disclination strength *s*, Burgers vector **b**, and misorientation angle *θ*) and their values are given.
The structures of all three types of topological defects are composed of pentagons (red) and
hexagons (blue) (Yazyev and Louie 2010a; Yazyev and Chen 2014)

coordination, no dangling bonds or overcoordinated atoms have been introduced,
and hence the defects are expected to have low formation energies by construction.
This hierarchical construction introduced by us in 2010 (Yazyev and Louie 2010a),
almost simultaneously with the similar work from the group of Boris Yakobson (Liu
and Yakobson 2010), opened a possibility to investigate computationally realistic
models of topological defects in graphene ahead of their experimental observation.

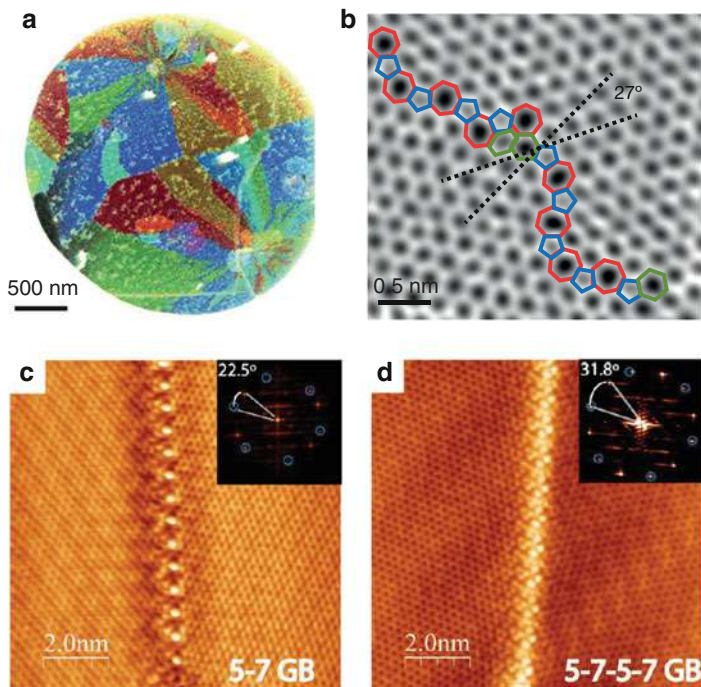
First experimental studies of topological defects in graphene followed less than
a year after our theoretical predictions (Huang et al. 2011; Kim et al. 2011; An
et al. 2011; followed by many other). Figure 5a shows the dark-field TEM image of
epitaxial graphene grown using chemical vapor deposition (CVD) on Cu substrate
(Huang et al. 2011). The image reveals an intricate polycrystalline morphology with
micrometer-size crystallites. High-resolution TEM further exposes the atomic-scale
details of grain boundaries in these epitaxial graphene samples. The segment of
large-angle grain boundary shown in Fig. 5b shares many similarities with the mod-
els in Fig. 4. Specifically, it is composed of an alternating chain of pentagons and
heptagons with no under- or overcoordinated carbon atoms whatsoever. However,


Fig. 5 Experimental observations of grain boundaries in graphene. (**a**) Dark-field TEM image color-coded according to the orientation of the crystalline lattice reveals the polycrystalline morphology of CVD-grown epitaxial graphene with micrometer-size single-crystalline domains. (**b**) High-resolution TEM image shows atomic structure details of the grain boundary as an alternating chain of pentagons and heptagons (Huang et al. 2011). (**c**, **d**) STM images of grain boundaries in thermally annealed epitaxial graphene showing highly periodic patterns that can be attributed to the grain boundary models shown in Fig. 4 (Yang et al. 2014)

unlike the models in Fig. 4, the observed structure is not linear and lacks clear periodicity. This discrepancy can be explained by assuming that the performed CVD growth process does not allow achieving thermodynamic equilibrium in full. In fact, thermal annealing of such epitaxial graphene samples leads to highly periodic structures as exemplified in Fig. 5c, d (Yang et al. 2014). Moreover, the two grain boundaries shown in Fig. 5c, d correspond exactly to the models in Fig. 4. It is striking that until this moment all predictions confirmed by experiments were done by means of modeling, but without doing any explicit computations. Further considerations, for example, rationalizing the stability of these two grain boundary structures would necessitate computer simulations.

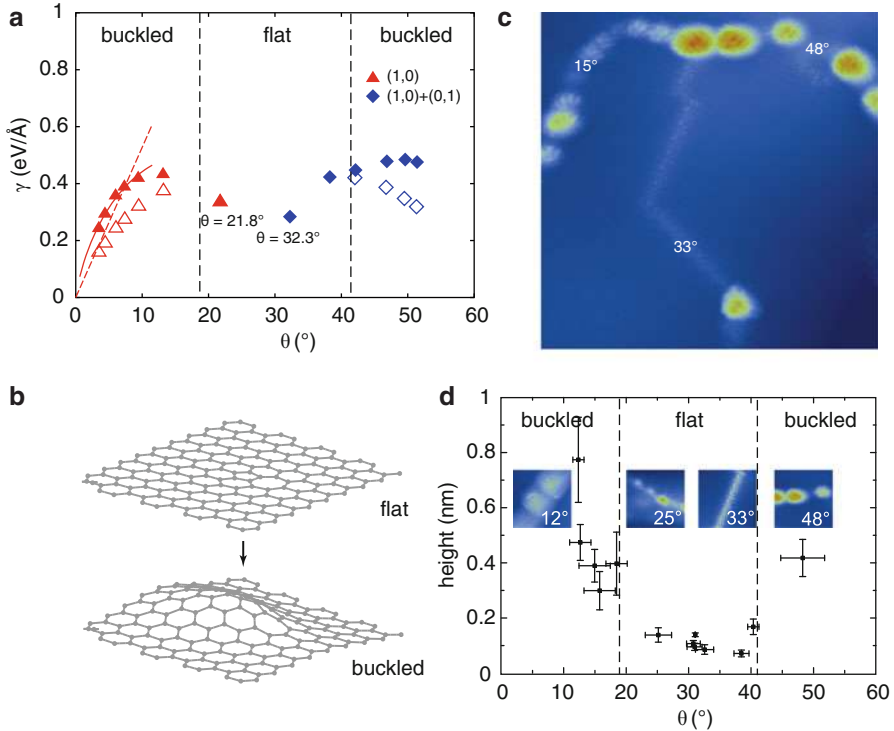
Figure 6a reproduces the formation energies per unit length γ as a function of misorientation angle θ calculated using density functional theory for a number of periodic models of grain boundaries in graphene (Yazyev and Louie 2010a). Filled symbols correspond to models that were artificially constrained to be flat. One can


Fig. 6 Formation energies and buckling of grain boundaries in graphene. (**a**) Calculated grain boundary formation energy per unit length γ as a function misorientation angle θ. Formation energies of flat and buckled models are shown as filled and empty symbols. The vertical dashed lines delimit the buckled and flat regimes (Yazyev and Louie 2010a). (**b**) Illustration of the buckling deformation produced by a single $b = (1, 0)$ dislocation. (**c**) STM image of epitaxial graphene grown on the C-face of SiC showing three grain boundaries with their corresponding misorientation angles indicated (Tison et al. 2014). (**d**) Apparent height of the observed grain boundaries as a function misorientation angle θ. The flat and buckled regimes with transition angle $\theta_c = 19 \pm 2°$ are clearly distinguished (Tison et al. 2014)

recognize a clear trend with a minimum at ca. 30° and the two large-angle grain boundary models introduced in Fig. 4 ($\theta = 21.8°$ and $\theta = 32.3°$) having particularly low formation energies, which agrees with their frequent experimental observation (see, e.g., Fig. 5c, d). This picture is similar to what is usually observed for bulk materials. The existence of a formation energy minimum at large values of θ can be rationalized by the fact that in large-angle grain boundaries the distance between the constituent dislocations is small; hence the in-plane elastic fields produced by the dislocations effectively cancel each other reducing the contribution of elastic energy to the defect formation energy.

By allowing the atoms to displace out of plane, we enable a physical mechanism which is not present in bulk materials. The fact that the dimensionality of graphene,

or any other 2D material, is one less compared to the dimensionality of host space gives an additional degree of freedom. Displacement in this extra dimension, below referred to as buckling, effectively relieves the in-plane compressive strain. Figure 6b illustrates the buckling pattern produced by a single $b = (1, 0)$ dislocation in graphene, and the experimentally observed pictures appear to be similar (Lehtinen et al. 2013). Such a screening of the in-plane elastic fields gives rise to a mechanism that competes with the abovementioned mutual cancellation of elastic fields produced by closely spaces dislocations. Indeed, calculations show that apart from several large-angle models buckling significantly lowers the grain boundary formation energies (empty symbols in Fig. 6a) (Yazyev and Louie 2010a). The transition from flat to buckled configurations, called the buckling transition, takes place at a well-defined critical misorientation angle (Carraro and Nelson 1993). The theoretically predicted buckling transition in graphene was experimentally observed in epitaxial graphene samples grown on SiC(000$\bar{1}$) substrate (Tison et al. 2014). Figure 6c reproduces a typical STM image that shows three single-crystalline domains separated by a junction of three grain boundaries. While the ordered large-angle grain boundary ($\theta = 33°$) shows little topographic contrast, the two small-angle grain boundaries ($\theta = 15°$ and $\theta = 48°$) display pronounced buckling, and the location of individual dislocations can be clearly tracked. All observed line defects can be distinguished as either flat or buckled grain boundaries (Fig. 6d). The measured buckling transition angle $\theta_c = 19 \pm 2°$ (and the symmetrically reflected value $\theta_c = 41 \pm 2°$) is in quantitative agreement with the results of DFT calculations (dashed vertical lines in Fig. 6a; Yazyev and Louie 2010a).

The above demonstrates spectacular success of modeling in predicting novel defect structures and achieving quantitative agreement with the experiments. Many physical phenomena related to topological defects in graphene have been studied computationally beyond the ones described above. For instance, electronic transport is of special importance because graphene is considered as a possible key material in the future information and communication technologies. Novel transport phenomena resulting from the periodic structure of grain boundaries such as the controllable transport gaps (Yazyev and Louie 2010b) and valley filtering (Gunlycke and White 2011; Chen et al. 2014) have been discussed. Thermal transport and mechanical properties of polycrystalline graphene are two more examples of properties relevant to practical applications (for review see Yazyev and Chen 2014). Other types of one-dimensional topological defects resulting from stacking order in multilayer graphene systems are possible. The so-called stacking domain boundaries have been observed, modeled, and extensively discussed in the context of topologically nontrivial electronic states (Alden et al. 2013; Butz et al. 2014; San-Jose et al. 2014; Ju et al. 2015; Gargiulo and Yazyev 2018). Finally, dislocations, grain boundaries, and polycrystalline morphologies are equally relevant to other 2D materials, such as monolayer transition metal dichalcogenides (TMDs). Due to the binary nature of these materials, however, dislocations and grain boundaries show a broader diversity in terms of atomic structure and local chemical composition (van der Zande et al. 2013; Najmaei et al. 2013; Zhang et al. 2013b).

4   Edges and Nanoribbons

Since the very first isolation of graphene, the absence of band gap in this material was recognized as the most important challenge on the way of realizing its potential in electronics. In particular, sizable band gaps are required for manufacturing field-effect transistors with on/off current ratios sufficient for applications in digital electronics. Exploiting quantum confinement in nanostructures based on graphene is probably the most evident route to controlling band gaps. Early works on top-down lithographically patterned nanostructures showed that the transport properties and deduced bands gaps indeed shows strong dependence on the nanostructure dimensions (Fig. 7a, b; Han et al. 2007). However, it also became clear that the local atomic structure details and the crystallographic orientation of the edges play even a more important role in defining the electronic properties of graphene
Fig. 7 Experimental approaches to manufacturing graphene nanostructures. (**a**) SEM image of a lithographically patterned device set containing multiple graphene nanoribbons of varying width (Han et al. 2007). (**b**) Dependence of the measured band gaps on the width and orientation of graphene nanoribbons (Han et al. 2007). (**c**) Scheme of the synthetic route leading to the $N = 7$ armchair nanoribbon (Cai et al. 2010). (**d**) STM image of the resulting $N = 7$ armchair graphene nanoribbons on Au(111) surface (Cai et al. 2010)

nanostructures. Common lithographic techniques are not able to provide the desired atomic precision; hence a broad range of alternative methods have been developed. It is worth highlighting the bottom-up self-assembly technique (Cai et al. 2010) covered in ▶ Chap. 31, "Electronic Structure of Atomically Precise Graphene Nanoribbons," by L. Talirz and C. Pignedoli. This approach relies on the surface-assisted self-assembly starting from precursor molecules, as, for instance, shown in Fig. 7c. It is possible to design molecular precursors that lead to uniquely defined nanostructures. An experimental STM image of highly ordered one-dimensional strips of graphene of 1 nm width produced by means of the synthetic route of Fig. 7c is shown in Fig. 7d. It is not our intention to cover in this chapter all proposed approaches for manufacturing graphene nanostructures. Instead, we will focus on reviewing the most important contributions from materials modeling to understanding the effects of reduced dimensions and *edges* on the electronic structure of nanostructured graphene.

The vast majority of computational studies on nanostructured graphene have been performed using one-dimensional periodic models commonly called *graphene nanoribbons*. Such models first introduced by Nakada et al. (1996) well before the first experimental isolation of graphene have become exceptionally popular. This is largely due to the fact that one-dimensional band structures of graphene nanoribbons proved to be a very insightful tool for analyzing the effects of reduced dimensions and edges. In addition, computationally tractable models of modest size could be constructed due to a small lattice constant of basic graphene nanoribbons. Such calculations have been performed using a broad range of techniques – from simple one-orbital nearest-neighbor tight-binding model to first-principles methods based on density functional theory or many-body perturbation theory. In the case of first-principles calculations, the outmost edge atoms are typically terminated by hydrogen atoms that provide a neutral from the point of view of electronic structure passivation of the dangling bonds. Among the short periodicity models, one distinguishes armchair and zigzag graphene nanoribbons that received their names from analogy with carbon nanotubes. The structure of an example of *armchair* graphene nanoribbon is shown in Fig. 8a, while in the case of *zigzag* graphene nanoribbon (Fig. 8b), the edge direction is rotated by 30° to be aligned with one of the lattice vectors of graphene.

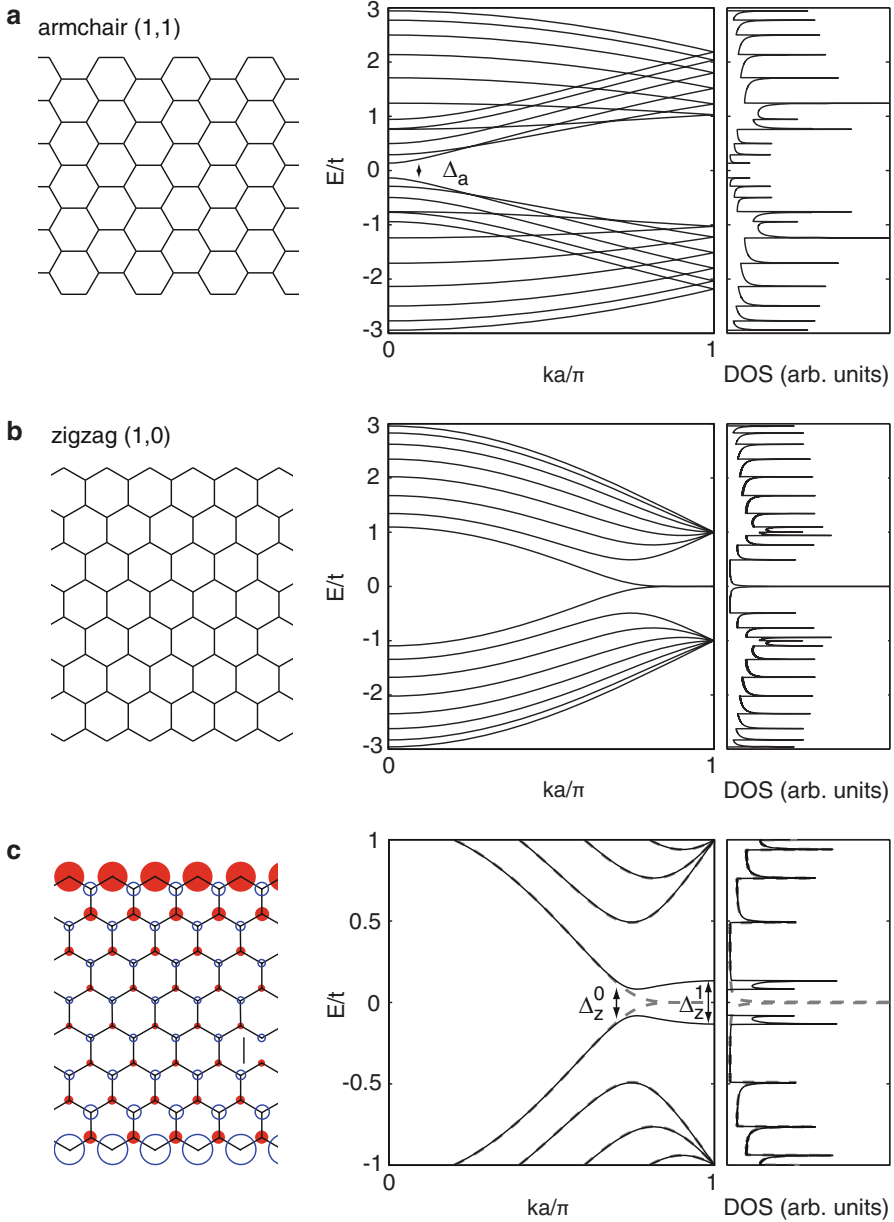
The band structure of the armchair graphene nanoribbon in Fig. 7a calculated using the one-orbital tight-binding model with a constant nearest-neighbor transfer integral t (≈ 3 eV in graphene) shows the presence of a direct band gap. The density of states shows a number of van Hove singularities that associated with band extrema of a one-dimensional system. In the case of armchair nanoribbons, the band gaps Δ_a are due to the lateral confinement of the Dirac fermion of graphene. Importantly, the band gap magnitude shows an oscillating behavior as the nanoribbon width increases, changing between metallic and semiconducting band structures in the case of nearest-neighbor tight-binding model calculations. When edge effects are taken into account in first-principles calculations, a small band gap opens in metallic armchair graphene nanoribbons (Fig. 9a; Son et al. 2006a; Barone et al. 2006). Nevertheless, such a non-monotonic dependence of the


Fig. 8 Atomistic models of (**a**) an armchair graphene nanoribbon and (**b**) a zigzag graphene nanoribbon, their corresponding band structures and density of states plots calculated using the nearest-neighbor tight-binding model. (**c**) Local magnetic moments in the ground-state configuration of the zigzag graphene nanoribbon calculated using the mean-field Hubbard model ($U/t = 1$). The area of red (filled) and blue (empty) circles represent the magnitudes of spin-up and spin-down local magnetic moments, respectively. The corresponding band structure and density of states plots are compared to the tight-binding solutions (dashed lines)

band gap magnitude on the nanoribbon width demonstrates the need of achieving atomic-precision control of graphene nanostructures if electronic properties are to be controlled. Recent works reporting bottom-up synthesis of armchair graphene nanoribbons of different width showed band gaps in very good agreement with the results of first-principles calculations, provided these calculations are performed at the level of many-body perturbation theory with screening effects of the metallic substrate taken into account (Ruffieux et al. 2012).

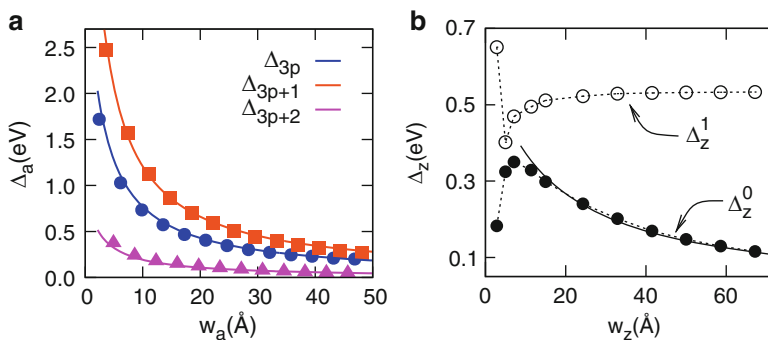
In contrast, zigzag graphene nanoribbons show a dramatically different electronic structure with a pronounced flat-band segment at the Fermi level when the effect of electron-electron interactions is neglected (Fig. 8b). This flat band feature is due to electronic states localized at the edges, and hence it exhibits no pronounced dependence on the nanoribbon width. The diverging density of states at the Fermi level resulting from the edge states is intrinsically unstable. One evident mechanism for relieving this electronic instability via electron-electron interactions is by developing magnetic ordering (Fujita et al. 1996). Indeed, both the spin-polarized density functional theory and the simple mean-field Hubbard model calculations result in a gapped band structure (Fig. 8c). The ground state is a broken symmetry spin-polarized configuration with localized magnetic moments at the edges (Fig. 7c). The edge spins show ferromagnetic coupling along the edge and antiferromagnetic across the nanoribbon. The band gap Δ_z^0 is related to the coupling across the nanoribbon and therefore decreases with increasing the width. In contrast, the zone-boundary splitting Δ_z^1 is related to exchange coupling along the edge and hence shows only a weak dependence on the width (Fig. 9b; Son et al. 2006a). The theoretical prediction of edge magnetism in graphene has stimulated considerable research efforts resulting in a large number of interesting ideas. For instance, Son, Cohen, and Louie predicted that by applying electric field across such magnetic zigzag graphene nanoribbons it would be possible to close the gap selectively in


Fig. 9 (**a**) Band gaps of armchair graphene nanoribbons Δ_a as a function width w_a from local density approximation (LDA) calculations. The oscillating dependence of Δ_a is due to three families of armchair graphene nanoribbons. (**b**) Dependence of band gap Δ_z^0 and zone-boundary splitting Δ_z^1 on the width w_z of zigzag graphene nanoribbons obtained from spin-polarized LDA calculations (Son et al. 2006a)

one of the spin channels, in other words induce a half-metallic state (Son et al. 2006b). Such electric control of spin properties could find numerous applications in spintronic devices. On the other hand, one has to clearly understand the limitations of magnetism at graphene edges resulting from their reduced dimensionality and the intrinsic weak magnetic anisotropy of carbon (Yazyev and Katsnelson 2008). Producing well-ordered zigzag graphene nanoribbons experimentally has proven to be a very challenging task. Only very recently zigzag graphene nanoribbons were prepared using an STM-based etching method (Magda et al. 2014) and the already mentioned bottom-up self-assembly technique (Ruffieux et al. 2016). In both cases the observed electronic structure properties support the existence of spin-polarized edge states.

Armchair and zigzag graphene nanoribbons represent convenient models due to the orientation of the edges along the high-symmetry directions of the honeycomb lattice of graphene. One would immediately start wondering about the properties of graphene nanoribbons with edges oriented in an arbitrary way. It turns out that the electronic structure of such arbitrarily oriented nanoribbons, commonly referred to as the *chiral* graphene nanoribbons, resembles that of zigzag graphene nanoribbons. Both in zigzag and chiral nanoribbons, electronic states localized at the edges are a result of the local breaking of the sublattice symmetry of the bipartite lattice of graphene. In this respect the armchair edges represent a special case with no edge states. The electronic properties of chiral edges were addressed both analytically (Akhmerov and Beenakker 2008) and computationally (Nakada et al. 1996; Yazyev et al. 2011). In presence of electron-electron interactions, the localized states at chiral edges were predicted to undergo spin polarization with edge magnetic moment per unit length continuously spanning the cases of magnetic zigzag and nonmagnetic armchair edges as the edge orientation changes (Yazyev et al. 2011). Edge states were experimentally observed in chiral graphene nanoribbons produced by chemical unzipping of carbon nanotubes (Tao et al. 2011; Zhang et al. 2013a). The detailed STM images of such chiral edges show a clear contrast due to the localized edge states (Fig. 10a), while first-principles simulations (Fig. 10b) reproduce the experimentally observed picture allowing to identify the atomic structure of the edge in an atom-by-atom fashion (Zhang et al. 2013a).

5   Conclusions and Outlook

To summarize, this chapter has illustrated how first-principles modeling combined with experimental techniques capable of providing atomically resolved images (TEM and STM) allows to elucidate the structure of defects and edges in graphene in an atom-by-atom fashion. The same simulations complemented by theoretical models reveal the effect of these structural irregularities on the electronic and transport properties of graphene. Understanding the effects of disorder is crucial for designing novel functional materials and devices based on graphene. Further advance in predicting power is expected upon a continuing development of computational methods capable of treating large-scale realistic models, e.g.,
Fig. 10 (**a**) Experimentally observed and (**b**) simulated from first-principles STM images of an edge of a chiral graphene nanoribbon obtained by chemical unzipping of carbon nanotubes followed by hydrogen plasma etching (Zhang et al. 2013a). The contrast due to the localized edge states is clearly seen in both images

explicitly taking into account the substrate or performing device-scale simulations. The biggest challenge, however, lies in the ability to control experimentally the amount, structure, and possibly location, of the discussed structural irregularities. Overcoming this challenge can potentially result in a number of novel technological applications. Point defects in graphene are considered as a platform for magnetic materials and spintronic devices based on light elements. While the presence of topological defects such as grain boundaries is inevitable in large-area samples of 2D materials, it should be possible to minimize their undesirable effect on the electrical characteristics. At the same time, when introduced in a controlled way, such defects may serve as components of novel electronic devices. Finally, the abovementioned surface-assisted self-assembly approach to graphene nanoribbons and junctions can lead to a disruptive technology for manufacturing nanometer-scale all-graphene integrated circuits.

Contents

Abstract

This chapter gives an overview of the progress in the field of computational superconductivity. Following the MgB_2 discovery (2001), there has been an impressive acceleration in the development of methods based on density functional theory to compute the critical temperature and other physical properties of actual superconductors from first principles. State-of-the-art ab initio methods have reached predictive accuracy for conventional (phonon-mediated) superconductors, and substantial progress is being made also for unconventional superconductors. The aim of this chapter is to give an overview of the existing

computational methods for superconductivity and present selected examples of material discoveries that exemplify the main advancements.

1   Introduction

The aim of this chapter is to offer an up-to-date perspective on the field of ab initio superconductivity and of the related development of numerical methods to compute critical temperatures and other physical properties of superconductors. The material-specific aspect is what distinguishes ab initio (= from first principles) approaches, based on density functional theory (DFT) and its extensions, from other theoretical approaches to superconductivity, which mainly focus on the general description of the phenomenon. The typical questions addressed by computational superconductivity are as follows: (i) What makes a certain compound a good (or bad) superconductor? (ii) How are its properties modified by external parameters, such as doping, pressure, and strain? (iii) Is it possible to find new materials with improved superconducting properties compared to existing ones?

The most relevant parameter that defines the performance of a superconductor for large-scale applications is its critical temperature (T_c): this means that addressing the questions above requires the development of methods accurate enough to predict the T_c of a superconductor and its dependence on external parameters. The progress in this direction, in the last 20 years, has been impressive.

For a large class of superconductors, i.e., conventional, phonon-mediated ones, ab initio methods are now so accurate that the focus of the field is gradually shifting from the description of existing superconductors to the design of new materials. The first successful example was the prediction of high-T_c conventional superconductivity in SH_3 (2014) (Drozdov et al. 2015a; Duan et al. 2014).

For unconventional superconductors, which comprise two of the most studied classes of materials, the high-T_c cuprates (Bednorz and Mueller 1986) and Fe-based superconductors, (Kamihara et al. 2008) ab initio approaches are still far from being predictive, but it is becoming more and more widely accepted that the single-particle electronic structure determines crucial properties of these materials, such as the symmetry of the superconducting gap and the behavior of magnetic excitations.

The topics and the structure of this chapter have been specifically thought out to illustrate the parallel progress in ab initio methods and material research for superconductors. I have chosen three discoveries that I consider the fundamental milestones of this process: (a) the report of superconductivity in MgB_2 in 2001, which has disproved the Cohen-Anderson limit for conventional superconductors; (b) the discovery of Fe-based superconductors, which has led to a much deeper understanding of the interplay between electronic structure, magnetism, and superconductivity in unconventional superconductors; and (c) the discovery of high-temperature superconductivity at megabar pressures in SH_3, which has given a spectacular demonstration of the predictive power of ab initio calculations.

Although I will give a general introduction to the theory of superconductivity and briefly describe the most recent advancements in ab initio methods, methodological

developments are not the main topic of this chapter: I refer the interested reader to excellent reviews in literature for a detailed discussion (Giustino 2017; Sanna 2017; Sanna et al. 2018). For space reasons, I am also forced to leave out some currently very active directions of superconductivity research, such as topological superconductivity (Sato and Ando 2017) superconductivity in 2D transition metal dichalcogenides (Klemm 2015), and artificial superlattices (Boschker and Mannhart 2017), and other more traditional topics, such as cuprates and other oxides (Chu et al. 2015), fullerenes (Gunnarsson 1997), layered halonitrides (Kasahara et al. 2015), etc.

On the other hand, I have included at the end a short perspective describing possible routes to high-T_c superconductivity which exploit novel developments in experimental and ab initio techniques, since I believe that in the next years, the combination of the two may lead to the discovery of many new superconductors.

The structure of the chapter is the following: I will start by giving a concise historical review of the most important discoveries in Sect. 2. In Sect. 3, I will then introduce the basic concepts of superconductivity theory and describe the most recent developments in ab initio methods. The main body of the paper is contained in Sect. 4, where, using selected material examples, I will try to give an impression of the rapid progress of the field in the understanding of both conventional and unconventional superconductors. Finally, in Sect. 5, I will propose possible practical routes to high-T_c superconductivity.

2 A Brief History of Research in Superconductivity

Superconductivity was discovered more than 100 years ago when H.K. Onnes observed that, when cooled below 4 K, mercury exhibits a vanishing resistivity (Onnes 1913). Perfect diamagnetism, which is the second fingerprint of a superconductor, was discovered by Meissner and Ochsenfeld around 20 years later (Meissner and Ochsenfeld 1933). While it was immediately clear that superconductors could have an enormous potential for applications, the low critical temperatures represented an insurmountable obstacle to large-scale applications.

In addition to presenting practical problems, superconductivity proved to be a major challenge also for theorists: fully microscopic theories of superconductivity – the Bardeen-Cooper-Schrieffer (BCS) and Migdal-Eliashberg (ME) theories – were developed only after almost 50 years after the original discovery (Bardeen et al. 1957; Migdal 1958; Eliashberg 1960; Allen and Mitrovic 1982; Scalapino 1969; Carbotte 1990). They describe superconductivity as due to the condensation of pairs of electrons of opposite spin and momentum (Cooper pairs), held together by an attractive *glue*. In conventional superconductors, the glue is provided by phonons (lattice vibrations), but other excitations such as plasmons, spin fluctuations, etc. can also mediate the superconducting pairing. We will treat here only the case of the so-called *boson-exchange* superconductors, and not other mechanisms, such as resonant valence bond, hole superconductivity, etc.

The understanding of the microscopic mechanism of superconductivity did not lead to any immediate, appreciable progress in the search for new superconductors; this translated into a general skepticism toward theory, which is well exemplified by one of Matthias' rules for superconductivity (*stay away from theorists!*). Indeed, rather than a predictive theory, ME theory was long considered a sophisticated phenomenological framework to describe existing superconductors, while the search for new materials was (unsuccessfully) guided by semiempirical rules. Even worse, two leading theorists used ME theory to demonstrate the existence of an intrinsic limit of around 25 K to the T_c of *conventional* superconductors. Although conceptually wrong, the *Cohen-Anderson limit* is still cited today as an argument against high-T_c superconductivity (Cohen and Anderson 1972).

The notion of an upper limit to T_c was first challenged by the discovery of the first unconventional superconductors, the cuprates, in 1986 (Bednorz and Mueller 1986). In contrast to conventional superconductors, which above T_c behave as ordinary metals, cuprates exhibit a complex phase diagram, with many coexisting phases and physical phenomena (charge and spin density waves, metal-insulator transitions, transport anomalies, etc.). In 1987 a cuprate, YBCO, broke the liquid N_2 barrier, with a T_c of 92 K (Wu et al. 1987), causing a general excitement in the media about a possible *superconducting revolution*; the highest T_c ever attained in this class is 156 K (Schilling et al. 1993). Despite almost 30 years of research and many different proposals, a quantitative theory of superconductivity in the cuprates is still lacking; furthermore, their large-scale applicability is also limited due to their high brittleness and manufacturing costs (Gurevich 2011).

The search for new materials took a different turn at the beginning of this century, when a T_c of 39 *K* was reported in a simple $s-p$ binary compound, magnesium diboride (MgB_2) (Nagamatsu et al. 2001). In contrast to the cuprates, MgB_2 is a conventional superconductor. In less than 2 years, ab initio calculations provided a key quantitative understanding of very specific aspects of superconductivity in this material, such as two-gap superconductivity, anharmonicity, role of magnetic and nonmagnetic impurities, doping, etc. (An and Pickett 2001; Kong et al. 2001; Kortus et al. 2001; Liu et al. 2001; Choi et al. 2002; Mazin et al. 2002). This stimulated a renewed enthusiasm in the search for new superconductors and, in parallel, the development of accurate ab initio methods to model them.

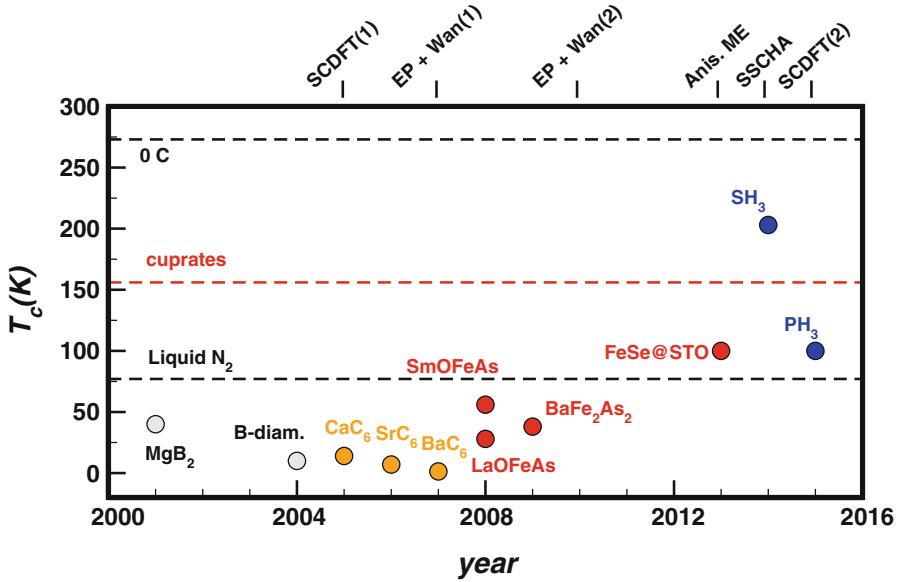
Indeed, in the last 17 years, superconductivity has been discovered in B-doped semiconductors (Ekimov et al. 2004; Bustarret et al. 2006), intercalated graphites (Weller et al. 2005), unconventional Fe-based superconductors (Kamihara et al. 2008), and, finally, high-pressure hydrides (Drozdov et al. 2015a,b). The T_cs as a function of the year of their discovery are shown as colored symbols in Fig. 1. The most important methodological developments are reported on the top axis: superconducting density functional theory (Lüders et al. 2005; Marques et al. 2005), electron-phonon interaction with Wannier functions (Giustino et al. 2007a; Calandra et al. 2010; Giustino 2017), ab initio anisotropic ME theory (Sanna et al. 2018; Margine and Giustino 2013), (stochastic) self-consistent harmonic approximation (Errea et al. 2014), and ab initio spin fluctuations (Essenberger et al. 2014, 2016).


Fig. 1 Main developments in the field of superconductivity in the twenty-first century: the T_cs of the most important experimental discoveries as a function of year are shown as colored symbols. The top axis reports the most important methodological developments in ab initio superconductivity: superconducting density functional theory (*SCDFT(1)*) (Lüders et al. 2005; Marques et al. 2005), electron-phonon interaction with Wannier functions (*EP+WAN(1) and EP+WAN(2)*) (Giustino 2017; Giustino et al. 2007a; Calandra et al. 2010), ab initio anisotropic ME theory (*Anis. ME*) (Margine and Giustino 2013; Sanna et al. 2018), (stochastic) self-consistent harmonic approximation (*SSCHA*) (Errea et al. 2014), ab initio spin fluctuations (*SCDFT(2)*) (Essenberger et al. 2014, 2016)

Thanks to these advancements, ab initio calculations for conventional superconductors have now reached an accuracy which gives them fully predictive power. Methods are being developed also to treat other types of interactions, such as plasmons and spin fluctuations (Essenberger et al. 2014, 2016; Akashi and Arita 2013), and parameter ranges where the standard approximations of strong-coupling ME theory break down (Grimaldi et al. 1995). Combined with the development of efficient methods for ab initio crystal structure prediction and the progress in synthesis and characterization techniques (Woodley and Catlow 2008; Zhang et al. 2017), this opens unprecedented possibilities for material discovery.

3   Methods

In this section, I describe the methodological background of computational superconductivity. The first part introduces the main concepts behind the microscopic theories of superconductivity, i.e., the early Bardeen-Cooper-Schrieffer (BCS)

theory and the strong-coupling Migdal-Eliashberg (ME) theory. Although extremely accurate and elegant, ME theory was for a long time employed only as a semi-phenomenological theory, relying on electronic and vibrational spectra extracted from experiments. Early attempts of obtaining these quantities from density functional theory date back to the early 1980s, but with limited success, due to inadequate computational resources and insufficient accuracy of methods to treat phonons and electron-phonon (*ep*) interaction (Gaspari and Gyorffy 1972; Chang et al. 1985). The required accuracy was only achieved with density functional perturbation theory (DFPT) (Savrasov and Savrasov 1996; Baroni et al. 2001) and recently substantially increased with Wannier function interpolation methods (Giustino et al. 2007a; Calandra et al. 2010; Marzari et al. 2012).

In a very influential paper, already in 1996, Savrasov and Savrasov demonstrated that linear response calculations combined with Migdal-Eliashberg theory could reproduce the critical temperatures and other properties of elemental metals (Savrasov and Savrasov 1996). However, since at that time the T_cs of known conventional superconductors were much smaller than those of the cuprates, this result was erroneously perceived as of limited importance.

The report of superconductivity in MgB_2 in 2001 gave a strong impulse to the development of ab initio methods for superconductors, which resulted in two parallel lines of research: ab initio Migdal-Eliashberg theory and superconducting density functional theory, described in Sect. 3.2. In their fully anisotropic versions, including screened Coulomb interactions, they have a comparable accuracy of 5–10% on the critical temperature, gap, etc. (Sanna 2017; Sanna et al. 2018; Margine and Giustino 2013). This gives them fully predictive power, and, combined with methods for crystal structure prediction, offers the unprecedented possibility of designing superconductors ab initio, overcoming the practical limitations of experiments.

3.1   A Short Compendium of Superconductivity Theory

The first fully microscopic theory of superconductivity was formulated by Bardeen, Cooper, and Schrieffer in 1957 and is known as BCS theory (Bardeen et al. 1957).

BCS theory describes the transition of superconductors from an ordinary metallic state (*normal state*) to a new state, characterized by vanishing resistivity and perfect diamagnetism. In this *superconducting state*, the electronic spectrum develops a gap Δ around the Fermi level, which is maximum at zero temperature and vanishes at the critical temperature T_c. The critical temperature exhibits an *isotope effect*, i.e., T_c increases (or decreases) upon partial replacement of an element with a lighter (heavier) isotope. Isotope effects are also measured for other characteristic properties of superconductors (gap, specific heat, etc.).

BCS theory reconciles all the above experimental observations in a consistent framework, based on three key concepts:

(i) A Fermi sea of electrons in the presence of an attractive interaction is unstable toward the formation of a pair of electrons with opposite spin and momentum

(**Cooper pair**), which effectively behaves as a boson. In a superconductor, below T_c, a small but macroscopic fraction of electrons, of order $\Delta/E_F \simeq 10^{-3}$, forms Cooper pairs – this is sometimes referred to as the *condensate fraction* of a superconductor.

(ii) A variational many-body wavefunction for the electrons is constructed from a superposition of ordinary single-particle states and Cooper pairs (**BCS wavefunction**). The existence of a condensate fraction leads to the appearance of a gap in the electronic spectrum $\varepsilon_\mathbf{k}$, which satisfies the self-consistent equation:

$$\Delta_\mathbf{k} = -\frac{1}{2} \sum_{\mathbf{k,k'}} \frac{V_{\mathbf{k,k'}} \Delta_{\mathbf{k'}}}{\sqrt{\varepsilon_\mathbf{k}^2 + \Delta_\mathbf{k}^2}} \cdot \tanh\left(\frac{\sqrt{\varepsilon_\mathbf{k}^2 + \Delta_\mathbf{k}^2}}{2T}\right). \tag{1}$$

iii) Using a simple model for the electron-electron interaction $V_{\mathbf{k,k'}}$, the so-called **BCS potential**, which is attractive only if the two electrons with wavevector $\mathbf{k}$, $\mathbf{k'}$ both lie in a small energy shell ω_D around the Fermi energy E_F, Eq. 1 can be solved analytically, and the gap and T_c are given by:

$$\Delta(T = 0) \simeq 2\omega_D \exp\left(-\frac{1}{N(E_F)V}\right), \qquad k_b T_c = 1.13\omega_D \exp\left(-\frac{1}{N(E_F)V}\right), \tag{2}$$

The original idea of Bardeen, Cooper, and Schrieffer is that the attractive interaction V between electrons is mediated by lattice vibrations (phonons). In this case, ω_D is a representative phonon energy scale, such as the Debye frequency; $N(E_F)$ is the electronic density of states at the Fermi level.

One of the first successes of BCS theory has been the explanation of the isotope effect on T_c, $\alpha_{T_c} = -\frac{d\ln(T_c)}{d\ln(M)} = 0.5$, where M is the ionic mass, as well as the prediction of several *magic ratios*, satisfied in most elemental superconductors: the most famous is probably the ratio $\frac{2\Delta(0)}{k_B T_c} = 3.53$.

However, BCS theory is valid only at weak-coupling ($\lambda = N(E_F)V < 0.2 - 0.3$) and instantaneous interactions; these assumptions are not verified in many conventional superconductors, where the actual values of T_c, isotope effect, magic ratios, etc. are spectacularly different from the BCS predictions (Marsiglio and Carbotte 1986).

A quantitative description of the strong-coupling, retarded regime is given by the many-body ME theory, based on a set of self-consistent coupled diagrammatic equations for the electronic and bosonic propagators (Allen and Mitrovic 1982; Scalapino 1969; Carbotte 1990; Margine and Giustino 2013). The bosons that mediate the superconducting pairing can be phonons or other excitations of the crystal, such as plasmons or spin fluctuations (Berk and Schrieffer). Below the critical temperature, electrons are described by a normal and an *anomalous* electronic propagator, the latter accounting for Cooper pairs. ME equations are then obtained from Dyson's equations for the normal and anomalous propagators; in their most commonly used, T-dependent form, they can be written as:

$$Z(\mathbf{k}, i\omega_n) = 1 + \frac{\pi T}{\omega_n} \sum_{\mathbf{k}'n'} \frac{\delta(\varepsilon_{\mathbf{k}'})}{N(E_F)} \frac{\omega_{n'}}{\sqrt{\omega_{n'}^2 + \Delta^2(\mathbf{k}, i\omega_{n'})}} \lambda(\mathbf{k}, \mathbf{k}', n - n') \quad (3)$$

$$Z(\mathbf{k}, i\omega_n)\Delta(\mathbf{k}, i\omega_n) = \pi T \sum_{\mathbf{k}'n'} \frac{\delta(\varepsilon_{\mathbf{k}'})}{N(E_F)} \frac{\Delta(\mathbf{k}', i\omega_{n'})}{\sqrt{\omega_{n'}^2 + \Delta^2(\mathbf{k}, i\omega_{n'})^2}} \times$$

$$\times \left[\lambda(\mathbf{k}, \mathbf{k}', n - n') - \mu(\mathbf{k} - \mathbf{k}')) \right] \quad (4)$$

where $Z(\mathbf{k}, i\omega_n)$ and $Z(\mathbf{k}, i\omega_n)\Delta(\mathbf{k}, i\omega_n)$ are the self-energy of the normal and anomalous electronic propagators, respectively; $i\omega_n = i(2n\pi T + 1)$ are Matsubara frequencies, and $\mathbf{k}, \mathbf{k}'$ are the electronic momenta; and the δ function restricts the sum over $\mathbf{k}'$ only to electronic states at the Fermi level. The electrons interact through a retarded attractive interaction $\lambda(\mathbf{k}, \mathbf{k}', n - n')$ and an instantaneous Coulomb repulsion $\mu(\mathbf{k} - \mathbf{k}')$. The interaction $\lambda(\mathbf{k}, \mathbf{k}', n - n')$ is usually expressed in terms of an electron-boson spectral function $\alpha^2 F(\mathbf{k}, \mathbf{k}', \omega)$ as :

$$\lambda(\mathbf{k}, \mathbf{k}', n - n') = \int_0^\infty d\omega \frac{2\omega}{(\omega_n - \omega_{n'})^2 + \omega^2} \alpha^2 F(\mathbf{k}, \mathbf{k}', \omega) \quad (5)$$

Equations (3) and (4) can be solved numerically to obtain the gap and other thermodynamic quantities. It is very common, and in most cases sufficiently accurate, to approximate the more general form with an isotropic version, replacing the sums on the electronic momenta $(\mathbf{k}, \mathbf{k}')$ with Fermi surface averages. If one is only interested in the T_c, there are excellent approximation formulas; a very popular choice for phonon-mediated superconductors is the McMillan-Allen-Dynes expression (Allen and Dynes 1975):

$$T_c = \frac{\omega_{\log}}{1.2 k_B} \exp\left[-\frac{1.04(1 + \lambda)}{\lambda - \mu^*(1 + 0.62\lambda)} \right], \quad (6)$$

where $\lambda = 2 \int d\omega \frac{\alpha^2 F(\omega)}{\omega}$ and $\omega_{\log} = \exp\left[\frac{2}{\lambda} \int \frac{d\omega}{\omega} \alpha^2 F(\omega) \ln(\omega) \right]$ are the *ep* coupling constant and logarithmic averaged phonon frequency, respectively; μ^* is the so-called Morel-Anderson pseudopotential, obtained by screening the full Coulomb potential up to a characteristic cutoff energy (Morel and Anderson 1962).

3.2   Ab Initio Methods

The two methods described in this section, ab initio anisotropic Migdal-Eliashberg theory (DFT-ME in the following) (Margine and Giustino 2013; Sanna et al. 2018) and superconducting density functional theory (SCDFT) (Oliveira et al. 1988; Lüders et al. 2005; Marques et al. 2005), represent a fundamental step forward in the study of actual superconductors, because they permit to obtain a full characterization of the normal and superconducting state of a system from the sole knowledge of the

chemical composition and crystal structure. Although there are fundamental and practical differences between the two, both methods rely crucially on the ability of DFT of providing accurate electronic and bosonic spectra for most materials at an affordable computational cost (Jones and Gunnarsson 1989; Baroni et al. 2001).

The basic assumptions are the following:

1. *Electronic quasiparticles* appearing in Eqs. (3) and (4) are replaced by the Kohn-Sham quasiparticles.
2. *Bosonic* excitation energies and electron-boson spectral functions are obtained from density functional perturbation theory (DFPT) (Baroni et al. 2001).

   For *phonons*, the spectral function is:

   $$\alpha^2 F_{ph}(\mathbf{k}, \mathbf{k}', \omega) = N(E_F) \sum_{\nu} g_{\mathbf{k}\mathbf{k}',\nu} \delta(\omega - \omega_{\mathbf{k}-\mathbf{k}',\nu}), \qquad (7)$$

   where $g_{\mathbf{k},\mathbf{k}'} = \left\langle \mathbf{k}' | \delta V_{scf}^{\nu,\mathbf{k}'-\mathbf{k}} | \mathbf{k} \right\rangle$ is the *ep* matrix element for the mode ν and $\delta V_{scf}^{\nu,\mathbf{q}}$ is the variation of the Kohn-Sham self-consistent potential due to an infinitesimal displacement along the eigenvector of the phonon mode ν with wavevector $\mathbf{q} = \mathbf{k}' - \mathbf{k}$.

   For *spin fluctuations*, the spectral function is proportional to the imaginary part of the longitudinal interacting spin susceptibility $\chi_{zz}(\mathbf{q} = \mathbf{k}-\mathbf{k}', \omega)$(Vignale and Singwi 1985), which, using linear response within the time-dependent density functional theory (TDDFT) framework (Runge and Gross 1984), can be written as:

   $$\chi_{zz}(\mathbf{q}, \omega) = \frac{\chi^{KS}(\mathbf{q}, \omega)}{1 - f_{xc}(\mathbf{q}, \omega)\chi^{ks}(\mathbf{q}, \omega)}, \qquad (8)$$

   where $\chi^{KS}(\mathbf{q}, \omega)$ is the Kohn-Sham susceptibility and $f_{xc}(\mathbf{q}, \omega)$ is the exchange and correlation kernel (Essenberger et al. 2012).
3. The *Coulomb potential* $\mu(\mathbf{k} - \mathbf{k}')$ which, in most empirical approaches, is treated as an adjustable parameter within the Morel-Anderson approximation (Morel and Anderson 1962), is treated fully ab initio by screening the bare Coulomb potential within RPA. Substantial deviations from typical values of $\mu^* = 0.1 - -0.15$ are found in strongly anisotropic systems such as MgB_2 and layered superconductors; in some cases, such as alkali metals at high pressure, the effect of Coulomb interactions is even stronger, giving rise to plasmonic effects (Akashi and Arita 2013).

Once the spectra of the quasiparticles and the interactions between them are known from first principles, DFT-ME or SCDFT can be applied to describe the superconducting state. DFT-ME theory amounts to solving the fully anisotropic ME equations, for electronic and bosonic spectra computed in DFT; the current implementations solve the equations in Matsubara frequencies and use Padé approximants

to continue them to real space. The obvious advantage of this method is that all quantities have an immediate physical interpretation through many-body theory.

SCDFT is a fundamentally different approach, which generalizes the original Hohenberg-Kohn idea of one-to-one correspondence between ground-state density and potential (Hohenberg and Kohn 1964), introducing two additional densities (and potentials) for the ionic system $\Gamma(\mathbf{R}_i)(V_{ext}(\mathbf{R}_i))$ and the superconducting electrons $\chi(\mathbf{r}, \mathbf{r}')(\Delta(\mathbf{r}, \mathbf{r}'))$ and finding the values that minimize a suitable energy functional. This permits to derive a gap equation which is analogous to the BCS one but instead of an empirical potential contains a *kernel* with all the relevant physical information on the system. I refer the reader to the original references for a full derivation (Lüders et al. 2005; Marques et al. 2005; Oliveira et al. 1988) and to Sanna (2017) for an excellent pedagogical introduction.

SCDFT equations are more easily solvable on a computer than fully anisotropic ME equations because they do not require expensive sums over Matsubara frequencies; however, the interpretation of many physical quantities, including the frequency dependence of the gap, is not equally transparent and straightforward. Another intrinsic limitation is that, like in all DFT-like methods, the quality of the results depends strongly on the quality of the functional.

The latest-developed functionals yield results with an *accuracy* comparable to that of the best DFT-ME calculations, which for most conventional superconductors is between 5 and 10% of the critical temperature. The most severe source of inaccuracy in DFT calculations for superconductors is usually an underconverged integration in reciprocal space in Eqs. (3) and (4), an issue that has considerably improved thanks to the use of Wannier interpolation techniques.

Achieving quantitative accuracy for conventional pairing also encouraged to address ab initio effects, which are often disregarded even in model approaches, such as anharmonicity, vertex corrections, and zero-point effects (Pietronero et al. 1995; Boeri et al. 2005; Lazzeri et al. 2003).

These turned out to be relevant for a wide variety of compounds, particularly for the newly discovered superconducting hydrides, where the energy scales of phonons and electrons are comparable (Errea et al. 2014, 2016; Sano et al. 2016). I refer the reader to the relevant references for an in-depth discussion.

For unconventional superconductors, on the other hand, the most severe source of inaccuracy is intrinsic and is the possible divergence in the spin-fluctuation propagator, which completely destroys the predictive power of DFT approaches for currently available functionals. Moreover, most unconventional superconductors suffer from the lack of accuracy of DFT in strongly correlated systems (Yin et al. 2013).

3.3   Developments in Related Fields: Ab Initio Material Design

The term *ab initio material design* indicates the combination of methods for ab initio crystal structure prediction and thermodynamics to predict the behavior of materials at arbitrary conditions of pressure and temperature, knowing only the initial chemical composition of the system. The development of these methods

represents a substantial step forward in computational condensed matter research, as it overcomes one of its biggest limitations, exemplified by the *Maddox Paradox* (1988): *"One of the continuing scandals in the physical sciences is that it remains in general impossible to predict the structure of even the simplest crystalline solids from a knowledge of their chemical composition."*

The basic working principle of **ab initio crystal structure prediction** is quite simple. Predicting the crystal structure of a material for a given regime of chemical composition and pressure amounts to finding the global minimum of a complicated landscape, generated by the ab initio total energies (or enthalpies) of all possible structures. The number of possible configurations for a typical problem is so large that a purely enumerative approach is unfeasible; in the last years, several methods have been devised to make the problem computationally manageable, such as ab initio random structure search, minima hopping, metadynamics, genetic algorithms, particle swarm algorithms, etc. (Woodley and Catlow 2008).

Once the most favorable crystal structure for a given composition and pressure is known, the ab initio CALPHAD (CALculation of PHAse Diagrams) approach permits to predict accurate **phase diagrams** (Lukas et al. 2007), as illustrated in Fig. 2. The binary Li-S phase diagram in panel (*a*) shows the stability ranges of different Li-S compositions and has been constructed repeating several *convex hull* calculations at different pressures.

The *convex hull* construction is shown in panel (b). The points represent the lowest-energy structure predicted by an evolutionary search for a given composition; for a binary phase with composition $A_x B_y$, the formation enthalpy ΔH is defined as: $\Delta H = H(A_x B_y) - [x H(A) + y H(B)]$. If this quantity is negative, the phase $A_x B_y$ is stable with respect to elemental decomposition; if it is positive, the phase is highly (or weakly) metastable, i.e., if formed, it will decompose into its elemental constituents in finite time. However, the decomposition into the two elements is often not the relevant one, as a compound could decompose into other phases, preserving the correct stoichiometry. To estimate all possible decompositions for the binary system, one constructs the most convex curve connecting the formation enthalpy of all known phases for a given stoichiometry. Points on this convex hull represent stable compositions into which phases which lie above the convex hull will decompose into given a sufficient interval of time. The figure also shows that, as pressure increases, the diversity of the phase diagram increases, i.e., off-stoichiometry compositions become possible (*forbidden chemistry*). The convex hull construction can be easily extended to multinary systems (Gibbs diagrams) and finite temperatures including entropic effects.

4   Materials

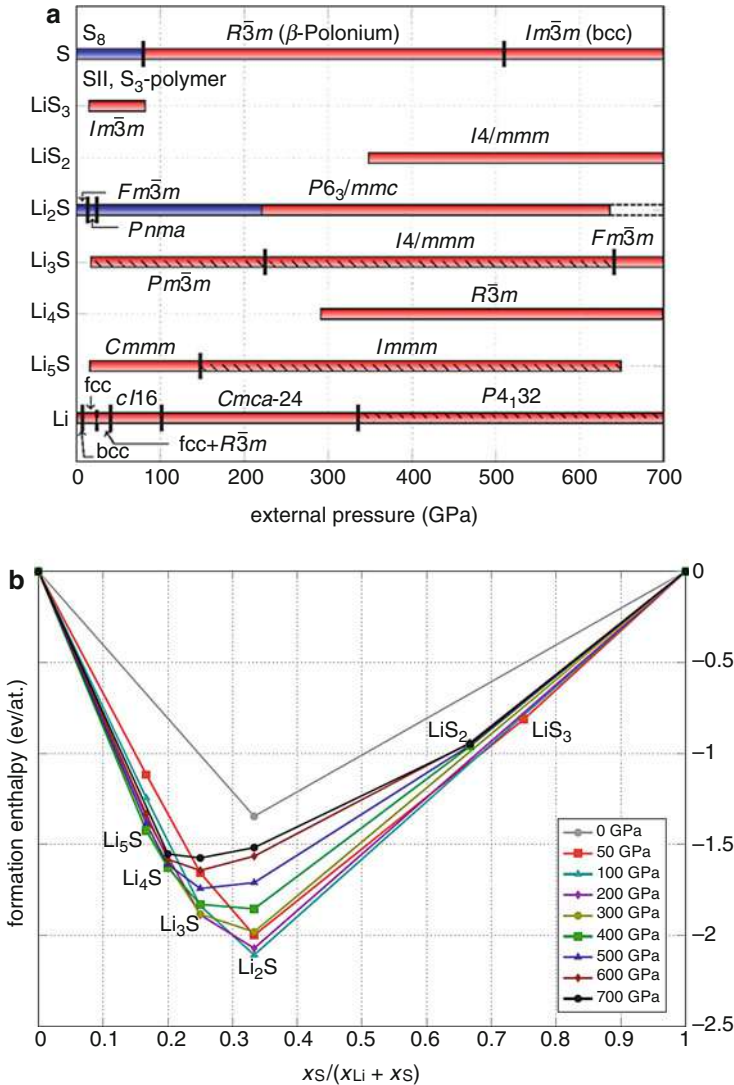
The aim of this section is to illustrate how, within a little bit more than a decade, an increased understanding of material-specific aspects of superconductivity gained from ab initio calculations has permitted to replace empirical rules to search for new superconductors with quantitative strategies.


Fig. 2 Basic steps of ab initio materials prediction: the complete phase diagram of a binary alloy as a function of pressure (**a**) can be constructed combining several convex hull constructions at different pressures (**b**) (see text). (Readapted from Kokail et al., Phys. Rev. B 94, 060502(R) (2016) – Copyright (2016) by the American Physical Society)

I will start with a general discussion that determine the T_c of conventional superconductors (Sect. 4.1), introducing the concepts of *dormant ep* interactions and lattice instabilities and showing how these can be used to interpret both the old empirical knowledge (Matthias' rules and Cohen-Anderson limit) and the latest experimental discoveries (Savrasov and Savrasov 1996; Boeri et al. 2002, 2007, 2008; Profeta et al. 2012).

I will then use a toy numerical model (simple graphite), to see how these concepts are realized in an actual physical system, and a very simple approximation to doping (rigid-band) to simulate the effect of physical doping and detect the sources of *ep* interaction in graphite-like materials. Both models are useful for a first exploration but inadequate to make accurate predictions for actual superconductors, where the doping is usually obtained via chemical substitution, which causes a major rearrangement of phononic and electronic states and hence sizable changes in the values of the *ep* interaction and T_c.

For simple graphite, nature provides two simple realizations of two of its sources of dormant *ep* interactions: MgB_2, a prototype of *covalent* superconductors, and graphite intercalated compounds, where superconductivity is correlated with the filling of *interlayer* states. In Sects. 4.3 and 4.4, I will discuss these two examples in detail and also indicate the main theoretical predictions and experimental discoveries which were inspired by them.

In particular, the line of research on covalent superconductors culminated in the discovery of high-T_c conventional superconductivity at extreme pressures in SH_3, discussed in Sect. 4.5, which also represents a fundamental step forward in the direction of the search of new superconductors using first-principles methods.

After describing the incredible evolution of the state of research in conventional superconductors, in Sect. 4.6, I will present a representative example of unconventional superconductors, iron pnictides, and chalcogenides (Fe-based superconductors), discovered in 2008, which shares many similarities with the high-T_c cuprates. This example will allow me to give an idea of the many challenges that theory faces in the description of unconventional superconductors, already in the normal state, and currently represent a fundamental obstacle to the derivation of numerical methods to compute T_cs.

4.1   Conventional Superconductors: Search Strategies

Matthias' rules The so-called Matthias' rules are a set of empirical rules that summarize the understanding of superconductors in the 1970s. The rules were allegedly formulated, and revised several times, by Bernd Matthias, one of the leading material scientists in superconductivity: they are usually cited in this form:

1. High symmetry is good; cubic symmetry is the best.
2. High density of electronic states is good.
3. Stay away from oxygen.
4. Stay away from magnetism.
5. Stay away from insulators.
6. Stay away from theorists.

Matthias' rules were inspired by A15 superconductors (cubic transition metal alloys, which can be easily doped, exhibit sharp peaks in the electronic DOS, and are prone to lattice and magnetic instabilities) and clearly disproved by subsequent experimental discoveries: cuprates and pnictides (first, third, fourth, and fifth rule) (Bednorz and Mueller 1986; Kamihara et al. 2008) but also conventional superconductors such as MgB_2 (Nagamatsu et al. 2001) (first and second rule) (Drozdov et al. 2015a). However, their impact on superconductivity research has been so important that they are still sometimes cited as arguments against conventional superconductivity or the possibility of theoretically predicting new superconductors, together with another old quasi-empirical rule, the Cohen-Anderson limit.

In order to derive more general, nonempirical strategies to search for new superconductors, I will begin with a simple analytical model. Instead of taking into account complexity of the electronic and vibrational properties of real superconductors, for the moment I consider an ideal case, in which a single phonon branch with frequency ω and a single electronic band with density of states at the Fermi level $N(E_F)$ is coupled through an average matrix element I. In this case, the T_c is well described by the McMillan-Allen-Dynes formula (Eq. 6) with all constant factors set to one, $\omega_{\ln} = \omega$, and the coupling constant is given by the Hopfield expression $\lambda = (N(E_F)I^2)/(M\omega^2)$:

$$T_c = \frac{\omega}{k_B} \exp\left[-\frac{(1+\lambda)}{\lambda - \mu^*(1+\lambda)}\right], \qquad (9)$$

These formulas indicate that there are three main strategies to optimize the critical temperature of a conventional superconductor: (i) maximize the value of the electronic DOS at the Fermi level $N(E_F)$ (first two Matthias' rules); (ii) select compounds which contain light elements (and stiff bonds), to maximize the characteristic lattice energy scales (ω); and (iii) increase the *ep* matrix elements (I).

While the first two strategies were already understood in the early 1970s, it became apparent only with the MgB_2 discovery that it is possible to find compounds where the intrinsic *ep* matrix elements I are much larger than in transition metals and their alloys, where the maximum T_c does not exceed 25 K. In a seminal paper, An and Pickett pointed out that the (relatively) high T_c of MgB_2 occurs because of *covalent bonds driven metallic* (An and Pickett 2001).

The reason why covalent metals have larger intrinsic *ep* coupling than ordinary metals can be intuitively understood looking at Fig. 3, which shows isosurfaces of the electronic localization function (ELF) for three different superconductors: Nb ($T_c = 9$ K), MgB_2 ($T_c = 39$ K), and SH_3 ($T_c = 203$ K). The ELF indicates regions where electrons are concentrated. It is clear that in MgB_2 and SH_3, the electrons localize along the bonds, while in Nb they are delocalized over the whole volume. When atoms undergo phonon vibrations, electrons localized along a bond will feel a much stronger perturbation than those spread out over the whole crystal. However, the arguments above are oversimplified, as the existence of strong directional bonds is a necessary prerequisite for large *ep* coupling, but it is not sufficient: due to the small energy scales involved in the superconducting pairing, it is also essential that
Fig. 3 Electronic localization function in conventional superconductors: bcc Nb ($T_c = 9$ K); MgB_2 ($T_c = 39$ K); SH_3 ($T_c = 203$ K)

the electronic states which contribute to this bond lie at the Fermi level; otherwise, they remain *dormant* and do not contribute to the superconducting pairing. More precisely, this means that shifting the position of the Fermi level (E_F) selects different matrix elements g in Eq. (7) when performing averages over the Fermi surfaces in in Eqs. (3) and (4), and the *ep* interaction λ, and hence T_c, is appreciable only for some positions of E_F.

A possible strategy to search for new conventional superconductors thus amounts to identifying, first, possible **dormant** *ep* **interactions** within a given material class and, second, physical mechanisms to activate them, such as doping, pressure, and alloying. Ab initio approaches permit to explore both steps of this process, at different levels of approximation. In the following, I will illustrate the basic working principle, using an example (simple graphite) and two practical realizations (MgB_2 and intercalated graphites); I will also refer to the same principles when discussing possible perspective of future research in Sect. 5.

Before moving on with the discussion, I need to introduce a second concept which is crucial in the search for new conventional superconductors: **lattice instabilities**. This argument is important because it is at the heart of the Cohen-Anderson limit (Cohen and Anderson 1972).

According to Eq. (9), T_c can apparently be increased indefinitely, increasing λ, which contradicts what is observed in practice, since the critical temperatures of actual superconductors are limited. However, in my discussion, I have so far disregarded the *feedback* effect between phonon frequencies and *ep* interaction, which is one of the main limiting factors to high T_c in actual materials. Indeed, the same *ep* interaction that pairs electrons leading to superconductivity also causes a decrease (softening) of the phonon frequencies. This means that the frequency ω appearing in McMillan's formula for T_c (Eq. 9) should be more correctly rewritten as: $\omega^2 = (\Omega_0)^2 (1 - 2\lambda_0)$, where Ω_0 is the bare frequency of the lattice, in the absence of *ep* interaction, and λ_0 is the corresponding coupling constant. It is now easy to see that the T_c for a fixed Ω_0 has a maximum for a given value of λ_0 and then decreases approaching a lattice instability ($\omega \to 0$); this means that within a given material class, T_c can only be increased up to a threshold value determined by λ_0, before incurring in a lattice instability. Using typical parameters for the

A15 compounds, which were the best known superconductors when the Cohen-Anderson limit was formulated, gives a maximum value of T_c of ~ 25 K. However, covalent superconductors such as MgB_2, doped diamond, and SH_3 have much larger characteristic phonon scales (Ω_0, λ_0) and can sustain much larger T_c.

4.2   Dormant *ep* Interaction in Graphite

To put general arguments on more physical grounds, we now consider a toy model based on an actual physical system, simple graphite, which is realized stacking several layers of graphene on top of each other (the stacking is thus AAA, in contrast to the ABA and ABC stacking of Bernal and rhombohedral graphite); for this experiment, we keep the interlayer distance equal to that of Bernal graphite.

The unit cell contains two inequivalent carbon atoms, which form a hexagonal lattice. This means that the four orbitals of carbon will split into three sp^2 hybrids and a p_z orbital, forming six σ and two π bands, of bonding and antibonding character. The blue arrow points to a fifth band, which has no carbon character: this is the so-called interlayer (IL) band, which is essentially a free-electron state confined between the carbon layers. The relative Wannier function, shown in the inset of the figure, is indeed centered in the middle of the interstitial region between the graphitic layers and has spherical symmetry (Boeri et al. 2007; Csaniy et al. 2005).

The phonon spectrum of pure graphite (not shown) is even simpler than its electronic structure: in-plane bond-stretching optical phonons form a rather narrow band between 150 and 200 meV, while optical out-of-plane and acoustical modes are more dispersive and extend up to 100 meV.

For the doping of pure graphite, corresponding to four electrons/carbon, the Fermi level cuts the band structure near the crossing point between π and π^* bands; the *ep* coupling is extremely low and gives rise to a negligible T_c. However, different *dormant ep* interactions can be activated if, with a *gedankenexperiment*, the Fermi level is shifted to higher or lower energies. This rigid-band shift is the simplest approximation to physical doping within an ab initio calculation.

The right panel of Fig. 4 shows a rigid-band calculation of the T_c of simple graphite, in an energy range of ± 8 eV around the Fermi level, corresponding to a doping of ± 1.5 electrons/carbon; in this calculation, the phonons and *ep* matrix elements are computed only once, for the physical doping of four electrons/carbon, but the averages and sums on the Fermi surface in Eqs. (3) and (4) are recomputed for different positions of the Fermi level (E_F).

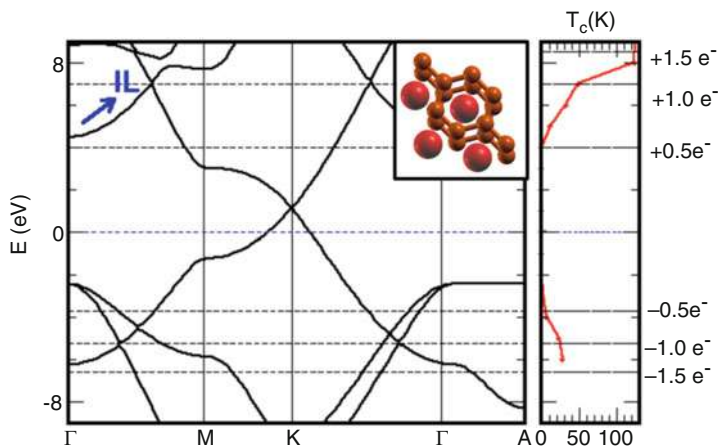
The figure clearly shows that T_c is still negligible for small variations of energy around the original Fermi level but has a marked increase as soon as holes or electrons are doped into the σ (bonding or antibonding) or IL bands, reaching a maximum of ~ 100 K, when the Fermi level reaches a large van Hove singularity at ~ 8 eV, corresponding to the bottom of the σ^* band. Apart from causing substantial deviations in T_cs, the coupling of phonons to σ, IL, and π electrons is also qualitatively different. σ and π electrons couple mostly to high-energy optical phonons, which modulate the interatomic distances in the hexagonal layers, and hence the


Fig. 4 Rigid-band study of superconductivity in simple graphite; dashed lines indicate the position of the Fermi level for a semi-integer doping of holes or electrons; the blue arrow marks the position of the interlayer band, whose Wannier function is shown in the inset

hopping between neighboring carbon sites; IL electrons, instead, respond to out-of-plane phonons, which modulate their overlap with the π wavefunctions that stick out-of-plane. This effect causes a substantial variation in the shape of the Eliashberg functions (not shown) and ω_{log}. The right scale on Fig. 4 indicates the position of the Fermi level for semi-integer values of hole($-$) or electron($+$) doping; in both cases, a finite T_c is obtained for a minimum doping of half an electron/carbon if needed, but obtaining a high T_c requires a much higher doping (~ 1 e^-/C atom). Note that the highest doping levels that can be obtained with field effect using liquid electrolytes are much lower, i.e., of the order of a few tenths of e^-/carbon, so that the only viable alternative to realize superconductivity in doped graphite is via chemical doping.

The rigid-band approximation is instructive to identify dormant *ep* interactions, but the calculated T_cs are often severely overestimated compared to other experiments or more sophisticated approximations for doping. In fact, the rigid-band approach neglects important effects due to the self-consistent rearrangement of electrons produced by doping, such as band shifts, renormalization of the phonon frequencies, and screening of the *ep* matrix elements (Subedi and Boeri 2011; Casula et al. 2012).

For simple graphite, nature provided two extremely ingenious realizations of our predictions, discussed in the next two sections.

4.3   Magnesium Diboride and Other Covalent Superconductors

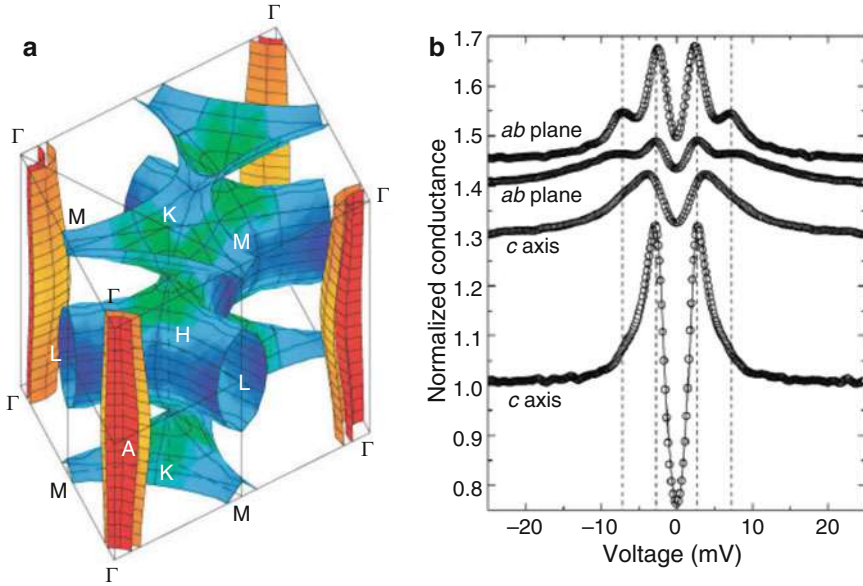
With a T_c of 39K, magnesium diboride (MgB_2) currently holds the record for conventional superconductivity at ambient pressure (Nagamatsu et al. 2001; Bhaumik et al. 2017). Its crystal structure is layered: boron forms graphite-like hexagonal planes; magnesium is placed in between, at the center of the hexagons. Mg is


Fig. 5 Two-gap superconductivity in MgB$_2$: anisotropic distribution of the gap on the Fermi surface, predicted by DFT (**a**) (Figure reprinted with permission from Nature publishing group, H.J. Choi et al., The origin of the anomalous superconducting properties of MgB2, Nature, 418, 758 (2002); Copyright (2002); evidence of two-gap behavior from tunneling experiments (**b**) (Figure reprinted with permission from R.S. Gonnelli et al., Phys. Rev. Lett. 89, 247004 (2002); Copyright (2002) by the American Physical Society)

completely ionized (Mg^{2+}) and thus MgB$_2$ is not only isostructural but also isoelectronic to graphite. However, due to the attractive potential of the Mg ions, the center of mass of the π bands is shifted up with respect to that of the σ bands compared to simple graphite, so that MgB$_2$ behaves effectively as a compensated (semi)-metal. The σ holes and π electrons form two cylinders around the center and a 3D tubular network around the corners of the Brillouin zone, respectively, as shown in Fig. 5a.

The two groups of electronic states experience a rather different coupling to phonons: over 70% of the total *ep* coupling, in fact, comes from σ holes and bond-stretching phonons; the rest is distributed over the remaining phonon modes and electronic states (Kong et al. 2001). The simplest approximation to account for the strong anisotropy of the *ep* coupling over the Fermi surface is to replace the *ep* coupling constant λ in Eq. (3) and (4), with 2×2 matrices of the form (Mazin et al. 2002):

$$\lambda = \begin{pmatrix} \lambda_{\sigma\sigma} & \lambda_{\sigma\pi} \\ \lambda_{\pi\sigma} & \lambda_{\pi\pi} \end{pmatrix} = \begin{pmatrix} 1.02 & 0.30 \\ 0.15 & 0.45 \end{pmatrix} \tag{10}$$

When the interband coupling is finite but appreciably smaller than the intraband one, $|\lambda_{\sigma\pi} + \lambda_{\pi\sigma}| < |\lambda_{\sigma\sigma} + \lambda_{\pi\pi}|$, the theory predicts that experiments should

observe two distinct gaps, closing at the same T_c (Suhl et al. 1959). Two-gap superconductivity was indeed observed by different experimental techniques: specific heat, tunneling, and angle-resolved photoemission spectroscopy (ARPES) for the first time in MgB_2 (Mazin et al. 2002).

Indeed, in most superconductors, multiband and anisotropic effects are extremely difficult to detect because they are suppressed by the interband scattering induced by sample impurities; in MgB_2 the real-space orthogonality of the σ and π electronic wavefunctions prevents interband scattering, and two-gap superconductivity can be detected also by techniques with a limited resolution (Mazin et al. 2002).

Figure 5b shows in- and out-of-plane tunneling spectra of MgB_2, which permit to unambiguously identify a σ (large) and π (small) gap (Gonnelli et al. 2002). The experimental spectra compare extremely well with the theoretical prediction of two different gaps on the σ and π sheets of the Fermi surface; the image in the left panel of the figure shows an anisotropic DFT-ME calculation of the gap; in the figure, the color of the Fermi surface is proportional to the size of the gap on that sheet (Choi et al. 2002).

Besides providing the first clear case of two-gap superconductivity, MgB_2 is the first example of superconductivity from *doping covalent bonds*. The most spectacular realization of this possibility came in 2004, with the report of a T_c of 4 K in heavily boron-doped diamond, raised to 11 K in thin films (Ekimov et al. 2004; Takano et al. 2004).

Diamond is a wideband insulator ($\Delta \sim 5.5$ eV); when boron is doped at small concentrations, an acceptor band forms within the gap. At the much higher doping levels ($\sim 1-10\%$) realized in superconducting samples, the impurity band overlaps so strongly with the valence band of diamond, that the net effect of B doping is to create holes at the top of the valence band (Yokoya et al. 2005). This band is formed by the bonding combination of the four carbon sp^3 hybrids. Boron-doped diamond can thus be seen as a 3D analogue of MgB_2, where, similarly to MgB_2, a small fraction of σ holes created by B doping exhibits an extremely strong coupling to bond-stretching phonons.

Since the *ep* coupling is concentrated in a single type of phonon modes and electronic states, the simplified formulas introduced in Sect. 4.1 give a reasonable approximation to T_c for both MgB_2 and diamond (Boeri et al. 2004; Lee and Pickett 2004; Blase et al. 2004; Giustino et al. 2007b; Hoesch et al. 2007). Furthermore, they permit to understand why, even though the C-C bonds in diamond are actually stiffer than the B-B bonds in MgB_2, the measured T_cs are much lower. In fact, near the bottom (or top) of a band, i.e., at low dopings, the DOS increases as $\sqrt{E}$ in 3D, while it is virtually constant in 2D. This implies that, as holes or electrons are doped into the system, $N(E_F)$, and hence λ, increases much more slowly in 3D systems than in 2D ones. Thus, for physical ranges of dopings, the maximum T_c in doped semiconductors is typically very low (Boeri et al. 2004; Bustarret et al. 2006).

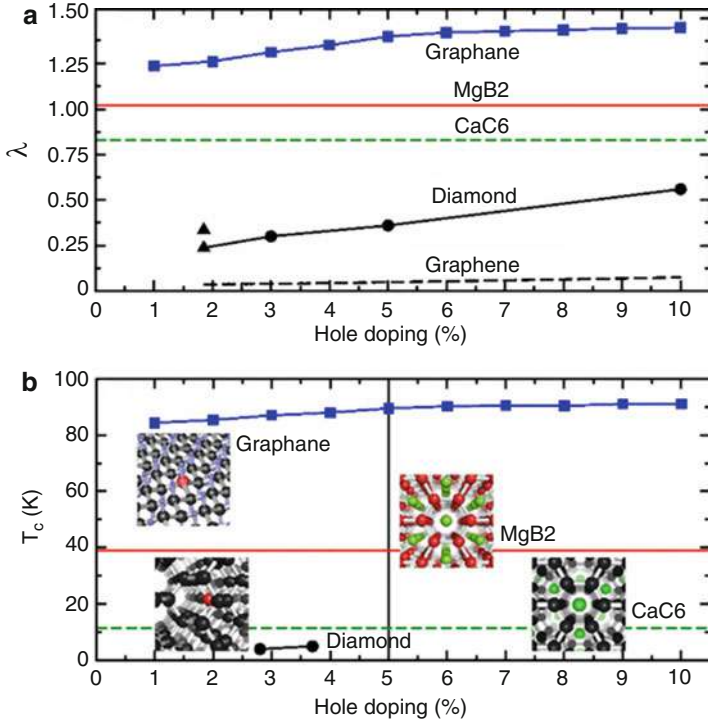
A very ingenious strategy that attains high-T_c conventional superconductivity in a doped sp^3 system avoiding negative dimensionality effects was proposed a few years later by Savini et al. (2010), i.e., realizing superconductivity in p-doped graphane (fully hydrogenated graphene). Graphane can be considered a 2D version


Fig. 6 Electron-phonon coupling (top) and T_c (bottom) as a function of doping in different carbon-based superconductors. (Figure reprinted with permission from G. Savini et al., Phys. Rev. Lett. 105, 037002 (2010), Copyright by the American Physical Society 2010)

of diamond, in which the bonding is still sp^3; hence, the matrix elements are as large as those of diamond, but the DOS is 2D; hence, λ is sizable already at low dopings. For this compound, the authors of Savini et al. (2010) estimate a T_c of $\sim$90 K already for 1% doping. Figure 6, from the original reference, compares the behavior of T_c with doping in the difference class of carbon-based superconductors discussed so far.

Although not as spectacular as graphane, in general, many carbon-based compounds doped with boron are good candidates for superconductivity with relatively high temperatures. For example, recent experiments indicate that Q-carbon, an amorphous form of carbon, in between diamond and graphite, can achieve T_cs as high as 56 K upon boron doping (Bhaumik et al. 2017).

A complementary idea is that of doping boron-rich phases with carbon; boron, being an electron-deficient material, forms a variety of structures with two- and three-center bonds. One of the most common motifs is the icosahedron (B_{12}), found, for example, in the α and β phases of elemental boron, as well as in superconducting dodecaborides (Matthias et al. 1968). Boron icosahedra doped with carbon are predicted to superconduct with T_cs as high as 37 K (Calandra et al. 2004).

4.4   Intercalated Graphites

While MgB_2 can be considered a natural realization of hole-doped graphite σ bonds, superconducting graphite intercalation compounds (GICs) are the practical realization of superconductivity by doping into the interlayer states. Although the T_cs are substantially lower than in covalent metals, this type of superconductivity is quite interesting, because it can be more easily manipulated by external means (doping, pressure) and also realized in "artificial" systems, such as mono- and bilayers of graphene decorated with alkali or noble metals.

Intercalated graphites had been extensively studied in the 1970s, because of their high mobilities, but the only known superconducting member of the family, KC_8, had an extremely small T_c ($<1 K$). Only in 2005, superconductivity with relatively high T_cs was reported in several AC_6 compounds: CaC_6 ($T_c = 11.5$ K), YbC_6 ($T_c = 6.5$ K), and later SrC_6 ($T_c = 1.6$ K) (Weller et al. 2005; Kim et al. 2007). At the same time, it was observed that for all newly discovered members of the family, the occurrence of superconductivity clearly correlates with the filling of the interlayer band, which is empty in non-superconductors (Csaniy et al. 2005).

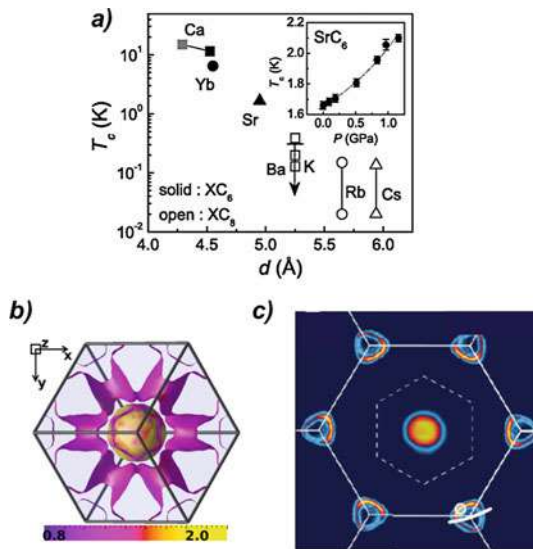
A strong correlation is also found between the T_c and the distance between two subsequent graphitic layers in different AC_6 compounds – Fig. 7a. This can be easily


Fig. 7 Physical properties of superconducting graphite intercalation compounds: (**a**) dependence of T_c on the interlayer separation in different GICs (Figure reprinted with permission from Kim et al., Phys. Rev. Lett. 99, 027001 (2007), Copyright by the American Physical Society (2007)); (**b**) anisotropic superconducting gap predicted from SCDFT calculations in CaC_6 (Figure reprinted with permission from A. Sanna et al., Phys. Rev. B 75, 020511(R) (2007), copyright by the American Physical Society (2007)); (**c**) superconducting gap measured by ARPES in Li-decorated graphene (Figure reprinted with permission from B.M. Ludbrook et al., PNAS 112, 11795 (2015))

explained within the conventional *ep* scenario (Calandra and Mauri 2005; Kim et al. 2006, 2007; Boeri et al. 2007), since, as demonstrated in Sect. 4.1, when localized due to doping and confinement effects, interlayer electrons can couple to π electrons through out-of-plane phonons of the carbon layers (in GICs, additional coupling is also provided by intercalant modes).

Like in MgB_2, the distribution of the *ep* interaction, and hence of the superconducting gap, is very anisotropic on the Fermi surface, being much larger for the interlayer electrons – central sphere in Fig. 7b – than for π ones, which form the outer tubular manifold.

The idea of superconductivity due to the localization of interlayer states was exploited in Profeta et al. (2012), proposing to achieve superconductivity in Li-decorated graphene. A T_c of 5.9 K, close to the theoretical prediction of 8.6 K, was reported in 2015 by Ludbrook et al. (2015). Figure 7c shows the superconducting gap, measured by ARPES. Note that also in this case there is a visible variation of the gap between π and IL sheets of the Fermi surface.

4.5 High-T_c Conventional Superconductivity in High-Pressure Hydrides

The most spectacular realization of high-T_c conventional superconductivity from doped covalent bonds can be found in SH_3, which, so far, holds the T_c the record among all (conventional and unconventional) superconductors.

Indeed, superconductivity at high pressures is a rather ubiquitous phenomenon, because high pressures tend to increase the hopping between neighboring sites and hence metallicity. Almost all the elements of the periodic table can be made superconducting; the typical T_cs are rather low, reaching a maximum of $\sim 20\,K$ in Li, Ca, Sc, Y, V, B, P, and S (Hamlin 2015), well reproduced by ab initio calculations (Profeta et al. 2006; Yao et al. 2009; Monni et al. 2017; Flores-Livas et al. 2017).

Hydrogen and its compounds represent a notable exception, having provided, in 2014, the first example of high-T_c conventional superconductivity. This discovery was the coronation of a 50-year-long search, inspired by two insightful papers by Neil Ashcroft, predicting high-T_c superconductivity in metallic hydrogen (1968) and covalent hydrides (2004) (Ashcroft 1968, 2004). Both predictions rely on the general arguments for high-T_c conventional superconductivity introduced in Sect. 4.1, i.e., large phonon frequencies due to the light hydrogen mass (ii) combined with large *ep* matrix elements due to the lack of screening from core electrons (iii) can yield remarkable superconducting transition temperatures, even if the density of states at the Fermi level is moderate (i).

In 1968, the first of Ashcroft's predictions, superconductivity in metallic hydrogen, seemed merely an academic speculation. The pressure required to metallize hydrogen, which is a large-gap insulator at ambient pressure ($\Delta \sim 10\,eV$), was clearly beyond reach for the experimental techniques of the time. However, 50 years

later, high-pressure research has advanced to such a point that at least three groups have reported evidences of hydrogen metallization, at pressures ranging from 360 to 500 GPa (3.6 to 5 Mbar) (Dalladay-Simpson and Howie 2016; Eremets et al. 2017; Dias and Silvera 2017).

These reports are still controversial, since the pressure ranges are close to the limit of current high-pressure techniques (Eremets and Drozdov 2017; Goncharov and Struzhkin 2017). The insulator-to-metal transition has two possible origins: band overlap, in the molecular $CmCa$ phase, or a structural transition to an atomic $\beta - Sn$ phase. The two phases are almost impossible to discern experimentally because hydrogen is a poor X-ray scatterer, and theoretical studies also predict an unusual spread of values (300–500) GPa for the transition boundary between the two phases, due to the different approximations used to account for quantum lattice effects (McMahon et al. 2012). However, according to DFT calculations, both the $CmCa$ and the $\beta - Sn$ structures should become superconducting at or above ambient temperature, suggesting that the first of Ashcroft's predictions may soon be realized (Cudazzo et al. 2008; McMahon and Ceperley 2011; Borinaga et al. 2016).

The second prediction, superconductivity in covalent hydrides, was experimentally verified at the end of 2014. The underlying idea is that in covalent hydrides, metallization of the hydrogen sublattice should occur at lower pressure than in pure hydrogen, because the other atoms exert an additional chemical pressure.

Indeed, in 2008, superconductivity was measured in compressed silane (SiH_4) at 120 GPa, but the measured T_c (17 K) was disappointingly low compared to theoretical prediction of 100 K (Eremets et al. 2008; Li et al. 2010). However, this finding proved that the experimental knowledge to make covalent hydrides was available, and it was only a matter of time before high-T_c conventional superconductivity would actually be observed. Ab initio calculations revealed two essential missing pieces of the puzzle: (a) megabar pressures can stabilize *superhydrides*, i.e., phases with much larger hydrogen content than the hydrides stable at ambient pressure, and (b) some of these *superhydrides* are metals with unusually strong bonds, which can lead to high-T_c superconductivity (Zurek et al. 2009).

The first high-T_c superconductor discovered experimentally is a sulfur superhydride (SH_3), which is stabilized under pressure, by compressing gaseous sulfur dihydride (SH_2) in a hydrogen-rich atmosphere. The compound metallizes at $\sim$100 GPa, where it exhibits a T_c of 40 K. The T_c increases reaching a maximum of over 203 K at 200 GPa; isotope effect measurements confirmed that superconductivity is of conventional origin. I refer the reader to the original experimental (Drozdov et al. 2015a; Goncharov et al. 2016; Einaga et al. 2016; Capitani et al. 2017) and theoretical (Duan et al. 2014; Heil and Boeri 2015; José et al. 2016; Errea et al. 2015, 2016; Bernstein et al. 2015; Quan and Pickett 2016; Akashi et al. 2016; Sano et al. 2016) references for a more detailed discussion of specific aspects of the SH_3 discovery, such as the nature and thermodynamics of the SH_2 to SH_3 transition and anharmonic and nonadiabatic effects (Gor'kov and Kresin 2018).

In the history of superconducting materials, SH_3 stands out for one main reason: it is the first example of a high-T_c superconductor whose chemical composition, crystal structure, and superconducting transition temperature were predicted from

first principles before the actual experimental discovery. In fact, a few months before the experimental report, Duan et al. (2014) predicted that SH_2 and H_2 would react under pressure and give rise to a highly symmetric bcc structure, later confirmed by X-ray experiments (Einaga et al. 2016), which could reach a T_c as high as 200 K at 200 GPa.

From the point of view of electronic structure, SH_3 is a paradigmatic example of high-T_c conventional superconductivity. Indeed, in this case, all three conditions reported in Sect. 4.1 are verified: SH_3 is a hydride, and hence its characteristic vibrational frequencies are high (i); the Fermi level falls in the vicinity of a van Hove singularity of the DOS of the bcc lattice (ii); and the *ep* matrix elements are high due to the unusual H-S covalent bonds stabilized by pressure (iii).

Replicating a similar combination is not simple, even in other high-pressure hydrides, where one can hope that high pressure may help stabilize unusual bonding environments and hydrogen-rich stoichiometries. Despite an intense theoretical exploration of the high-pressure superconducting phase diagrams of binary hydrides (Zurek et al. 2009), only a few candidates match or surpass the T_c of SH_3: Ca, Y, and La (Wang et al. 2012; Liu et al. 2017).

In fact, the formation of covalent directional bonds between hydrogen and other atoms appears to be very sensitive to their electronegativity difference (Bernstein et al. 2015; Fu et al. 2016), and in binary hydrides, the possibilities to optimize this parameter are obviously limited. A possible strategy to overcome this limitation is to explore ternary hydrides, where the electronegativity, atomic size, etc. can be tuned continuously combining different elements. However, since ternary Gibb's diagrams are computationally much more expensive than binary convex hulls, fully ab initio studies of ternaries are rare. Two recent studies explore two different strategies toward high T_c in ternary hydrides: doping low-pressure molecular phases of covalent binary hydrides, like water (Flores-Livas et al. 2017), and off-stoichiometry phases of alkali-metal alanates and borates, which permit to independently tune the degree of metallicity and covalency (Kokail et al. 2017).

Due to the intrinsic difficulty of reaching megabar pressures and the limited information that can be extracted from X-ray spectra, the experimental information on high-pressure hydrides is much scarcer than theoretical predictions. Nevertheless, there has been a substantial progress in the last 5 years: metallic superhydrides predicted by theory have been reported in hydrides of alkali metals (Li,Na), (Pépin et al. 2015; Struzhkin et al. 2016) transition metals (Fe), (Pépin et al. 2017) group IV elements, etc. For some of these systems, first-principles calculations predict substantial superconducting temperatures (Zurek et al. 2009), while other cases are controversial (Majumdar et al. 2017; Kvashnin et al. 2018; Heil et al. 2018).

Resistivity and susceptibility measurements required to detect superconductivity under pressure are even more challenging, and therefore the available information on superconductivity in high-pressure hydrides is still very scarce: besides SH_3, only one other hydride, PH_3, has been shown to superconduct at high pressures, albeit with a lower T_c ($\sim$100 K) (Drozdov et al. 2015b). At variance with SH_3, PH_3 is highly metastable, and samples rapidly degrade over time, consistently with ab initio predictions of metastability (Fu et al. 2016; Flores-Livas et al. 2016; Shamp et al.

2016). SeH_3, which should exhibit T_cs comparable to SH_3, has been successfully synthesized at the end of last year (Pace et al. 2017), but superconductivity has not been measured yet.

The same arguments that motivated the search for high-T_c conventional superconductivity in high-pressure hydrides can be applied to other compounds that contain light elements, such as Li, B, C, etc. Some of these elements form covalent structures with strong directional bonds already at ambient pressure, and high pressures could be used to optimize doping, stoichiometry, etc. However, element-specific factors can unpredictably affect properties relevant in high-pressure superconductivity. For example, elemental phases of alkali metals at high pressure exhibit a characteristic *interstitial charge localization*, due to avoided core overlap. The same effect, which is extremely detrimental for conventional superconductivity (charge localized in the interstitial regions has an intrinsically low coupling to phonons), also occurs in many of their compounds. This was shown, for example, for the Li-S system, whose behavior at high pressure is remarkably different from H-S (Kokail et al. 2016).

4.6   Unconventional Superconductivity in Fe Pnictides and Chalcogenides

After illustrating the remarkable progress in the research on conventional superconductors, I have chosen to discuss the single largest class of unconventional superconductors, formed by Fe pnictides and chalcogenides (Fe-based superconductors, FeSC). The T_cs of these compounds, discovered in 2008, go up to 56 K in the bulk, and allegedly up to 100 K in monolayers of FeSe grown on $SrTiO_3$ (Kamihara et al. 2008; Ge et al. 2014; Paglione and Greene 2010; Johnston 2010; Huang and Hoffman 2017). Their rich phase diagram, the quasi-2D crystal structure and the unconventional behavior of the superconducting gaps, is strongly reminiscent of the high-T_c cuprates. Thus, I will use FeSC as a representative example to illustrate the challenges faced by ab initio methods in unconventional superconductors, both in the normal and in the superconducting state (Basov and Chubukov 2011).

Figure 8 shows the main features, common to most compounds:

- (a)–(b) A common structural motif, consisting of square planes of iron atoms, and X_4 tetrahedra; X is either a pnictogen (As,P) or a chalchogen (Se,Te).
- (c) A quasi-two-dimensional Fermi surface, comprising two hole and two electron sheets, strongly nested with one other.
- (d) A phase diagram, in which superconductivity sets in after suppressing a spin density wave (SDW) ordered state, by means of doping or pressure. The most common SDW pattern is a stripe one, in which the Fe spins are aligned ferromagnetically along one of the edges of the Fe squares and antiferromagnetically along the other. The SDW transition is usually preceded by a structural-nematic transition (Fernandes et al. 2014).
Fig. 8 Common features of Fe-based superconductors (FeSC): FeX layers, seen from the top (**a**) and side (**b**); Fe and X atoms are red and green, respectively. (**c**) Two-dimensional Fermi surface of LaOFeAs, from Andersen and Boeri (2011), with the hole and electron pockets centered at $\bar{X}$, $\bar{Y}$, and $\bar{M}$, respectively. Here a third hole pocket at $\bar{\Gamma}$ is also present. (**d**) Phase diagram, showing the transition from SDW to superconducting (SC) state; x is an external tuning parameter (doping, pressure)

FeSC can be grouped in different *families*, depending on the nature of the FeX layers and of the intercalating blocks; the most common are 11 Fe chalcogenides (FeS, FeSe, FeTe), 111 alkali-metal pnictides (LiFeAs, LiFeP, NaFeAs, NaFeP, etc.), 122 pnictides (Ba/KFe$_2$As$_2$, BaFe$_2$P$_2$, CaFeAs$_2$, EuFe$_2$As$_2$, etc.), 1111 pnictides (LaOFeAs, LaOFeP, etc.), and 122 chalcogenides (KFe$_2$Se$_2$, etc.). In most of these cases, superconductivity appears around a Fe d^6 configuration, but it survives up to high hole or electron dopings in 122 K pnictides and chalcogenides.

In most FeSC, the superconducting gap exhibits a feature which is distinctive of unconventional superconductors, i.e., changes sign over the Fermi surface. According to Eq. 1, this is only possible if, unlike *ep* interaction, the pairing interaction $V_{\mathbf{k},\mathbf{k}'}$ is repulsive over some regions of reciprocal space.

In contrast to the cuprates, where the Fermi surface topology favors d-wave superconductivity, the gap of most FeSC exhibits a characteristic $s^{\pm}$ symmetry, with opposite signs on the hole and electron sheets of the Fermi surface. However, substantial variations in the symmetry and magnitude of the superconducting gap are observed among and within different FeSC families, which can be related to changes in the general shape and orbital distribution of Fermi surface sheets (Hirschfeld et al. 2011).

The general topology of the Fermi surface is well described by DFT calculations; however, quasiparticle bands measured by ARPES exhibit renormalizations and shifts, which hint to strong local correlation effects beyond DFT, which require the use of specialized methods, such as DFT+DMFT (Kotliar et al. 2006).

Figure 9a, from Yin et al. (2011), shows the Fermi surfaces calculated within DFT (upper panel) and DFT+DMFT (lower panel) for representative FeSC: LaFePO, $BaFe_2As_2$, LiFeAs, and KFe_2As_2. The first three are d^6 pnictides, with the typical hole-electron topology shown in Fig. 8, eventually deformed due to interlayer hopping (Andersen and Boeri 2011). In KFe_2As_2, where the electron count is $d^{5.5}$, the hole pocket is expanded, and the electron pocket has lost its typical circular shape.

The figure shows that, in most cases, the inclusion of electronic correlation modifies the Fermi surface quantitatively, but not qualitatively, with respect to the DFT prediction. The renormalization of the quasiparticle band dispersion depends on their orbital character, being stronger for Fe t_2 (xz, yz, xy) than for e ($x^2 - y^2$, $3z^2 - 1$) orbitals, and on the nature of the X atom; correlation effects are in fact weakest for $X=P$ and increase moving to As,S,Se and Te (de' Medici et al. 2014; Yin et al. 2011). Orbital-selective mass renormalizations and poor Fermi liquid behavior are characteristic of a special correlation regime, known as *Hund's metal* regime, which has been extensively studied by several authors (Werner et al. 2008; Haule and Kotliar 2009; de' Medici et al. 2011; Yin et al. 2011); excellent reviews can be found in Georges et al. (2013) and de' Medici (2017).

A very important consequence of the interplay between metallicity, strong correlations, and multiband character in FeSC is their anomalous magnetic behavior. Early DFT studies pointed out that magnetism cannot be consistently described within neither the itinerant (Slater) nor the localized (Heisenberg) scenario (Mazin et al. 2008b; Mazin and Johannes 2008). A regime which is intermediate between the two cannot be treated in DFT, which is a mean-field theory, but requires methods able to capture the *dynamics* of the magnetic moments at different frequency scales (Yin et al. 2011; Aichhorn et al. 2011; Hansmann et al. 2010; Toschi et al. 2012; Skornyakov et al. 2011; Schickling et al. 2012).

Panel (c) shows a DFT+DMFT calculation of the magnetically ordered state for a variety of FeSC (Yin et al. 2011). Circles (and stars) indicate the theoretical (experimental) value of the ordered SDW magnetic moment, which shows large variations among different compounds. Chalcogenides exhibit large ordered moments, while 111 and 1111 pnictides and phosphides exhibit smaller values. (Gray) Squares indicate the value of the local magnetic moment, which oscillates over a much smaller range of values around 2.5 μ_B. In the SDW phase, the two moments coexist; when the itinerant moment is suppressed with doping or pressure, only the local moment survives, meaning that in the nonmagnetic regions of the phase diagram, FeSC is in a paramagnetic state.

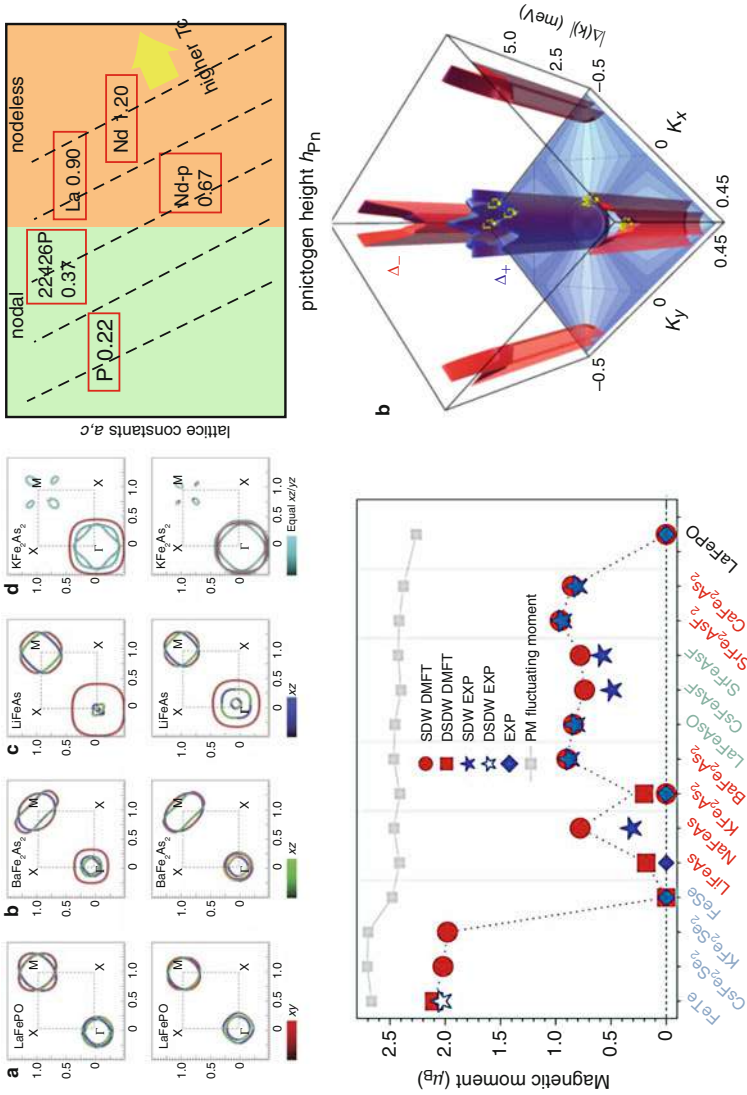
The superconducting state that emerges from this complicated normal state is clearly unconventional. According to linear response calculations, *ep* coupling plays a marginal role in the superconducting pairing, since the values of the calculated coupling constant λ in all FeSC are extremely small, even including


Fig. 9 Normal and superconducting-state properties of FeSC, predicted by DFT+many-body methods. (**a**) Renormalization of the Fermi surfaces and (**b**) variation of the ordered and local magnetic moment across different families of FeSC, predicted by in DFT+DMFT (Figures reprinted with permission from Nature publishing group, Y. Yin et al., Nat. Phys. 7, 294 (2011), Copyright Nature (2011)); (**c**) superconducting trends in 1111 pnictides predicted by DFT+RPA (Figures reprinted with permission from K. Kuroki et al., Phys. Rev. B (2009), Copyright American Physical Society (2009)); (**d**) superconducting gap of FeSe predicted by SCDFT (Figure reprinted with permission from F. Essenberger et al., Phys. Rev. magnetoelastic effects[1] (Boeri et al. 2008, 2010; Subedi et al. 2008). The strongest candidate as superconducting mediator are spin fluctuations, as suggested by the unconventional symmetry of the superconducting gap and the proximity of SDW and superconductivity in the phase diagram (Chubukov et al. 2008; Kuroki et al. 2008; Mazin et al. 2008a). As discussed in Sect. 3.2, there is currently no first-principles theory of spin fluctuations with an accuracy comparable to that for *ep* interaction. Most studies of superconductivity in FeSC have therefore adopted a *hybrid* approach, in which the electronic structure in the vicinity of the Fermi level is downfolded or projected to an effective analytical tight-binding model (Graser et al. 2009; Kuroki et al. 2009; Miyake et al. 2010; Andersen and Boeri 2011), and electron-electron interactions leading to spin and charge fluctuations are included at a second stage with many-body techniques. The most common are the random phase approximation (RPA), fluctuation exchange (FLEX), and functional renormalization group (FRG) (Chubukov et al. 2008; Thomale et al. 2009; Hirschfeld et al. 2011; Platt et al. 2012). Although not quantitatively predictive, these *weak-coupling* approaches have provided a detailed understanding of the superconducting gap symmetry, competition of superconductivity with other ordered phases, and occurrence of nematic order and traced their common origin to multi-orbital physics (Yi et al. 2017). Figure 9c, from Kuroki et al. (2009), shows that the variations in T_c across different 1111 pnictides can be reproduced within RPA and derive from changes in orbital composition of the Fermi surface.

A first, very elegant, fully first-principles study of superconductivity in FeSC was carried out by the Gross group, who applied their recently derived ab initio theory for spin fluctuations to FeSe – see Sect. 3.2 for details. Figure 9d shows the superconducting gap calculated in SCDFT, which exhibits an $s^{\pm}$ symmetry, consistently with previous *hybrid* studies. It is important to remark, however, that the gap in Fig. 9d was calculated treating the contributions of all pairing channels (phonons, spin fluctuations, charge fluctuations) on equal footing and without any intermediate mapping on an effective many-body model. However, even this calculation cannot be considered fully ab initio as, in order to obtain a physically meaningful value for the superconducting gap and T_c, the authors had to introduce an artificial *scaling* factor in the spin-fluctuation propagator, which would otherwise diverge (Essenberger et al. 2014; Ortenzi et al. 2012).

The divergence is associated to the specific choice of TDDFT exchange functional (adiabatic local density approximation, ALDA) made by the authors which, being the time-dependent equivalent to the standard local density approximation (LDA), overestimates the tendency to magnetism in FeSC (Mazin et al. 2008b). Proposals to cure this critical divergence in a nonempirical fashion are underway (Sharma et al. 2018) and could lead to a very important step forward in the

---

[1](This result is generally accepted, although DFT+DMFT studies evidenced a strong renormalization of some phonon modes, due to strong electronic correlations (Mandal et al. 2014) *ep* coupling has also been suggested to play a primary role in the enhancement of the superconducting T_c in FeSe monolayers grown on $SrTiO_3$ (Huang and Hoffman 2017), although in this case, the modes involved in the pairing belong to the substrate.)

understanding of unconventional superconductors. However, it is also important to stress that, even if divergence issues are solved, T_c computed within DFT may still be inaccurate, because it neglects renormalization effects of quasiparticle energies and interaction vertices due to strong local electronic correlations, which, in some FeSC, may be sizable (Yin et al. 2013; de' Medici et al. 2017).

5   Outlook and Perspectives

The results described in this chapter show that in the last 20 years, there has been a substantial advancement in the understanding of superconductors, driven by the progress of ab initio electronic structure methods. The SH_3 discovery has demonstrated that room-temperature superconductivity can be attained, at least at extreme pressures (Drozdov et al. 2015a), and that ab initio methods can be very effectively employed to predict new superconductors. The next challenge in the field is clearly to devise practical strategies to replicate the same result at ambient conditions, exploiting novel synthesis and doping techniques. Obviously, the development of ab initio methods that can treat these regimes is a crucial step in this direction.

   The aim of this final section is to give a short overview of promising strategies to high-T_c superconductivity, exemplified in Fig. 10a–e.

(a) **Design by Analogy:** This is one of the most common routes to search for new superconductors, i.e., achieve high-T_c designing materials with a similar geometry, chemistry, electronic structure, etc. as the best existing superconductors. This route has lead to several predictions of high-T_c superconductivity in layered borides and carbides after the discovery of MgB_2, as well as hole-doped LiBC, and, more recently, doped graphane (Satta et al. 2001; Rosner et al. 2002; Savini et al. 2010). The main drawback of many of these early works is that many of these hypothetical compounds are thermodynamically unstable. Nowadays, studies of the thermodynamic stability of compounds are well established but were very rare at the time of the MgB_2 discovery. One of the first studies to take this aspect into account is the prediction of superconductivity in LiB, (Kolmogorov and Curtarolo 2006) shown in Fig. 10a.

(b) **Chemical Doping of Molecular Crystals:** Similar to covalent solids, molecular ones exhibit stiff bonds, and hence their electronic states can couple strongly to lattice vibrations, which is a prerequisite for high-T_c conventional superconductivity. However, similar to covalent solids, molecular ones are usually insulating at ambient pressures. Making them superconducting requires either very high pressures or chemical doping, which is often hard to control experimentally and to model ab initio.

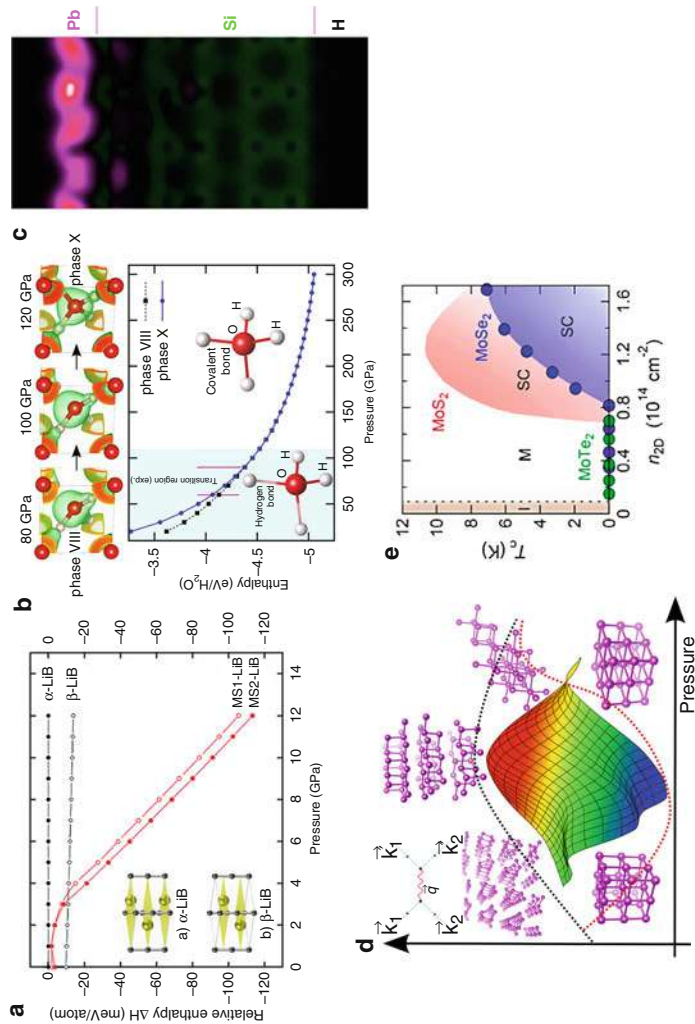
   One of the most complete studies of the effect of doping on superconductivity in molecular crystals is the study of superconductivity in doped ice, by Flores-Livas et al. (2017) Here, analyzing the effect of different dopants using supercells, the authors found that nitrogen acts as an effective dopant


Fig. 10 Selected literature examples of possible strategies to room-temperature superconductivity at ambient pressures: (**a**) first-principles prediction of α and β-LiB (Figure reprinted with permission from A. Kolmogorov and S. Curtarolo, Phys. Rev. B 74, 224507 (2006), Copyright by the American Physical Society (2006)) (*Design by Analogy*); (**b**) superconductivity in doped ices (Flores-Livas et al. 2017) (*Chemical Doping of molecular crystals*); (**c**) charge-density profile of superconducting Pb@Si(111) surface (Linscheid et al. 2015a) (*Atomic-scale design and Dimensionality*); (**d**) high-pressure superconducting phase diagram of phosphorus (Figure reprinted with permission from Flores Livas et al., Phys. Rev. Mat. 1 024802 (2017), Copyright by the American Physical Society (2017)); (*Quenching of High-pressure metastable phases*); (**e**) T$_c$ vs field effect and chemical doping in monolayer MoS$_2$ (W. Shi et al. Sci. Rep. 5, 12534 (2015)) (*Doping by field effect*)

at the oxygen site, leading to a T_c of 60 K. The study nicely evidences the crucial difference between actual doping, modeled with supercells, and more approximate approaches, as rigid-band or jellium doping.

(c) **Atomic-Scale Design and Dimensionality:** Another recent trend in condensed matter research opened by the development of novel techniques, such as molecular beam epitaxy (MBE), or exfoliation (Novoselov et al. 2004), is the design of materials at the atomic scale, through heterostructuring, controlled deposition, strain engineering, etc. This permits to tune superconductivity in existing materials; induce it in semiconductors and semimetals through doping, like Li-decorated graphene and phosphorene; or create completely artificial superconductors, depositing superconducting elements on semiconductor surfaces, as in Fig. 10c, which shows a SCDFT calculation for Pb on the 111 surface (Zhang et al. 2010; Linschied et al. 2015a). For this type of problems, real-space approaches may be more appropriate than reciprocal-space ones (Linscheid et al. 2015b).

(d) **Quenching of High-Pressure Metastable Phases** down to ambient pressure is another very attractive route to stabilize unusual bonding environments, enabled by recent developments in high-pressure techniques. In fact, controlled heating and cooling cycles permit to selectively stabilize different metastable phases, realizing pressure hysteresis cycles. Figure 10d, from Flores-Livas et al. (2017), shows the crystal structures of the different phases that form the complicated superconducting phase diagram of elemental phosphorus. In this element, a high-T_c branch, clearly distinct from the low-T_c ground-state one, can be accessed by laser heating and is associated with metastable black phosphorus; similar branchings between high-T_c and low-T_c phases have been predicted at higher pressures.

(e) Doping via **Field Effect** is an attractive route to tune the properties of materials continuously, without impurities and distortions associated to chemical doping. Modern techniques based on liquid electrolytes permit to achieve doping levels as high as $10^{15} carriers/cm^3$, corresponding to tenths of electrons, around three orders of magnitude larger than standard solid-state techniques. The first successful applications have been to cuprates, ZrNiCl, and 2D materials – Fig. 10e. Rigorous modeling of field-effect devices has been derived in Sohier et al. (2015), Sohier et al. (2017).

Although not an experimental technique, methods for machine learning, which can be used to prescreen ab initio proposals, will most likely play a bigger and bigger role in the design and discovery of new materials (Curtarolo et al. 2013).

Note that all of the specific examples discussed above are based on the assumption of *conventional* (phonon-mediated) pairing. The same techniques have been, and can be, applied also to *unconventional* superconductors, which remain the likeliest candidates for high-T_c superconductivity. However, without a quantitative theory of the superconducting pairing, it is at the moment impossible to formulate reliable predictions of T_c and other superconducting properties. A progress in this direction is therefore an essential prerequisite to any meaningful computational search.

Abstract

Like many structural materials, titanium alloys have complex multiscale hierarchical structures that enabled a variety of mechanical properties. The elastic modulus, strength, ductility, fatigue, and creep behavior may depend strongly on the multiscale structures, from the bonding between atoms, to microstructures up to grain level, and their texture. However, their interdependences are usually not straightforward and sometimes not easy to reveal solely by experiments. Multiscale modeling and simulation in the last two decades have promoted the understanding of various aspects of titanium alloys. The progresses range from electronic structural calculation of alloying effects on modulus, strength, ductility, creep and oxidation, etc., to the ordering behavior in intermetallic phases and interaction between alloying elements and dislocation or twinning; atomic simulations of dislocation interaction and point defect formation, deformation and fracture mechanisms of polycrystalline titanium with grain boundaries of different nature under various stress; phase transformation and microstructure evolution under different conditions, and the effects of internal and external factors on the microstructure evolution and mechanical behavior of titanium alloys; finally FEM type simulations to optimize the thermo-mechanical processing, such as rolling and canned extrusion, etc. In spite of the increasing capabilities of multiscale materials modeling and simulation, many challenges still exist, and further seamless interdisciplinary collaborations among materials scientists, system designers, and industry production sections are needed to solve the grand challenge of the overall optimization of the titanium alloys for specific applications.

1   Introduction

Titanium alloys are widely used in aero-space and chemical industry mainly owing to their high strength, low density and good corrosion resistance, and applied recently as human implant, due to their good biological and mechanical compatibility with human bones. Pure titanium melts at 1670 °C, and has a solid-state phase transformation at 882 °C, above which it stabilizes as β phase with bcc structure, while below as α phase with hcp structure. Adding alloying elements can alter this transformation temperature, and cause other phases with different crystal structures to form. Very different microstructures can be obtained by changing alloy composition, heat treatment, and thermomechanical treatment schemes (Leyens and Peters 2003; Lütjering and Williams 2007).

Traditionally, titanium alloys are classified into three groups, namely, α, β and α + β alloys, depending on the main phases present in the alloys (Lütjering and Williams 2007); later, intermetallic alloys were introduced. Each type of alloys has their field of application according to their specific properties. For example, pure titanium and α alloys with minor alloying are usually used as corrosion resistant alloy, for chemical reaction chamber, pipe, valve and pump, etc., while β alloys, containing β stabilizing elements, are used in situation such as critical structural

components in aircraft where high strength and toughness are required or as bio-implant materials requiring low elastic modulus to improve the stress transfer to bone (Zhao et al. 2006), while some near α alloys can work continuously up to 600 °C and can be used in jet engines (Banerjee and Williams 2013).

Above 600 °C, conventional disordered alloys cannot work for long anymore, and alloys based on ordered intermetallic compound such as TiAl, Ti_3Al, or Ti_2AlNb may be used (Leyens and Peters 2003). By adding large amount of Al, the compound formed becomes even lighter than conventional titanium alloy, in addition to increasing their working temperature, and is very attractive for improving the efficiency of jet engine, especially the γ-TiAl-based alloy (density: ~4 g/cm^3), allowing for making components rotating at higher speed in jet engine, and even working up to 700 °C or higher (Appel et al. 2011). However, these ordered phases are usually brittle and difficult to fabricate. Various studies have been carried out to improve their different properties in the last 20 years (Kim 1998; Appel et al. 2011; Clemens and Mayer 2013; Yang 2015a).

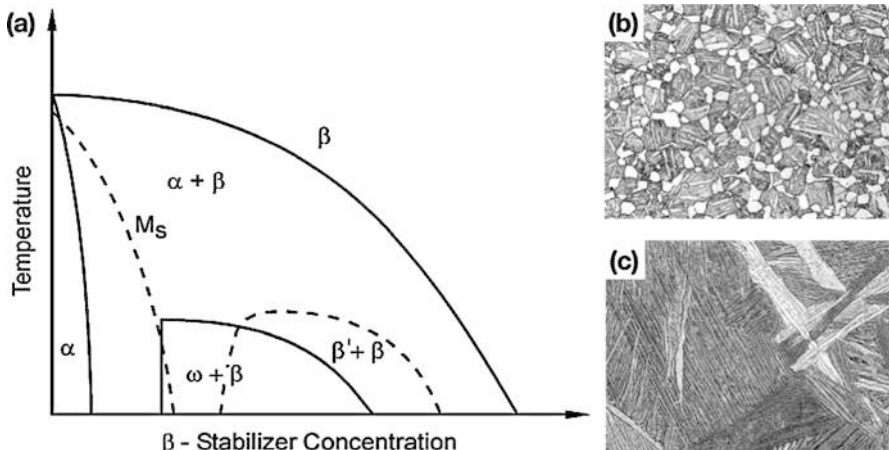
Similar to steels and many other structural materials, the properties of titanium alloys depend strongly on their multiscale microstructures. These hierarchical structures mainly result from the rich phase transformations in this system with various stable and metastable phases (Fig. 1a) during different thermo-mechanical processing. Multielement additions may cause more phases or even amorphous phase to form, making available very large room for microstructure and properties adjustment, especially for components obtained through thermo-mechanical processing route (Banerjee and Williams 2013). At the same time, the fine details of the hierarchical microstructures formed by the multistep deformation/transformation


Fig. 1 (**a**) Schematic pseudo-binary phase diagram showing some metastable phases for alloys containing β stabilizers (Lütjering and Williams 2007). (**b**) and (**c**) Typical microstructure of titanium alloys: bimodal (TIMETAL 834) and lamellar (TIMETAL 1100), respectively, formed from different processing routes (Leyens and Peters 2003)

depend sensitively on the composition and hot working condition (Fig. 1b, c) (Leyens and Peters 2003) and are not easily characterized and related to the processing parameters in each step of high temperature deformation and heat treatment. Due to the lack of scientific understanding of each subprocess, a very good control over all the properties cannot be done rationally and can only be realized largely according to experience of engineers.

For ordered intermetallic compounds, it was shown in very early days that some high temperature properties are superior compared to conventional alloys, and the strength of certain compounds increases with temperature, hence suggesting higher service temperature. Some aluminides like Ni_3Al and TiAl have high strength and stiffness retention at high temperature and are lighter compared to their disordered counterpart, therefore ideal for high temperature rotating components in jet engines. For this reason, intensive investigations had been carried out; however, lack of room temperature ductility and low toughness, a general feature of intermetallics, made it difficult for system designers to accept them. After many years of work, the intermetallics community reached the conclusion in 1960 that this type of materials is not suitable for structural applications (Westbrook 1960). In 1980s, it was found that the poor room temperature ductility of Ni_3Al is not its intrinsic property, and grain boundary detachment due to hydrogen from water in moisture is the root cause of fracture. This discovery led to a period of concentrated research in intermetallic compounds. After several decades of effort, the TiAl intermetallic alloy has been used successfully in jet engine, e.g., on GEnx as low pressure turbine (LPT) blades (Kim and Kim 2018), each engine reducing ∼200 pounds. The successful insertion signified only the first step in overcoming many challenges facing the application of intermetallic alloys, and integrated study combining multiscale simulations and advanced characterization is needed for the rational design and optimization of new alloys. In the following, examples of the progress of computational studies will be given, and the prospective and challenges discussed.

2   Recent Approaches for Computational Design of Titanium-Based Alloys

Despite the great achievements in R&D of titanium alloys in the last 60 years, there is no straight forward way to design new alloys, and it takes 20 years or more to develop a new alloy for jet engine application. With the rapid progress of the computing technology in the last 30 years, multiscale modeling and simulation have been carried out extensively for many alloy systems. For alloy for specific application, identifying the bottleneck in each case and finding ways to overcome it utilizing multiscale simulation is an effective strategy to lower cost and accelerate development process.

In searching new alloys, first principles calculation can be a critical step in screening elements for property improvements, while for alloy optimization, analyzing limiting properties and process bottlenecks, identifying influencing factors, and utilizing multiscale simulations to reveal hidden mechanisms is crucial.

For conventional titanium alloys, how the multiscale microstructures arise during the long history of component fabrication and what their contribution is to each of the properties are not clear, while for intermetallic alloys such as TiAl, their poor deformability and long-term stability during high temperature service need further understanding. These problems need computational studies from electronic to macroscale, from fundamental defect properties, e.g., point defect, dislocation and twinning, to their contribution to comprehensive mechanical properties, e.g., strength, fatigue and creep. Phase stability, atomic ordering, point defect interaction, and various alloying effects are calculated on the electronic scale (Xu et al. 1997a; Song et al. 1999; Hu et al. 2001, 2003; Li et al. 2011), using simulation method mostly based on density functional theory, such as CASTEP (Clark et al. 2005), VASP (Hafner 2008) with plane wave basis, SIESTA (Soler et al. 2002), or DVM (Yang et al. 1993) using localized atomic basis. The recent high throughput computation following the emergence of ICME and MGI may greatly accelerate the materials simulation and analysis and promote alloying element selection (Curtarolo et al. 2012; Christodoulou 2013; Kubel 2013). The deformation mechanisms including dislocation and twinning properties have been studied with atomistic simulations (Wooding et al. 1995; Xu et al. 2008a; Girshick et al. 1998; Hu et al. 2001, 2004, 2014; Li et al. 2011; Ghazisaeidi and Trinkle 2012, 2014; Wang et al. 2014b; Clouet et al. 2015; He et al. 2018), e.g., molecular dynamics (MD). Phase transformation and microstructure evolution have been studied with mesoscale simulations, such as phase field (PF) and cellular automata (CA), often with help from atomistic simulation for input (Chen 2002, 2014; Trinkle et al. 2003; Hennig et al. 2005, 2008; Teng et al. 2012; Shi et al. 2014, 2015). Thermo-mechanical processing involving hot deformation and transformation has been studied with macroscale simulations (Manonukul and Dunne 2004; Dunne et al. 2007a, b, c, 2012; Dunne and Rugg 2008; Anahid and Ghosh 2013; Ghosh and Anahid 2013b; Ghosh and Chakraborty 2013a), e.g., finite element method (FEM) and crystal-plasticity finite element method (CPFEM). Thermo-dynamic phase diagram and kinetic calculation also play important roles in different stages of development, using ThermoCalc, Pandat, etc. It is worth noting that owing to the complex microstructure of titanium-based alloys, their behaviors usually depend on subprocesses on several different scales; hence, these results should always be incorporated with results on other scales for correct understanding. Nevertheless, it has been observed that multiscale modeling plays increasingly important roles in the development of titanium-based alloys, and these will be exemplified in the following (Hennig et al. 2005; Raabe et al. 2007; Ghosh and Anahid 2013b; Clouet et al. 2015; Yu et al. 2015; Appel et al. 2016).

3   First Principles Prediction of Alloying Effects for Composition Design

Most properties of materials have their electronic origin, some with direct relevance, e.g., stability and elastic modulus of phases are related to energy and its second

derivative, respectively, so that they are predictable by electronic structure calculation, while others may depend on structures at multiple scales, such as strength, toughness, ductility, and fatigue resistance, with indirect link via some elementary process, such as dislocation, twinning, or grain boundary sliding. In such case, multiscale simulations are needed for thorough understanding.

3.1   Electronic Structure Calculation for Alloying Selection

Before large-scale calculation of electronic structure was available, predicting the formation of phases was difficult for multielement alloys. Certain experience-based model was developed, e.g., Mo- or Al-equivalent was calculated according to the concentration of alloying additions and the resulting change rate of the phase transformation temperature, and criteria were established for phase stability estimation. However, sometimes the summation rule does not work well for multicomponent alloys. One early example considering electronic factor was to control strictly the precipitation of Ti_3X phase in titanium alloys (to achieve balance between long-term microstructure stability and high temperature strength) using the electron concentration criterion but with experimentally determined valance electron number (Li et al. 1984).

For titanium alloys working at high temperature as rotating components in jet engines, once the balance of microstructure stability and hot strength has been achieved, high temperature creep during long-term service may arise as a major problem. It was recognized that high temperature diffusion may be the main cause of creep under relatively low stress, and the interaction between vacancies and alloying atoms is related to diffusion. However, this interaction is not measurable experimentally. First-principles calculations have been carried out to investigate the interactions between vacancies and alloying elements (Hu et al. 2001) (Fig. 2). Analysis shows alloying elements attractive to vacancy may reduce the diffusion rate, while those repulsive or noninteractive with vacancies, such as Fe, Co, or Ni, diffuse much faster and need to be restricted. The calculated interaction energy variation corresponds well with diffusion rate and creep measurements. This can be used as a guideline for alloying element selection for creep resistance design. These efforts led to the successful design of Ti55, a titanium alloy for applications upto 550 °C (Guan et al. 1998), and Ti60 at 600 °C and beyond (Wang et al. 2014d).

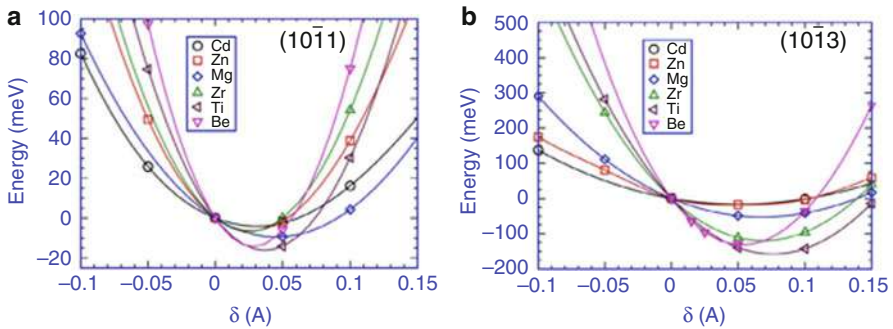
Oxidation may become a major concern as temperature increases further. Since Ti is very reactive, once a TiO_2 layer is formed, it is very stable at low temperature either in air or in water, even seawater. At high temperature however, the TiO_2 layer becomes no longer protective, a layer of Al_2O_3 may provide better protection to the titanium alloy underneath. The oxidation resistance of these oxides depends on both defect structure in the oxidation layer and the bonding of the layer with matrix, and a detailed understanding needs electronic calculation of the bonding and defect properties (Wang et al. 2015; ▶ Chap. 4, "Titania and Its Outstanding Properties: Insights from First Principles Calculations").
Fig. 2 Interaction energies between solutes and vacancy in α-Ti, where positive interaction means repulsive to vacancy, and negative attractive (Hu et al. 2001)


Fig. 3 Variation in excess energy of the simulation cell as a function of δ for six metals: (**a**) (10$\bar{1}$1) twin boundary; (**b**) (10$\bar{1}$3) twin boundary (Kumar et al. 2015)

Early exploration of electronic scale calculation has been utilized in other titanium alloys, such as for anticorrosion design with calculated bond order and energy level of d electrons for alloying elements selection (Morishita et al. 1991). First-principles calculation has also been carried out to predict the alloying effects on elastic modulus, which has promoted the design of low modulus titanium alloys for bio-implants and other applications (Song et al. 1999; Hao et al. 2007). Twin-associated boundaries were systematically investigated in a series of hexagonal metals including Ti, with energy and solubility calculated for different types of interfaces under different stress (Fig. 3) (Kumar et al. 2015). Recent high-throughput computation carried out to investigate the alloying effects on the energy trend of stacking fault of various types in Ti system with a view of understanding the strengthening effect in some engineering alloys (Wang et al. 2018). Apart from

the major elements, Al, V, Nb, Zr, Mo, Sn, etc., which are mostly substitutional in lattice, some interstitial elements, e.g., O, C, N or B, are either alloyed or exist as impurities. It was found that despite their limited concentration, some impurities may have stronger effect than the major elements, such as higher hardening rate or weakening effect, but the reason remains unclear. The strong hardening effects have been clarified recently by combination of advanced characterization and first-principles calculation of the interaction between interstitial atoms O and dislocations (Yu et al. 2015). It can be expected that deeper understanding will be achieved via close collaboration between first-principles calculation and experiments, for other elements as well.

3.2   The Ordering Behavior in Intermetallic Alloys

Above 600 °C, conventional disordered titanium alloys are not capable of long time service, and ordered intermetallic phase such as α_2 and γ phases can be introduced either as strengthening phase or as matrix to increase the working temperature further to 650 °C or even 900 °C. The ordering status in intermetallics has important effects on many properties like electric, magnetic, and mechanical properties via different mechanisms, such as affecting dislocation dissociation or twinning tendency. For the temperature dependence of ordering, a self-consistent scheme based on first-principles calculation and statistical mechanics was proposed to evaluate the point defect concentration and order-disorder transformation temperature in binary intermetallics (Hu et al. 2004). The dependence of defect concentration and ordering status of multielement compounds needs both new model and accurate defect energy.

Although intermetallic compounds have many advantages at high temperature, most of them are very brittle, partly due to the partially covalent bonding between atoms. Various alloying elements were added in order to improve the room temperature ductility and other properties, but a detailed understanding relies on electronic structure calculations that require information of atomic position. The site occupation of alloying elements in ordered intermetallic compounds TiNi, TiAl, and Ti_3Al, etc., was studied on the basis of the bond order or binding energy of alloying elements with matrix (Xu et al. 1997a, b). A new method was proposed to predict the site occupation behavior of alloying elements in ordered phases, where two straight lines were used in the diagram to separate the alloying behavior into three regions (Fig. 4). For elements lying between the two lines, the site occupation is composition dependent and therefore may be adjusted. This dependence has been observed experimentally by ALCHEMI measurement (Tadaki et al. 1995; Hao et al. 1999).

Due to different ordering tendencies, the elements may have "site competition" between them, and the lattice may have a "stepped ordering" behavior, as more alloying elements were introduced (Xu et al. 1997a, b). These new findings can be utilized in fine-tuning the mechanical or other properties of intermetallic alloys.
Fig. 4 Site occupation diagram in Ti$_3$Al. The elements above and below the lines occupy Al and Ti sites, respectively; the occupancy of those in between the lines depends on alloy composition (Xu et al. 1997a)

4   Atomistic Simulation of Deformation Mechanisms

Atomic-scale simulation has become a powerful tool to study atomic processes between electronic and mesoscale simulations. In metals and alloys, point defect, dislocation, twinning, grain and phase boundary behavior are investigated with atomic-scale simulations in order to understand corresponding mechanical properties. In titanium alloys, despite their strong anisotropy and complex microstructure, atomic-scale simulations have been extensively used in modeling various defects, to reveal the detailed deformation and fracture mechanisms under different conditions. For titanium alloys in jet engines, fatigue resistance is critical and is the most difficult to understand, especially for dwell fatigue, which often results in large scattering of fatigue life, while for TiAl alloys, its brittleness and long-term microstructure stability are both important. How defects accumulate and fatigue damage proceeds in materials finally causing crack and fracture is a challenging problem, which could not be solved solely by experimental observation, partly because crack nucleation is often subsurface, and the crack embryo is very small. Various deformation mechanisms, formation and interaction among defects, and transformation mechanisms had been revealed with atomic resolution.

4.1   Dislocation Structure and Dipole Transformation in Titanium and TiAl

Dislocations are the most important plastic deformation carrier in metals and alloys. To model single dislocations, the key is the reproduction of correct core structures. This requires a good description of the interactions between atoms, i.e., interatomic potential, and a proper simulation box either large enough or with carefully designed size and shape to minimize the influence of image dislocations (Cai et al. 2000). For instance, with modified embedded-atom method (EAM) (Ghazisaeidi and Trinkle 2012) and mean-field EAM (Liu et al. 2014) interatomic potentials, respectively, the core structures of screw dislocations in α-titanium and of edge dislocations in β-titanium are studied. Qualitative agreement is achieved with ab initio calculations on the core configurations (Fig. 5a), whereas detailed atomic structures depend on potential, e.g., the dislocation dissociates on the basal plane according to the stacking fault energy predicted by the potential. With ab initio calculations, dislocation cores in Ti and Zr were modeled and different glide behaviors were observed (Clouet et al. 2015), which explains the locking and easy glide in Ti and Zr, respectively (Fig. 5b).

There has been extensive work on modeling dislocations in titanium aluminides (Simmons et al. 1997; Panova and Farkas 1998; Porizek et al. 2003; Woodward and Rao 2004; Katzarov et al. 2007; Xu et al. 2014). The bond-order potential was employed to study the glide behavior of 1/2[<110] ordinary dislocations. The MD simulation using an EAM potential found the asymmetric core configurations and motion of <011] superdislocations, and the core structure depends sensitively on dislocation characteristics (Xu et al. 2014). Relevant work on multicomponent titanium alloys has been rare. In particular, a 4-element potential was constructed using mean field concept (Liu et al. 2014) and was able to obtain dislocation cores in a β-type titanium alloy, Ti2448 (Hao et al. 2007).

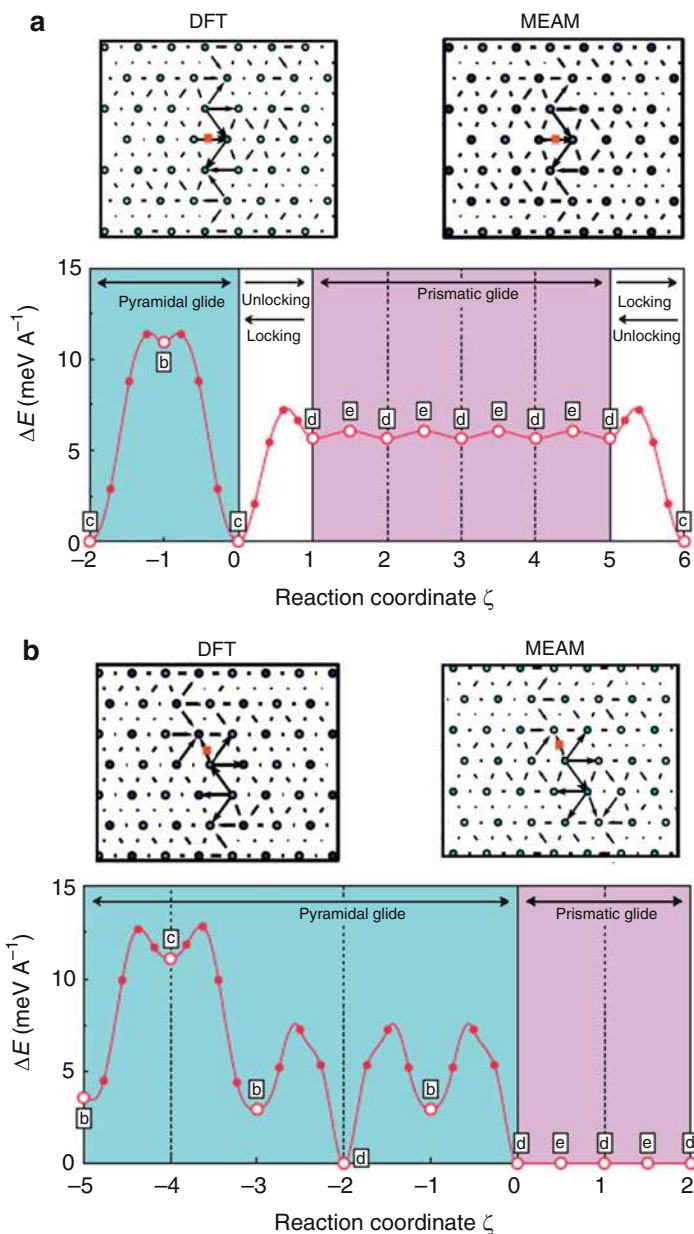
Dislocation interaction of various types such as dipolar or forest interaction is crucial for the understanding of strength and hardening of metals, while dislocation dipole annihilation is the most important processes during fatigue. It was found 40 years ago that dislocation density saturates as fatigue proceeds, leading people to consider that the dipolar dislocation within a certain height disappeared completely after annihilation (Essmann and Mughrabi 1979). Simulations show that dipoles can form through the meeting of parallel dislocations with opposite Burgers vectors or the motion of jogged screw dislocations under single or multiple slip, or even form homogeneously if the lattice was sheared strongly (Veyssiere et al. 2009; Xu et al. 2009). It was also shown that dipoles may weaken the lattice, and the lattice strength decreases as the density of dipoles increases, therefore causing the lattice to crack easily (Gu et al. 2010). The behavior of nonscrew dislocation dipoles in a series of metallic systems has been systematically investigated (Wang et al. 2008a, 2009c, 2013a, 2014b). In titanium (Wang et al. 2014b) and TiAl (Wang et al. 2013a), narrow dipoles were found to transform into individual defects, producing debris depending on dipole height, orientation, and temperature. Reconstructed configurations are formed at low temperature, while vacancy clusters, stacking fault tetrahedra, and


Fig. 5 (**a**) Typical core structures of 1/3[1$\underline{2}$10] screw dislocation in titanium (Ghazisaeidi and Trinkle 2012). (**b**) Different glide energy barriers in Ti (left) and Zr (right) that relate to locking and easy glide, respectively (Clouet et al. 2015)
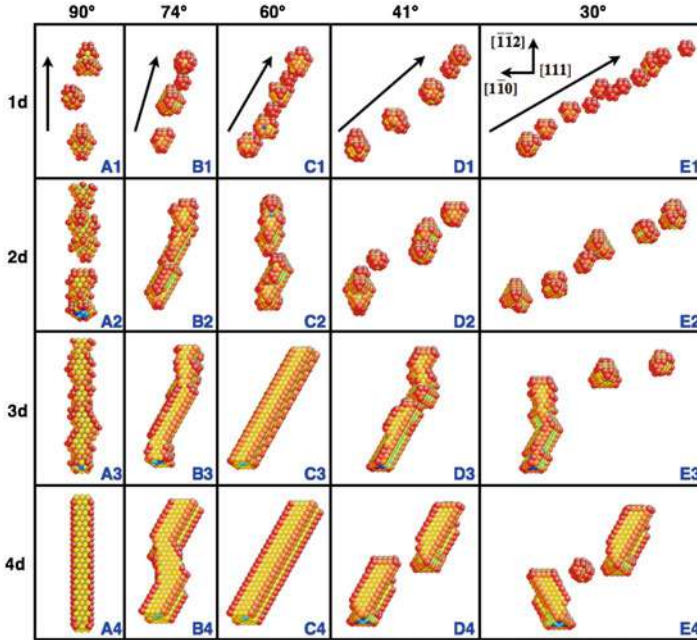

Fig. 6 [111] projection of vacancy dipoles after 1700 K-aging for 1 ns in TiAl, with orientation from 30° to 90° and heights of 1*d* to 4*d*. Initial orientations are indicated with arrows in the first line. (Wang et al. 2013a)

vacancy or interstitial type loops may form at high temperature (Fig. 6). An SFT formation mechanism from deformation was proposed on the basis of atomistic simulation and later observed experimentally (Wang et al. 2011c, b, d, 2013c). Employing saddle-point search methods, activation energies of the atomic processes therein are obtained and the lifetime of the above by-products is estimated, showing the extreme stability of certain clusters and loops on the experimental timescale (He et al. 2018). Such point defects may interact with dislocations hindering their motion and form a basis for work-hardening and crack nucleation during monotonic deformation and fatigue. For defects on the surface, they may have a stronger impact on the deformation and fracture compared with internal ones of similar size. Depending on the defect shape, location, and orientation, they may serve as the nucleation site for dislocation, twinning, or crack (Wu et al. 2016).

4.2   Deformation Twinning in Pure Ti and TiAl

Due to the limited slip systems in α-Ti and TiAl, twinning becomes important to accommodate plastic deformation. Despite the extensive investigations on twinning in Mg and Zr, there have been relatively few modeling investigations on Ti on the
Fig. 7 A new twin growth model in TiAl through a five-step process involving the synchro-shear of two atomic layers by a pesudotwinning shear (Xu et al. 2008a)

atomic scale (Serra and Bacon 1986; Oberson et al. 2011; Wang et al. 2011f, 2013b, 2014c; Li et al. 2012; Ren et al. 2014; Zong et al. 2014). High throughput MD simulations have been carried out for different type of interfaces under various loads, in search for possible new mechanism to increase the deformability of these systems. For TiAl, shear deformation under different pressure was simulated. It was found the pseudo-twinning shear deformation mechanisms are sensitive to the hydrostatic pressure under which shear is imposed. Under hydrostatic tension, true twin can still proceeds in TiAl with $L1_0$ structure even when sheared along pseudo-twining directions, by a new mechanism involving the movement of 5 partials on two nearby slip plane (Fig. 7), while under compression, the same shear produces a pseudo-twin with an $L1_1$ structure (Xu et al. 2008a). First principles calculations show that some elements such as Nb, Ta may promote the $L1_1$ pseudo-twinning during deformation and therefore may shed some light on increasing the ductility of TiAl alloys (Xu et al. 2008b).

It should be noted that the pressure effect is very difficult to examine experimentally, especially during dynamic loading, while MD simulation is especially good for that. In fact, historically it is believed that twin is mainly formed under pressure, because it is often observed in the explosive impacted samples. Our MD simulation in Mo shows that tension prefers twin formation, and the impacted sample may form twin during the tension period, as evidenced by the fact that twins are often observed around the hole formed in laser impacted sample, and more twins were observed often in tension samples at the position that breaks the last (Xu et al. 2004).

4.3 Grain Boundary-Mediated Deformation in Ti

Critical components in aircraft or jet engine are mostly wrought processed with complex microstructure, where dislocation-grain boundary (GB) interaction is crucial in determining their mechanical properties, especially in the case of fatigue
Fig. 8 Yielding behavior for different GB-dislocation interactions under loading in various directions (Wang et al. 2016a)

(Leyens and Peters 2003). Atomic scale information of dislocation-GB interaction not only provides penetrating understanding of plastic behaviors but also helps to establish constitutive models, thus contributing to the elucidation of relevant property dependence. Especially in a series of α-titanium alloys, previous experiments and phenomenological simulations indicated that dislocation-GB interaction has potential, however, unclarified, importance during fatigue (Dunne et al. 2012).

Employing a bicrystal model with soft-hard orientation, the behavior of different grain boundary (GB) interaction with dislocations is systematically investigated (Wang et al. 2012, 2016a). Depending on the GB orientation and the loading direction, yielding initiates through grain boundary cracking, dislocation emission, or grain protrusion (Fig. 8). The residual dislocation weakens the GB and the critical stress is found sensitive to the loading direction. The largest orientation sensitivity occurs when GB plane is parallel to the *c*-axes of both grains. A new plastic deformation mode is identified, which produces grain protrusion from the soft to the hard grain through lattice reorientation, and provides relatively large tensile strain of 8.3% with activation energy of 0.04 eV/atom. Lattice analysis shows that the protruded part has a special twin relation with the matrix grain. High throughput computations are carried out to search for the alloying element, which may benefit this new twinning mechanism (Zhou et al. 2018).

The atomic mechanism revealed through the atomic simulation may shed some light on improving the properties of the titanium-based alloys.

5 Mesoscale Simulation of Microstructure Evolution Under Various Conditions

The mechanical properties of titanium alloys such as strength, stiffness, fatigue and damage tolerance depend largely on their microstructures. Various microstructures can be obtained from heat treatment or thermo-mechanical processing. Accurate prediction and control of microstructure are of great importance for achieving outstanding mechanical properties (Banerjee and Williams 2013). However, the relations among the microstructure, processing, and performance are not clear, even the description of the multiscale hierarchical structure is not simple. On the simulation, alongside the rapid development of computational power in the last 20 years, many mesoscale methods have been developed, such as CA (Ding and Guo 2002; Pourian et al. 2015), Monte Carlo (MC) (Zhang et al. 2012; Tan et al. 2017), phase field (PF) (Chen 2002; Steinbach 2013), CPFEM (Raabe and Roters 2004; Roters et al. 2010) and level set (LS), smoothing modeling (Park et al. 2014) (Vermaak et al. 2014; Xu et al. 2015), and have been successfully utilized to simulate microstructural evolution under different conditions. These models and simulations have been able to characterize microstructure, reveal mechanism of complex microstructural evolution during thermo-mechanical processing, and have promoted microstructure design for certain application and accelerated the optimization of titanium alloys, some of which are exemplified below.

5.1 Microstructure Evolution During Heat-Treatment

Rich microstructure can be obtained in titanium alloys by solid-state transformation during heat-treatment. In order to understand how various microstructures form, the influence of several factors such as interfacial energy, elastic strain energy, chemical driving forces, and the interplay among these factors are analyzed based on phase field and other simulations.

The β to α transformation is the main transformation in titanium alloys most microstructures rely on; however, because the lattice change and diffusion occur jointly, it is not clear how the transformations happen under different conditions. Systematic simulations were carried out in the last decade for understanding and design such transformations. The nucleation of precipitates was found to depend on interfacial energy, elastic strain energy, and chemical driving force. Elastic interaction determined by the lattice parameters of the two phases was identified as the major controlling factor of forming the lath shape during β to α transformation. Figure 9 shows the microstructure formed and phase evolution during the martensitic transformation in Ti alloys, calculated with the newly developed generic phase-field model for displacive-type transformations in polycrystals under different condition (Heo and Chen 2014a).

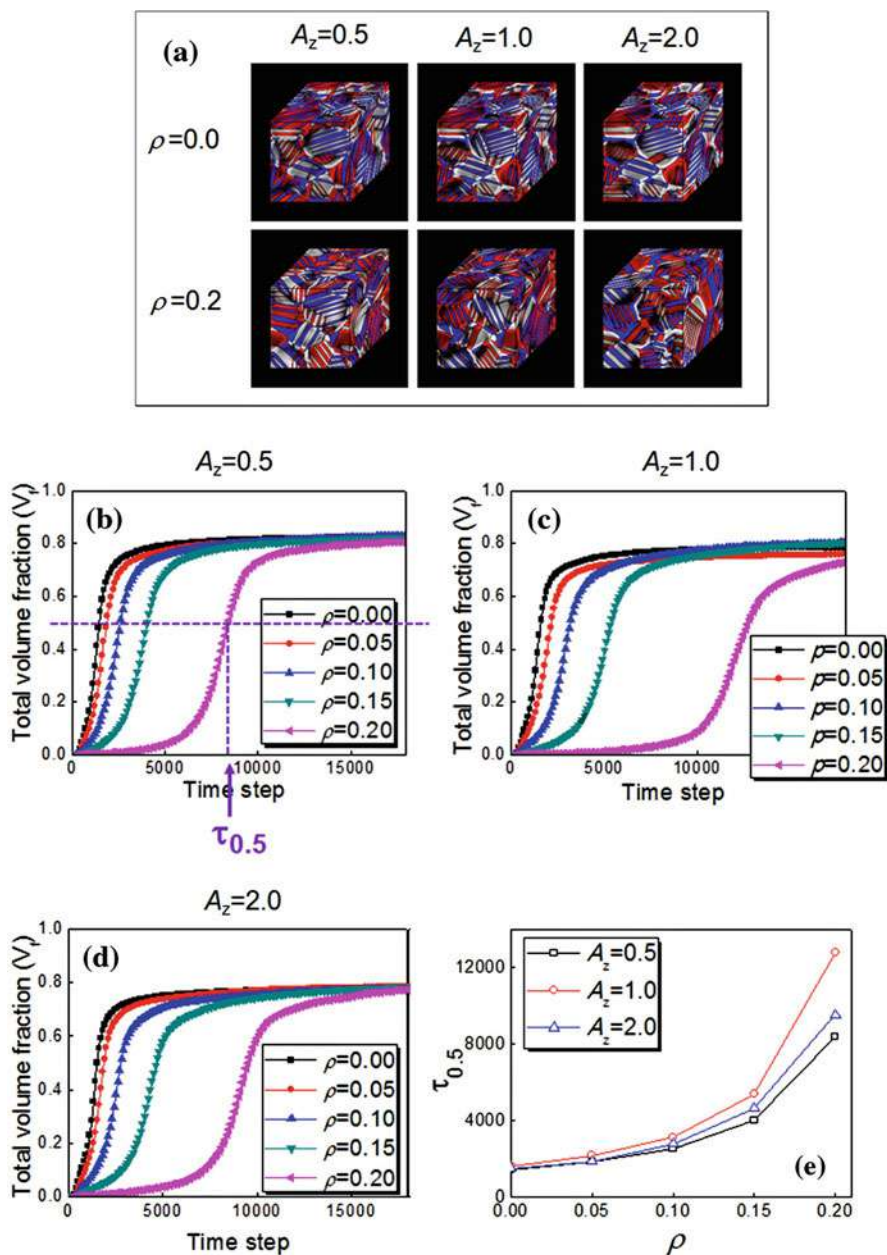
The microstructure of titanium alloys depends not only on the fraction of the two main phases, α and β, but also on the transformation path. α may form directly


Fig. 9 (**a**) Microstructures of Ti alloy for two misfit strain relaxation with different elastic anisotropy. (**b**–**e**) Evolution of β fraction with different q and A_z (Heo and Chen 2014a)

from β phase, or from defect mediated nucleation, or by some intermediate phases, such as α'' martensite and metastable ω phase, or from concentration modulation by prior-ω phase, or even spinodal decomposition. The detailed path chosen and microstructure formation process can only be observed through simulation considering these factors (Ni and Khachaturyan 2009; Nag et al. 2012; Shi et al. 2016) (Heo et al. 2014b).

Thermodynamic data are crucial for microstructure simulation and phase equilibrium estimation. If we could consider kinetics further, unconventional kinetic pathways can be predicted, based on systematic analysis of phase transformation in multicomponent alloy, such as pseudospinodal decomposition involving both displacive transformation and long-range diffusion. Such pathways may lead to different microstructure under different treatment (Ji et al. 2016). Transformation strain not only affects the microstructure and mechanical properties but also has a strong impact on many functional properties such as electric conductivity, magnetic moment, and even multiferrous behavior coupling electro-magnetic and mechanical strain, with special strain stabilized domain structure and certain properties, which may results in components with different functions (Hu et al. 2013).

Another important alloy type of interest is the γ-TiAl-based ordered intermetallics (recently named gammalloy). Extensive studies were carried out to control their microstructure and improve their ductility for aero-space applications (Kim and Kim 2018). Different commercial alloys were developed for various components including turbine blade for jet engine and exhaust valve for car engine. The lamellar structure has good strength and toughness at ambient temperature, but the long-term stability of the lamellar structure during service is a concern for components such as turbine blades. The high density of interface in lamellar structure increased the energy of the structure. During high-temperature service, it may transform to bulk structure with lower energy, and then the properties from the lamellar structure will be degraded and the blade may become extremely brittle and weak. Recently, it is recognized that lamellae with high density of interfaces with lower energy may be a good choice. Twin boundary is such an interface with much lower energy compared with others; therefore, lamellar structure containing high fraction of twin boundary will benefit long-term stability. In this context, the effects of several factors on twin boundary fraction in lamellar TiAl were studied by phase-field simulations (Teng et al. 2012). The influences of coherency stress, interfacial energy, and undercooling on the nucleation and colony growth were analyzed. Twin boundary fraction was found to increase with increasing coherency strain energy and increasing energy difference among different types of interfaces but decrease with the increase of driving force for phase transformation (undercooling) (Fig. 10). Depending on the relative contributions of elastic strain energy, simulation found that gamma phase nucleation events could be collective, correlated, or independent. Further simulations show that external stress can also affect the twin boundary fraction strongly and could be utilized for microstructure control (Teng et al. 2015). It is expected that by detailed adjusting the above parameters, and controlling the nucleation and growth carefully, relatively stable microstructure can be achieved.

(**c**) Twin boundary probabilities as a function of the elastic energy amplitude. (**d**) Twin boundary probabilities as a function of chemical driving force ratio (Teng et al. 2012)

The idea above for heat-treatment route design may also be applied to other titanium alloys. In order to understand how α plate is formed, phase field model considering inhomogeneous and anisotropic elasticity was developed to study the growth of acicular precipitates observed in Widmanstätten structures under isothermal conditions (Cottura et al. 2014). When the plate-like precipitate grow large, the elastic energy anisotropy plays a key role even during diffusion-controlled process. When only one soft direction exists, stationary growth is obtained after a transient stage, while if several soft directions are in competition, sharp concomitant morphological and kinetic transitions are observed. To understand what controls texture formation, the morphology and variant selection (VS) of grain boundary allotriomorphs and Widmanstätten sideplates are investigated using 3D phase field model (Qiu et al. 2016). Quantitative analysis indicates that precipitate morphology and VS are determined by the interplay among elastic interaction between nucleating precipitates and GB dislocation networks, while growth anisotropy is determined by the relative inclination of the habit plane with respect to GB dislocations, density of nucleation sites and coalescence during growth, and spatial confinement from simultaneously nucleated neighboring variants of dissimilar types.

The recently designed ultralow modulus Ti2448 alloy has very unique mechanical properties (Hao et al. 2012): when quenched to 193 K, martensitic transformation (MT) may become a major deformation mechanisms (Zhu et al. 2017). Both crystallographic analysis and phase field simulations have revealed the diverse strain accommodating modes, especially the excellent geometrical compatibilities of twins and herringbone structures, providing the MT with great flexibility for arbitrary shape changes and defect structures generated during plastic deformation, which may have contributed to the exceptional mechanical properties of the alloy. Phase field simulations have also been used to study the effects of many other factors on the microstructure, such as sideplate formation from grain boundary in Ti-6Al-4 V alloy (Wang et al. 2009b), effect of interfacial energy anisotropy (Yang et al. 2012), and the effect of initial particle size distribution (Wang et al. 2009a). Apart from growth of precipitates, the dissolution and coarsening process were also simulated in order to gain understanding of the kinetics of these processes. These may help with the heat treatment route design (Wang et al. 2009a, 2011a).

5.2 Microstructure Evolution During Thermo-Mechanical Processing

Titanium ingots are usually broken down and deformed into various shapes through different thermo-mechanical processes, such as forging, rolling, or extrusion, into required rod, sheet, or plate. Further forming can be accomplished by isothermal forging or friction welding. These processing operations play a significant role to produce microstructure with outstanding properties. However, the whole process is long and complicated, with each step having influence on later ones, the link between microstructure and processing being not clear. With the fast progress of
Fig. 11 Microstructure with VS caused by prestrain of uniaxial tension or compression (50 MPa) along [101]$_\beta$ (Shi and Wang 2013)

microstructure simulation method recently, the difficulties could be partly overcome by computer simulation.

Simulations considering the influence of certain factors separately is feasible and may be superior compared to experiment. Phase field model was developed to predict VS and microstructural evolution of α precipitates during β to α transformation (Fig. 11). It is found that the microtexture with VS is determined by the interplay between external stress and internal stress from precipitation (Shi and Wang 2013). Further simulation in polycrystalline Ti-6Al-4 V (Shi et al. 2015) found that local stresses lead to obvious VS and, under certain prestrains, polycrystalline β sample could end up with a relatively weak α texture even if it has a strong starting β phase texture. Simulation also shows that due to the strong anisotropy of α precipitates, the 2D sampling may introduce "pseudo VS," thus when analyzing texture data, one must bear this in mind. The findings may shed some light on the control of transformation texture by thermomechanical processing.

Besides PF, CA is also used for modeling microstructure evolution, e.g., to simulate the micromechanical behavior in a Ti alloy under dwell-fatigue loading (Pourian et al. 2016). Simulations show clearly the load transfer from a deformed cell to its neighbors, during cyclic loading, with hard cells experiencing higher stress until they start to deform plastically and eventually generate a crack. Although CA model is simple, it could describe high level of complexity and allow the statistical description of polycrystals by considering stress-strain transfers between neighbors. Another simplified CA model is developed to simulate the 3D local behavior of nontextured microstructures in elasticity with reasonable results compared to more sophisticated FEM (Pourian et al. 2014).

The CPFEM is an integrated theoretical framework containing micromechanical models and concepts under a unified theory of crystal plasticity. It is a powerful

tool for solving mechanical events during hot working. A microstructure-sensitive fatigue study in Ti-6Al-4V and Ti-18 alloy by CPFEM (Smith et al. 2016) suggests that reduced lamellar colony sizes, α phase, and transverse texture can enhance the resistance to formation and early growth of fatigue cracks. The CPFE investigation of the micromechanical behavior of Ti-6Al-4V shows that the nanoindentation results depend sensitively on grain orientations (Han et al. 2015). The CPFE simulation of the deformation of titanium sheet under different strain shows that twinning affected significantly the anisotropies in Lankford value and work hardening under compression, and cause tension-compression asymmetries (Hama et al. 2017).

A simulation can be coupled with another to restore the thermo-mechanical progress, e.g., 3D CA-CPFE coupling (Li et al. 2016), with dynamical recrystallization (DRX) evolution built into CPFE framework that allows the investigation of isothermal compression in the β phase field. The DRX-induced reduction of slip resistance and GB migration cause a relatively large subsequent plastic deformation around GB, while small strain is found within recrystallized grains. Finally, simulation combining Monte Carlo with stochastic CPFE in a self-consistent viscoplasticity framework shows that microstructural features such as grain size distribution and crystallite orientations govern the uncertainty in the mechanical response of the polycrystalline materials (Askari et al. 2015).

Some special models are introduced to simulate the microstructure evolution during processing and service conditions. A deterministic model was established to account for the effect of initial crack size, microtextured region size, and aspect ratio on the fatigue life of titanium alloys (Pilchak 2014b). The results indicate that dwell and cyclic fatigue life depend mostly on microtextured region size and initial crack size, respectively. The creation of a process-structure-property database for dual-phase titanium alloys by a synthetic microstructure generation method and a mesh-free fast Fourier transform-based micromechanical model has been worked out (Ozturk and Rollett 2017). It is found that the response is most sensitive to α fraction and prior β texture. Increase in α fraction enhanced the tensile strength, as the α phase is harder. Increased prior β (001) texture decreases tensile strength. Microstructural evolution was modeled by LS method to explore the lath spheroidization phenomenon in α/β titanium alloy, with consideration of interface diffusion and the motion driven by curvature (Polychronopoulou et al. 2016), but since deformation was not accounted for in detail, further study is still needed. Thorough understanding may rely on further integration of new technology and simulation (Pilchak et al. 2014a).

5.3 Microstructure Evolution During Advanced Forming Processes

Many new processes emerged in the last decade, some of which may in some way be superior to conventional forming, and can replace them in certain circumstances. Powder metallurgy may produce very uniform composition since it has no

solidification process causing macrosegregation, while additive manufacturing may produce original shape from draft, without mold. For some advanced forming techniques that combine high energy beam melting and solidification process in small volume, the details are difficult to reveal solely by experiments, and their microstructure evolution and defect formation are not easy to control. More complicated model considering various factors needs to be developed and implemented.

Additive manufacturing or 3D printing is an emerging technology based on computer-aided design and manufacture. It can shape complex structure quickly and overcome the limitations of traditional processes. The microstructure generated by this novel technology has been investigated by experiments, and simulated by MC, FE, and CA, or coupling of these methods. Recently, a Potts MC-based model implemented in the SPPARKS framework has been utilized to simulate melting, solidification, and microstructural evolution in the fusion and heat-affected zones of welds (Theron et al. 2017) (Fig. 12). It was shown that weld speed is a key process parameter. Together with shape parameters describing various possible pool shapes and heat-affected zones representing different heating method, it facilitated the design of many possible welding processes.

The evolution of grain structure is simulated using 3D MC model of grain growth in the heat-affected zone of CP-Ti welds (Yang et al. 2000). The calculated grain sizes for various heat inputs were comparable with the results of corresponding experiments. The mean grain size in regions equidistant from the fusion plane increased along the circumferential direction from the top surface to the weld root.

Besides these models, 3D model is proposed to analyze heat transfer and fluid flow in weld pool during electron beam freeform fabrication of Ti-6Al-4 V (Tang et al. 2014). Vigorous fluid flows were found in the front part of weld pool with thermal-capillary force as the main driving force, and frequent droplet impacting influences heat and mass transfer in the weld pool. Scanning electron beam could decrease temperature gradient and magnitude of fluid flow in the weld pool. The grain structure of Ti-6Al-4V after laser melting is explained using a new model combining 3D FE and CA validated by experiments (Dezfoli et al. 2017). The growth direction of elongated grains is controlled by heat flow direction, which is a function of laser scanning speed, and the grain size decreases with increasing laser speed.

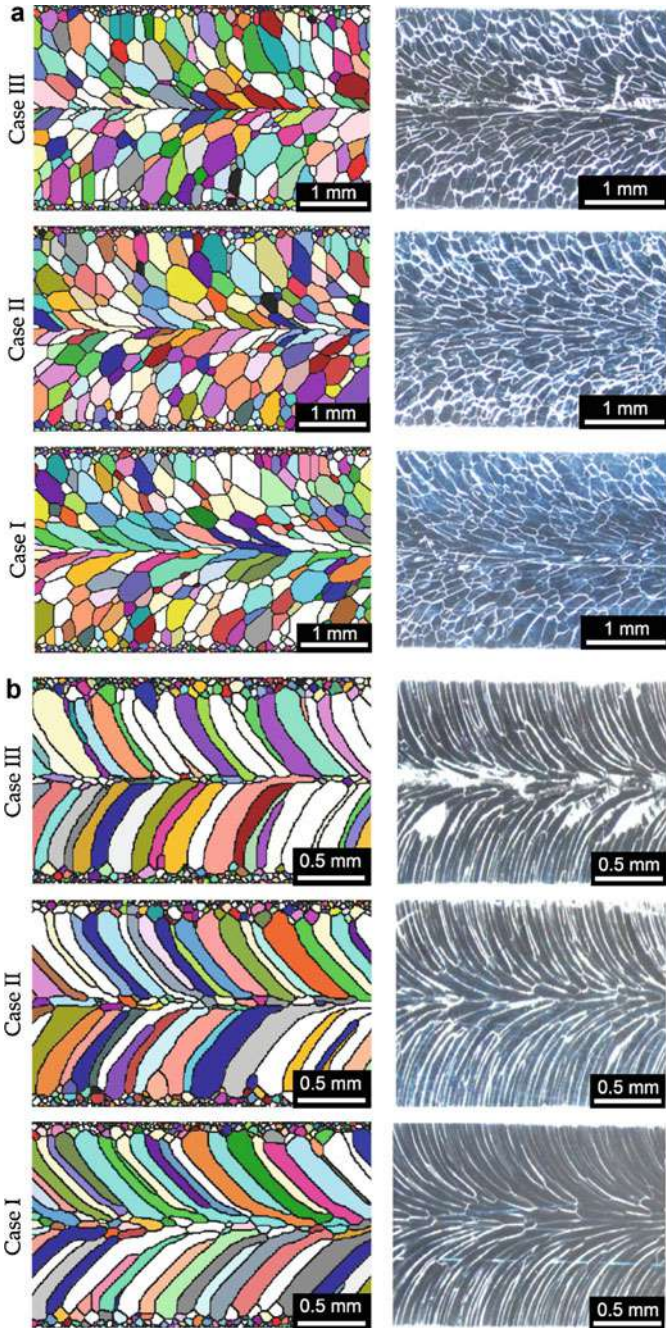
Recently a new AM process, hybrid deposition and microrolling (HDMR), is introduced that integrates arc deposition and microrolling. A 2D CA coupling finite volume method is developed for simulating microstructure evolution including solidification and dynamic recrystallization during HDMR forming (Zhou et al. 2016). Rolling reduction was found to control the dynamic recrystallization region and size of recrystallized grains. Computational analysis was also made on linear friction welding of titanium alloys, and the effect of processing parameters evaluated (Li et al. 2010; Yang et al. 2015b). Apparently the simulation on these complicated new processes needs more efforts.


Fig. 12 (**a**) Comparison between simulated and experimental microstructures along the top and (**b**) the bottom surface of a weld (Theron et al. 2017)

6   Finite Element Simulation for Understanding and Optimization of Forming Process

Titanium alloy components are fabricated traditionally through melt-casting, forging, rolling, extrusion, powder metallurgy, and recently additive manufacturing, and many factors should be controlled to achieve the best performance. In addition, optimizations are made to shorten processing routes, alongside performance enhancement and defect control. In order to obtain a consistent quality product at a minimal cost, various simulations are carried out for each manufacturing process in order to reduce the long and costly trial-and-error design iteration and lower the cost at production stage (Avitzur 1968; Semiatin 1984; Gegel et al. 1988; Schey 1997). FEM is the most popular technique to improve the designer's capability to evaluate and optimize various aspects of forming process (Luo et al. 2007; Lacki et al. 2010; Wu and Zhang 2014; Wang et al. 2016b).

6.1   Development of FEM for Various Processes Simulation

Early process simulations relied on simple analytical techniques to estimate forming load, workability limits, and mold design features, then with complex analytical equations converted to charts for easy use. FEM for metal forming was introduced in early-1970, and has impacted industry since mid-1980. Due to its capability and industry demand, FEM has evolved into true 3D models, with robust functionalities since late-1980 (Kobayashi et al. 1989; Malas and Seetharaman 1992; Rowe et al. 2005), and succeeded in reducing R&D cost for various processes for titanium alloys, from vacuum arc remelting (VAR), to forming analysis for processing window control, mold design evaluation, and defect prevention.

The melting of titanium alloy is the most complicated process for simulation, an example being the most popular VAR technology. This process involves melting, liquid flow, diffusion, solidification, and electro-magnetic stirring and cooling, and cannot be solved by a single simulation; models should be established focusing on each aspect. Robust and efficient model for transient analysis of electromagnetic field, flow, heat transfer, macro-segregation, and inclusion behavior was established for the VAR process, and simulations in the last two decades have promoted effectively the development of this technology (Mitchell et al. 1991; Hernandez-Morales and Mitchell 1999; Kelkar et al. 2004; Mitchell 2005; Mitchell and Reed 2009) (Kelkar et al. 2007), see Fig. 13. Recent development of continuous casting of titanium rod and plate ingot for direct rolling may reduce significantly the cost of titanium products (Yu 2013) but is still challenging for various alloys, and simulations are strongly needed.

After melting, ingots are broken down into large rod in the high temperature β phase field and then forged at progressively lower temperature, mostly down to the two-phase field. A typical process for making components for aviation application needs a dozen passes of forging and rolling, and may undergo isothermal forging to

Time = 540 min
Ingot Length = 2.49 m
Fig. 13 Simulated variation of Al concentration in Ti-6Al-4V VAR ingot with and without magnetic stirring (Kelkar et al. 2007)

final shape, and then heat-treated to desired microstructure. Shortening processing route is challenging work for production cost reduction without sacrificing performance.

For hot forming technology like extrusion, lubrication is crucial for protection of the alloys and mold, since titanium is extremely reactive at high temperature and reacts with most molds if in direct contact. A continuous film of viscous glass can be good lubricant and separator between titanium and mold; however, the viscosity control is not an easy task, due to the very high temperature gradient across the contact. The glass viscosity is too low and will leak out if temperature is too high, while it becomes hard and brittle otherwise; in such circumstances not only is the lubricant effect lost, but the product may be scratched and destroyed. FEM simulation was carried out to investigate the temperature and viscosity distribution within glass lubricant film under different extrusion condition and, based on that,

lubricant was designed and successful extrusion was achieved. For the canned extrusion of TiAl, the situation becomes more complicated: apart from lubricant, a right dwell time in air is needed for the container to achieve a similar strength to that of the TiAl billet inside. FEM simulations provide key information to glass lubricant design and extrusion process, and lead to successful extrusion after only very limited number of trial (Bai et al. 2010).

6.2 Integrated Simulation for Complete Manufacturing Process Optimization

Most titanium alloy components go through a long manufacturing cycle, which typically includes melting, ingot breakdown, forging, heat-treating, welding, machining, and assembling and installation. The cast microstructure in titanium alloy ingot is usually very coarse, can be broken down through cogging, upsetting and drawing, and forged into semi-finished microstructure, and then die-forged into final products. For each step, the results of last procedure will have strong influence on the next, such as in temperature and microstructure distribution, strain or even defect state; therefore, integrated simulation of the whole process is the dream of the process design engineer. However, since the numerous details need to be considered in each step of the long and complicated process, and tremendous amount of computation is involved in each step, there is no truly integrated simulation throughout. Numerous efforts on these integrations were made in the last decades to produce software enabling the integration of two or more procedures, such as sequential forging or rolling simulation with output of the last simulation into the next as input, or integrate two or more scales, such as FEM simulation with consideration of microstructure changes. FEM simulation was carried out for forging, rolling, extrusion, casting, and powder metallurgy process, with partial consideration of integration of scales e. g., CPFEM, Yada model are used to predict microstructure during deformation, and phase field simulation of microstructure evolution considers various factors under different condition. Since a complete material flow and thermal mechanical history is important to model the behavior properly during production or during service, it is ideal to have integration of different subprocess in a group, if not in one simulation, to gain understanding of microstructure and performance evolution throughout the entire manufacturing process.

The forging of TA15 titanium alloy cylindrical ingot was investigated using 3D FEM simulation. It was found that the deformation strain at each pass influences strain distribution strongly: very small strain of each strike results in near surface deformation, while very large strain forms localized strain in the center. The deformation beneath hammer and between two hammers have opposite distribution, sometimes with the latter having much larger accumulated strain. The forging process was optimized on the basis of FEM strain analysis (Yu et al. 2010). After the ingot was forged into bars, they go through rolling passes or through extrusion into

tube or rod with profiled cross-section. The rolling stress is high in the two-phase field, and the microstructures are sensitive to temperature and strain, which make the processing window narrow, and the pass design and process control difficult. Special Y-shaped roller and unique caliber are designed based on quantitative FEM analysis of the effects of each parameter on temperature and deformation characteristics within rolled bars. Continuous rolling succeeded in making the wire for fasteners with required uniform microstructure and texture.

The constitutive relations are crucial for FEM simulation, and are usually determined experimentally, using physical simulation like Gleeble thermo-mechanical simulator, which gives the stress-strain relations at different temperature and strain rate by controlled tension or compression. The flow stress-strain data should cover the whole process window of actual forming process, including temperature, strain, and strain rate at each position of the components simulated. Large extrapolation of data range usually results in unexpected error. During Gleeble test, factors introducing error should be considered carefully, including the temperature change due to heat loss into anvils and air, the friction between specimen and anvils, and the temperature rise caused by plastic deformation (Meng et al. 2018). FEM simulations on Ti60 and TiAl alloys showed that the temperature distribution in specimen is not uniform during hot compression, resulting in significant deformation inhomogeneity and unignorable error in the flow stress-strain relation, invalidating the uniform strain assumption commonly employed to extract the constitutive relation from Gleeble tests (Yu et al. 2012). Based on FEM simulations with iterative corrections, a scheme to refine the constitutive relations from Gleeble tests was proposed, through which more accurate constitutive relations can be obtained (Yu et al. 2019).

6.3 Integrated Simulation of Microstructure Evolution During Hot Processing

Currently, most FEM modeling considers only isotropic and unchanged behavior of materials. In fact, many factors can alter the material, such as recrystallization, texture formation, phase transformation, grain size evolution, precipitate size and distribution, and even damage, could all potentially affect deformation behavior (Banerjee and Williams 2013; Collins et al. 2013). Understanding the microstructure/properties evolution during thermal mechanical processing and its associated effect on mechanical properties, such as flow stress, modulus, and creep behavior, is very crucial to the model accuracy since these properties are generally the most important input to FEM analysis.

Artificial intelligence method play an increasingly important role as big data (both experimental and simulation) of titanium alloy composition/processing/microstructure/properties are accumulated. The microstructural evolution of titanium alloy under isothermal and other hot forging was predicted using artificial neural networks (ANN) and finite element (FE) simulation (Kim et al. 2009). The change in phase fraction, grain size, and dynamic globularization fraction were

modeled considering various hot working conditions, based on input parameters such as initial specimen/die/environment temperature, steady-state phase fraction, and elapsed time during forging. Resulted ANN models were coupled into FE simulation, with grain size variation and a globularization model developed for hot forging, and validated on Ti-6Al-4V hot-worked under various conditions.

Apart from phase fraction, texture is also very important for mechanical properties. For example, the existence of microtexture is believed to be the root cause of the large fatigue life scattering during dwell fatigue for some titanium alloys such as Ti6242 as rotating components in jet engine (Kassner et al. 1999; Sinha et al. 2006; Rugg et al. 2007; Dunne and Rugg 2008; Germain et al. 2008; Pilchak et al. 2009; Qiu et al. 2014). The mechanism of texture evolution in TA15 sheets during hot tension along the rolling direction was investigated by both experiment and CP simulation (Zhao et al. 2017). Four main orientations in undeformed TA15 sheets were found to evolve in different ways. CPFEM simulation shows that basal slip would rotate <0001> axis off the tensile direction, while prismatic slip rotates $[10\bar{1}0]$ axis oppositely. This lattice rotation results in the transition of orientation C and D, while keeping the orientation of A and B steady. Such understanding on texture change may shed some light on the process design for texture optimization in titanium alloys for critical application such as rotating components in jet engine. Various models and methods to describe the deformation character of various microstructures were developed, while more effort is still needed to couple these seamlessly with fabrication process simulation (Li et al. 2019).

Beyond traditional titanium research community, there are much broader ranges of new idea we may learn from, to advance titanium alloy development. For better mechanical properties, we need to overcome the conflicts between the strength and toughness of material or find a balance between strength and ductility (Ritchie 2011). New strategies for this can be employed, including analyzing the mechanism of each property with the help of simulation, and learning from nature to achieve good strength and damage tolerance (Gao 2006; Lu 2010). With the help of multiscale simulation and new characterization technique, more possibilities of microstructure modification can be found, e.g., ultra-fine microstructure can be obtained by carefully designing thermal-mechanical processing or heat treatment route through nonconventional transformation pathways utilizing some metastable phases such as ω or O″ phase (Wang et al. 2008b, 2010; Ping 2014; Zheng et al. 2016a, b, c). Through specially engineered coherency of internal boundaries and stability control, both high strength and conductivity can be achieved (Lu et al. 2009). Ultra-strong steel was designed by introducing high-density of nanoscale precipitates with minimum lattice misfit (Jiang et al. 2017), or even forming amorphous phase with the help of martensitic transformation (Zhang et al. 2018). New approach to achieve smaller grains with strong GB may be realized with the help of deeper understanding of the segregation and embrittlement of GB by integrated simulation (Chookajorn et al. 2012; Kalidindi et al. 2015; Polyakov et al. 2016; Lejcek et al. 2017).

7   Perspective and Challenges

7.1   Perspectives

1. The performance requirement for titanium alloys is becoming more application specific, so materials are now not an independent choice as before. In order to enhance performance further to fit new design, application-specific developments are needed for critical components. It is the whole processing technology that ensures the successful and economic application of material. Therefore, the development of new materials needs to take a different route, to achieve better performance balance for each usage, using simulation as much as possible, and make early contact between materials researcher, manufacturer and system designer, and communicate what they really need and what they can offer.

2. Developing a new material needs to go through composition selection, microstructure and properties optimization, and processing optimization, etc., then a series of component design is tried, to obtain the best component design. In order to accelerate this process, in the future, the different stages of materials development and the system design can proceed in parallel, with the help from multiscale computation. The performance of components is simulated well in advance before materials are made, and materials designer needs to work together with component designer to adjust the composition, microstructure, and processing route according to the requirement of the specific application. More challenging problem can only be solved efficiently by strong collaboration between computational specialist and experimentalist, and between materials and system designer (Rugg 2014).

3. Future computations should focus on bottleneck problems in each application and serve either to identify the controlling factor in processing or to reveal working mechanism which is not easy to uncover solely by experiments. Materials for the compressor of jet engine require high strength, toughness, fatigue, creep and oxidation resistance under high temperature, etc., but from the first to the end stage, the temperature and pressure increase gradually, and the bottleneck may shift from fatigue to creep, or even oxidation, so the materials design should adjust accordingly.

4. Traditionally our processing route is designed to achieve uniform microstructure throughout components; as the demanding for materials increases, position-specific inhomogeneous microstructure and composition (functional gradient microstructure, or architectured microstructure) may be designed. With special arrangements, microstructure such as gradient/intermixed grain size/composition/phase may enhance the strength-ductility compatibility, and be beneficial to the performance of components (Lu 2014; Zeng et al. 2016; Jiang et al. 2017). Computation at different scales may help on designing better materials and processes of fabrication.

5. With the advancement of computation, various integrations are possible, either of different scales, e.g., FEM with microstructure changes, or MD with experimental timescale, or linking different processes, such as passing details of component along different stages of manufacturing. New advances in computing such as artificial intelligence should also be employed in both simulation and analysis.

7.2   Challenges

1. The rapid development of high-techs need more advanced titanium alloys, often urgently, but cannot tolerate its long insertion time of 10–20 years like before. The MGI and ICME approach should be adopted throughout materials composition design until fabrication, to accelerate new materials development (Kubel 2013; Glavicic and Venkatesh 2014). How to communicate between different parties and what information to share need some new regulations, involving not only science and technology, but also economy or even politics, especially for the strategically important materials like titanium alloys.
2. Computations focused on more specific processes need better input, such as proper boundary conditions and constitutive relation. However, realistic determination of processing parameters, such as constitutive relation under different stresses, elastic properties of phases with different composition/temperature, and friction/thermal conductivity coefficient at interfaces between different parts during hot working, may not be an easy task. New technologies for achieving such parameters are needed for titanium alloys studies, including high throughput computation/characterization method, or from some data sharing mechanism (Curtarolo et al. 2012; Christodoulou 2013; Jain et al. 2013; Agren 2014; Wang et al. 2014a, e; Zhao 2014).
3. Multiscale modeling and simulation have been utilized in the last few decades to solve basic properties, such as energy and modulus of phases, and gradually to more complicated problems, such as strength, toughness, fatigue, and stress corrosion cracking, which are much more challenging. Modeling and simulation should be fully utilized and designed carefully to help identify the controlling factors, and to promote our understanding, and help reduce the number of experiment and cost of the development, and finally to help materials to get out of the "death valley."
4. Simulations have been successful in promoting manufacturing of different types, such as casting, ingot melting, forging, rolling, extrusion, and welding. New processing technologies may need more help from the simulation community, e.g., powder metallurgy, additive manufacturing, and friction stir welding. In each of these processes, the microstructure changes and properties variation during processing are difficult to control and largely unknown, and simulation may do more to solve these challenging problems.

Quantitative Rheological Model for Granular Materials: The Importance of Particle Size

8

Ken Kamrin

Contents

Abstract

One of the great puzzles in describing the constitutive behavior of flowing granular media is the role of grain size. Even for relatively simple, stiff, round grains, the length scale of grains themselves is large enough to influence the continuum rheology, causing departures from local model predictions in the presence of flow heterogeneity and thin geometries. Here we present the development of a particular nonlocal model, the nonlocal granular fluidity (NGF) model, which has shown to be quantitatively predictive and able to capture this effect in the various forms it emerges. We show that the model correctly gives steady flow fields of grains over multiple orders of magnitude in many different 2D and 3D geometries without refitting. The same model captures the

size-dependent strengthening of thin granular bodies, a phenomenon that may at first glance appear separate from that of predicting steady flow profiles. NGF also correctly captures the so-called secondary rheology of grains, wherein faraway flow alters the apparent yield stress everywhere. The underlying physics of the nonlocal rheology is gradually becoming clearer, as it has recently been shown that the nonlocal fluidity field, which is a key field variable in the model, is a true kinematic state variable. We also discuss the remaining open questions and future directions.

1   Introduction

The problem of determining accurate constitutive relations for granular media is a challenging and long-lasting problem going back to the days of Coulomb. Numerous models have been proposed – far too many to attempt to summarize here. See Andreotti et al. (2013), Mitchell et al. (2005), and Goddard (2014) for a rather current review of models. The civil engineering community has traditionally modeled granular media using principles of continuum solid mechanics, which emphasizes the role of density, evolving internal variables, and pressure on the plastic yield condition. This modeling approach tends to focus on the behavior of natural grains, typically soils, undergoing moderate levels of total strain. On the other hand, one can consider problems of developed granular flow, where strains are enormous and one may consider something closer to a fluid-like treatment of the material. This viewpoint has been studied in recent decades by physicists and fluid mechanicians from both discrete-particle and continuum perspectives. Here, even with idealized simple grains, the issue of determining a precise "Navier–Stokes Equations" of granular flow has been elusive.

This chapter describes recent developments geared more toward the latter perspective, with the aim of coming up with a geometrically general, quantitatively accurate model that predicts the rheological behavior of systems of simple particles. The emphasis will be on developed flow problems and conditions related to existence of developed flows. The chapter proceeds for the most part chronologically in the order the developments were made. We begin by describing the state of the art as of the early 2000s, in particular the *inertial rheology* of granular flow. This model is fully local, and we discuss a number of key granular phenomena that cannot be represented under this approach, which leads to well-known accuracy losses. We then describe the reasoning behind adding a particular nonlocal term into the constitutive relation to rectify these shortcomings of the local model. The resulting model, which is denoted *nonlocal granular fluidity* (NGF), is then tested in a variety of flow geometries and shown to produce accurate predictions over several order of magnitude of flow speed, in both 2D and 3D. The same model is then tested against other unusual manifestations of grain-size cooperativity known in the granular materials literature, including the effect known as *secondary rheology* and the so-called H_{stop} effect. The latter demonstration is accompanied by a theoretical description of how the steady form of NGF is derived from an appropriate dynamic

form. We close with ongoing efforts to explain the microscopic underpinnings of NGF, including studies to relate its parameters back to grain-level descriptors, and results that show the model's key order parameter field, the *granular fluidity*, is in fact well-defined from microscopically observable grain behaviors.

2   Local Model

Over the last 15 or so years, significant progress has been made in determining the rheology of isotropically shaped, stiff grains in simple shearing (da Cruz et al. 2005; Jop et al. 2006). The model that has arisen, known as the "inertial rheology," could be seen as a generalization of Bagnold's scaling law (Bagnold 1954) for constant volume shearing. The model has been applied to a variety of problems, including silo drainage (Staron et al. 2012a, b; Kamrin 2010; Dunatunga and Kamrin 2015), heap flows (Jop et al. 2006, 2007; Kamrin 2010), granular column collapse (Lagrée et al. 2011; Dunatunga and Kamrin 2015; Valette et al. 2017), and projectile impact into dense granular media (Dunatunga and Kamrin 2017). A major feature of the inertial rheology is that its form can be deduced primarily from dimensional considerations, as we review now.

Consider a (planar) simple shear cell, containing quasi-monodisperse grains having characteristic size d, density ρ_s, surface friction μ_{surf}, restitution coefficient e, and "shape" s. The grains are presumed stiff enough that the stiffness k is not relevant to the rheology. Suppose a wall pressure P is imposed on walls of the cell and a tangential wall velocity is prescribed such that, at steady state, the granular strain rate is $\dot{\gamma}$. From these input conditions, a shear stress τ arises as the stress needed to sustain the steady motion. The system can be described by the following dimensionless groups:

$$\mu = \tau/P, \quad I = \dot{\gamma}\sqrt{\frac{\rho_s d^2}{P}}, \quad \mu_{\text{surf}}, \quad e, \quad s \tag{1}$$

where μ is the *stress ratio* and I is the *inertial number*. Thus, by Buckingham's theorem, the rheology of the grains must be expressible as

$$\mu = \hat{\mu}(I, \mu_{\text{surf}}, e, s). \tag{2}$$

For a fixed material, we can absorb the grain properties and tersely re-express the relation above as

$$\mu = \hat{\mu}(I). \tag{3}$$

This functional relationship is known as the *inertial rheology*. For $\mu_{\text{surf}} > 0$, it commonly fits well to a form

$$\mu = \mu_s + \frac{\Delta\mu}{\Delta\mu/bI + 1} \tag{4}$$

where μ_s, b, and $\Delta\mu$ are material constants. It is approximately linear in I when $I \ll 1$ but asymptotes to a value $\mu \to \mu_s + \Delta\mu$ as $I \to \infty$. It is also common, when interested in slow to moderate flows, to expand the above to linear order near $I \sim 0$ and use

$$\mu = \mu_s + bI. \tag{5}$$

If $\mu < \mu_s$ there is no flow. Hence, μ_s acts as a critical internal (bulk) friction coefficient. On the other hand, the more the applied stress ratio μ exceeds μ_s, the higher the relative flow rate I.

3   Departures from Locality

Although the inertial rheology is quite successful at describing homogeneous, steady-state simple shear flows in systems large compared to d, it was noticed fairly soon after its introduction that the relationship is violated in a number of important situations. In general, the $\hat{\mu}(I)$ relation is not satisfied in inhomogeneous steady flow geometries, particularly in regions of slowly flowing material (MiDi 2004). Moreover, a variety of other, seemingly independent phenomena stand in contrast to the outcomes that would be given by $\hat{\mu}(I)$. For example, it is observed that as geometries shrink in size, granular materials act as if they are stronger, i.e., a larger than expected stress ratio μ is needed to maintain a steady flow. This occurs in thin flows down inclined chutes (Pouliquen 1999), hourglass nozzles (Beverloo et al. 1961), and other geometries (Liu and Henann 2018) whose size scale impinges on the size scale of $< O(100)$ grains. As another unusual phenomenon, a "secondary rheology" is observed in granular flows (Reddy et al. 2011), wherein the motion of a boundary causes even the static looking parts of a domain far from the said boundary to lose their yield stress and flow under arbitrarily small forcing of a probe.

All of these behaviors are intrinsically nonlocal; the particle size is producing cooperativity in the dynamics over a grain-based length scale, and this causes the rheology at a point to divert from a relationship between local stress and local strain rate, as would be implied by Eq. 3. Whatever the remedy is, it involves explicitly accounting for the mean grain size as a length scale within the rheology. Previous size-dependent modeling approaches exist, such as Cosserat (micropolar) continua (Mohan et al. 2002), kinetic theory (Jenkins and Berzi 2010), self-activation (Pouliquen and Forterre 2009), partial fluidization (Aranson and Tsimring 2001), nonlocal inertial-number modeling (Bouzid et al. 2013) and the void/spot models (Kamrin and Bazant 2007). The key advantages of the theory we present below are its relative simplicity, as it depends on few parameters, and its ability to accurately capture the different departures from local mechanics exhibited by grains.

4   Nonlocal Granular Fluidity Model

The sieve that leads to the nonlocal model presented here lies in a set of data gathered by Koval and co-workers in 2009, which gives very clear indications as to how the local inertial relation is violated in inhomogeneous flow geometries (Koval et al. 2009). The authors use the discrete element method (DEM) to compute steady flows of quasi-monodisperse ($\sim$20% polydispersity) frictional disks in an annular Couette geometry. The Couette's exterior wall pressure is controlled but cannot displace in the θ direction, and its inner wall is rigid with rotational velocity prescribed (see Fig. 1a). All walls are fully rough. The output flow is characterized by a large speed near the inner wall that decays rapidly as r increases. By varying the grain size, as measured through R/d, and inner wall speed v_{wall}, many different flows are obtained. By coarse-graining stress and velocity in space and sampling many different locations, a scatter plot of μ and I is obtained for each test, and how well μ vs. I remains well-collapsed onto one curve can be tested. Since locally the flow in this geometry looks everywhere like steady simple shear, any departure from the one-to-one μ vs. I relation observed in homogeneous shear can *only* be explained through nonlocal effects that call upon higher flow gradients.

As shown in Fig. 1, for low values of I, which correspond to positions far from the inner wall, the plots from different tests do not converge onto one curve. In fact, as long as $R/d < \infty$, we see many data points where flow is occurring, $I > 0$, but the stress level is below what the local model would predict is the yield condition, i.e., $\mu < \mu_s$. In the tests where wall speed is varied, those tests where the wall speed is very slow all have the same range of μ present in the flow field, however the different slow wall speeds each have entirely different ranges of I. Here, the stress fields are nearly unchanged between the different tests, however the flow fields are all scaled by the speed of the wall. This rate-independent phenomenon in slow creeping zones, which runs directly counter to the rate-dependent nature of the inertial rheology, must be reconciled with nonlocal modeling.

The approach we take herein is a granular extension of a mathematical model proposed in 2007 for emulsions called the kinetic elastoplastic (KEP) model (Goyon et al. 2008; Bocquet et al. 2009). Though the KEP model was originally justified with micro-statistical arguments, our motivation for modifying the KEP model for granular media is primarily one of practicality, as its mathematical form possesses features that at the outset appear uniquely capable of rectifying the basic departures from locality apparent in the Koval data, yet the model remains fairly simple. We present the model now, which we refer to as the *nonlocal granular fluidity* (NGF) model.

Define the granular fluidity field g as an order parameter that exists throughout the granular domain. The fluidity plays a key role in the constitutive relation as it is the field that specifies how local loading causes local flow, via

$$\dot{\gamma} = g\mu. \tag{6}$$
Fig. 1 (Left) The annular Couette flow setup. (Middle) Locus of μ vs. I in many steady DEM flows (symbols) each simulation having different R/d but all having same v_{wall}. (Right) Locus of μ vs. I for DEM flows with fixed R/d but various V_{wall}. Dotted line is local rheology prediction. Colored lines are predictions of NGF. (Images modified from Kamrin and Koval 2012 and Henann and Kamrin 2014a)

Larger g means more susceptibility to flow, whereas $g = 0$ represents solid material. If the inertial rheology were correct, g would have a formula, denoted g_{loc}, given by Eq. 5 in the slow flow regime:

$$g_{\text{loc}}(\mu, P) = \hat{\mu}^{-1}(\mu, P)/\mu = \frac{\langle \mu - \mu_s \rangle}{b\mu} \sqrt{\frac{P}{\rho_s d^2}} \qquad (7)$$

where $\langle \cdot \rangle$ denotes the Macaulay bracket. The proposed nonlocal rheology in its steady-state form states the true fluidity g is the solution to the following PDE:

$$g = g_{\text{loc}}(\mu, P) + \xi^2 \nabla^2 g. \qquad (8)$$

Equations 6 and 8 constitute the NGF constitutive model in steady, scalar form. Here, ξ is a length scale explicitly scaled by the mean grain size d. It can be seen in the above that the true fluidity is obtained as the solution of a PDE, for which g_{loc} serves as a source term. The true fluidity field, g, is a diffused version the field of g_{loc}. This allows regions to flow ($g > 0$) even if those regions have $\mu < \mu_s$. Secondly, in regions where $\mu < \mu_s$, g_{loc} vanishes and the PDE reduces to $g = \xi^2 \nabla^2 g$, which is linear in g and allows a solution to be scaled by a constant and still be a solution. This fact implies the system transitions to a rate-independent form in creeping zones whose stress is under the local yield criterion. If the flow is homogeneous or the length scale ξ vanishes, the $\nabla^2 g$ term vanishes, and one is left with the inertial rheology. All these checks pass the sieve of Koval's data.

The length scale above is given by $\xi = d\frac{A}{\sqrt{|\mu - \mu_s|}}$ as inspired by the form in Bocquet et al. (2009). It turns out this formula can be derived by considering the dynamic version of the fluidity PDE, which will be considered in an upcoming section. The divergence of the length scale as $\mu \to \mu_s$ was directly observed in DEM simulations in Kamrin and Koval (2012). The parameter A is the only new material parameter in the model. It is called the *nonlocal amplitude*; it is dimensionless and order one in size and depends only on grain information excluding grain size. Lastly, the system is closed by applying a set of boundary conditions to the new field. Since the fluidity PDE is of source-diffusion type, the choice of boundary conditions is less important than in boundary-only-sourced PDEs. In the 2D demonstrations provided next, $g = g_{\text{loc}}$ is applied at all boundaries.

The solid lines in Fig. 1 display the solutions of the NGF model in the annular Couette geometry, using $A = 0.8$. The parameters μ_s and b are taken from simple shear tests of the same DEM disks in Koval et al. (2009). It is observed that the NGF model correctly captures all data points from the DEM simulations. Contrary to the local model, NGF captures all the low-I data, which does not converge on a single μ vs. I curve.

5   Steady Flows

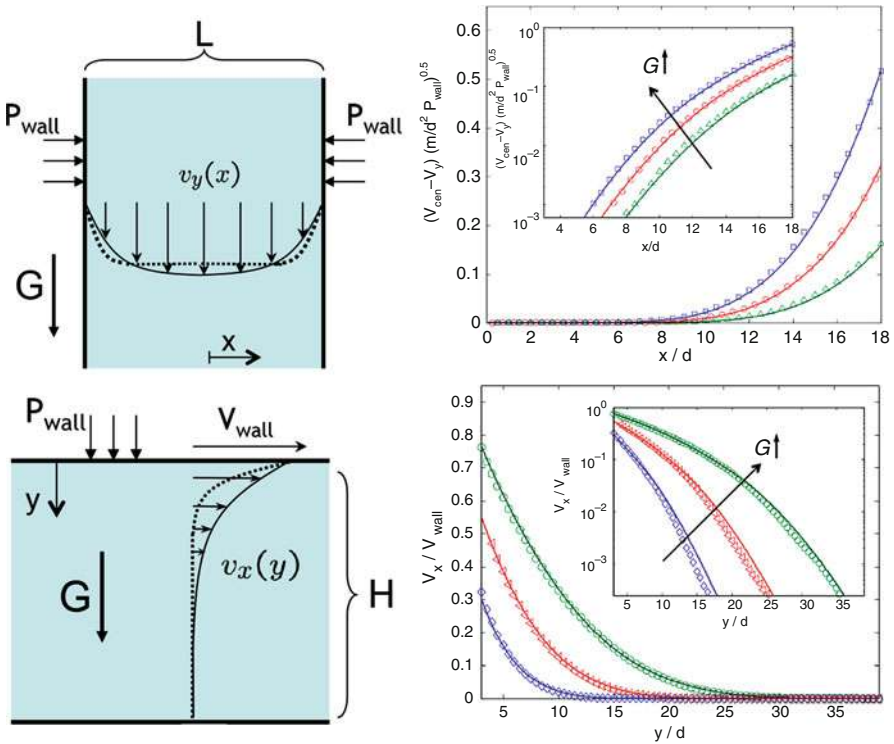
In light of the rheological check above, we conducted robustness tests to see how well this same model predicts motion of the same material in different geometries. Using the DEM disk material from before, we conducted tests of flow down a vertical chute and shear flow in the presence of gravity (Kamrin and Koval 2012). In both geometries, the gravity G is varied through several values. Results are shown in Fig. 2. It can be seen that the NGF model predicts the steady flow field correctly over several orders of magnitude without any model recalibration. Of note it captures the exponential-type decay of the fields and correctly finds that there are *no* regions where the flow rate is zero; however small it may get, it is nonvanishing *everywhere* as long as flow exists *somewhere*. This is in contrast to the inertial rheology which predicts sharp flow cutoffs.


Fig. 2 (Top) (left) Chute flow geometry (gravity G indicated). Dotted line shows a cartoon of local model prediction with sharp flow-rate cutoffs at particular locations, unlike typical observations (solid line). (right) Direct flow field comparisons (measured relative to velocity at $x = 0$). Symbols are DEM solutions; lines are corresponding solutions to NGF model. In axis, m is the mean particle mass. Inset in semilog to highlight slow flowing areas. (Bottom) Same but for shearing with gravity present. (Images modified from Kamrin and Koval 2012; Henann and Kamrin 2013, 2014a, and Zhang and Kamrin 2017).

With verification that the model correctly predicts 2D flows in discrete simulations, we move on to show the same model predicts 3D flows in real experiments. We extend the scalar form of the model to a general form by presuming codirectionality of the stress deviator and the strain-rate tensor, which is a relatively good approximation in developed flows of simple grains (Koval et al. 2009; Rycroft et al. 2009; Weinhart et al. 2012; Henann and Kamrin 2013). If we also presume the rate of change of free volume has vanished at steady state, we obtain the following system:

$$\boldsymbol{\sigma} = -P\mathbf{1} + 2\frac{P}{g}\mathbf{D} \qquad \text{stress constitutive relation} \qquad (9)$$

$$\mathrm{tr}(\mathbf{D}) = 0 \qquad \text{constant-volume constraint} \qquad (10)$$

$$g = g_{\mathrm{loc}}(\mu, P) + \xi^2 \nabla^2 g \qquad \text{nonlocal rheology} \qquad (11)$$

where $\mathbf{D}$ is the deformation-rate tensor, $\boldsymbol{\sigma}$ is the Cauchy stress, and μ and P are now defined from stress invariants: $P = -\mathrm{tr}\boldsymbol{\sigma}/3$, $\tau = \sqrt{\sigma' : \sigma'/2}$, and $\mu = \tau/P$. Here, $'$ denotes the deviator. The function for the length scale ξ carries the same definition as before, though now its arguments are defined from these stress invariants. Coupling the above to the standard equations of momentum balance closes the system.

To test the 3D model, we simulate flows in a "split-bottom Couette" cell (Fenistein and van Hecke 2003). This geometry, pictured in Fig. 3, was chosen primarily because no existing continuum model had correctly predicted its flow fields; it is a notorious benchmark case (Dijksman and van Hecke 2010). The geometry is essentially an annular trough whose floor is split along a circle. Grains fill the trough and are set into motion by rotating the outer part of the trough with respect to the inner. The tantalizing observation in this geometry is that the flow field on the free surface is amazingly close to an error function as long as the fill height is relatively shallow. That is, the surface flow field $\omega = v_\theta / r$ fits almost exactly to

$$\omega(\lambda) = \frac{1}{2} + \frac{1}{2}\mathrm{erf}(\lambda), \quad \lambda = \frac{r - R_c}{W} \qquad (12)$$

where R_c is the shear-zone center and W is the shear-zone width. It is observed that as filling height H increases, R_c shrinks and W grows, but the error-function shape is robust.

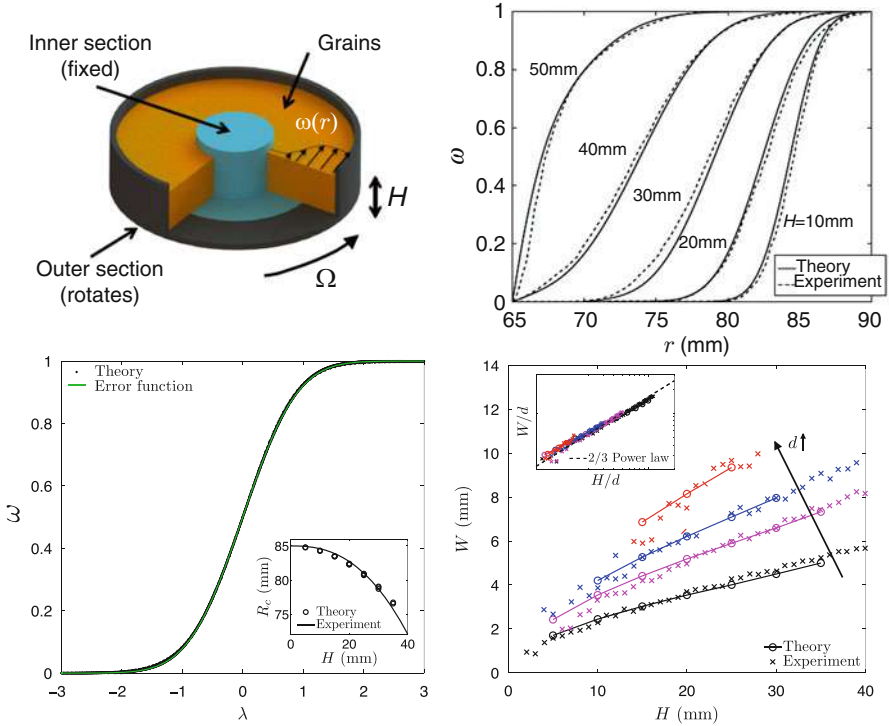
To simulate the NGF model in 3D, a user element routine in Abaqus was written (Henann and Kamrin 2016), with Neumann boundary conditions on the g field. As for material parameters, we consider only experiments that used glass beads and surmise a value of $A = 0.48$ this material. The other material constants (μ_s and b) are taken directly from the literature on simple shear of glass beads (Jop et al. 2005). As can be seen in Fig. 3, the NGF model captures the experimental flow data very well. It concurs in the way that smaller fill heights H produce thinner shear zones on the free surface and the shear-band center moves inward as H increases. Figure 3 also shows data from 20 simulated flows, varying H and d in the NGF


Fig. 3 (Top left) The split-bottom Couette geometry and free-surface flow field $\omega(r)$. (Top right) Comparison of the flow fields of 0.35 mm glass beads to solutions of a single calibration of NGF. (Bottom left) Twenty combinations of H and d reveal a universal error-function shape predicted by NGF (dust of black dots). Inset shows model captures shear-zone center as well. (Bottom right) Model captures correct interrelationship between W, H, and d compared to over 150 experimental measurements. (Images modified from Kamrin and Koval 2012; Henann and Kamrin 2013, 2014a, and Zhang and Kamrin 2017)

model, within the shallow range. When the output data is rescaled in terms of R_c and W, we see that in fact every flow curve is an almost exact error function.

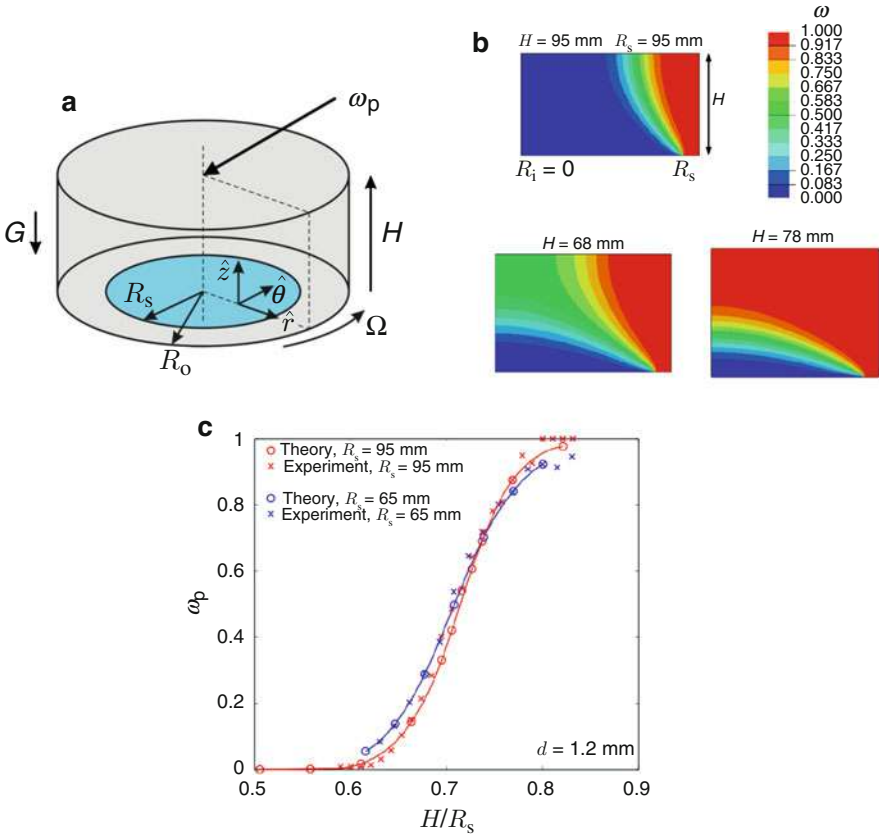
We note that the split-bottom geometry brings about a complex interrelationship between three important lengths: the grain size d, the fill height H, and the shear-zone width at the free surface W. A stringent test of the NGF model is to check if it correctly captures this interrelationship. Figure 3, bottom right, shows data from over 150 experiments of glass beads in a split-bottom cell, varying d and H and outputting the resulting W (Fenistein et al. 2004). The NGF model reproduces the behavior very well, showing that it captures the subtle way in which the various lengths in the problem affect the length scales of the flow field. While this process of flow going from a Heaviside solution on the floor to an error function at the free surface may resemble "diffusion," experiments reveal the power law between H and W is closer to 2/3 than a diffusive 1/2. The NGF model concurs that the power law is about 2/3 (see inset).


Fig. 4 (**a**) Schematic of the modified split-bottom cell. (**b**) Finite-element results of the NGF model in the rz-plane. Revolution rate ω shown. (**c**) Experiment (Fenistein et al. 2006) vs. NGF prediction for ω_P for two different modified split cells. (Images modified from Henann and Kamrin 2013, 2014a)

After the initial experimental results in the split-bottom Couette cell, modified split-bottom experiments were conducted where the inner wall was completely removed (see Fig. 4a) so that deeper layers could be studied without the flow field being interrupted by the inner wall (Fenistein et al. 2006). A wide transition in the flow behavior occurs as H increases – when H is still rather small, the flow looks like that of a standard split-bottom cell (Fig. 4b, top) but transitions to a flow in which a dome of grains is essentially "stuck" on the stationary platform, and the other material moves around it (Fig. 4b, right). The transition can be characterized by the normalized rotation rate, ω_P, of the grain located at the center of the free surface. Figure 4c shows experimental data of ω_P versus H for glass beads in two modified split cells, differing in the split radius R_c. The NGF model was then simulated in both these geometries, and the results are shown as well. The

predictions of the model match the experiments quite well. The fact that the model is able to sense correctly the small difference in the solution as the split radius varies is encouraging.

The same NGF model was solved in other geometries for which data on glass bead flows exist, including 3D annular shear cells, plate dragging with lateral gravity, and heap flows. The NGF model makes similarly quantitative predictions in these cases with no model recalibration (Henann and Kamrin 2013; Liu and Henann 2017).

6   Secondary Rheology

As noted in the introduction, not only is the particle length scale needed to correctly predict flow fields, but a number of unusual granular phenomena appear tied to the importance of grain size. Multiple experiments have established that when an intruder is placed in apparently quiescent material far away from zones of pronounced flow, it will move as long as *any* finite force is applied to it (Nichol et al. 2010; Reddy et al. 2011; Wandersman and Van Hecke 2014) . That is, flow *somewhere* effectively removes the yield stress *everywhere*, even in zones that appear virtually stationary. Conversely, if there is no existing "primary flow," a critical force must be exceeded to move an intruder through the grains. The term *secondary rheology* was coined to describe this effect, i.e., how the rheology of a probe changes due to the presence of a primary flow far away.

As a clear example, consider the setup shown in Fig. 5a, which was used in the experiments of Reddy et al. (2011). Here, an annular shear cell has a rod intruder dipped into the grains at some distance L from the inner wall, and a force F can be applied to it. When the inner wall is spinning, $\Omega > 0$, it creates a primary flow that is concentrated near the inner wall, and for much of the domain the grains are nearly static. When the wall is stationary, $\Omega = 0$, a critical force F_c must be applied
Fig. 5 (**a**) Schematic of the secondary rheology experiment of Reddy et al. (2011), (**b**) 2D version we consider. (Image from Henann and Kamrin 2014a)

to the rod to cause it to move. However, when the wall is moving, any force on the rod allows it to move; it translates with intermittent jerks about a robust mean speed. The mean motion of the intruder is observed to have several robust features: (i) it is rate-independent in that the speed of the rod is directly proportional to the speed of the moving wall for fixed L and F; (ii) at a fixed wall speed and L, the rod speed is exponentially dependent on the rod force (in the regime $F/F_c < 1$); (iii) the rod creeps faster when it is placed closer to the region of primary flow, i.e., smaller L. It is the fact that "close" in the third point is measured relative to grain size that we see this process as yet another manifestation of the grain-size effect, i.e., nonlocality.

In fact, through the equations of NGF, we can gain some insight into what is happening here. When the wall is stationary, the rod forcing alone must be large enough to create non-zero g_{loc} in the surrounding grains in order for non-zero fluidity to emerge in the granular material and permit rod motion. Because g_{loc} vanishes when stresses are too small, a finite critical force F_c emerges in order for rod motion to occur. However, when the inner wall is moving, the region adjacent to the inner wall has a non-zero g_{loc}, which now plays the role of a fluidity source in the NGF equation. The fluidity generated at the inner wall diffuses throughout the system, causing $g > 0$ everywhere including the region surrounding the rod. This permits rod motion under any force. The NGF PDE induces a decaying fluidity as one moves away from fluidity sources, which explains why larger L means slower rod speed, point (iii) above. The rate independence of the intruder, point (i), arises because, as previously discussed, the fluidity system reduces to a linear PDE in regions where g_{loc} vanishes. As long as the wall is slowly moving, the primary flow has $g_{loc} > 0$ only within a tiny ring about the inner wall, and the g_{loc} value is proportional to the wall speed. Hence, the fluidity field everywhere is scaled directly by the wall speed.

To check these ideas more directly, we simulated the NGF model in an analogous geometry in 2D for ease (Henann and Kamrin 2014a); see Fig. 5b. Here, instead of a rod, a rigid disk is pushed within a 2D annular cell of NGF material. As is evident in Fig. 6, all the signatures of secondary rheology emerge in solutions of the equations in this geometry. We observe the presence of a yield force F_c when the primary flow is off ($\Omega = 0$), but this critical force vanishes when the primary flow is on. We also see the rate independence of the rod motion when the primary flow is on, the exponential-type relationship relating intruder motion and intruder force, and diminishing of intruder speed as distance from the primary flow increases.

7   Fluidity Dynamics and Thin-Domain Strengthening

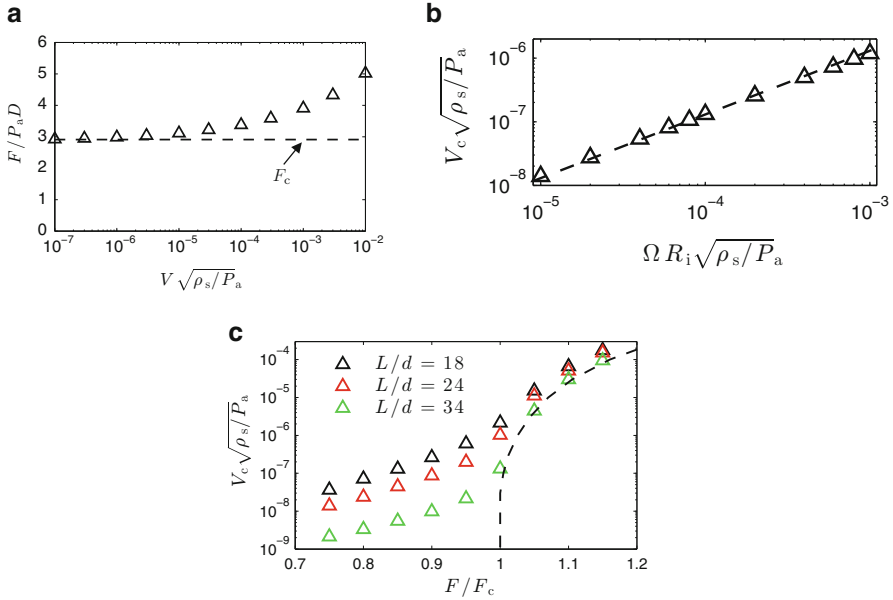
As we have noted throughout, the NGF PDE represented in Eq. 8 is for quasi-steady-state flow. As was shown in Henann and Kamrin (2014b), the steady-state system can be obtained as an approximate steady solution to a more primitive, dynamic form that describes the evolution of g through time. This dynamic form is justified thermomechanically with the aid of a virtual power argument. Like the steady-state


Fig. 6 NGF model results relating to secondary rheology. (**a**) When the inner wall is stationary, the force F on the rod must exceed a finite value F_c for any non-zero rod speed V to occur. (**b**) The rod's creep speed is proportional to the inner wall speed ΩR_i at fixed L and fixed $F < F_c$. (**c**) At fixed wall speed, an exponential-type behavior relating creep speed of the rod and rod force is observed when $F < F_c$. Rod motion decreases as L increases. Dashed line is the drag force data from part (**a**). (Images from Henann and Kamrin 2014a; Kamrin and Koval 2014)

form, the dynamic version of NGF is customized to the desired form of the local rheology; this is what the model will give in a uniform, steady, planar shear test. For example, if one desires Eq. 5 for the local response, the corresponding dynamic NGF equation is

$$t_0 \dot{g} = A^2 d^2 \nabla^2 g - (\mu_s - \mu)g - b\sqrt{\frac{\rho_s d^2}{P}}\mu g^2. \tag{13}$$

for some positive t_0, whose actual value is irrelevant to the upcoming studies. It is important to see how the above form relates to Eqs. 5 and 8 as it does not arise merely by setting the left-hand side to zero. The dynamic form above can have multiple steady solutions – note that $g = 0$ is always a solution. However, in flowing systems this is an *unstable* solution, and instead a solution with $g > 0$ emerges as time increases. So the steady-state form we have been discussing is in fact an approximate system satisfied only by the *stable* steady solutions of Eq. 13. It is arrived at as follows (more details in Henann and Kamrin (2014b)).

Let $g_{\text{hom}}(\mathbf{x}, t)$ be defined to satisfy Eq. 13 in the case of homogeneous flow. That is,

$$t_0 \dot{g}_{\text{hom}} = -(\mu_s - \mu)g_{\text{hom}} - b\sqrt{\frac{\rho_s d^2}{P}} \mu g_{\text{hom}}^2. \qquad (14)$$

Performing a fixed point analysis of this ODE reveals that when $\mu < \mu_s$, the only stable solution is $g_{\text{hom}} = 0$. In contrast, when $\mu > \mu_s$, a bifurcation occurs, and the only stable solution is $g_{\text{hom}} = \frac{\mu - \mu_s}{b\mu}\sqrt{\frac{P}{\rho_s d^2}}$. We can join these two solutions over the range of μ with the aid of the Macaulay bracket, $\langle \cdot \rangle$, giving the following general formula for the stable fixed points, g_{hom}^{ss}, of g_{hom}:

$$g_{\text{hom}}^{ss} = \frac{\langle \mu - \mu_s \rangle}{b\mu}\sqrt{\frac{P}{\rho_s d^2}}. \qquad (15)$$

We recognize this formula is precisely that of Eq. 5 for g_{loc}, which confirms that the intended local response emerges as the steady stable solution under homogeneous flow constraints.

Next, we approximate that in inhomogeneous cases at steady state, the fluidity is a small deviation away from $g_{\text{loc}} = g_{\text{hom}}^{ss}$. That is, $g = g_{\text{loc}} + \delta$ for some small δ. Wherever $\mu < \mu_s$, g_{loc} vanishes, so $g \approx \delta$ and up to first order in δ Eq. 13 becomes

$$0 = A^2 d^2 \nabla^2 \delta - (\mu_s - \mu)\delta \quad \rightarrow \quad 0 = A^2 d^2 \nabla^2 g - (\mu_s - \mu)g. \qquad (16)$$

Wherever $\mu > \mu_s$, to first order we have $g^2 = (g_{\text{loc}} + \delta)^2 \approx g_{\text{loc}}^2 + 2g_{\text{loc}}\delta = g_{\text{loc}}^2 + 2g_{\text{loc}}(g - g_{\text{loc}}) = -g_{\text{loc}}^2 + 2g_{\text{loc}}g$, and thus Eq. 13 becomes

$$0 = A^2 d^2 \nabla^2 g - (\mu_s - \mu)g - b\sqrt{\frac{\rho_s d^2}{P}} \mu(-g_{\text{loc}}^2 + 2g_{\text{loc}}g)$$

$$= A^2 d^2 \nabla^2 g - (\mu_s - \mu)g - (\mu_s - \mu)(g_{\text{loc}} - 2g)$$

$$= A^2 d^2 \nabla^2 g - (\mu - \mu_s)(g - g_{\text{loc}}). \qquad (17)$$

Equations 16 and 17 can be put into a single relation over the range of μ:

$$0 = A^2 d^2 \nabla^2 g - |\mu - \mu_s|(g - g_{\text{loc}}) \qquad (18)$$

which we recognize to be identical to the steady NGF PDE (8) with $\xi = d\frac{A}{\sqrt{|\mu - \mu_s|}}$ as claimed previously.

The approximations made in deriving the steady form, Eq. 8, from Eq. 13 are important to recognize. One interesting problem area for which the approximations do not hold is that of thin-body strengthening. In this case, bodies that are thin can experience μ significantly greater than μ_s and not flow, corresponding to a situation where g_{loc} is rather large but $g = 0$. This violates the small δ assumption of the

$g \approx g_{\text{loc}} + \delta$ approximation. This fact is of no concern, since we can instead use the more primitive, dynamic form to address these cases. We will do so now.

The specific problem we will consider is the well-known "H_{stop} effect" (Pouliquen 1999). A layer of grains of thickness H on a rough planar surface will flow if tilted high enough and stop if the tilt angle is reduced. Due to static determinacy, the stress distribution in a tilted layer is fairly straightforward to compute. For Φ the packing fraction, θ the tilt angle from horizontal, and G the acceleration of gravity, one finds $\mu = \tan\theta$ and $P = \rho_s \Phi G z \cos\theta$, where z measures depth orthogonally from the free surface. Because μ is dependent solely on tilt angle, local mechanics would suggest that H has no effect on the critical angle that stops a flowing layer. However, many experiments confirm this is not the case (MiDi 2004) even while confirming the stress distribution above and a near uniform Φ. In fact, thinner layers act stronger. That is, a flowing layer at a given tilt can be made to stop by decreasing its thickness, H. The critical arrest curve that determines the thickness at which flow stops is denoted $H_{\text{stop}}(\theta)$. It is directly proportional to the grain size, which indicates that this phenomenon is a consequence of nonlocal rheological effects. It could be said that what is happening here is that for thin layers, the entire system is experiencing cooperativity with the fixed bottom boundary, which promotes diminished motion in the granular system.

Because the H dependence of the flow threshold often permits stopped flow for large μ, approaching the maximum value of $\mu_2 = \mu_s + \Delta\mu$, for added precision we use the dynamic form whose local response is Eq. 4. It is

$$t_0 \dot{g} = A^2 d^2 \nabla^2 g - \Delta\mu \frac{\mu_s - \mu}{\mu_2 - \mu} g - b \sqrt{\frac{\rho_s d^2}{P}} \mu g^2. \tag{19}$$

Because NGF does not (yet) account for hysteresis effects, it is sufficient to consider what H and θ combinations render the no-flow, $g = 0$ solution, stable in this geometry. In these cases, a layer perturbed to flow would return to a stopped solution. The $H_{\text{stop}}(\theta)$ curve represents the phase separator between the stable and unstable states. We linearize the above PDE about $g = 0$, which amounts simply to neglecting the g^2 term, leaving us with

$$t_0 \dot{g} = A^2 d^2 \nabla^2 g - \Delta\mu \frac{\mu_s - \mu}{\mu_2 - \mu} g. \tag{20}$$

Since we are interested in thin layers, where most material is near a boundary, it is more important now than before to ensure we have a precise boundary condition for g. DEM evidence from Silbert et al. (2003) suggests that at the rough floor, $z = H$, the shear rate vanishes, and near the free surface, $z = 0$, the shear-rate gradient vanishes. Because μ is spatially constant, these observations, in light of Eq. 6, suggest the correct conditions are $g(z = H) = 0$ and $\frac{\partial g}{\partial z}\big|_{z=0} = 0$. The lowest mode solution to Eq. 20 under these boundary conditions is

$$g(z, t) = C \exp\left[\left(-\frac{\pi^2 A^2 d^2}{4H^2} + \Delta\mu \frac{\tan\theta - \mu_s}{\mu_2 - \tan\theta} \right) \frac{t}{t_0} \right] \cos\left(\frac{\pi z}{2H} \right). \tag{21}$$

for arbitrary C. Based on the sign of the term in the exponential, we see that a perturbed layer solidifies, i.e., returns to $g = 0$, if

$$H < \frac{\pi A d}{2} \sqrt{\frac{\mu_2 - \tan\theta}{\Delta\mu(\tan\theta - \mu_s)}} = H_{\text{stop}}(\theta). \tag{22}$$

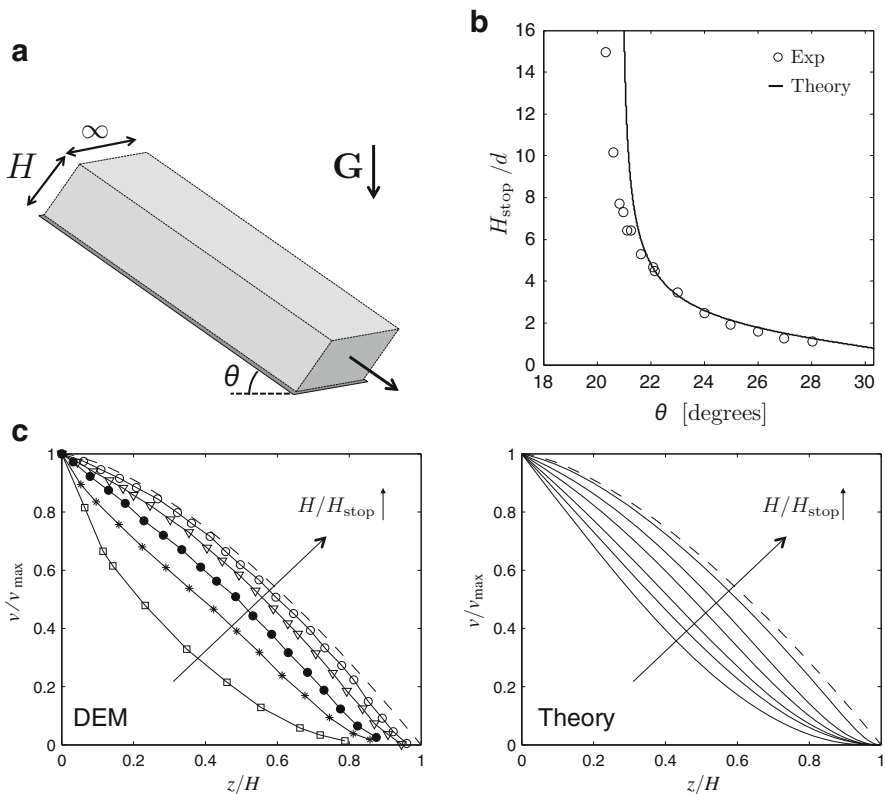
We can compare this analytical solution using the *same* model parameters as before, plus a value of μ_2 for beads from the literature Jop et al. (2005). The result is shown in Fig. 7b. The model does an excellent job predicting the experimental flow stoppage curve (Kamrin and Henann 2015). The extent to which this curve is not a vertical straight line reflects the nontrivial size-dependent strengthening.


Fig. 7 (**a**) The inclined flow setup. (**b**) Theoretical vs. experimental H_{stop} curves for glass beads (Kamrin and Henann 2015; Pouliquen 1999). (**c**) The variation in flow profile shape for layers just above H_{stop} to thick layers at a common θ compared to DEM (Silbert et al. 2003). Dotted line is the solution from the local, inertial rheology, i.e., "Bagnold's profile"

Recent work in Liu and Henann (2018) has shown that the same dynamic NGF model correctly predicts grain-size-dependent flow thresholds in other geometries, including vertical chutes, shear flows with gravity, and annular shear flows.

We can also numerically run Eq. 19 to see what the shape of the flow profiles is for values of H above H_{stop}. Figure 7c shows a comparison of solutions to a sequence of DEM data sets from Silbert et al. (2003). It is notable that the model captures the concavity switch of shallow layers to deep ones that local modeling does not capture – the dotted line indicates the solution of the local law, Eq. 4, for any H.

8   Microscopic Physics of NGF Model

There exist a number of open questions on the physics underpinning the NGF model, relating to how the model connects back to the grain-scale dynamics. However, progress has been made in couple areas, which we discuss now.

8.1   Effect of Grain Information on Continuum Parameters

One issue is to seek how the NGF material parameters connect back to grain properties. There ought to be a direct correspondence between, say, the grain shape, surface friction, restitution, and stiffness and the resulting continuum model parameters, most importantly the nonlocal amplitude A.

In Kamrin and Koval (2014), a set of DEM simulations were used to determine the effect of surface friction, μ_{surf}, on the NGF continuum parameters. This was done using a sequence of DEM simulations where all other grain properties were fixed to the values used in Koval et al. (2009). The simulation produced flow fields in planar shear and in annular shear, the former is enough to determine g_{loc}, and the latter is used to determine A. Some results of the study are shown in Fig. 8. The grains used were relatively stiff disks with coefficient of restitution of 0.1% and 20% polydispersity.

Interestingly, the value of A does not appear to depend much on particle surface friction unless μ_{surf} is very small (<0.1). Over the entire range tested, A remains order one. These observations suggest the cooperativity distance of granular motion, which A essentially measures, is driven strongly by the geometry of the non-affine motion of particles densely traversing over other particles, more so than the details of the specific contact interaction.

8.2   Microscopic Meaning of the g Field

It is tempting, though not physically instructive, to state that g is defined by inverting the flow rule Eq. 6 to yield $g = \dot{\gamma}/\mu$. While this definition may be true, it confuses the *role* g plays in the flow rule with the *meaning* of g. Granted, one need not

Fig. 8 Dependence of local bulk friction coefficient μ_s and nonlocal amplitude A on particle surface friction. (Image from Kamrin and Koval 2014)
understand the meaning of g to use the NGF model as it is mathematically closed. However, a model that works ought to have a microphysical foundation, and we stipulate that in fact g is a real kinematically measurable field, which can be extracted from particle motions. The treatment of g as a kinematic state variable was implicitly presumed in the virtual power derivation of Eq. 13 (see Henann and Kamrin 2014b), where g and ∇g were both presumed to play the role of kinematic variables over which power can be expended. But this analysis does not elucidate the specific formula for g based on particle dynamics. In Zhang and Kamrin (2017), such a formula was obtained. We hypothesized that two inputs that should influence the flow susceptibility are the packing fraction Φ and the velocity fluctuations δv of the particles about their mean velocity. It can be checked if these are sufficient to describe g by first applying a dimensional argument to produce an appropriately general function of these variables that has units of granular fluidity, inverse time. One obtains

$$g = \frac{\delta v}{d} F(\Phi) \qquad (23)$$

where F is some unknown function. To see if this form describes the g field well, we conducted numerous 3D DEM simulations of a common granular material (spherical particles) in multiple inhomogeneous flow geometries. We extracted the coarse-grained field variables δv, $g = \dot{\gamma}/\mu$, and Φ when the flows reached steady state. Plotting $gd/\delta v$ versus Φ in each case yields Fig. 9. The 20 different flows tested over 3 distinct configurations all appear to collapse onto a universal curve for the F function, which is roughly constant at low Φ but approaches 0 as Φ approaches random close packing.

By fitting F from this plot, we can use Eq. 23 to see the fluidity field spatially whenever data on particle fluctuations and packing can be obtained. For example,

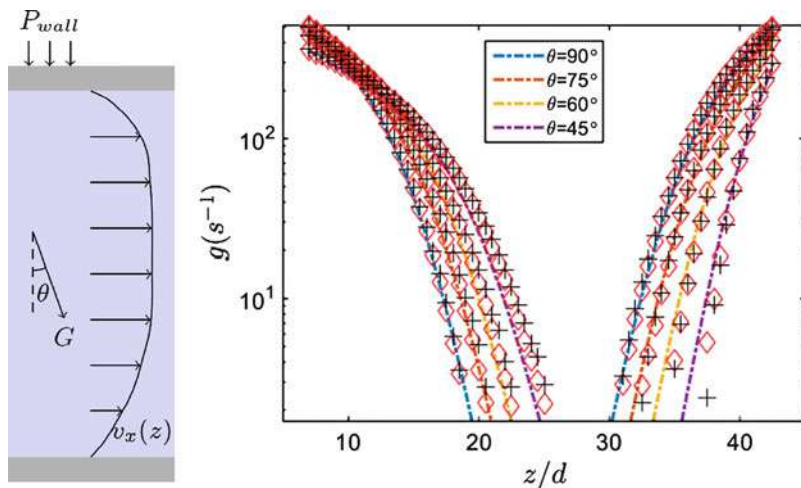
Fig. 9 Normalized fluidity $gd/\delta v$ and packing fraction Φ cross-plotted from 20 different flows in 3 different flow configurations, revealing a universal relationship. Blue line is a fit for $F(\Phi)$ used in Fig. 10. (Images from Zhang and Kamrin 2017)


Fig. 10 Comparison of three ways to define the g field in the tilted incline chute geometry for various tilt angles with respect to gravity, G. DEM results of $\dot{\gamma}/\mu$ (diamonds), steady solutions of Eq. 19 (lines), and predictions of the microscopic formula, Eq. 23 (plusses). (Image from Zhang and Kamrin 2017)

Fig. 10 shows results for a tilted double-walled chute at four different tilt angles. DEM simulations were conducted, from which the inverted flow rule definition of the fluidity field $g = \dot{\gamma}/\mu$ can be extracted and plotted as a function of space. This was compared to two other ways to obtain the steady g field: by solving Eq. 19 to steady state, and by applying the new microscopic formula, Eq. 23. As can be seen in the figure, all three ways of obtaining the g field agree with each other over a large range of g.

With this understanding in tow, we can see that the NGF model is in fact a model that tracks the evolution of this conjoined microphysical field. Since granular temperature may be defined as $T \propto \delta v^2$, one might view the NGF PDE as some variant of a heat equation, though more study is needed to make this connection. The kinetic theory of granular flows (Jenkins and Savage 1983; Jenkins and Berzi 2010) may provide useful insights toward this aim; however, there is evidence that kinetic theory hypotheses are not all well-represented in our flow data. For example, even though $g = \dot{\gamma}/\mu = \frac{\delta v}{d} F(\Phi)$ is seen to hold generally across all flows, kinetic theory would suggest that other variables such as pressure P and viscosity η should collapse as $P = P(\Phi, T)$ and $\eta = \eta(\Phi, T)$. Our data does not show a strong collapse for these variables, except in dilute zones, where $\Phi < 0.57$. Of course, dilute flows have conditions more conducive to the basic collision-based hypotheses of kinetic theory. It appears that the g field is somewhat special in its ability to continually be represented in terms of δv and Φ even in the dense regime, across various inhomogeneous flows.

9   Conclusion and Future Work

The NGF model has shown the ability to describe granular flows of simple grains down to a fairly significant level of accuracy, over a variety of different cases. The model is notable for the range of effects it captures by adding, essentially, one new term to an existing local model, which brings about only one new material parameter, the dimensionless nonlocal amplitude A. Much of the future work on this approach breaks down into three areas: (i) going beyond dense, developed flows, (ii) going beyond simple grains, and (iii) understanding more microscale physics behind the model.

Regarding (i), there are current efforts to extend the model to permit a separated phase, so grains need not stay dense-packed. This model extension is needed to simulate the falling stream of grains in silo drainage, for example, and is needed to properly model size-dependent flow stoppage in nozzles where some grains fall away leaving an arched blockage. To go beyond the well-developed flow regime, it is important to recognize that even though Eq. 19 has dynamics, we only believe these dynamics to hold when the dynamics of other internal variables, like the contact statistics of the system, have steadied out. A model that allows for a full treatment of granular transients – including volume-strength coupling like in critical state models or the evolution of internal contact anisotropy variables like a fabric tensor – would need to be coupled to the NGF system. Also, while the value of t_0 in Eq. 19 was unimportant to computing the H_{stop} curve or steady flow profiles, capturing the correct time dependence of fluidity evolution would require a deeper study of t_0.

Regarding (ii), the most important additional effect to consider is polydispersity. The current model allows a small range of polydispersity; all experiments and DEM tests used herein have had some polydispersity, not exceeding 20%, and d has represented the *mean* particle size. The reason wider polydispersity has not yet been considered is because it tends to cause granular size segregation. Once

particle size is no longer uniformly distributed, *d* becomes a function of space, and thus a separate model is needed to track the spatial evolution of *d* before NGF can be applied to give the rheology. We also need to test the model with different grain shapes. As grains become more anisotropic in shape, it is possible the fluidity diffusion term becomes anisotropic based on mean grain orientation.

Regarding (iii), it remains important to continue the effort to derive the model in full from small-scale statistical principles. Even though NGF is thermomechanically justified and has a microscopically meaningful order parameter (Henann and Kamrin 2014b; Zhang and Kamrin 2017), we recall it was proposed primarily as a practical top-down constitutive form with potential to capture a number of puzzling observations. And indeed, the model has demonstrated accuracy in flow predictions, versatility across flow geometries, and the ability to capture other particle size effects beyond the prediction of flow fields. However, connecting to a bottom-up derivation is necessary to complete the picture.

Mesoscale Mechanisms of Cement Hydration: BNG Model and Particle Simulations

9

Enrico Masoero

Contents

Abstract

Cement paste is the most widely used artificial material on Earth, causing massive CO_2 emissions. To address the problem, new chemical formulations are being explored, but these come with uncertainties around the kinetics of strength development and degradation. This kinetics is largely controlled by the precipitation of mesoporous solid phases from ionic aqueous solution. Modeling the precipitation process is a key step to understand and control the properties of future, more sustainable, cements. This manuscript starts by considering the classical boundary nucleation and growth (BNG) model of cement minerals precipitation. The mechanisms of nucleation and growth and the corresponding

E. Masoero (✉)
School of Engineering, Newcastle University, Newcastle upon Tyne, UK
e-mail: enrico.masoero@newcastle.ac.uk

parameters governing the model are discussed. The next step is to relate these mechanisms and parameters to the chemistry of the liquid and solid phases involved. This requires more fundamental models, and, to this end, nanoparticle simulations of cement mineral precipitation and morphology development are presented. These simulations are indeed shown to relate some input parameters of the BNG model to the chemistry of the paste. An outlook is finally provided, discussing some outstanding extensions of nanoparticle simulations that could deepen the current understanding of cement hydration.

1   Introduction

Hardened cement paste is the matrix of concrete, providing its binding ability and mechanical properties (Taylor 1997). With a yearly production of 2.5 billion tons, cement is the most widely used artificial material on Earth. This comes with important environmental concerns; in particular, for each ton of cement that is produced, one ton of CO_2 is released (notation: "cement" indicates the material before mixing with water; "cement paste" is cement mixed with water). On a global scale, this leads to an impressive 8% of anthropogenic CO_2 emissions being currently due to cement production alone (Olivier and Muntean 2014). Cement production is also expected to grow to more than 3.5 billion tons by 2050, which conflicts with the international target of drastically reducing greenhouse gas emissions by the same year (European Commission 2011; Scrivener et al. 2018).

Approximately 50% of cement-related CO_2 emissions are intrinsic to the chemical reactions taking place during the production of cement. This motivates research on new chemical compositions, different from today's ordinary cements (Juenger et al. 2011). New chemistries, however, entail uncertainties around controlling the temporal evolution of mechanical properties during cement hydration, viz., as the cement reacts chemically with water and the paste undergoes the "setting" transition from liquid to solid (Taylor 1997). There is hope that modeling and simulations could help predict and control the chemistry-dependent hydration kinetics of ordinary and new cements. Macroscale engineering models typically assume that the rate of hydration is a function of the microstructure of the paste, which evolves as the cement dissolves in water and new minerals precipitate. In such macroscale models, the relationship between rate and microstructure is summarized into "affinity" functions, which in principle depend on chemical composition, temperature, humidity, and other variables (Ulm and Coussy 1996). However, affinity functions are typically fitted to reproduce specific experimental results, thus not predictively linking cement chemistry with microstructural evolution and hydration rate.

This paper delves into the relationship between microstructure and hydration rate. In particular, the focus is on the first hours after mixing cement with water, when the structural features controlling hydration are at the micrometer length scale or below (Bullard et al. 2011). Section 2 provides a basic introduction to ordinary cement chemistry. Section 3 presents some typical experimental data on

the hydration rate of cement and on the concomitant evolution of pore structures at multiple length scales, from nano to macro. Section 4 presents the boundary nucleation and growth (BNG) model, widely used to relate the hydration rate to the evolving morphology of cement minerals precipitating from solution. The main assumptions and input parameters of the BNG model are discussed. Finally, Section 5 introduces nanoparticle simulations, which are a more recent and fundamental approach to modeling mineral precipitation and morphology development during cement hydration. Results from nanoparticle simulations show that the evolution of morphology and mechanical properties in a cement paste are manifestations of nanoscale processes driven by both chemical potentials and mechanical interactions. Opportunities and challenges for nanoparticle simulations to link the BNG model to the chemical composition and curing conditions of the cement paste are ultimately discussed.

2   Introduction to Ordinary Cement Chemistry

Ordinary cements are mostly made of calcium and aluminum silicates (Taylor 1997). They also contain significant amounts of other elements and impurities, leading to a very complex chemistry overall. This section will not address such complexity by contrast, only one key product of the calcium-silicate hydration is presented, alongside several chemical reactions that are necessary to contextualize the subsequent sections. Despite this simplification, the modeling techniques discussed in later sections will be generalizable to more complex chemical formulations.

The main mineral phase providing mechanical strength to ordinary cement pastes is calcium-silicate-hydrate, $(CaO)_x(SiO_2)(H_2O)_z$ (Grant et al. 2006), or simply C–S–H in cement oxide notation (where $C = CaO$, $S = SiO_2$, and $H = H_2O$). At the molecular level, water in C–S–H is partly bound as OH groups and partly adsorbed as highly confined H_2O molecules inside sub-nanometric spaces between calcium-silicate layers (Manzano et al. 2012). C–S–H is structurally heterogeneous and porous already at the scale of few nanometers; hence it is often modeled as a mesoporous agglomerate of 5–10 nm particles (Jennings 2008), leaving mesopores with characteristic width between 2 and 50 nm. These agglomerates are called "C–S–H gel." The x and z coefficients in the C–S–H formula indicate that the stoichiometry is not fixed, but it can change from one place to another within the same sample. This local composition is quantified by the calcium-to-silicon molar ratio, $x = Ca/Si$.

C–S–H forms by precipitation from aqueous ionic solution. A simple chemical reaction for this may be (Grant et al. 2006):

$$x\, Ca(OH)_2\, (aq) + H_2SiO_4\, (aq) + (z - x)\, H_2O = C{-}S{-}H + 2OH \quad (1)$$
The solution is the result of the progressive dissolution of cement powder in water. In a typical ordinary cement, the main dissolving phase during the first weeks of

hydration is tricalcium silicate, Ca_3SiO_5, or simply C_3S in cement oxide notation (Grant et al. 2006):

$$C_3S + 3H_2O + 2OH = 3Ca(OH)_2\ (aq) + H_2SiO_4\ (aq) \qquad (2)$$
Producing C_3S is a CO_2 intensive process, mostly due to the thermal decomposition of calcium carbonate forming the CaO component of the C_3S. Reducing the reliance of cementitious materials on calcium oxide is possible, but this would lead to different reacting phases and thus alter the hydration reactions, the chemical composition of the solution, and the chemical composition and structure of the hydration product, including the C–S–H. All this explains the current interest in predicting how changes to the cement chemistry would affect the formation kinetics, structure, and mechanical properties of the hydration product and in particular of the C–S–H.

3 Early Hydration Kinetics: Experimental Results

"Early hydration" indicates the collection of chemical reactions taking place during approximately the first 24 h after mixing cement with water (Taylor 1997). These reactions control the fluid-solid transition of the paste, viz., its setting; hence they are crucial for the structure and mechanical performance of the hardened paste and concrete. The hydration rate is typically measured via the heat release rate, obtained from calorimetry experiment, with the dissolution of calcium silicates being the main source of heat. Typical evolutions of early hydration rates are shown in Fig. 1a.

Three interesting features emerge from Fig. 1:

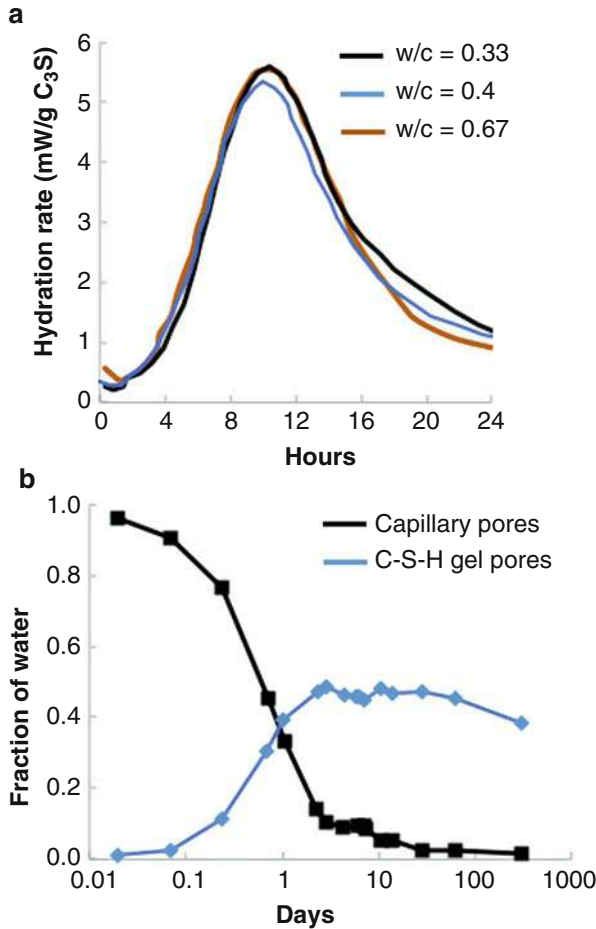
1. The reaction accelerates during the first 10 h, as shown in Fig. 1a (except for a very rapid deceleration during the first minutes (Juilland et al. 2010), which will not be discussed here). This acceleration cannot be explained only by the evolving concentrations of ions in solution. Indeed, the undersaturation of the solution with respect to C_3S increases during early hydration, due to the precipitation of calcium hydroxide (Nicoleau and Nonat 2016; Bullard et al. 2015). However, the increase in undersaturation may only explain acceleration by a factor 2–3 compared to the rate at 1 h, not the order of magnitude in Fig. 1a. The observed strong acceleration is influenced by the evolving morphology of the cement paste microstructure, as discussed later in Sect. 4.
2. The reaction starts decelerating after *ca.* 10 h (see Fig. 1a). The deceleration cannot be simply explained by the C_3S being entirely consumed: indeed, only a small fraction of the C_3S is typically consumed when the deceleration starts (Garrault et al. 2006). Neither the deceleration can be explained by C–S–H filling all the available space for precipitation in the paste, this latter being proportional to the water-to-cement molar ratio, w/c. Indeed, Fig. 1a shows that the early hydration rate, including the deceleration stage, does not depend on


Fig. 1 (**a**) Heat release rate from isothermal calorimetry of hydrating C_3S pastes, which is analogous to the hydration of ordinary cements, except faster. (Data adapted from Thomas 2007). w/c is the mass ratio between water and cement (here C_3S) in the mix. (**b**) Evolution of fraction of water in pores with different sizes, in a hydrating cement paste with $w/c = 0.4$. (Data adapted from Muller et al. 2012). Data from deconvoluted ^{1}H NMR relaxometry spectra. Gel pores have width *ca.* between 1 and 10 nm; capillary pores are larger than that

w/c. Furthermore, Fig. 1b shows that after 1 day of hydration, there is still plenty of volume associated to large pores, where new C–S–H gel can precipitate. Possible explanations of the deceleration stage will be discussed in the next sections.

3. After the first week of hydration, the volume of gel pores in the C–S–H stabilizes and even starts to decrease (see Fig. 1b). Experiments have shown that the hydration of cement can continue logarithmically (hence with decreasing rate) for years and even decades (Bažant et al. 2015). The decrease in C–S–H gel

porosity thus indicates that the gel morphology is continuously evolving at the sub-micrometer scale, and specifically that the gel is getting denser (Muller et al. 2012; Königsberger et al. 2016).

4   The BNG Model: Boundary Nucleation and Growth

Boundary nucleation and growth (BNG) is the name by which the Cahn model of heterogeneous nucleation and growth is known in the cement chemistry literature (Cahn 1956; Thomas 2007). The model provides a framework to discuss the mechanistic origin of the acceleration and deceleration stages of early hydration in Fig. 1a. The BNG model describes the precipitation of C–S–H gel domains at the micrometer length scale, under the assumption that C–S–H precipitation is the rate-controlling process during early hydration. Recently, a model similar to BNG has been used instead to describe the dissolution of C_3S during early hydration, considering this latter as the rate-controlling process (Nicoleau and Nonat 2016). Such dissolution-based models will not be presented in this manuscript, whose focus is on C–S–H precipitation only.

4.1   BNG Model Formulation

A simple way to introduce the BNG model is to start with its homogeneous counterpart: the Avrami model of nucleation and growth (Avrami 1939, 1940; Thomas 2007). The Avrami model starts with considering a unit volume of bulk solution, supersaturated with respect to the precipitation of a solid phase. Under the so-called site saturation hypothesis, a number, N_v^0 of infinitely small nuclei of solid appear at time $t = 0$ (alternative formulations assuming instead a constant nucleation rate are also available in the literature (Scherer et al. 2012)). The model is "homogeneous" in the sense that the solution is the same everywhere and the nuclei can form anywhere with identical probability. As the time increases, the radii of the nuclei (initially null) grow with constant rate G in all directions; hence the domains of precipitating C–S–H gel are represented by growing spheres. G is called "linear growth rate," because it entails radii that increase linearly with time. The last ingredient of the Avrami model is the distinction between "extended" X^e and actual X volume fractions of precipitated solid phases. $X^e(t)$ is simply the cumulative volume of all the above-defined spheres at time t divided by the initial volume of the solution at time $t = 0$. If two spheres, i and j, overlap, $X^e(t)$ double-counts the overlapped volume, considering it as pertaining to both the impinging spheres i and j. $X(t)$ corrects for the overlapping by excluding this double-counting; thus $X(t) \leq X^e(t)$ always. If the spheres are at uncorrelated random locations inside an infinitely large volume of solution, the following relationship between X and X^e holds on average:

$$X = 1 - \exp(-X^e) \qquad (3)$$

The temporal evolution of X resulting from the Avrami model is (Scherer et al. 2012):

$$X = 1 - \exp\left(-\frac{4\pi G^3 N_V^0}{3} t^3\right) \tag{4}$$

The Cahn, or BNG, model is analogous to the Avrami model, except that (i) the initial nuclei appear only on randomly distributed planar surfaces inside the unit volume of solution and (ii) the domains of solid (here C–S–H gel) grow as hemispheres starting from these nuclei, still with constant rate of radial growth G. Two sources of impingement characterize this scenario: a tangential impingement between hemispheres growing from the same planar surface and a bulk impingement between hemispheres growing from different planar surfaces. Each of these two sources of impingement introduce an exponential term akin to Eq. 3. The resulting temporal evolution of X for the BNG model is:

$$X = 1 - \exp\left\{-2O_v^B \int_0^{Gt} \left[1 - \exp\left(-\pi N_S \left(G^2 t^2 - y^2\right)\right)\right] dy\right\} \tag{5}$$

In Eq. 5, y is a spatial coordinate starting from a generic planar surface on which the nuclei lie and increasing perpendicular to the surface itself. N_S is the number of nuclei per unit surface, and O_v^B is the surface available for nucleation per unit volume of solution at time $t = 0$.

4.2 BNG Model Applied to Cement Hydration

For a cement paste, O_v^B in Eq. 5 can be expressed as follows (if one neglects the change of volume of the cement grains due to their partial dissolution during early hydration):

$$O_v^B = \frac{S_c}{V_{w,0}} = S_c \frac{wc}{\rho_w} \tag{6}$$

S_c and $V_{w,0}$ are the initial cement surface and the initial volume of water per unit mass of anhydrous cement. ρ_w is the specific weight of water, and wc is the water-to-cement mass ratio at time $t = 0$.

The volume fraction of precipitated phases, X, is related to the cumulative heat released per unit mass of initially anhydrous cement, $H(t)$, whose derivative provides rate curves as in Fig. 1:

$$H(t) = H_{0,c} \frac{MM_c}{MV_{gel}} X(t) V_{w,0} = \quad \rightarrow \quad \alpha(t) = \frac{H(t)}{H_{0,c}} = \frac{MM_c}{MV_{gel}} \cdot X(t) \frac{wc}{\rho_w} \tag{7}$$

$\alpha(t)$ is the degree of hydration, i.e., the fraction of solid C_3S that has been dissolved and converted to C–S–H at time t. $H_{0,c}$ is the heat released per unit mass of dissolving cement, viz., the reaction enthalpy: –517 J/g of C_3S for the reaction

in Eq. 2 (Costoya 2008). MM_c is the molar mass of cement, and MV_{gel} is the molar volume of the C–S–H gel. The latter depends on the gel porosity and thus on the morphology of the gel itself. Similarly to Eq. 6, also Eq. 7 neglects the change of volume of anhydrous cement dissolving during early hydration. Equation 7 also exploits the fact that each mole of precipitated C–S–H requires a mole of dissolved C_3S: see Eqs. 1 and 2. $H(t)$ is directly proportional to the degree of hydration $\alpha(t)$, which is the mass ratio between the cement that has dissolved at time t and the initial mass of anhydrous cement.

Equations 5, 6, and 7 show that the BNG model includes physical variables whose values are assigned during the preparation of the cement mix: wc, S_c, ρ_w, $H_{0,c}$, and MM_c. On the other hand, the model also relies on three parameters that are not assigned and that describe the structure and precipitation kinetics of the C–S–H gel: G, N_S, and MV_{gel}. These three parameters are typically unknown and difficult to measure; hence they are used to fit experimental data of cement hydration, e.g., those in Fig. 1. Therefore the BNG model is typically used to infer information about the structure and precipitation kinetics of the C–S–H gel (Thomas et al. 2011). On the other hand, the model per se cannot predict changes in hydration rate, precipitation kinetics, or C–S–H gel morphology that may be caused by changes in the chemical composition of the cement. Despite these limitations, the BNG model provides a useful framework to discuss some of the mechanisms that may control the early kinetics of cement hydration.

4.3   BNG Results and the Issue with the Water-to-Cement Ratio

Figure 2 shows hydration rate curves predicted by BNG simulations of a C_3S paste, where all the C_3S particles are assumed to be spherical and with same initial diameter of $7\,\mu$m. The results in Fig. 2 are obtained using a C–S–H gel growth rate $G = 0.036\,\mu$mh^{-1}, a density of C–S–H nuclei on the C_3S surface $N_S = 4\,\mu$m^{-2}, and a molar volume of the gel (including solid and gel pores) MV_{gel} $= 110\,$cm^{3}mol^{-1}: all these values are in the range of previous literature results for C_3S hydration modeled by BNG (Thomas 2007; Scherer et al. 2012; Masoero et al. 2014c).

All the curves in Fig. 2 display a strong initial acceleration, in agreement with the experimental results in Fig. 1a. In the model, the acceleration stems from the increasing surface of the hemispherical C–S–H gel domains growing from the randomly distributed C_3S surfaces. The acceleration is independent of the water-to-cement mass ratio w/c. All the curves in Fig. 2 display a peak rate at *ca.* 10 h. The peak is caused by both tangential impingement of C–S–H gel domains growing from the same C_3S surface and bulk impingement of C–S–H gel growing from different surfaces. In particular, the effect of tangential impingement is indicated by the fact that simulations with very high w/c, and therefore with negligible bulk impingement, still display a peak. On the other hand, the effect of bulk impingement is indicated by the fact that increasing the w/c leads to a large rate at its peak value, and it also shifts the hydration peak to a later time.
Fig. 2 BNG-simulated rates for C_3S pastes with different water to cement mass ratios (w/c). The specific weight and molar mass of C_3S are $\rho_c = 3150 \, \text{kg/m}^3$ and $MM_c = 228.4 \, \text{g/mol}$

The curve with w/c = 0.33 in Fig. 2 well resembles the experimental results in Fig. 1a. However, the experiments in Fig. 1a show that the w/c ratio does not affect the early hydration rate, and a similar weak effect of w/c has also been shown in experiments at much higher w/c levels than those in Fig. 1a (Garrault et al. 2006). By contrast, the BNG results in Fig. 2 predict a strong impact of w/c, both on the peak rate at *ca.* 10 h and on the post-peak deceleration. This suggests that deceleration in the experiments is not controlled by bulk impingement of C-S-H gel, which is the main post-peak deceleration mechanism in the BNG model.

One possible way to reconcile the BNG model with the weak effect of w/c on early hydration is to assume that (1) the C–S–H gel grows initially with much smaller density (viz., higher MV_{gel}) compared to the C–S–H gel in mature pastes and (2) that the density of early-age C–S–H gel is a decreasing function of the w/c. Recent analyses of experimental results from ^{1}H NMR relaxometry support these hypotheses (Königsberger et al. 2016). However, (i) it is still unclear whether the NMR results are quantitatively in agreement with hydration data; (ii) the lack of w/c dependence in samples hydrating at very high w/c, e.g., 50 or more (Garrault et al. 2006), would imply extremely and unlikely low C–S–H densities; and (iii) the possible physical origin of a w/c-dependent C–S–H gel density is not understood.

Another possible hypothesis to remove w/c dependence from the results of BNG simulations is to assume that early C–S–H precipitation occurs only within a "reaction zone," which is a limited distance from the surface of the cement grains (Masoero et al. 2014c). BNG simulations have shown that the size of this reaction zone would be between 0.4 and 1 μm, which is in the same range as the size of C–S–H gel domains observed experimentally after early hydration (Masoero et al. 2014c; Garrault et al. 2006). However, a mechanistic explanation for such a reaction zone has not been provided yet. The next section shows that the evolving

concentrations of calcium and silicon ions in the cement solution may provide an explanation for the deceleration and thus a mechanistic explanation of the reaction zone hypothesis.

4.4   Chemical Drive for Deceleration in the BNG Model

The BNG model can predict early deceleration without invoking bulk impingement of C–S–H domains, if one considers that the linear growth rate G depends on the evolving chemical composition of the cement solution. Recently, Bullard et al. (2015) implemented this concept into the BNG model by taking:

$$G = G_0 \left[\beta_{CSH}(t) - 1\right] \qquad (8)$$

G_0 is a constant and β_{CSH} is the supersaturation of the cement solution with respect to C–S–H precipitation (Eq. 1). The linear relationship between G and β in Eq. 8 is consistent with linear transition state theory (Lasaga 2014).

β_{CSH} is a function of the concentrations of ions in solution; hence G changes in time following the evolution of these concentrations. Using cellular automaton (CA) simulations, Bullard et al. (2015) modeled the dissolution, diffusion, and precipitation reactions taking place during the early hydration of a high-w/c C$_3$S paste, obtaining the $\beta_{CSH}(t)$ curves in Fig. 3a. The figure highlights the effect of varying a so-called opacity parameter in the CA simulations. This opacity is an empirical parameter associated with the domains of precipitated C–S–H gel in the CA simulations and is related to the inverse of the C–S–H gel permeability. A high opacity means that the precipitated C–S–H gel creates a diffusion barrier between the dissolving C$_3$S grains and the bulk cement solution, leading to lower concentrations of ions in solution and thus a lower β_{CSH} (and G) during the early hydration, as shown in Fig. 3a.

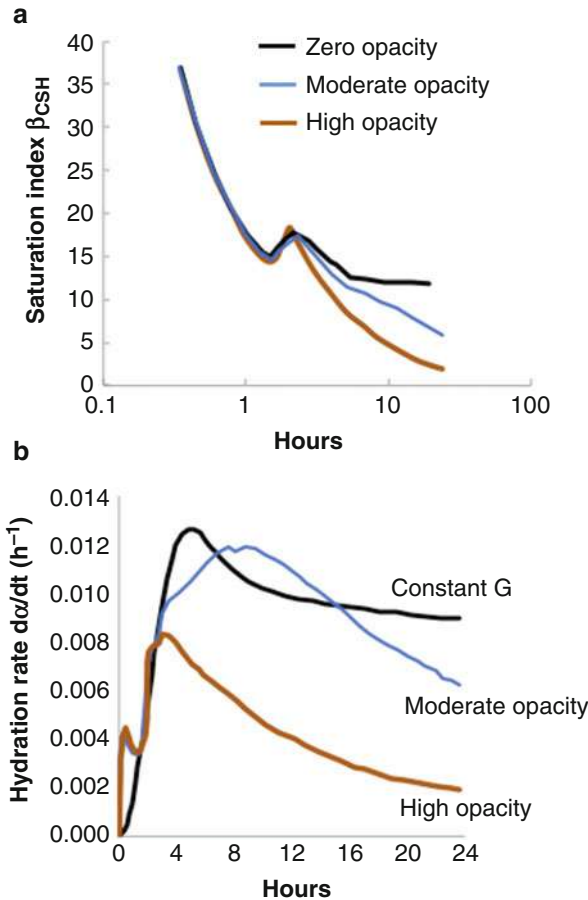
Combining the $\beta_{CSH}(t)$ curves in Fig. 3a with the β-dependent expression of G in Eq. 8, the BNG model leads to the hydration rate curves in Fig. 3b. The curve assuming a constant G, independent of β_{CSH}, is qualitatively similar to the high-w/c curves in Fig. 2, which captures qualitatively well the experiments (e.g., in Fig. 1a) during the acceleration stage but then significantly differs from the experiments at the rate peak and beyond. The curves in Fig. 3b assuming β-dependent G show an initial acceleration that is similar to the case with constant G, except for an initial spike at time $t \approx 0$, which is due to β_{CSH} in Fig. 3a starting very high and then decaying exponentially fast during the first minutes of hydration. Acceleration up to the main hydration peak is still due to the hemispherical growth of C–S–H gel domains. The solution supersaturation becomes important at the hydration peak: Fig. 3a shows that the maximum rate at the peak is indeed an increasing function of β_{CSH}, which is smaller when the opacity is assumed to be high. Past the peak, the deceleration displayed by the β-dependent curves in Fig. 3b is caused by the continuous decrease of β_{CSH} during early hydration. In this way, the BNG model with β-dependent linear growth rate G is effectively uncoupling deceleration from bulk impingement of C–S–H gel. This allows for BNG simulations of pastes with high w/c to still display deceleration, in line with the experiments.


Fig. 3 (**a**) Temporal evolution of C_3S solution supersaturation with respect to C–S–H precipitation: results from cellular automata simulations assuming different levels of C–S–H "opacity" (Bullard et al. 2015). This opacity is an empirical parameter quantifying the difficulty for ions to diffuse through domains of C–S–H gel: see the main text for further discussion. (**b**) BNG simulation results for the hydration of a C_3S paste with high w/c: effect of the relationship between G and β_{CSH} from panel (**a**). (All data in this figure are adapted from Bullard et al. 2015)

5   Nanoparticle Simulations at the Nano-to-Micro Mesoscale

The previous section has shown that if a BNG model accounts for the dependence of the precipitation kinetics on the supersaturation of the solution, the resulting calculations capture both morphology-driven acceleration and w/c-independent deceleration during cement early hydration. However BNG per se can only be used to fit experimental results and not to predict the hydration of new cements. The cause of this limitation is that BNG models rely on four parameters to describe the precipitation kinetics and morphology of the C–S–H gel. These parameters are the linear growth rate of the gel (G), the number of C–S–H nuclei per unit surface

of C_3S (N_S), the molar volume of the gel (MV_{gel}), and the "opacity" of the gel with regard to ion diffusion. Quantifying these parameters as functions of cement chemical composition and curing conditions is difficult. A possible way to address this task is to couple BNG with other models describing the chemo-mechanics of C–S–H precipitation at smaller length scales. Such models must therefore address the mesoscale between the nanometer of chemical reactions and the micrometer above which the gel can be considered as a homogeneous phase in BNG. This is the mesoscale at which the porous morphology of the C–S–H gel develops. In the past decade, nanoparticle simulations have emerged as a possible framework for mesoscale models of C–S–H precipitation (Del Gado et al. 2014; Ioannidou et al. 2016).

5.1 Monte Carlo Insertion and Aggregation of Nanoparticles

Nanoparticle simulations of C–S–H gel precipitation are based on two processes: (i) inserting new particles into a simulation box, to model the precipitation of solid C–S–H nano-units, and (ii) rearranging the particles to minimize the free energy of the system between subsequent particle insertions (Masoero et al. 2012). Both these processes depend on energy contributions coming from interaction potentials, which generate interaction forces between the particles.

5.1.1 Interaction Potentials for C–S–H

The most common interaction potentials in nanoparticle simulations of C–S–H gel precipitation are pairwise, spherical, single-well, or well-shoulder potentials. The main energy well, defining the equilibrium distance between two particles, is typically described by a Lennard-Jones term or by a more general Mie term (Masoero et al. 2012; Ioannidou et al. 2014) (viz., a Lennard-Jones-like potential with exponents that may differ from the usual 12–6 (Mie 1903)). The depth of the energy well ε_0, viz., the interaction strength, is usually particle size dependent (Masoero et al. 2014a). Concerning the magnitude of ε_0 for C–S–H, three options have been proposed thus far (the values below are for particles with a 10 nm diameter):

- Weak interactions, mostly electrostatic, experimentally measured by atomic force microscopy indentation (Plassard et al. 2005). These led to well-shoulder potentials with ε_0 in the 200–500 $k_B T$ range, depending on the concentration of calcium ions in solution (Ioannidou et al. 2014). Interactions of this type imply that C–S–H nanoparticles are not covalently bonded.
- Strong interactions, with ε_0 being the energy to separate two covalently bonded C–S–H particles. This leads to $\varepsilon_0 \approx 19{,}000$ $k_B T$, which includes the strain energy inside the particles that are being separated (Masoero et al. 2014b). These interactions capture the experimentally measured mechanical properties of the C–S–H gel, but they overestimate the changes of interaction energy during precipitation.

- Intermediate interactions, with $\varepsilon_0 \approx 1{,}100 \ k_B T$ linearly related to the surface energy of the C–S–H. The rationale is that two particles at their equilibrium distance have no interface between them (Shvab et al. 2017). In this way, the C–S–H gel is effectively considered as a porous continuum, albeit modeled as an agglomerate of nanoparticles, as opposite to the case of weak electrostatic interactions above.

The weak and intermediate interactions above have ε_0 in the same order of magnitude. To date, they are the most appropriate ones to describe interactions during cement early hydration. However, these interactions underestimate the mechanical properties of the C–S–H gel by at least one order of magnitude (Ioannidou et al. 2016) when compared to experimental measurements from nanoindentation (e.g., Constantinides and Ulm 2007). Future improved formulations of interaction potentials should combine a weak/intermediate ε_0 during precipitation, with strong interactions when the system is mechanically deformed. This would require history-dependent interactions, because two particles at a given distance from each other may represent either incomplete contact during precipitation (weak interaction) or two coalesced particles under strain (strong interaction). History-dependent interactions are yet to be addressed in nanoparticle simulations of C–S–H precipitation.

Another challenge is orientation-dependent interactions. At the molecular level, C–S–H is an anisotropic, layered material (Taylor 1997). This anisotropy contributes to the variety of morphologies that the C–S–H gel can display at the micrometer level, e.g., granular, fibrillar, or foil-like, depending on the ionic strength of the cement solution (Richardson 2008; Tajuelo Rodriguez et al. 2015). Orientation-dependent Gay-Berne interactions have been proposed to obtain complex morphologies in particle simulations, but their use is still limited (Yu and Lau 2015).

Finally, one should note that all the interactions in this section have $\varepsilon_0 \gg k_B T$: this will become a problem for the Monte Carlo particle insertion procedure discussed hereafter.

5.1.2   Monte Carlo Particle Insertions and Deletions

Monte Carlo simulations of C–S–H precipitation define probabilities to decide whether to insert a new particle with assigned diameter at a certain random location in the simulation box (P^{in}) or to delete a randomly selected particle (P^{del}) (Frenkel and Smit 2002; Masoero et al. 2012). Typical formulations for these probabilities are:

$$P^{in} = \min\left[1 \ , \ \Psi \exp\left(\frac{\mu - \Delta U}{k_B T}\right)\right] = \min\left[1 \ , \ \Psi \beta_{CSH} \exp\left(-\frac{\Delta U}{k_B T}\right)\right] \quad (9)$$

$$P^{del} = \min\left[1 \ , \ \Psi \exp\left(-\frac{\Delta U}{k_B T}\right)\right] \quad (10)$$

ΔU is the change in total interaction energy caused by the insertion or deletion event. μ is the chemical potential of the solution with regard to C–S–H precipitation,

which is related to the supersaturation β_{CSH} (Lasaga 2014). $\Psi < 1$ is an arbitrary positive constant controlling the quality of the sampling of possible locations for particle insertion and of possible particle deletions. Small Ψ imply that the Monte Carlo algorithm will attempt many possible insertions and deletions before accepting an event: this leads to time-consuming simulations resulting however into more stable configurations (viz., configurations with lower total interaction energy) compared to simulations with large Ψ. Vice versa, large Ψ lead to faster simulations but also favor metastable configurations.

Both cases of small and large Ψ are problematic. Starting with the case of large Ψ, e.g., $\Psi = 1$, the energy scale $\varepsilon_0 \gg k_B T$ discussed in the previous section implies that particle insertion at any location (not overlapping with other existing particles) has $P^{in} = 1$, because $\beta_{CSH} > 1$ during early hydration (Fig. 3a), $\Delta U < 0$ in Lennard-Jones like potentials, and ΔU is scaled by a large ε_0. Vice versa, deleting an existing particle implies $\Delta U > 0$, and this, scaled by a large ε_0, gives $P^{del} \approx 0$. In this case, the simulation reduces to random space filling (Masoero et al. 2014a). This becomes an issue when one tries to capture a BNG process using nanoparticle simulations. To understand why, consider an empty simulation box containing only a surface made of particles representing C_3S, and assume that the interaction potential between a C_3S particle and the C–S–H particles to be inserted is similar to the interaction potential between two C–S–H particles. In principle, new C–S–H particles should have a higher probability to form near the C_3S surface, but in practice any location for insertion has $P^{in} = 1$ due to the large Ψ. Therefore, one can only capture mechanisms of homogeneous nucleation using Monte Carlo simulations of particle insertion and deletion with large Ψ.

At the other end, simulations with a very small $\Psi \ll 1$ and with monodisperse C–S–H particles (viz., diameter fixed to a single possible value, typically around 5–10 nm Allen et al. 2007) would indeed predict a BNG-like mechanism in the scenario described in the previous paragraph. In this case, what BNG models call "growth" is actually the product of subsequent aggregations of new C–S–H particles forming nearby the previously inserted ones. On the other hand, simulation with $\Psi \ll 1$ are problematic when the C–S–H particles are allowed to have diameters within a certain range, viz., if size polydispersity is considered. In this case, the proportionality between ε_0 and the particle size (e.g., with the particle surface, as discussed in Sect. 5.1.1) implies that large particles have higher P^{in} as long as there is space to insert term with $\Delta U < 0$, i.e., not overlapping with other particles. In the extreme case of $\Psi \rightarrow 0$ and infinite particle size polydispersity (i.e., newly inserted particles can have diameter ranging from 0 to the size of the simulation box), the first particle to be inserted would be the largest possible one, thus as large as the simulation box. This is indeed the correct answer for a Monte Carlo algorithm whose target is to find the lowest-energy state. This is also realistic for C–S–H, in the sense that in the limit of time tending to infinity, a fully crystallized single domain of C–S–H is the most thermodynamically stable state. On the other hand, this thermodynamic limit bears only limited relevance to the process of C–S–H precipitation and morphology development during cement early hydration (Del Gado et al. 2015).

In conclusion to this section, Monte Carlo simulations of particle insertion/deletion using the probabilities in Eqs. 9 and 10 lead to unrealistic or irrelevant mesoscale mechanisms of C–S–H precipitation, in the limits of $\Psi \to 0$ and $\Psi \to 1$. More realistic configurations, able to capture various experimentally observed structural and mechanical features of the C–S–H gel (Ioannidou et al. 2016), can be enforced by using intermediate values of Ψ, or restricting the range of possible particle sizes, or alternating steps of particle insertion/deletion with multiple steps of particles displacement (not discussed here but explored in the literature, e.g., in Ioannidou et al. 2014). In these cases, however, one should always remember that the sequence of Monte Carlo moves going from an initially empty simulation box to a final C–S–H gel morphology bears no physical information about the actual kinetics of the precipitation process. The only rigorous results of these Monte Carlo simulations are the final morphologies and configurations that they produce, not their temporal evolution during hydration.

5.2   Chemical Kinetics and Kinetic Monte Carlo

The limitations of Monte Carlo simulations with regard to describing realistic kinetics of precipitation can be overcome using kinetic Monte Carlo (KMC) (Voter 2007). In KMC simulations, the probability of inserting a particle is (only insertions are discussed in this section, but the same concepts apply to particle deletions):

$$P^{in} = \frac{R^{in}}{Q} \tag{11}$$

where R^{in} is the rate of the average insertion event at the selected location and Q is a normalizing constant. R^{in} can be expressed starting from fundamental concepts of chemical kinetics, as shown later in this section. Q plays a similar role as the inverse of Ψ in Eqs. 9 and 10, but differently from Ψ, it is not arbitrary and is defined as the sum of the rates of all the possible events. Furthermore, Q is related to the average waiting time for an event; hence KMC generates a proper temporal evolution of the system, differently from the previously discussed Monte Carlo simulations, which did not have a timescale.

Akin to P^{in} in Eq. 9, the position-dependent insertion rate R^{in} depends on both the chemical drive for precipitation, β_{CSH}, and on the interaction free energy ΔU. However, differently from P^{in}, the dependence on ΔU is not simply $\exp[-\Delta U)/(k_B T)]$, but a more complex expression that accounts for the size of the particle to be inserted. A physically sound expression of this dependence of R^{in} on ΔU avoids the issue of large particles appearing before small ones in the simulations. A recently proposed derivation of R^{in} by Shvab et al. (2017) is presented hereafter.

To express R^{in}, one must consider that a particle insertion is actually a coarse-grained representation of n chemical reactions taking place at the molecular scale. For example, forming a C–S–H nanoparticle with a diameter of 10 nm implies

ca. 1,000 chemical reactions of C–S–H precipitations as per Eq. 1. The rate of an individual chemical reaction, r_i, is the building block of R^{in}. Following transition state theory, one can write:

$$r_i = \frac{k_B T}{h} \frac{1}{\gamma^*} \beta_{CSH} \ \exp\left[-\frac{\Delta G^* + \chi(\gamma \Delta \Omega_i + \Delta U_i)}{k_B T} \right] \tag{12}$$

h is the Planck constant. γ^* and ΔG^* are the standard state activity coefficient and activation energy of the transition state associated with the chemical reaction. γ is the solid-solution interfacial energy. $\Delta \Omega_i$ and ΔU_i are the changes in particle surface area and total interaction potential caused by the ith chemical reaction during particle formation. χ is a number between 0 and 1, quantifying the contribution of $\Delta \Omega_i$ and ΔU_i to the precipitation rate (see Shvab et al. 2017 for more details).

To go from r_i in Eq. 12 to the coarse-grained R^{in}, one must describe the spatially resolved mechanism by which the molecules assemble to form a particle. Various classical and nonclassical mechanisms are employed today across the field of chemical kinetics (Van Driessche et al. 2017). For C–S–H, Shvab et al. (2017) have recently obtained an expression for R^{in} under the assumptions that one-molecular C–S–H nuclei are always present in the cement solution with fixed concentration C_{cn} and that their growth into particles follows a classical mechanism of layer-by-layer radial growth. For interactions with $\varepsilon_0 \sim \Omega$, where Ω is the particle surface area, this leads to:

$$R^{in} = k r_0^* \beta_{CSH} \ a^2 \left\{ \sum_{i=1}^{n} \exp\left[\chi \left(\frac{\gamma_i + \frac{\Delta U^{in}}{\Omega}}{k_B T} \right) \frac{8a^2 i}{(2i-1)^2} \right] \right\}^{-1} \tag{13}$$

k is a constant that depends: on the algorithm to sample the possible positions for particle insertion, on C_{cn}, and on the solid volume fraction in the surrounding of the location chosen to attempt the insertion. $r_0^* = \frac{k_B T}{h} \frac{1}{\gamma^*} \exp\left(-\frac{\Delta G^*}{k_B T}\right)$ is the reaction rate in standard state. a is the characteristic linear size of a molecule, *ca.* 0.67 nm for C–S–H. n is the number of reactions taking place in series: for the classical layer-by-layer growth mechanisms, n is equal to the particle radius divided by a. Similar to P^{in} Eq. 9, also R^{in} in Eq. 13 depends linearly on β_{CSH} and exponentially on ΔU. However, ΔU in R^{in} is divided by Ω, and this ratio is independent of the particle size (because Eq. 13 is based on the assumption that $\Delta U \sim \Omega$). Furthermore, R^{in} is inversely related to n, which is a measure of the particle size; hence large particles will have smaller R^{in} than small particles, as is realistic to expect.

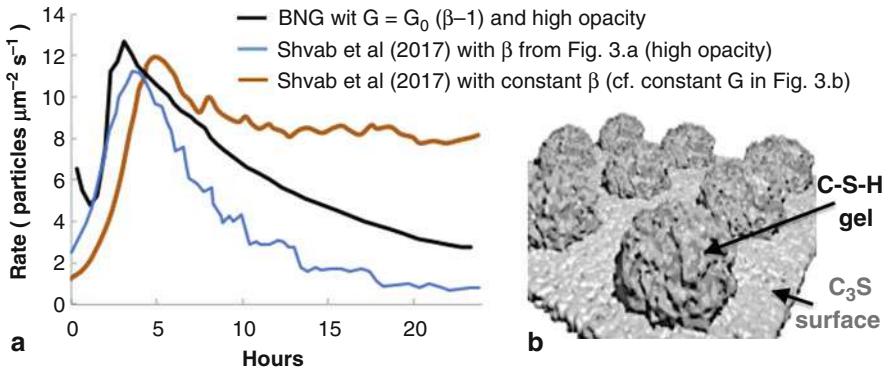
Figure 4 shows results from KMC simulations of C–S–H precipitation, which employ R^{in} from Eq. 13 and a similarly defined rate for particle deletion (see Shvab et al. 2017). All the parameters in R^{in} have been taken from the literature on C–S–H, except for two of them: r_0^*, which is assumed to be constant and calibrated to capture the correct timescale, and the interaction strength (75% of ε_0) between C–S–H particles and the particles forming the C_3S surface. Depending on the simulation, β_{CSH} was assumed to either be constant or to change in time as shown


Fig. 4 (**a**) Hydration rate curves from BNG and from KMC simulations: effect of β (**b**) Snapshot from a KMC simulation showing a BNG mechanism emerging from particle insertion and aggregation. (Data adapted from Bullard et al. 2015 and from Shvab et al. 2017)

in Fig. 2a. The curves in Fig. 4a are consistent with the BNG results in Fig. 2b, in that the acceleration stage is weakly affected by β_{CSH} and is instead governed by the morphological evolution of the hemispherical domains of C–S–H gel (see Fig. 4b) and that the deceleration stage is controlled by the decrease of $\beta_{CSH}(t)$ during hydration.

5.3 Insights into BNG Parameters from Nanoparticle Simulations

Nanoparticle KMC simulations provide a more fundamental insight into the four free parameters of BNG (see introduction to Sect. 5), also linking them to the chemistry of the cement paste.

- The linear growth rate G can be read directly from a nanoparticle simulation by looking at the time derivative of the radius of the hemispherical domains in Fig. 4b. G depends on all the quantities contributing to R^{in} in Eq. 13: this also entails the linear dependence on β_{CSH} already included in recent BNG simulations. Furthermore, Eq. 13 shows that R^{in} and thus G are functions of other chemistry-dependent quantities such as the standard state rate r_0^*, the solid-solution interfacial energy γ, and the interaction potentials. Finally, since the hemispherical gel domains in Fig. 4b include pores between the particles, G also depends on the gel morphology (e.g., its porosity) which depends in turn on the interaction potentials and again on the material's chemistry.
- The number of nuclei N_S per unit surface of C$_3$S depends on the interaction strength between C–S–H and C$_3$S and thus also on their interfacial energy. However, N_S depends also on the morphology and roughness of the C$_3$S surface, as well as on the presence of crystallographic or chemical defects that may locally

    increase the surface energy or the strain energy of the C_3S. KMC nanoparticle simulations can be used to explore the impact of these factors on N_S.

- The molar volume of the C–S–H gel MV_{gel} depends on the porosity and thus on the morphology of the agglomerates in Fig. 4b. There is significant scope for nanoparticle simulations to relate the emergence of complex morphologies to the functional form and chemistry dependence of the interactions between particles.
- The "opacity" of the C–S–H gel is also related to the pore structure and morphology of the C–S–H particle agglomerates in Fig. 4b. Coupling nanoparticle simulations with simulations of ion diffusion through the C–S–H gel, e.g., Lattice-Boltzmann simulations (Zalzale 2014; Patel 2016), would help with rigorously defining and quantifying the opacity parameter.

6   Conclusion

Boundary nucleation and growth (BNG) models predict an acceleration of the rate of C–S–H formation that is consistent with the acceleration of cement early hydration rate measured by isothermal calorimetry. However, BNG models also predict that the water-to-cement ratio of a cement paste should have a significant impact on the early hydration rate: this prediction disagrees with the experimental evidence. This issue can be overcome by considering a linear growth rate in BNG that depends linearly on the supersaturation of the cement solution with respect to C–S–H precipitation.

    BNG relies on four parameters describing the sub-micrometer structure and precipitation kinetics of the C–S–H. These parameters are usually calibrated from experimental results. New cement formulations require new calibrations; hence the predictive ability of BNG is limited. An alternative approach to inform BNG is offered by nanoparticle simulations of C–S–H nucleation and growth by aggregation. When used in the Monte Carlo framework, nanoparticle simulations produce configurations that capture a number of structural features and mechanical properties of the mesoporous C–S–H gel phase. However, Monte Carlo simulations lead to unphysical kinetics, also due to the large energy scale of the mechanical interactions between C–S–H nanoparticles.

    To overcome the limitations of Monte Carlo simulations, new simulations of nanoparticle insertion, deletion, and aggregation have been recently proposed in the framework of kinetic Monte Carlo (KMC). The key advantages of KMC simulations are to (i) reformulate the probabilities of particle insertion and deletion in terms of rates, which introduce an explicit dependence on particles size that removes the issues raised by the large energy scale in Monte Carlo simulations; (ii) provide a rigorous definition of time; (iii) link precipitation rates to solution chemistry using coarse-grained transition state theory; and (iv) predict mechanisms and overall precipitation kinetics that are consistent with BNG simulations. As a result, KMC simulations of C–S–H precipitation enable a more fundamental approach to the calibration of the parameters in the BNG model, linking them to the chemistry of the cement solution and thus expanding the predictive ability of the BGN model.

Overall, this manuscript shows that top-down BNG modeling can be combined with bottom-up simulations to gain a better understanding of the mechanisms of C–S–H precipitation and to clarify how these depend on the chemical composition and on the curing conditions of the cement paste. A similar approach can also benefit research on a wider class of mesostructured materials, whose formation occurs by gelation and precipitation from solution. KMC simulations however still need to overcome several barriers before being fully deployed to predict the kinetics of mesostructured materials formation. To this end, and focusing on simulations of cement hydration, future efforts should address (i) more accurate interaction potentials, which will probably have to consider anisotropy and history dependence; (ii) more chemical complexity and multiple hydration products beyond C–S-H; (iii) describing more in detail the mechanism and kinetics of C–S–H precipitation at the molecular scale; (iv) coupling particle simulations with ion diffusion and local saturation in the solution; (v) allowing for particles to grow and dissolve partially, and anisotropically, to capture complex morphologies that have been experimentally observed, e.g., fibrils and foils (Tajuelo Rodriguez et al. 2015); and (vi) describing more in detail the morphology and chemical structure of the C_3S surface, as well as its interactions with the C–S–H. Driven by a collective effort in the materials modeling and simulation community, nanoparticle simulations are displaying an increasing promise to support the formulation of future more sustainable cements, by providing improved and more fundamental predictions of cement hydration, properties, and durability.

In Situ AFM Investigations and Fracture Mechanics Modeling of Slow Fracture Propagation in Oxide and Polymer Glasses

10

Matteo Ciccotti and Matthieu George

Contents

Abstract

Fracture propagation is inherently a multiscale problem, involving the coupling of many length scales from sample dimension to molecular level. Fracture mechanics provides a valuable link between the macroscopic scale of the structural loading of the samples and the scale of the process zone for brittle materials. Modeling the toughness of materials requires yet an investigation at scales smaller than this process zone, which is nanometric in oxide glasses and micrometric in polymer glasses. We present here the important insights that have

been obtained through an in situ experimental investigation of the strain fields in the micrometric neighborhood of a propagating crack. We show the richness of atomic force microscopy combined with digital image correlation although it limits the observations to the external surface of the sample and to very slow crack propagation (below nm/s). For oxide glasses, this novel technique provided enlightening information on the nanoscale mechanisms of stress corrosion during subcritical crack propagation (Ciccotti, J Phys D Appl Phys 42:214006, 2009; Pallares et al., Corros Rev 33(6):501–514, 2015), including the relevance of crack tip plasticity (Han et al., EPL 89:66003, 2010), stress-induced ion exchange processes (Célarié et al., J Non-Cryst Solids 353:51–68, 2007), and capillary condensation in the crack tip cavity (Grimaldi et al., Phys Rev Lett 100:165505, 2008; Pallares et al., J Am Ceram Soc 94:2613–2618, 2011). An extension of this technique has recently been developed for glassy polymers (George et al., J Mech Phys Solids 112:109–125, 2018), leading to novel insights on the transition between crazing and shear yielding mechanisms and to promising new ways to link the toughness properties to the time-dependent large strain material properties of these nominally brittle materials.

1   Introduction

Fracture propagation is inherently a multiscale problem, involving the coupling of many length scales from sample dimension to molecular level. Fracture mechanics provides a valuable link between the macroscopic scale of the structural loading of the samples and the scale of the process zone for brittle materials such as oxide and polymer glasses. On the one hand, LEFM (see Insert A) allows measuring toughness of a given material on a given standard test sample and uses this information to predict the resistance to fracture propagation of a different structure composed of the same material including a well-defined crack. On the other hand, LEFM does not allow explaining the measured toughness value based on the macroscopic properties of the material, nor its dependence on crack propagation velocity or temperature.

Figure 1 shows that the toughness of very different materials (including the ones investigated in the present manuscript) presents significant variations when crack propagation velocity spans over many different orders of magnitude, going from pm/s to km/s. The overall trend of these curves is surprisingly similar, consisting of a slow velocity regime (frequently called "subcritical") with a $\Gamma(v)$ with positive slope as a function of the velocity v up to a critical velocity v_c. Above this instability point (see Insert A), crack propagation velocity rapidly attains values close to the sound propagation speed in the material. Kinetic energy dominates the fracture energy in this dynamic regime (Freund 1990; Fineberg and Marder 1999). On the other hand, in the slow velocity regime, which is the object of the present manuscript, crack propagation is quasi-static, and the materials toughness is determined by the dissipative processes associated with crack propagation.
Fig. 1 Fracture energy curves $\Gamma(v)$ for some different materials

The ranking of the materials toughness in this subcritical regime is thus not trivially related to the strength of the specific interatomic bonds.

Insert A: Linear Elastic Fracture Mechanics (LEFM)

LEFM describes the conditions of propagation of a preexisting sharp crack in linear elastic materials. The original argument by Griffith (1920) associated the creation of a new crack to the conversion of mechanical energy (external work W and variations of the elastic energy U_{el}) into a thermodynamic (reversible) energy cost per unit area $\Gamma = 2\gamma$ to create two new free surfaces:

$$G = \frac{\partial W}{\partial A} - \frac{\partial U_{el}}{\partial A} = \Gamma \qquad [\text{J/m}^2]$$

where the *strain energy release rate G* represents the loading condition and structural response of the precracked sample and the *fracture energy Γ* is a material property.

An equivalent description of LEFM can be expressed in terms of a singular stress field $\sigma_{ij}(r, \theta)$ in the neighborhood of the crack tip in the form of an inverse square root dependence of the stress tensor σ_{ij} on the distance r from the crack tip:

$$\sigma_{ij}(r, \theta) = \frac{K_I}{\sqrt{2\pi r}} f_{ij}(\theta)$$
where $f_{ij}(\vartheta)$ are universal oscillating functions of the angle θ.

When limiting to mode I (opening) cracks, the equilibrium/propagation condition can thus be expressed as $K_I \geq K_{Ic}$ [Pa·m$^{1/2}$], where the *stress intensity factor* (SIF) $K_I = \sqrt{E'G}$ is the loading parameter and the *fracture toughness* $K_{Ic} = \sqrt{E'\Gamma}$ is a material property. The effective elastic modulus is $E' = E$ for plane stress and $E' = E/(1 - v^2)$ for plane strain, E and v being the Young modulus and Poisson's ratio of the material.

The elastic crack opening profile $u_y(x)$ of an initially sharp slit can be shown to have locally a parabolic shape:

$$u_y(x) = \frac{K_I}{E'}\sqrt{\frac{8x}{\pi}}$$

The LEFM formalisms can be extended to inelastic materials provided all inelastic deformations are limited to small region around the crack tip, called the "process zone" as shown by Irwin and Orowan (Orowan 1955; Irwin 1957). The irreversible fracture energy $\Gamma(v, T) \gg w$ includes energy dissipation and can become several orders of magnitude larger than 2γ. Moreover, it can depend on crack propagation velocity v, on temperature and environmental conditions (especially relative humidity). The stability of steady-state crack propagation requires both the structural stability of the sample $dG(c)/dc \geq 0$ and intrinsic stability of the material $d\Gamma(v)/dv \leq 0$.

For hard and stiff elastoplastic materials, the size of the plastic process zone can be estimated as a function of their yield stress σ_Y through Dugdale model:

$$\ell_D = \chi \frac{K_{Ic}^2}{\sigma_y^2}$$

where χ ranges between $1/2\pi \simeq 0.16$ and $\pi/8 \simeq 0.39$ depending on the choice of a circular (McClintock and Irwin 1964) or elongated (Dugdale 1960) process zone.

Typical dissipation mechanisms involve plastic or viscoelastic deformation of the bulk material in the neighborhood of the crack tip which is affected by a propagating stress singularity. Moreover, the strong deformation of the material in this process zone can induce the activation of some mesoscale mechanisms, such as microcracks, cavitation, crazing/fibrillation, shear banding/localization, rupture and/or sliding of interfaces between different phases of the material (Lawn 1993; Williams 1984; Jones 2015), or molecular processes such as stress-induced diffusion of ions or molecules, stress-activated chemical reactions, or phase changes (Lawn 1993; Ciccotti 2009; Hutter 2013).

The scientific field of modeling materials toughness is thus a strongly multi-disciplinary domain, which implies handling mechanics at the macroscopic scale, in situ investigations of micromechanisms at the mesoscale, and physicochemical modeling at the atomistic scales. The focus of the present manuscript is in the development of novel AFM-based techniques to provide in situ investigation of the mesoscale mechanisms in brittle materials such as oxide and polymer glasses, where the size of the process zone is, respectively, nanometric and micrometric (see Insert A). On the one hand, an appropriate modeling of these mesoscale observations requires to accurately investigate and model the mechanical aspects at the macroscopic scale, which provides the pertinent loading and boundary conditions for the process zone scale. On the other hand, the clear observation and modeling of the mesoscale mechanisms provide the pertinent conditions that affect the molecular processes acting at an even smaller scale. The mesoscale is frequently the scale where most of the energy dissipation takes place, but the amount of this energy dissipation is conditioned by the phenomena acting in a molecular neighborhood of the crack tip. The mesoscale is thus an essential bridge between the mechanical and molecular scales and a key factor to model materials toughness.

The key for a proper communication between the three scales lays into the achievement of a well-conditioned steady-state propagating fracture, where the processes at all scales are conveniently synchronized. This allows the energy flow to be coherently defined from the macroscopic scale of the loading stage down to the ultimate molecular failure scale and thus to attribute to each scale the proper contribution in the emergence of the fracture toughness of the material.

The novel technique presented here exploits the combination of an AFM (Bruker ICON, Santa Barbara, USA) with a very stable and compact in situ loading configuration (Fig. 2) based on the double cleavage drilled compression (DCDC) sample (Janssen 1974) and a very stiff and compact loading stage (Deben Microtest, Woolpit, UK). The macroscopic nature of the sample and its excellent stability allow obtaining a well-defined mode I loading and a very straight crack path. This allows for a very stable steady-state fracture propagation in materials where the fracture toughness K_c can be expressed as an increasing function of the crack propagation velocity v (see Insert A).

The straight AFM topographical imaging (see Insert B) of the crack tip neighborhood allows to identify the pertinent mechanisms acting at the process zone scale. Furthermore, the continuum imaging of the same region of the sample surface while it is progressively crossed by the slowly propagating crack allows extracting the
Fig. 2 (**a**) Sketch of the DCDC specimen. (**b**) Experimental setup for in-situ AFM imaging of the slow crack propagation in a DCDC specimen

crack tip displacement field and in turn determines the surface strain and strain rate fields. The variations of the direct topographical signal provide the out-of-plane displacements associated with crack propagation, while the access to the in-plane displacement field can be obtained through digital image correlation (see Insert D).

The in situ AFM technique allows accessing the process zone with unprecedented spatial resolution and real-time monitoring. However, experimental access to such a high spatial resolution entails two main constraints arising from the intrinsic nature of scanning probe microscopies. The first is that observations are limited to the free surface of the sample, which is subjected to a different mechanical condition than the bulk. The second is that the maximum imaging rate is presently limited to one image per minute, which limits the crack propagation velocity to the slow range between pm/s and nm/s. While the use of these techniques is limited to a range of temperature around ambient conditions, the composition of the atmosphere in a glove box containing the setup can be set with great precision to a given mixture of N_2, H_2O, and CO_2, which is a very important asset to study stress corrosion or more general environmental effects on crack propagation.

Figure 3 represents a typical image that was obtained in the process zone of a crack propagating in a glassy thermoplastic polymer (PMMA) where one can appreciate the richness of information on the detailed mechanisms at action. Before we can attempt any interpretation it is wise to fully examine the multiscale mechanical condition corresponding to the observed phenomenon.

The manuscript will be organized as follows. Chapter 2 presents the developments of the multiscale modeling of the DCDC crack propagation technique. Chapter 3 presents the well-established advances in modeling the stress-corrosion crack propagation in oxide glasses made possible by the in situ AFM technique. Chapter 4 presents recent extensions of the technique to investigate slow crack propagation in glassy polymers and very promising new observations. Chapter 5 drives a critical conclusion about the technique and its perspectives toward linking the worlds of nanoscale mechanics and numerical modeling. Four Inserts are distributed along the text to consistently provide with required base knowledge in fracture mechanics, atomic force microscopy, capillary condensation, and digital image correlation.

Insert B: Atomic Force Microscopy (AFM)

Atomic force microscopy is widely used to non-destructively characterize the surface structure of materials at the nanometric scale. In imaging mode, the AFM sharp probing tip, mounted on a flexible cantilever, is scanned over the surface of the material, and the interactions between the tip and the surface, measured through the deflection of the cantilever, are translated into a three-dimensional image of the surface topology.
figure from Roduit (2010)

Topographical images can be obtained either in contact (static) mode or in dynamic mode (also called *tapping*), in which the cantilever is submitted

to a sinusoidal excitation. A feedback loop acting on the vertical position of the cantilever is used to keep the amplitude of the deflection (or of the oscillations) constant during the scan, in order to get the surface topography by recording the vertical position or *height signal*. A second kind of image, called the *error signal image*, represents the difference between the measured deflection (or oscillation amplitude) and its prescribed setpoint value. This image is very precious to highlight the contours of the structures in the imaged region. The vertical resolution of the AFM topographical images can be as small as 0.1 nm and is essentially limited by vibrational and electronic noise, whereas lateral resolution is essentially hampered by the finite radius of the scanning tip which induces a smearing of the measurement along the surface plane and is thus generally at best of the order of 10 nanometers. At the nanometric scale of the AFM images, it is important to keep in mind that differential thermal dilations between the sample and the instrument during a scan are generally not negligible, inducing image distortions (called *thermal drifts*) that must be minimized and taken into account.

When operating in dynamic mode, the phase delay between the sinusoidal excitation and the response of the cantilever can also be acquired during the scan. This provides a third kind of image, called *phase image*, which can contain useful information on the nature of the scanned surface. The phase signal is indeed related to the energy dissipated per cycle by the surface-tip interactions (Cleveland et al. 1998) and is generally used to reveal changes of the viscoelastic properties of the sample materials and changes of wetting properties of the sample surface or to detect the presence of nanoscale liquid film condensed on the solid substrate.

2   Multiscale Modeling of the DCDC Sample

The DCDC sample was initially developed by Janssen (1974) to study slow fracture in silicate glasses, which possess very high values for both Young modulus $E \approx 70$ GPa and yield strength $\sigma_y \approx 10$ GPa. The sample (Fig. 2a) consists of a prism of dimensions $2L \times 2w \times 2t$ (corresponding to x, y, z directions) with a cylindrical cross hole of radius R drilled through the specimen thickness $2t$. The sample is loaded with a compressive force F and thus a compressive stress $\sigma = F/4wt$ applied to the two opposite faces. This induces a tensile stress at the two poles of the central hole that are aligned with the sample loading direction. During the test in stiff and hard materials like glass, two symmetric cracks of length c are spontaneously nucleated at the crown of the central hole. The two cracks then propagate in opposite directions along the midplane of the sample (direction x in the $x - z$ plane), driven by the mode I opening induced at the crack tip.

In order to fit the DCDC sample into a compact loading setup to be set into an AFM apparatus, the glass sample dimensions are fixed to $40 \times 4 \times 4 \, \text{mm}^3$, with a hole radius $R = 500 \, \mu\text{m}$. A precision of $10 \, \mu\text{m}$ is required on all dimensions, and the surfaces should be polished to a RMS roughness of 0.5 nm (for an area of $1 \times 1 \, \mu\text{m}^2$) to insure proper AFM imaging.

In these very brittle materials, the macroscopic sample deformation is essentially linear elastic. The stress intensity factor has been derived by several authors via 2D finite element simulations (Janssen 1974; Michalske and Freiman 1983; He et al. 1995; Pallares et al. 2009). When the crack tip is at a sufficient distance ($>w$) from the central hole and the sample extremities, the mode I stress intensity factor is a decreasing function of the crack length c. The most refined analytical approximation for this relation is (Pallares et al. 2015):

$$\frac{\sigma \sqrt{\pi R}}{K_I} = \left[d_0 + d_1 \frac{w}{R} + d_2 \left(\frac{w}{R} \right)^2 \right] + \left[d_3 + d_4 \frac{w}{R} + d_5 \left(\frac{w}{R} \right)^2 \right] \frac{c}{R} \qquad (1)$$

where $d_0 = 0.3156$, $d_1 = 0.7350$, $d_2 = 0.0346$, $d_3 = -0.4093$, $d_4 = 0.3794$, and $d_5 = -0.0257$. Since $dK_I/dc < 0$, crack propagation is very stable at both imposed load and imposed displacement. Moreover, the directional stability of the straight crack propagation is excellent due to the strongly negative values of the T stress induced at the crack tip by the applied compression (Fett et al. 2005).

When using the DCDC sample to study subcritical propagation with a constant applied displacement, the crack progressively slows down as a consequence of the increase of the crack length. This allows to progressively reach very slow velocities without any activation of the loading stage. At the very low crack propagation velocities required by AFM observations (below 10 nm/s), the variations of the crack length c, and consequently of K_I, are very weak. A steady-state propagation in very pure asymptotic mode I loading ($K_{II}/K_I \leq 5\%$) can thus be observed over conveniently long in situ investigations: a few days or weeks depending on the crack propagation velocity. The details of the setup and techniques can be found in Celarie (2004) and Grimaldi et al. (2008).

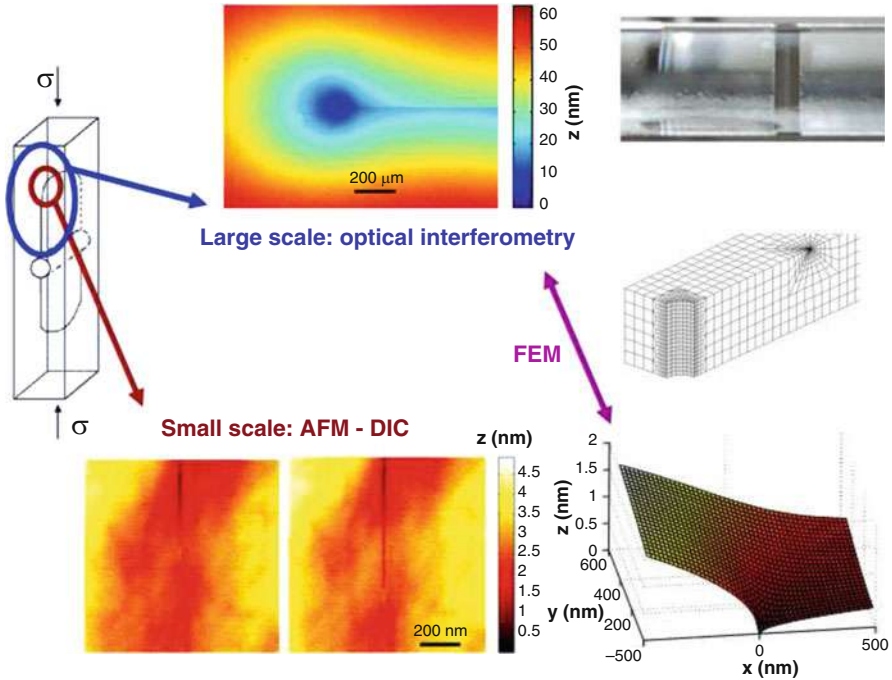
We address here a first major issue related to the necessity of establishing the proper mechanical loading in the neighborhood of the micrometric region observed by AFM where the crack front intersects the external surface of the DCDC sample (cf. red circle in Fig. 4). While the 2D modeling of the DCDC sample assumes the invariance of stress and displacement fields along the z axis, the boundary effects on a finite thickness sample generally imply the crack front to assume a curved shape, which is parabolic for the DCDC sample (cf. top right image in Fig. 4). The 2D symmetry of the crack tip field is thus broken in the proximity of the external surface, which is intersected by the crack front with a non-normal angle $\alpha \sim 10°$. In the presence of such a tilted configuration, the singularity of the crack tip stress field takes a radically different mathematical form, called "corner point singularity," which should be expressed in terms of spherical coordinates around the intersection point (Benthem 1977; Bazant and Estenssoro 1979; Dimitrov et al.


Fig. 4 Multiscale combined experimental and numerical analysis of the DCDC sample. The large-scale measurements by optical interferometry are illustrated on the top. The two small-scale AFM images in the bottom represent two successive steps of steady-state crack propagation that lead to the estimation of the local out-of-plane displacement field represented on their right. The finite-element mesh on the right is used to bridge the two scales

2006). The practical consequence is that the crack propagation at the surface may be different than in the bulk. However, if we insure a well-conditioned steady-state crack propagation, the crack front assumes a constant shape, and the intersection angle α can be shown to be a function of the material's Poisson ratio (Pallares et al. 2015). Under these specific conditions, the stress intensity factor takes an essentially constant value along the crack front and up to the external surface. Both the loading conditions and propagation kinetics become thus consistent between the surface and the bulk of the sample.

This scenario was validated as illustrated in Fig. 4 by combining (1) a 3D finite element modeling of the linear elastic deformation of a DCDC sample taking into account a curved crack front shape, (2) the experimental measurement by optical reflection interferometry of the elastic crack opening profile, and (3) the experimental measurement by optical profilometry of the out-of-plane displacement field of the external surface of the sample, which is the same observable measured in the in situ AFM investigation but at larger macroscopic scale.

The outcome of the excellent agreement between all these measured and calculated displacement fields is that:

(1) the crack opening profile in the midplane of the sample is well described by the Williams expansion (Williams 1957; Pallares et al. 2009):

$$u_y(X) = \frac{K_I}{E'} \sqrt{\frac{8}{\pi}} \left(X^{1/2} + \alpha_3 X^{3/2} + \alpha_5 X^{5/2} \right) \qquad (2)$$

where K_I is provided by Eq. (1), $\alpha_3 = 1.319/w$ and $\alpha_5 = 0.515/w^2$.

(2) the out-of-plane displacement field u_z at the external surface can be expressed as (Han et al. 2010; Pallares et al. 2009):

$$u_z(r, \theta) = \frac{K_I(1 + \nu)}{\sqrt{2\pi}E} \sqrt{r} \left(A + B \cos \frac{\theta}{2} + C \cos \theta \right) \qquad (3)$$

where K_I is again provided by Eq. (1) and the angular dependence is approximated by a truncated Fourier expansion (the coefficients are $A = 0.28$, $B = 0.67$, $C = -0.72$ for our sample configuration and mechanical properties). We remark that the fact that the $\sqrt{r}$ singularity for u_z is the same as for the in-plane crack opening profile is not a trivial result, and it is not predicted by 2D solutions neither in plane stress nor in plane strain.

3   Stress Corrosion in Oxide Glasses

Stress corrosion is a hydrolysis chemical reaction happening at the crack tip, which would normally be very slow on glass at ambient temperature, but is significantly accelerated due to local stress concentration (cf. Ciccotti 2009 for a recent review). Most ordinary oxide glasses are silicate glasses, where about 80 wt.% is constituted by a densely cross-linked network of silica tetrahedra, SiO_4, bonded by a common oxygen atom, thus creating $Si - O - Si$ (siloxane) bridges that locally form some rings of radii down to 0.5 nm. The basic corrosion reaction is a three-step reaction involving water adsorption on the $Si - O$ bonds, then the hydrolysis reaction itself (exchange of electron and proton), and finally the separation of the bond in two separate silanol groups ($Si - OH$), which correspond to one step advance of the fracture in the main silicate network of the glass (Fig. 5 Left). The vision of stress corrosion as a sequence of individual bond breakings by stress (and temperature)-enhanced hydrolysis was established in the 1970s (Wiederhorn 1967; Wiederhorn and Bolz 1970; Michalske and Bunker 1984). The kinetics of stress corrosion crack propagation can be represented by a three-region scheme on a graph describing the logarithm of crack velocity v (spanning from cm/s to pm/s) against the stress intensity factor (SIF) K_I (Fig. 5 Right), when K_I is smaller than the toughness K_{Ic} that is of the order of 1 MPa·m$^{1/2}$ for most glasses.

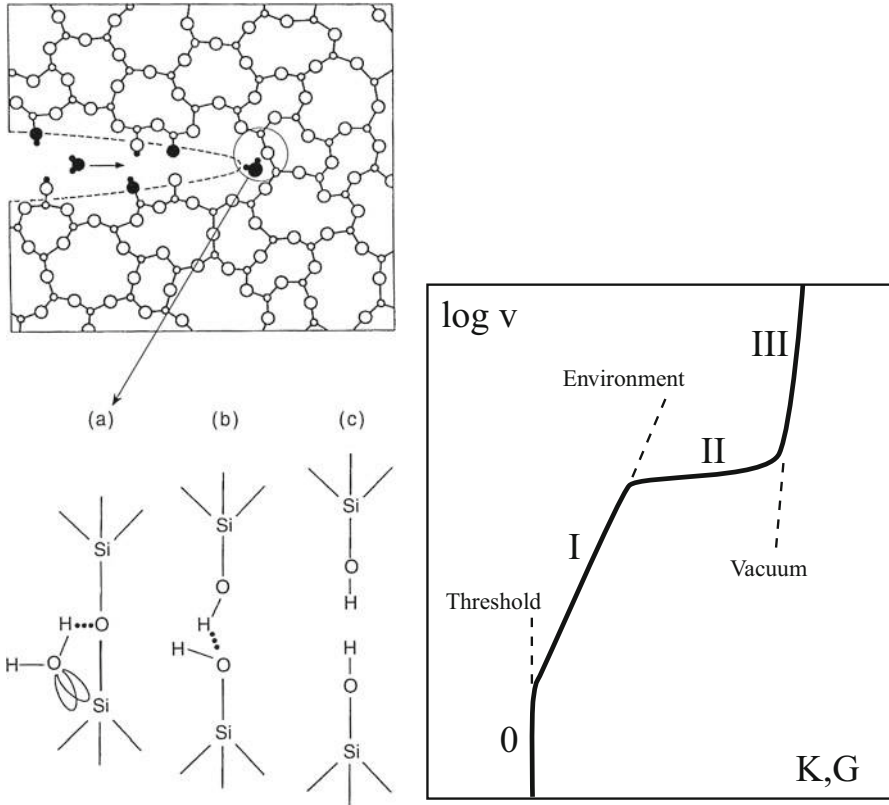
Region I is the proper stress-corrosion regime, where the stress enhances exponentially crack propagation velocity according to accelerated hydrolysis reactions. Region II is a plateau where crack velocity is limited by the migration of water molecules toward the very confined crack tip. Region III is a very steep region


Fig. 5 Left: basic mechanisms of the stress-corrosion reactions (from Michalske and Freiman 1983). Right: Schematic $v(K)$ diagram for subcritical crack propagation in oxide glasses

where the SIF is so high that the crack can propagate without any contribution from water hydrolysis. In some glasses such as alkali-silicate glasses, an additional region 0 corresponds to a threshold for crack propagation. The phenomenology of the stress-corrosion regime (region I) consists of an exponential dependence of the crack velocity on the stress intensity factor, an almost proportional dependence on humidity, and an increase of crack velocity with temperature. This was experimentally established by Sheldon Wiederhorn (Wiederhorn 1967; Wiederhorn and Bolz 1970) who also proposed the following model equation:

$$v = A \left(\frac{p_{H_2O}}{p_0} \right)^m \exp\left(-\frac{\Delta E_a - bK_I}{RT} \right) \tag{4}$$

which is based on the chemical reaction rate theory for the hydrolysis of siloxane bonds by water molecules. The dependency on humidity p_{H_2O}/p_0, the main reactant, is a multiplicative power law with an exponent m close to 1, which is

the order of the reaction. The dependency on both temperature T and K_I appears through an Arrhenius term, where R is the gas constant and the activation barrier ΔE_a can be reduced by the presence of local tensile stress σ_{tip} at the crack tip of radius (we can write $\sigma_{tip} V_a = b K_I$, where V_a is an activation volume of molecular dimensions).

Phenomenological equations such as Wiederhorn's (Eq. 4) can describe the dependence of crack velocity on stress and on environmental parameters for most typical glasses and are compatible with a thorough consistent modeling based on the sharp-crack atomic-bonding paradigm (Lawn 1993). Yet the detailed nature of the stress-corrosion mechanisms that occur at the crack tip has been debated for decades (Marsh 1964; Maugis 1985; Gehrke et al. 1991; Tomozawa 1996), and a general disagreement can be found on the relevance of several accessory phenomena that may participate in the stress-corrosion mechanisms at different stages of the process. Stress corrosion can involve a complex interplay between the diffusion of reactive molecules (mainly water) into the crack cavity and into the glass network, the corrosion (or dissolution) of the network itself, and the migration of weakly bonded alkali ions under chemical or stress gradient (Gehrke et al. 1991; Bunker 1994). We note that in pure silica glass, the absence of ion migration can lead to significantly different local corrosion mechanisms. All three phenomena are typically very slow under ambient conditions in the unstressed material, but they can significantly accelerate in the highly stressed neighborhood of the crack tip, depending especially on the nature of the environment and of its confinement in the crack tip cavity.

3.1 Crack Tip Environmental Condition

In the classical picture of stress corrosion in moist air, the local environmental condition at the crack tip is assumed to be dry, and water molecules have to diffuse in the air phase along the sharp crack cavity before reaching the most strained bonds at the crack tip (Wiederhorn 1967). However, several speculations or indirect observations (Crichton et al. 1999; Lawn 1993) have suggested the presence of liquid phase due to capillary condensation inside the very sharp cracks in hydrophilic materials such as glass (see Insert C). According to theoretical estimations, the Kelvin radius for capillary condensation of water at ambient conditions is subnanometric (see Insert C) and comparable with the radius of stretched crack tips in glass (Wiederhorn 1967). If present, this capillary-condensed phase should be very small and difficult to detect with optical methods.

The phase-imaging technique associated with the in situ AFM observations (see Insert B) provided the first clear observations of this wet phase filling the crack cavity over a length of about 1 micron (Fig. 6). This allowed to establish that the crack tips in silicate glasses in moist atmosphere are invariably filled with a stable liquid phase, mainly composed by water. Since macroscopic failure properties of materials are essentially governed by mechanisms taking place in the vicinity of the crack tip, such a liquid condensate has a potential for playing an important role on
Fig. 6 Analysis of water condensate at the crack tip in silica glass: (left) Sketch of the coupling between the crack opening profile and the water condensate; (center) AFM phase image of the water condensate; (right) length of the condensate L as a function of the stress intensity factor K_I for different values of relative humidity. (Data after Grimaldi et al. 2008)

the propagation of the crack, in spite of its micrometric extension. First, it affects the chemistry allowing for crack propagation at low velocity by determining the local environmental condition for the stress-corrosion reactions at the crack tip. But it can also have a mechanical effect due to the highly negative Laplace pressure in the condensate (see Insert C) that acts on the crack walls and is responsible for the closure of the crack when the stresses become lower than some threshold K_0.

Insert C: Capillary condensation

Capillary condensation consists of the spontaneous condensation of a liquid water into a small gap confined between solid surfaces in the presence of an unsaturated moist atmosphere.
It is an ubiquitous phenomenon at nanoscale, occurring in all confined geometries, divided media, cracks, or contacts between surfaces (Bowden and Tabor 1950). Because of the curvature of the meniscus delimiting the condensation, the pressure in the two phases is not equal due to the *Laplace law* of capillarity:

$$P_L - P_{ATM} = \frac{\gamma_{lv}}{r}$$

where γ_{lv} is the liquid-vapor surface tension and r is the radius of mean curvature of the interface, the pressure being higher on the concave side. This induces a pressure drop in the pressure P_L of the liquid meniscus, which in turn induces a decrease of its chemical potential and thus allows to reach equilibrium with an undersaturated atmosphere when the average curvature radius equals the *Kelvin radius* r_k according to the *Laplace-Kelvin equation*:

$$\frac{\gamma_{lv}}{r_K} = -\rho_l k_B T \ln(RH) \tag{5}$$

where ρ_l is the number of molecules per unit volume in the liquid phase (Thomson 1871) and RH stands for the relative humidity.

In the case of perfect wetting, as for water on silica surfaces, the solid surfaces are also covered by an equilibrium condensed film of nanometric thickness e due to the effect of van der Waals short-range interactions between the surface and the water molecules through the condensed film (which is characterized by the *Hamaker constant A_{slv}*). In equilibrium conditions, the condensed film has the same negative pressure as the capillary-condensed phase, and the equilibrium thickness e of the film is given by:

$$e = \left(-\frac{A_{lsv}}{6\pi \rho_l k_B T \ln(RH)} \right)^{1/3} \tag{6}$$

In order to have capillary condensation, the gap H between two silica surfaces should be inferior to the critical value H_c (cf. Charlaix and Ciccotti 2010 for more details):

$$H_c = 2r_k + 3e \tag{7}$$

Silica glass is particularly suited to investigate the physicochemical properties of the capillary condensate since the stress-corrosion reaction does not involve corrosion products nor ion exchange phenomena. When measuring the length L of the condensate as a function of the stress intensity factor K_I (that controls the crack opening profile as seen in Insert A and Sect. 2), the condensation was shown to be at equilibrium with an atmosphere of moist nitrogen (Fig. 6), and the critical condensation distance H_c (see Insert C) was measured for several values of the relative humidity (Grimaldi et al. 2008).

When progressively unloading a crack, the condensate length L keeps increasing up to a maximum value $L_{\max}$, where the capillary forces overcome the crack opening forces associated to the macroscopical loading K_0. At this point, the crack is macroscopically observed to suddenly recede leading to complete closure. When

combining the measurement of the closure threshold K_0 with the $L - K_I$ curves by AFM phase imaging, the value of $L_{\max}$ can be adjusted as the single fitting parameter of the equation:

$$\frac{L}{L_{\max}} = \left(\frac{K_I}{K_0} - \sqrt{\left(\frac{K_I}{K_0} \right)^2 - 1} \right)^2 \tag{8}$$

and the values of both the Laplace pressure ΔP and the critical condensation distance H_c (see Insert C) can be determined by:

$$\Delta P = K_0 \sqrt{\frac{\pi}{8 L_{\max}}} \qquad H_c = \frac{K_0}{E'} \sqrt{\frac{8 L_{\max}}{\pi}} \tag{9}$$

This provided the first access to the physical properties of the wetting liquid at crack tip during stress-corrosion propagation. Concerning silica glass, these properties were shown to be very sensitive to impurities (Grimaldi et al. 2008) and to reach very stable values close to those of pure water in perfect wetting conditions when performing the experiment under a mixture of pure nitrogen and moisture (Pallares et al. 2011). Since the water condensate is in equilibrium with the moist atmosphere, the chemical activity of liquid water under the equilibrated negative Laplace pressure is the same as that of the neighboring moist air (see Insert C). This can explain why the classical stress-corrosion Eq. (4) well describes the dependency of the crack propagation data on relative humidity (Ciccotti 2009).

When studying more common glass compositions, such as soda-lime glass, the role of the crack tip condensation can be more pernicious due to stress-enhanced leaching that causes alkali ions to diffuse into the liquid condensate. The in situ AFM phase imaging reveals that the condensate length is significantly larger than for the silica glass (Célarié et al. 2007). Moreover, this length increases with time under constant loading and environmental conditions, without reaching a clear equilibrium. This reflects the change in composition of the liquid condensate due to the progressive enrichment in alkali ions that can be monitored by the AFM technique.

This unprecedented access to the composition of the nanoscale liquid condensate opens the way to more accurate investigations of two important factors affecting stress-corrosion kinetics: (1) the first major point is that this local environmental condition directly affects the rate of the corrosion reactions; (2) the second major point is that it allows for an estimation of the amount of alkali leached out of the bulk glass, which is responsible for a compressive stress buildup at the neighborhood of the crack tip (Wiederhorn et al. 2011), which also affects the stress-corrosion rate according to Eq. (4), and which was shown to cause the occurrence of a stress-propagation threshold in alkali-modified glasses (Fett et al. 2005).

Mastering the concomitant role of the local environmental condition and the compressive stress buildup induced by the interplay of hydration, leaching, and

hydrolysis reveal to be the necessary path toward a better modeling of the unsolved issue of the effect of glass composition on stress-corrosion kinetics in moist air (Wiederhorn et al. 2013).

3.2   Role of Plastic Deformation

In previous sections we used linear elastic fracture mechanics down to the molecular scale to interpret stress-corrosion mechanisms. A major objection to the sharp-crack atomic-bonding paradigm comes from the hypothesis of a significant contribution of plastic deformation at the crack tip in the slow crack propagation mechanisms. Since the early works of Dugdale (Dugdale 1960) on metals and the observations of plastic behavior of glass under compression in indentation and scratch marks (Taylor 1949), several investigations have been carried out to track the evidence of plastic behavior in the strong tensile stress field at crack tips in glasses.

The fracture energies measured by Wiederhorn (1969) for six glasses in an inert environment range between 7 and $10 \, J/m^2$, a figure that is tenfold higher than twice the typical values of the surface tension of glasses $\gamma = 0.5 \, J/m^2$ (Griffith 1920), which suggests a significant contribution of irreversible processes in crack propagation (see Insert A). By considering a typical yield stress of $\sigma_y \sim 10 \, GPa$ for glass, the size of the crack tip plastic region associated to such fracture energies by the Dugdale model would be limited to a few nanometers (see Insert A). In the subcritical stress-corrosion regime, the fracture energies and the estimated sizes of the plastic regions are even lower. However, the extent of penetration of reactive molecules from the environment into the glass network has been much debated (Marsh 1964; Tomozawa 1984), and this can enhance damage and plasticity on larger regions around the crack tip (cf. Ciccotti 2009).

Since the early development of AFM techniques, it has been possible to probe in situ crack propagation or the post-mortem crack surface morphologies to explore these mechanisms at their relevant nanometric scale, leading to remarkable observations (Guilloteau et al. 1996; Celarie et al. 2003; Bonamy et al. 2006) suggesting that crack tip plasticity would affect a region of about 100 nm, which is significantly larger than Dugdale's prediction. These have attracted a lot of attention on the nanomechanics of oxide glasses since they were thought to be connected with interesting out-of-equilibrium issues (Tomozawa 1996). Yet, a coherent interpretation of these AFM nanoscale investigations was only achieved after the development of the thorough multiscale analysis of the mechanics of fracture from the macroscopic scale where the loading is applied to the sample, to the submicrometric scale where the crack tip singularity lives (presented in Sect. 2).

When estimated at the scale of the in situ AFM images of the crack tip region, the displacements provided by the proper local elastic solution are of the order of the nanometer. While the in-plane displacements are below the lateral resolution of the AFM, the out-of-plane displacements are measurable, but they are of the same order
Fig. 7 (**a**) and (**b**) are, respectively, the reference and deformed AFM height images for the IDIC analysis. (**c**) Raw residual field obtained after correction of in-plane displacement. Note that the crack path is masked for the IDIC analysis. (**d**) Fitted displacement field. (**e**) Remaining residual after fit subtraction. (**f**) Out-of-plane displacement associated with the crack opening. A cut through the symmetry plane $y = 0$ is shown, with the crack tip located at the origin. (After Han et al. 2010)

of magnitude as the lowest surface roughness that can be obtained by polishing. In order to achieve an accurate measurement of both these displacement fields, an extension of the digital image correlation (DIC) technique to AFM topographical images was performed by Han et al. (2010) (see Insert D).

The results of this analysis (reported in Fig. 7) provide strong evidence that the proper 3D elastic solutions describe faithfully the mechanics of the DCDC sample from the macroscopic scale, where the load is applied down to the lateral resolution limit of the AFM measurements, represented by the 10-nm size of the probe. The values of the SIF K_I independently obtained by either the macroscopic mechanical analysis of the structural response of the DCDC sample or by the submicroscale measurement of the crack tip asymptotic displacement fields are in excellent agreement (within 5% uncertainty).

A complementary piece of information to the in situ investigations of fracture propagation is the post-mortem AFM analysis of the fracture surfaces. Concerning the quest for traces of plastic deformations, (Guin and Wiederhorn 2004) performed a careful recombination of the nanoscale topography of two opposite fracture surfaces, obtaining a perfect match down to the AFM height resolution of 0.1 nm. Bonamy et al. (2006) have looked for traces of plastic deformations by examining the post-mortem fracture surface profile in terms of crack propagation path. The fracture surfaces of brittle materials are known to possess self-affine statistical scaling properties that can be analyzed by estimating the lateral correlation functions. While the observed cutoffs between different scaling regimes have frequently been interpreted as signatures of changes from brittle to ductile fracture propagation regimes, an accurate metrologic analysis of AFM roughness images showed that for such small roughness amplitudes, the small-scale regime is likely to be caused by intrinsic bias in the AFM imaging process (Lechenault et al. 2010) and suggested that only the large-scale regime contains relevant metrologic information on the fracture surfaces. Pallares et al. (2017) showed that this large-scale regime is likely to be extended down to the relevant scale of material heterogeneities, which are close to molecular dimensions in glasses. Moreover, as shown by Wiederhorn et al. (2007) and Pallares et al. (2017), the amplitude of the surface roughness in the stress-corrosion regime is a decreasing function of the applied stress intensity factor K_I. This result, which has the opposite trend than what is observed during dynamic crack propagation (giving origin to mist, mirror, and hackle progressive roughening during instable crack acceleration), can be understood in terms of a model based on brittle crack propagation by LEFM down to the molecular scales, where the crack tip propagation is deflected by residual stress fields induced by heterogeneities in the local elastic moduli or in the local thermal expansion coefficients (Wiederhorn et al. 2007). This is a further coherent observation with the fact that stress-corrosion fracture is strongly coupled to residual stress fields and not significantly affected by crack tip plasticity. These very subtle issues constitute a playground where MD simulations could bring relevant modeling.

Insert D: Digital Image Correlation (DIC)

Digital image correlation is classically used to extract the in-plane displacement field $u(\mathbf{x})$ in a region of interest Ω between a reference image $f(\mathbf{x})$ and a deformed image $g(\mathbf{x})$, taken on the same surface at different times. $f(\mathbf{x})$ and $g(\mathbf{x})$ usually represent the gray level at the position $\mathbf{x}$ in the image. The *conservation of the optical flow* between the two images can be written as:

$$f(\mathbf{x}) = g(\mathbf{x} + \mathbf{u}(\mathbf{x})) \tag{10}$$

The in-plane displacement field $\mathbf{u}(\mathbf{x})$ can thus be found by minimizing the sum of squared differences:

$$\int_{\Omega} (f(\mathbf{x}) - g(\mathbf{x} + \mathbf{u}(\mathbf{x})))^2 \, d\mathbf{x} \tag{11}$$

To measure a non-integer displacement, an interpolation scheme of the grey level between pixels can be used. With AFM topographic images, DIC can be expanded to deal with displacements in three dimensions since $f(\mathbf{x})$ and $g(\mathbf{x})$ represent the vertical positions corresponding to each pixel. Equation (10) can be generalized as:

$$f(\mathbf{x}) = g(\mathbf{x} + \mathbf{u}(\mathbf{x})) + v(\mathbf{x}) \tag{12}$$

where $v(\mathbf{x})$ denotes the out-of-plane displacement field. In this case, the roughness of the two surfaces is used to obtain the in-plane displacement field, and then the subtraction of the registered images allows obtaining the out-of-plane displacement field by eliminating the contribution of roughness.

Roux and Hild (2006) have developed a more robust method, called *"Integrated" DIC approach* (IDIC), where kinematic or mechanical information are taken into account in the minimization procedure. The displacement field $[\mathbf{u}(\mathbf{x}), v(\mathbf{x})]$ is then sought as a linear combination of a few expected fields.

When treating the in situ AFM images, some of these fields are chosen to represent regular transformations such as uniform extension or shear caused by the AFM drifts, whereas the others represent the linear elastic fracture mechanics of in-plane and out-of-plane singular fields on each image. The steady-state crack propagation condition can be used to enforce the identity of the crack tip fields on the two images after translation along the crack path direction, thus reducing the number of unknowns and providing robust values for the stress intensity factor K_I.

4   Toughness of Glassy Polymers

4.1   About Fracture in Glassy Polymers

Glassy polymers are widespread in technical and structural applications since the 1930s due to their excellent mechanical properties, combined with low mass density and ease of implementation. Although their elastic moduli and yield strength are lower than other structural materials such as glasses or metals, glassy polymers possess a relatively high fracture energy. This results from a combination of plastic deformation and the occurrence of several localization mechanisms such as crazing and shear banding (Donald and Kramer 1982). Extensive studies have been devoted to the modeling of the relationship between the mechanical properties and the material composition and microstructure. Their main aim was combining contributions from both macroscopic constitutive laws, mesoscale damage mechanisms, and molecular issues (Williams 1984; Brown 1991; Réthoré and Estevez 2013; Halary et al. 2011).

   Although glassy polymers (i.e., with a glass transition temperature well above ambient temperature) can belong to different families with different macromolecular structures such as thermoplastics, thermosets, and semicrystalline polymers, their macroscopic mechanical properties are qualitatively quite similar up to yield condition. These materials have a typical elastic modulus of $E \approx 1\,\text{GPa}$, a yield strength of about $\sigma_y \approx 100\,\text{MPa}$, and a fracture toughness of about $K_c \approx 1\,\text{MPa}\sqrt{\text{m}}$. The size of the inelastic process zone at the crack tip is thus of the order of magnitude of the Dugdale length $\ell_D \sim 15 \div 40\,\mu\text{m}$ (see Insert A).

   Understanding and engineering the toughness of these polymers rely on the ability of describing and modeling the bulk deformation and energy dissipation mechanisms at the process zone scale. It is thus pertinent to use the same DCDC sample geometry and loading setup to perform in situ AFM investigations while dealing with the macroscopic scale of the sample by using the tools of linear elastic fracture mechanics. Although the materials of this class share similar properties on scales larger than ℓ_D, the nature of the inelastic processes occurring in the process zone can be very different depending on the nature and structure of the macromolecular network, which results in a very different large strain behavior. The kinetics of crack propagation can also be very variable, changing from very stable steady-state crack propagation over a wide range of velocities in thermoplastics to jerky stick-slip fracture propagation in thermosets.

   On the opposite of oxide glasses, the major dissipation mechanism in glassy polymers is provided by plastic deformation and acts on a more mesoscopic scale that is $1000\times$ larger. As a consequence, fracture propagation appears to be significantly less sensitive to the degree of cleanness and purity of the atmosphere, and most of current measurements are conducted under current atmosphere with controlled temperature.

The first applications of the in situ AFM technique have been focused on two prototypes of thermoplastic and thermoset glassy polymers, namely, PMMA and DGEBA-IPD epoxy resin. The fracture properties of these well-known glassy polymers were extensively investigated with optical and post-mortem investigations in the 1970s, which resulted in the proposition of several microscale models for their toughness (Kinloch and Williams 1980; Williams 1984). The implementation of in situ AFM techniques allows the visualization at the pertinent scales and is thus a very promising tool for stating which are the pertinent mechanisms at action for different polymers under well-defined crack propagation conditions.

For thermoplastics (such as PMMA) slow fracture propagation is a smooth process up to an instability leading to dynamic crack propagation. The fracture properties are described by a curve reporting the toughness $K_c(v, T)$ or the fracture energy $\Gamma(v, T)$ as a function of the steady-state crack propagation velocity v and temperature T (cf. Fig. 1). The quasi-static slow regime and dynamic regime are associated to the two positive slope branches of the $\Gamma(v)$ curve, which are separated by a hypothetic negative slope region where steady-state crack propagation is unstable and cannot be measured. The slow quasi-static regime extends over several decades of propagation velocities, and the $\Gamma(v)$ curve is dominated by viscoplastic dissipation in a crack tip process zone of the size of tens of micrometers. For PMMA at ambient conditions, the process zone has long been known to be constituted of crazes, i.e., of nanometric fibrils being nucleated and drawn across the crack lips thus providing extensive energy dissipation and crack propagation resistance (Doll 1983; Kramer 1983).

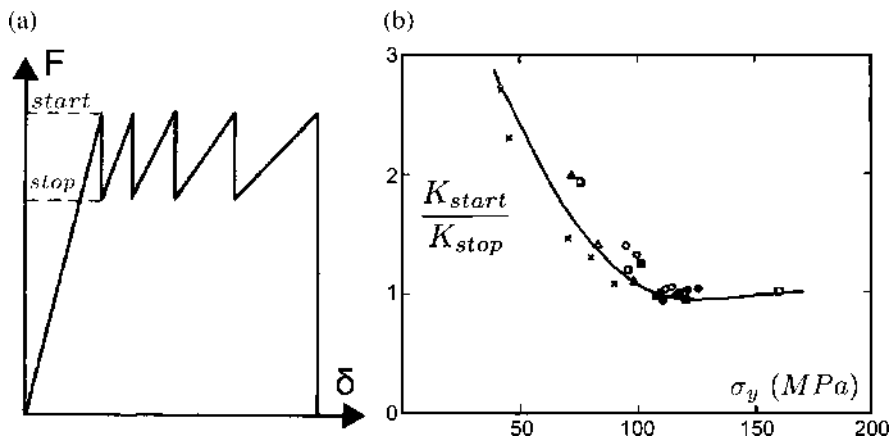
For thermosets (such as epoxy resins), fracture propagation is affected by stick-slip dynamics (cf. Fig. 8a). A static crack will not propagate up to an initiation SIF, named $K_{\text{start}}(\dot{\delta}, T)$, that is, a decreasing function of the macroscopic loading rate $\dot{\delta}$


Fig. 8 Characteristics of the stick-slip behavior in thermosets. (**a**) The sample loading curve $F(\delta)$ presents a saw tooth behavior. (**b**) The stick-slip amplitude $K_{\text{Start}}/K_{\text{Stop}}$ diminishes with the yield stress σ_y or equivalently when increasing the loading rate $\dot{\delta}$ or decreasing temperature T

applied to the sample or of decreasing temperature T. Crack initiation is followed by dynamic propagation ($v \sim 100\,\text{m/s}$) that causes the sudden drop of the load observed in Fig. 8a. Eventually, the crack will stop for a lower value of K_I, called K_{stop}, which is quite insensitive to the rate of loading and temperature. As shown by Kinloch and Williams (1980), the coupled dependency of K_{start} on the loading rate and temperature can be expressed as a single master curve in terms of the yield stress σ_y taken at a reference strain rate and temperature (cf. Fig. 8b). As proposed by Phillips et al. (1978), based on poorly resolved optical observations, the stick-slip mechanism can be interpreted as the consequence of plastic blunting of the crack tip during the stick phase, followed by the nucleation of a sharp fast brittle fracture inside the stretched static process zone.

4.2   DCDC Techniques for Glassy Polymers

The application of the DCDC configuration to glassy polymers implies solving several technical issues since these materials are less stiff ($E \approx 1\,\text{GPa}$) and less hard ($\sigma_y \approx 100\,\text{MPa}$) than silicate glasses. Moreover, they present a slow viscoelastic relaxation at macroscopic scale. Since these materials are not brittle enough to provide a spontaneous crack initiation from the central hole, the crack initiation has to be implemented with the help of instrumented blades. Sample dimensions have to be optimized (George et al. 2018) in order to minimize buckling and yielding during crack propagation while preserving the small sample dimensions required by in situ AFM investigations (for PMMA we used $2L = 45\,\text{mm}$, $2w = 7.2\,\text{mm}$, $2t = 4.95\,\text{mm}$, and $R = 1.2\,\text{mm}$; for epoxy resin $2L = 40\,\text{mm}$, $2w = 8\,\text{mm}$, $2t = 4\,\text{mm}$, and $R = 1.33\,\text{mm}$). Under these conditions, the stable propagation of very straight cracks with slow velocities in the desired range for AFM investigation can be achieved on both our test polymers, presenting steady-state conditions over several days. We remark that for epoxy, this slow fracture regime was never observed before.

The estimation of the stress intensity factor acting at the crack tip is made considerably more difficult by the occurrence of stress relaxation, larger deformations, and plastic yield due to the shear stress concentration in the region of the central hole. A main point is that during slow crack propagation ($v < 10\,\text{nm/s}$ for AFM investigations), bulk stress relaxation in the DCDC sample is the dominating cause of the reduction of K_I during a test rather than crack propagation, which is very limited in extent. Although the linear elastic modeling of the whole sample (cf. Eq. (1)) is not any more adequate to provide K_I, an experimental measurement of the crack opening profile can be used to estimate K_I (cf. Eq. (2)) at the elastic scale surrounding the process zone (far from the central hole where bulk plastic yielding can occur). Since the accuracy of this technique is limited to 10%, it can only be used to set the average value of K_I during the test. However, since the crack length is not changing significantly during the test, we can use the recording of the measured applied force F to obtain the time evolution of K_I to be combined with the measurement of the crack tip velocity v performed by optical or atomic
Fig. 9 $K_{Ic}(v)$ data for PMMA (four samples) and DGEBA-IPD epoxy resin (two samples) obtained by the present technique

force microscopy (cf. George et al. 2018 for more details). In order to provide a better control and resolution on the measurement of K_I, a full multiscale analysis of the DCDC sample under the proper elastoplastic constitutive laws is under way combining both experimental techniques and finite element modeling. However, the present level of control is sufficient to soundly interpret the in situ AFM observations that were recently obtained for the two polymers (George et al. 2018; Nziakou et al. 2019).

4.3 Slow Crack Propagation in Glassy Polymers

During our experimental campaign, we could obtain a successful crack initiation and well-conditioned steady-state crack propagation over different samples of PMMA and epoxy resin. With the estimation of K_I explained in the last section, $K_{Ic}(v)$ curves presented in Fig. 9 were obtained. For PMMA the $K_{Ic}(v)$ are in excellent agreement with data from the literature Doll (1983) within the expected 10% accuracy. For brittle epoxy resins, these curves are the first experimental evidence of the existence of a steady-state slow crack propagation regime. Propagation velocities for the epoxy resin were found to be below 10^{-9} m/s, which explains why they could not be detected by optical methods, while they are comfortably in the range of in situ AFM measurements.

The following section illustrates how in situ AFM imaging during steady-state crack propagation provides an unprecedented way to investigate the process zone at the crack tip in two polymers.

4.3.1 In-Situ AFM Observation in PMMA Samples

In the case of PMMA, optical microscopy revealed that steady-state crack propagation is accompanied by a whole range of localized yield and damage processes at the free surface of the sample, extending over a large neighborhood of the crack tip. In situ AFM measurements acquired in the crack tip region allow nevertheless to provide a much more accurate observation and quantification of this complex process zone (cf. Fig. 3). On the one hand, AFM images reveal an extended "necking" of the free surface of the sample (a few micrometer deep), inside which a sharp crack tip is propagating. On the other hand, a network of secondary minor surface grooves of very shallow depth and small width are superimposed to the main necking region. Note that the very fine lines that can be distinguished on the AFM images correspond to surface scratches due to polishing of the sample surface prior to the mechanical tests. The surface necking region at the free surface of the sample extends about 300 μm ahead of the observed crack tip, which is significantly larger than the typical 30–40 μm size generally observed for the craze region in the middle of the sample Doll (1983). However, an enhancement and potential modification of the mechanisms of crack plasticity at the free surface should be expected Kramer (1983). In order to proceed to a more systematic characterization of this extended process zone region over its whole size, we positioned the AFM scanning head in an initially unyielded region 300 μm ahead of a crack tip propagating at a few nm/s. A series of 150 AFM images of $40 \times 40\,\mu m^2$ size (the largest scan size providing sufficient spatial resolution) was then acquired every 15 min over a period of about 36 h without moving the scanning head position. The imaging ended after the crack tip had passed through the imaging region and traveled 300 μm ahead of it. The extreme stability of the steady-state propagation of the crack in our experimental setup allowed to maintain a well-conditioned crack propagation over the 36 h of measurements (average velocity $\langle v \rangle = 5 \pm 3$ nm/s). The full movie obtained from these successive acquisitions as well as the full-field reconstruction can be found in George et al. (2018).

For glassy polymers in situ topographic AFM images directly provide the vertical component u_z of the crack tip displacement field, which is much larger than surface roughness. The in-plane components (u_x, u_y) can be obtained by analyzing the progressive distortion of the dense array of the initially straight and crossed polishing lines, which can easily be identified on the AFM error images (see Insert B) as illustrated in Fig. 10.

The qualitative observation of the distorted polishing lines allows appreciating the smoothly changing nature of the strain field in the central necking region, opposed to the sharp transitions to a large uniform stretch of about 450% inside the secondary grooves (as estimated from the sharp changes of direction of the polishing lines).

In order to provide a straightforward measurement of the 2D projected strain tensor averaged over a gage length of about 2 μm in the main necking region, the change of length and orientation of the base vectors of a series of triplets (three
Fig. 10 Measurement of the in-plane strain field of the sample surface by tracking the changes of shape of the polishing line network. A limited series of remarkable lines has been highlighted in red and numbered in order to allow for an easier interpretation of the complex deformation field. The blue square box is zoomed in the right picture to highlight the sharp deflections of the polishing lines on the secondary grooves
Fig. 11 In-plane nominal strain field $\varepsilon_{yy}(X)$ in the direction normal to the crack as a function of the distance X from the crack tip and for two values of the initial offset Y_0 from the central axis of the main necking region

intersection points between polishing lines) are monitored through the whole image series as a function of the position center of the gage region. Figure 11 presents the evolution of the normal strain component $\varepsilon_{yy}(X)$ for two such triplets centered at different distances from the crack axis ($Y_0 = 0.2$ and $2\,\mu$m). For both curves, the nominal strain presents a significant rise starting at about the same distance of $150\,\mu$m from the crack tip and then follows an approximately linear trend with distance. While for $Y_0 = 2\,\mu$m, the strain saturates at 20% at a $100\,\mu$m distance from the crack tip, for the triplet along the crack axis ($Y_0 = 0.2$), the plastic strain keeps rising until the crack tip reaches a large figure of about $\varepsilon_{yy} = 70\%$. In both cases, the plastic strain remains frozen behind the crack tip. The longitudinal strain component $\varepsilon_{xx}(X)$ did not present any significant trend out of the 5% scatter that

constitutes the detection limit. This manual image correlation technique is thus very efficient for identifying the plastic process zone and evaluating the plastic strain field inside it.

This very rich surface fracture pattern is quite different from the well-known crazing behavior that occurs at the crack front in the bulk of the PMMA samples where plane strain conditions are prevailing Doll (1983); Kramer (1983). The analysis of the surface displacement field associated with crack propagation, together with post-mortem investigation by scanning electron microscopy (SEM), leads to the interpretation of these observations as a change of fracture mechanism from crazing in the bulk to shear yielding in a surface layer, where the prevailing plane-stress conditions involve a local reduction of stress triaxiality. The thickness of the layer affected by this change of mechanism is about $10\,\mu m$, which is the same order of magnitude as the Dugdale length in plane strain as argued by Williams (1984).

The maximum plastic stretch of 70% reached close to the crack tip is comparable to the maximum plastic extension obtainable in uniaxial tensile tests on PMMA close to its glass transition temperature (Gsell and Jonas 1979). This observation is a nice proof that although PMMA is macroscopically brittle in tension at ambient temperature, it can be plastically cold drawn at scales smaller or comparable with the Dugdale length. The limiting extension is provided by the entanglement network, which still resists plastic flow before the material is broken.

The complex pattern of secondary grooves that develops along the main necking region was attributed to secondary surface crazing by carefully analyzing the real-time development of the surface strain fields (George et al. 2018). These secondary surface crazes are shown to be formed in the first half of the main necking region, where only elastic tensile deformations are prevailing with a principal direction orthogonal to the fracture plane. The secondary crazes are shown to be nucleated on these polishing lines (cf. movie in the SI of George et al. (2018)) that are more closely orthogonal to the surface tensile stress and which act as surface defects for craze nucleation.

4.3.2   In-Situ AFM Observation in DGEBA-IPD Epoxy Resin

In the case of epoxy resin, the neighborhood area of the crack tip presents a very different organization as can be seen in Fig. 12. The absence of both the very extended surface necking region and of the secondary grooves is to be noticed. The surface displacement field rather appears as a very smooth shear yielding field with a clear strain concentration toward the crack tip. This process zone mechanism is essentially the same as the one expected for the crack propagation in the bulk, even if probably enhanced in size due to the surface loss of triaxiality (Williams 1984). The absence of crazing in epoxies is generally attributed to the high cross-linking density (Halary et al. 2011).

By applying the same triplet analysis described for PMMA along the crack propagation axis, we can clearly identify a plastic zone starting at $7\,\mu m$ from the crack tip, where the plastic strain increases almost linearly up to a maximum of about 30%. These measurements are compatible, respectively, with Dugdale
Fig. 12 (Left) 3D representation of the topography of the crack tip region $(50 \times 50\,\mu\text{m}^2)$ measured by AFM at the free surface of an epoxy resin sample. (Right) Strain field ε_{yy} between two $50\,\mu\text{m}$ size AFM images separated by crack propagation of $1\,\mu\text{m}$ as obtained by DIC (after Nziakou et al. 2019)

estimation of the process zone size and with the maximum strain allowed by the finite stretchability of the tightly cross-linked polymer network. In the presence of such a smooth strain field, it is possible to compute the full strain field between successive steps of crack propagation by digital image correlation (see Insert D) as represented in Fig. 12(right). This can be interpreted either as the gradient of ε_{yy} along the direction of crack propagation (if divided over a gage length of $\Delta X = 1\,\mu\text{m}$, corresponding to the distance traveled by the crack between the two images) or as the strain rate (if divided over the time lag of $\Delta t = 1.5$ days).

This analysis reveals that under steady-state propagation condition, the crack tip strain field presents two highly active regions forming an angle of about 38° to the crack propagation axis. We can remark that this picture is quite different from the crack tip fields obtained for the monotonic loading of a non-propagating crack. This information is very precious when modeling the difference between the fracture energy in steady-state and stick-slip crack propagation.

4.4 Link Between Steady-State and Stick-Slip Crack Propagation

The in situ AFM investigation with nanometric resolution has shown for the first time that for brittle thermosets like epoxy resin, a steady-state slow crack propagation behavior can be observed pretty in the same way as in thermoplastics. We also provided the measurement of the $K_{Ic}(v)$ curve over the accessible velocity range $[10^{-12}\text{–}10^{-9}]$ m/s in a well-conditioned steady-state regime. This phenomenon was never detected before because the maximum velocity v_c attainable in this slow velocity regime is in the range of nm/s, which is comparable with the growth rate of human nails. While this low velocity was very difficult to measure by optical techniques available in the 1970s, our AFM in situ investigation can accurately measure propagation velocities down to pm/s.

Fig. 13 Classical representation of stick-slip dynamics as a cycle (in red) on the $K_{Ic}(v)$ curve of steady-state fracture propagation
An important complementary observation by Takahashi and Arakawa (1984) has allowed to characterize the dynamic crack propagation in epoxy resins as a $K_{Ic}(v)$ curve with v systematically larger than 100 m/s, which is difficult to be measured during stick-slip dynamics, even with a fast camera. On the other hand, Hattali et al. (2012) have recently developed an advanced loading fixture allowing to obtain very high loading rates, and they have shown that thermoplastics like PMMA can also present stick-slip dynamics under these rapid loading conditions.

The combination of all these observations suggests that the steady-state crack propagation curve $K_{Ic}(v, T)$ and the characteristic stick-slip curve $K_{start}/K_{stop}(\dot{\delta}, T)$ are two complementary facets of a unified crack propagation physics for all glassy polymers, in an analog way to what is observed in the peeling of adhesive tapes (Maugis 1985).

However, the link between these two curves is not trivial. The classical picture to link the $K_{Ic}(v)$ with stick-slip dynamics is to identify K_{start} with the peak value K_{max} at the end of the slow quasi-static branch of the $K_{Ic}(v)$ curve and K_{stop} with the minimum value K_{min} of the dynamic branch (cf. Fig. 13), where the change of slope in the $K_{Ic}(v)$ curve induces a crack propagation instability (Maugis 1985). However, this picture cannot account for the reduction of K_{start} with the sample loading velocity $\dot{\delta}$ as represented in Fig. 8 for epoxy resins.

The in situ AFM observations on epoxy resin have recently lead us to propose a unified scenario that links the $K_{Ic}(v)$ and $K_{start}/K_{stop}(\dot{\delta})$ curves through the characterization of the viscoplastic behavior of the glassy polymer as well as the measured strain fields associated to crack propagation (Nziakou et al. 2019).

The key point is that steady-state fracture curve $K_{Ic}(v)$ can only be established after the crack has traveled several times the process zone size R_{ZP} at the same constant velocity v (cf. Fig. 14). We can thus define a characteristic minimum time for steady state:

$$t_{PZ} \sim \frac{R_{PZ}}{v} \tag{13}$$

When observing crack propagation over a longer time $t \gg t_{PZ}$, the steady-state crack tip strain field is well established, and it advances at a constant velocity v. The material's elements in the process zone are thus submitted to a plastic strain from an initial yield value ε_y (that we assume to be small) to a maximum plastic strain ε_{max}, which we assume to be related to the maximum strain sustainable by

Fig. 14 Sketch of the
plastically blunted crack tip
with crack tip radius ρ. The
red region represents the
process zone with size R_{ZP}
the polymer network in the process zone (and that we can measure by the in situ
AFM measurements). This defines a characteristic strain rate in the process zone
under steady-state crack propagation:

$$\dot{\varepsilon}_{\text{Steady}} \sim \frac{\varepsilon_{\max}}{t_{PZ}} \sim \frac{\varepsilon_{\max} v}{R_{PZ}} \tag{14}$$

The typical value for the volume density of dissipated work in the process zone
is thus:

$$\mathscr{W}_{\text{Steady}}(\dot{\varepsilon}_{\text{Steady}}) \sim \int_0^{\varepsilon_{\max}} \sigma(\varepsilon, \dot{\varepsilon}_{\text{Steady}}) d\varepsilon \tag{15}$$

where the elastoplastic constitutive behavior of the polymer $\sigma(\varepsilon, \dot{\varepsilon}_{\text{Steady}})$ can be
approximated by uniaxial tests performed in the corresponding strain rate range.
We remark that while glassy polymers are brittle under traction at macroscopic
scale, their behavior in the micrometric process zone was shown to experience large
stretches similar to the ones observed in compressive stretches in the same material.
We thus use uniaxial compression tests to estimate the pertinent elastoplastic
behavior by assuming that the strain hardening functions remain the same.

We can thus estimate the steady-state fracture energy $\Gamma(v)$ by multiplying this
typical volume density by the volume of the process zone bR_{ZP}^2 and dividing by
the cross-sectional area bR_{ZP}, where b is the transverse dimension of the sample,
which results in:

$$\Gamma(v) \sim R_{ZP} W_{\text{Steady}}(\dot{\varepsilon}_{\text{Steady}}) \sim R_{ZP} \int_0^{\varepsilon_{\max}} \sigma(\varepsilon, \dot{\varepsilon}_{\text{Steady}}) d\varepsilon \qquad (16)$$

We remark that this rough modeling is only based on measured quantities and it does not possess any adjustable parameter. When substituting typical values of the quantities measured for glassy polymers, we can obtain $\Gamma \sim R_{ZP} \sigma_y \varepsilon_{\max} \sim 10\,\mu\text{m} \cdot 100\,\text{MPa} \cdot 0.3 \sim 300\,\text{J/m}^2$, which provides the good order of magnitude. In principle, R_{ZP} and $\varepsilon_{\max}$ depend on the crack velocity v through the strain rate $\dot{\varepsilon}_{\text{Steady}}$. However, glassy polymers are only weakly viscoplastic, and the process zone size and crack opening displacement in PMMA were observed to be only weakly variable over many decades of velocity (cf. Doll 1983 and Fig. 1). We can thus expect that the weak slope of the $\Gamma(v)$ curves should be related to the weak dependency of the constitutive behavior $\sigma(\varepsilon, \dot{\varepsilon})$ over the strain rate $\dot{\varepsilon}$. This hypothesis has been shown to be consistent with data by Nziakou (2015).

We now turn to explain the link of this modeling with the crack initiation toughness Γ_{Stick} in the stick-slip dynamics, by considering the loading of a sample with a constant velocity $\dot{\delta}$ applied at the loading points. In LEFM, the sample can be characterized by its elastic compliance that depends on the crack length, so that we can write a linear relation $K_I = B(c)\delta$, where $B(c)$ can depend on the structure of the specific sample and can be calculated by FE modeling. Since the crack propagation is only weakly changing during the sample loading, the rate of increase of the stress intensity factor $\dot{K}_I$ is thus proportional to $\dot{\delta}$, and the sample-dependent loading time can be written as:

$$t_{\text{Stick}} = \frac{K_{\text{Start}} - K_{\text{Stop}}}{\dot{K}} \sim \frac{K_{\text{Start}} - K_{\text{Stop}}}{\dot{B}(c) \cdot \dot{\delta}} \qquad (17)$$

Now, if this loading time is shorter than the time t_{PZ} that is necessary for a crack to cross the process zone and reach steady state, we can consider that the strain rate in the process zone is no longer determined by the crack velocity v but rather from the loading rate $\dot{\delta}$ according to:

$$\dot{\varepsilon}_{\text{Stick}} = \frac{\varepsilon_{\text{Start}} - \varepsilon_{\text{Stop}}}{t_{\text{Stick}}} \sim \frac{\varepsilon_{\max}}{K_{\text{Start}} - K_{\text{Stop}}} B(c) \cdot \dot{\delta} \qquad (18)$$

By assuming that the mechanism of plastic blunting and crack reinitiation in the process zone remain similar, so that R_{ZP} and $\varepsilon_{\max}$ assume similar values for the same values of the local strain rate $\dot{\varepsilon}$, we can write a similar prediction for the fracture energy $\Gamma_{\text{Start}}(\dot{\varepsilon})$:

$$\Gamma_{\text{Start}} \sim R_{ZP} \int_0^{\varepsilon_{\max}} \sigma(\varepsilon, \dot{\varepsilon}_{\text{Stick}}) d\varepsilon \qquad (19)$$

where this time the strain rate is determined by the loading rate $\dot{\delta}$ in a sample dependent way as in Eq. (18).

The transition between steady state and stick-slip dynamics is thus related to the value of the loading rate $\dot{\delta}$. If we consider the maximum velocity v_C for which stable steady state can be obtained, this defines a minimum duration of the loading time:

$$t_{\text{Stick}} \sim \frac{K_{\text{Start}} - K_{\text{Stop}}}{B(c) \cdot \dot{\delta}} > t_{PZ} \sim \frac{R_{PZ}}{v_C} \tag{20}$$

And this corresponds to a maximum loading rate $\dot{\delta}_C$ to attain steady-state propagation before initiating stick-slip:

$$\dot{\delta} < \dot{\delta}_C \sim \frac{K_{\text{Start}} - K_{\text{Stop}}}{B(c)} \frac{v_C}{R_{PZ}} \tag{21}$$

This estimation is consistent with the fact that v_C is about 1 cm/s for PMMA, while it is only 1 nm/s for epoxy resins. The critical loading time for PMMA is 3 ms, while it is 8 h for epoxy. Since loading times in a typical fracture test are about minutes, it is sound that we generally obtain steady state in PMMA and stick-slip in epoxy. During our in situ AFM measurements, the loading stage is arrested after a single stick-slip event, and we can thus comfortably explore slow steady-state fracture in epoxy for several days. On the other hand, the measurements of Hattali et al. (2012) have proven that PMMA can undergo stick-slip dynamics under very fast loading, which is also consistent with the experience of brittle behavior of notched PMMA samples under impact loading.

We remark that the conditions given above imply that the strain rates explored in the process zone during stick-slip fracture are larger than the ones explored during the whole steady-state curve $\Gamma(v)$ up to v_C. Since the dependency of K_{Start} on $\dot{\delta}$ is negative, we can relate the transition velocity v_C to the critical velocity for which the steady-state fracture energy, calculated with the steady-state Eq. (16), would change to negative slope.

On the one hand, this is consistent with the classical LEFM modeling relating the stick-slip to a change of slope in the $\Gamma(v)$ curve (Maugis 1985). On the other hand, the negative branch of the $\Gamma(v)$ curve is not defined since steady-state fracture is unstable. The good way to understand the transition is to start from the measured large strain constitutive behavior $\sigma(\varepsilon, \dot{\varepsilon})$ and to determine the change of slope of the energy density $\mathscr{W}(\dot{\varepsilon})$ as a function of strain rate according to Eq. 15.

As a conclusion, the steady-state curve $\Gamma(v)$ and the stick-slip curve $K_{\text{Start}}(\dot{\delta})$ are two different expressions of the same process zone mechanism. Both can be related to the measured constitutive behavior $\sigma(\varepsilon, \dot{\varepsilon})$, but in the first case, the pertinent strain rate of the process zone is determined by the crack propagation velocity v, while for the second it is determined by the loading rate $\dot{\delta}$.

5   Conclusions

The present multiscale investigation offers a consistent mechanical view of the steady-state subcritical fracture propagation in a DCDC specimen for both oxide glasses and glassy polymers. The 3D analysis of the crack tip field is shown to be an unavoidable step to link the macroscopic features of the loading and the nanoscale asymptotic crack tip field as measured at the accessible free surface of the sample through in situ AFM observations. One key of the analysis is the quality of the steady-state crack propagation. By enforcing several hours of equilibrated slow crack growth in a very stable sample such as DCDC, the crack front progressively finds a shape that remains invariant throughout the entire propagation, equilibrated through all scales and under a very pure mode I loading (thanks to the principle of local symmetry). In this frame, observations performed at the nanoscale during slow crack propagation provide rich informations on the local environment of the crack tip, on the mechanical behavior of micrometric neighborhood of the crack tip, and finally on the mechanisms driving its propagation.

Our in situ AFM investigation technique allowed to deepen the understanding of the stress-corrosion mechanisms in oxide glasses. By using AFM phase imaging, we showed that the crack tip cavity is so sharp that it is filled with a spontaneous water condensation from the ambient moist atmosphere in a submicrometric neighborhood of the crack tip (Grimaldi et al. 2008). While this condensate was shown to be close to pure water at condensation equilibrium in pure silica glass (Pallares et al. 2011), complementary observations on alkali-silicate glasses (Célarié et al. 2007) have shown that the chemical composition of this condensate keeps evolving in time due to the leaching of sodium out from the glass. These observations are of the greatest importance to the understanding of the stress-corrosion kinetics under ordinary moist atmosphere since this condensate constitutes the effective local environmental condition at the crack tip region where the stress corrosion occurs. In silicate glasses, we also proved that the use of continuum mechanics and linear elasticity was valid down to 10-nm scales from the crack tip. Full 3D elastic solutions were used here as a first reasonable guess to establish a connection from the macroscopic scale down to the nanometric neighborhood of the corner point singularity. When these corner point solutions are tested against the in situ AFM submicrometric images by digital image correlation, the residual fields present extremely low values and especially no observable trends out of a 10-nm region from the crack tip, thus providing a striking evidence of the appropriateness of these elastic solutions to describe the crack tip fields down to the extreme lateral resolution of AFM imaging. This set of measurements constitutes a clear and sound solution to the long debate on the length scales of the inelastic processes acting at the crack tip of glasses during stress-corrosion slow crack propagation (Wiederhorn et al. 2013). We can conclude our discussion on oxide glasses by stating that the combination of the investigations of crack tip stresses along with the understanding of the local environmental condition is likely to offer an undisputable key to a thorough modeling of the role of glass

composition on the measured phenomenological parameters of the stress-corrosion curves (Wiederhorn et al. 2013). Another major perspective comes from the recent outstanding developments in the performances of molecular dynamics toward the simulation of stress-corrosion reactions on space and time scales that could soon approach from below the limits of the measurable range accessible by our in situ AFM experimental investigations (DuCormack and Cormack 2005; Kermode et al. 2008; Mischler et al. 2005), thereby opening a formidable opportunity for a novel experimental/modeling dialog.

Concerning glassy polymers, the first important required achievement is the ability to properly initiate and propagate a very well-conditioned mode I fracture and to ensure a stable steady-state condition over several days in order to allow for an extensive campaign of in situ AFM observations. The second achieved step is to obtain a valuable estimation of the crack driving conditions (in terms of a stress intensity factor K_I) even when the DCDC sample undergoes some bulk plastic yielding in the central hole region due to low strength/toughness ratio. This is assessed by the agreement of the measured $K_{Ic}(v)$ crack propagation curves with the ones reported in the literature. These two achievements are a necessary condition to link the microscopic scale observations of the crack tip mechanisms with the macroscopic scale of the sample loading. The acquisition of long AFM image series during several days of slow steady-state crack propagation allows for a rich and quantitative real-time evaluation of the damage mechanisms and the related strain fields at the free surface of the sample in a region that is progressively crossed by the crack tip process zone. While the out-of-plane displacement field is directly provided by the AFM topographic images, the in-plane displacement field can be obtained by tracking the relative motion of remarkable surface points or by applying full digital image correlation when possible. Our results obtained on typical thermoplastic and thermoset polymers confirm the general applicability of the technique to different glassy polymers and allow to appreciate a very different organization of the plastic strain fields in the process zone.

The AFM observations presented for PMMA reveal a very rich and unexpected surface fracture pattern, which is quite different from the well-known crazing behavior that occurs at the crack front in the bulk of the PMMA samples where plane strain conditions are prevailing (Doll 1983; Kramer 1983). The analysis of the surface displacement field associated with crack propagation leads to the interpretation of these observations as a change of fracture mechanism from crazing in the bulk to shear yielding in a surface layer, where the prevailing plane-stress conditions involve a local reduction of stress triaxiality. While changes in the process zone size are well known to occur in plane-stress surface layers (Williams 1984), our in situ AFM investigation was the first to provide a clear observation of a global change of mechanisms at the surface of a thick sample. The surface shear necking region presents a tenfold increased length with respect to the craze in the bulk of the sample. The plastic strain field is shown to affect only half of this length, and it presents a very smooth evolution up to 70% plastic extension close to the crack tip. This is comparable to the maximum plastic extension obtainable in uniaxial tensile tests on PMMA close to its glass transition temperature (Gsell and Jonas

1979). This observation is a nice proof that although PMMA is macroscopically brittle in tension at ambient temperature, it can be plastically cold drawn at scales smaller or comparable with the Dugdale length. The limiting extension is provided by the entanglement network, which still resists plastic flow before the material is broken. The complex pattern of secondary grooves that develops along the main necking region can be attributed to secondary surface crazing by carefully analyzing the real-time development of the surface strain fields.

The in situ AFM observations also revealed for the first time the existence of a steady-state slow crack propagation regime for an epoxy resin at velocity below 1 nm/s. Local measurements of the strain field showed that epoxy resin can also be plastically cold drawn, at scales smaller or comparable with the Dugdale length, up to an extent comparable to the maximal reachable plastic stretch allowed by the crosslink network. These results are the first steps for the development of a model unifying steady-state crack propagation curve $K_{Ic}(v, T)$ and the characteristic stick-slip curve $K_{\text{start}}/K_{\text{stop}}(\dot{\delta}, T)$ as two complementary facets of the same crack propagation physics for all glassy polymers.

This novel technique is thus very promising to achieve important insights on the effect of the different macromolecular structures of glassy polymers on their fracture toughness. It opens also the way toward well-conditioned nanoscale experimental measurements that can be confronted to molecular modeling. A very promising direction is the investigation of the effect of confinement on crack propagation in composite materials when the characteristic size of the structure is comparable to the size of the process zone.

Long Time-Scale Atomistic Modeling and Simulation of Deformation and Flow in Solids

11

Yue Fan and Penghui Cao

Contents

Abstract

Atom-based modeling and simulation are essential for the understanding and development of structural materials such as crystalline and amorphous metals. Classical molecular dynamics simulation enables the following of atomic-level structural evolution to elucidate the atomic processes underlying many macroscopic behaviors; however its predictive power is constrained by an intrinsic time-scale limitation. Here, we describe an alternative approach based on potential energy landscape modeling and transition state theory to probe the microscopic mechanisms controlling deformation and plastic flow observed in experiments. We survey several examples of slow deformation in crystals and metallic glasses to illustrate the computational algorithms used to perform the

simulations and to reveal the underpinning elementary plastic processes that operate in crystalline and amorphous materials. We first show the evolution of dislocations and their interactions with obstacles over a wide range of strain rates and temperatures and discuss how they lead to macroscopic behaviors such as flow stress upturn and dislocation channeling. Then we turn to amorphous plasticity where discrete stress relaxation (avalanche) processes arise in serrated flow and creep in metallic glasses. A nonlinear interplay between nonaffine atomic displacement and local shear transformation distortion is revealed that provides a molecular explanation of the deformation-rate upturn.

1   Introduction

To meet the demand of advanced materials with unique functionalities, it is becoming increasingly important to study material performance in complex environments at the fundamental level. Computational modeling and simulation, as widely applied techniques nowadays, can provide unprecedented details on materials from atomic level. While simulations have particular advantages over "real" experiments in terms of lower cost, faster progress, and better control of isolated parameters in affecting the modeled system, there are still unsolved problems in terms of the limited spatial and temporal scales in traditional atomistic modeling techniques. The length scale issue is less challenging because even a few thousand atoms, with the use of periodic boundary condition, can reasonably represent many materials' bulk properties. In addition, the length scale limitation can, at least partially, be addressed by parallelizing the problem and exploiting supercomputer systems. However, the time step in the integration over time cannot be parallelized in the computations. This makes it a formidable challenge to reach long timescales with atomistic simulations. For example, as will be discussed below, the widely used molecular dynamics (MD) simulation can hardly go beyond nanoseconds, which is often more than ten orders of magnitude away from the timescales of the phenomena of interest in real experiments. It is therefore highly desirable to develop and employ new modeling algorithms that can address such timescale issues, while still retaining the atomistic details.

The properties of condensed matter systems are primarily governed by the interactions between constituent atoms in the system. The system's potential energy is a function of its atomic configurations. For a many-body interacting system with defects (i.e., topological disorders), there are many local energy minima, known as inherent structures, representing metastable states of the system. The hyperdimensional energy surface in configuration space is called potential energy landscape (PEL), and material microstructural evolutions correspond to the progressive exploration of different local minima in PEL (Suo 2000; Wei and Zhigang 1996). In the scope of this chapter, the microstructural evolution consists of non-equilibrium processes, which are governed by collective, rare events in the PEL. Since the activation barriers for the rare events are very high, according to transition state theory (TST), the system will be trapped in deep energy basins for an amount

of time (proportional to $\exp\left[\Delta E / k_B T\right]$, where ΔE is the activation barrier), which can be well beyond that accessible by MD. To enable long timescale modeling, an alternative approach is to proactively explore the structures of energy landscape, identify the transition pathways and barriers, and incorporate that information into TST calculations. Different atomistic algorithms have been developed, including the activation-relaxation technique (ART) (Barkema and Mousseau 1996; Cances et al. 2009), the dimer method (Henkelman et al. 1999; Haixuan et al. 2012), hyper- (or meta-)dynamics (Haixuan 1997; Laio and Parrinello 2002), temperature-accelerated dynamics (TAD) (Sorensen and Voter 2000; Bai et al. 2010), and the autonomous basin climbing (ABC) method (Kushima et al. 2009a; Fan et al. 2014; Cao et al. 2012; Yip 2016). Each technique has its own advantages and drawbacks (Fan et al. 2014; Fan 2013). In this chapter we focus on the ABC method. To the best of our knowledge, such algorithm has been found useful in both dislocation system (Fan et al. 2012, 2013; Bai and Fan 2018; Wang et al. 2013; Tao et al. 2018a, b) and amorphous system (Kushima et al. 2009a; Cao et al. 2012, 2013, 2017, 2018; Kushima et al. 2009b) as discussed below in Sects. 2 and 3, respectively. The development of original ABC algorithm (Kushima et al. 2009a) was inspired by Laio and Parrinello's idea of escaping from free-energy minima (Laio and Parrinello 2002). To be more specific, a series of penalty function are applied, and total relaxations are performed to allow the system to climb out of the local basin in the PEL. More recently the ABC method has been extended to capture the multiple competitive pathways in the PEL (Fan et al. 2014). In addition, to enhance the computation efficiency, a novel strategy termed self-learning metabasin escape (SLME) was formulated to merge the newly applied penalty function with those already added ones. Given the limited space here, we refer the readers to the original references for implementation details (Cao et al. 2012; Yan et al. 2016).

2   Evolution of Dislocations in Crystalline Materials

The mechanical behavior of structural metals is controlled by evolutions and interactions between microstructural features known as defects in the materials. Among various types of defects affecting the mechanical properties of structural materials, dislocations are one of the most critical microstructures because they are the main carriers of plastic deformation (Hull and Bacon 2011). In particular, when there are obstacles in slip planes, they will resist the glide motion of dislocations and hence significantly change the system's mechanical performance, including the yield strength, work hardening, strain-rate sensitivity, strain localization, elastic-viscoplastic behavior, etc. (Bakó et al. 2006; Bulatov et al. 2006; Brechet and Estrin 1995; Dunlop et al. 2007; Lebyodkin et al. 1995). Therefore, probing dislocation evolutions and their interactions with obstacles at various environments are the keys to understand, predict, and control mechanical properties of materials. This is a subject that has been extensively studied over the past few decades (Fan et al. 2013; Bacon et al. 2006; Domain and Monnet 2005; Dutta et al. 2012; Gordon et al. 2010;

Gussev et al. 2015; Iyer et al. 2015; Kabir et al. 2010; Kioussis and Ghoniem 2010; Norfleet et al. 2008; Onimus et al. 2004; Osetsky et al. 2006a).

Computational modeling and simulation, accompanied by the continuous enhancement of computing power, have become an effective quantitative approach in materials research, constructively complementing theories and experiments (Yip 2003). Although first principle calculations and MD studies have yielded notable advances in the knowledge of dislocation-mediated mechanics from fundamental levels, they face formidable challenges in probing the non-equilibrium phenomena at realistic timescales. To be more specific, typical MD studies on dislocations are performed either at very high strain rates greater than $10^6\,\mathrm{s}^{-1}$ (Bacon et al. 2006, 2009; Terentyev et al. 2010a, 2008), while on the other hand, typical mechanical test experiments are performed under low strain-rate conditions, i.e., slower than $10^0\,\mathrm{s}^{-1}$ (Dunlop et al. 2007; Onimus et al. 2004; Onimus and Béchade 2009). It has been found that intrinsic timescale limitations in conventional modeling not only could induce huge errors in yield strength quantifications (Zhu et al. 2008) but, more importantly, might provide misleading microstructural evolution mechanisms (Fan et al. 2013). Such challenge therefore calls for the development of a reliable predictive model that can capture the fundamental mechanisms at realistic timescale.

In this section we consider two examples concerning the activities of dislocations over a broad range of timescales by using the ABC-based modeling technique introduced above: (i) nonlinear variation of dislocation mobilities and onset of flow stress upturn and (ii) interaction mechanism map between dislocation and obstacle under various thermomechanical conditions.

2.1   Flow Stress of an Individual Dislocation

At low temperature, the deformation of metals is largely governed by the thermal activation of dislocation glide (Hoge and Mukherjee 1977). Experiments on different structures of metals, including Fe, Ta, Cu, Al, and Zn (Hoge and Mukherjee 1977; Ferguson et al. 1967; Kumar et al. 1968; Campbell and Ferguson 1970; Follansbee et al. 1984; Regazzoni et al. 1987), indicate the dislocation flow stress varies with strain rate in an apparently universal manner. The flow stress increases slowly in an Arrhenius manner at low strain rates but turns upward sharply beyond a certain range of strain rate. Although the results for different metals can be quantitatively different, the flow stress "upturn" behavior when the strain rate reaches the range of 10^3–$10^4\,\mathrm{s}^{-1}$ (Regazzoni et al. 1987; Armstrong et al. 2009) appears to have a more fundamental origin. The onset of non-Arrhenius response has elicited the development of several empirical constitutive models (Hoge and Mukherjee 1977; Armstrong et al. 2009; Zerilli and Armstrong 1987; Follansbee and Kocks 1988; Steinberg et al. 1989; Preston et al. 2003; Remington et al. 2006), including the assumption of phonon drag effects to account for the data at high strain rates. All existing models to date use adjustable parameters to connect the flow stress below and above the critical strain rate for "upturn." Therefore, it would be of interest to seek a more fundamental understanding with less postulated mechanisms or adjustable parameters.

From the PEL perspective, a dislocation line is located on the bottom of the so-called Peierls energy valley until a thermal fluctuation enables it to climb over the activation barrier to glide to the next valley. When an external stress is applied, the depth of the valley, i.e., the glide activation barrier $E(\sigma)$, can be decreased, making the dislocation easier to escape from the valley. As a result, the escape rate can be calculated by using transition state theory (TST):

$$k(\sigma) = k_0 e^{-\frac{E(\sigma)}{k_B T}} \tag{1}$$

where k_0 is the attempt frequency. The activation barrier $E(\sigma)$ can be either empirically assigned or directly identified by employing ABC method at various stress levels.

In the elastic deformation regime, the dependence of stress on applied strain rate as a function of time, t, is given by

$$\sigma = G\varepsilon = G\dot{\varepsilon}t \tag{2}$$

where G is the shear modulus. The ε in Eq. (2) represents the elastic strain, because in this case study we focus on the initiation of dislocation flow, which pertains to the transition from elastic deformation regime to plastic deformation regime. In light of Eq. (2), $k(\sigma)$ can be represented as a function of time, $k(t)$.

The residence probability P(t) that the dislocation does not escape to a neighboring potential energy valley during time t (i.e., the system remains in the elastic deformation regime) is defined as Zhu et al. (2008)

$$\frac{dP(t)}{dt} = -k(t)P(t) \tag{3}$$

or

$$P(t) = \frac{1}{C} \exp\left[-\int_0^t k(t')dt'\right] \tag{4}$$

where C is the normalization factor. Accordingly, the first escape probability distribution p(t) is given by

$$p(t) = -\frac{dP(t)}{dt} = \frac{1}{C}k(t)\exp\left[-\int_0^t k(t')dt'\right] \tag{5}$$

with normalization,

$$\int_0^{t_c} p(t)dt = 1 \Rightarrow C = \int_0^{t_c} k(t)\exp\left[-\int_0^t k(t')dt'\right]dt \tag{6}$$

where $t_c = \sigma_c/G\dot{\varepsilon}$ represents the maximum residence time, at a given non-zero strain rate $\dot{\varepsilon}$. The average residence time is therefore given by

$$\bar{t} = \int_0^{t_c} tp(t)dt = \frac{\int_0^{t_c} tk(t)\exp\left[-\int_0^t k(t')dt'\right]dt}{\int_0^{t_c} k(t)\exp\left[-\int_0^t k(t')dt'\right]dt} \tag{7}$$

In the limit of vanishing $\dot{\varepsilon}$, $k(t)$ is a constant, k, and $t_c \to \infty$, Eq. (7) gives the average time as $\bar{t} = 1/k$, which follows the Arrhenius law. However, for the general condition of non-zero strain rate, the result of Eq. (7) will deviate from the Arrhenius behavior.

We would like to stress here that the derivations of Eqs. (1), (2), (3), (4), (5), (6), and (7) represent a general formalism that is applicable to a wide range of systems where the reaction rate is time-dependent. Relevant examples in the present context would include dislocation nucleation under constant strain-rate loading, glass transition at different cooling rates, as well as dislocation flow. In this case study, we are particularly interested in predicting the variation of flow stress with temperature and strain rate. Since the dislocation will start to glide beyond the residence time $\bar{t}$, we obtain the flow stress by combining Eqs. (2) and (7):

$$\bar{\sigma}_{flow} = G\dot{\varepsilon}\bar{t} = \frac{\int_0^{\sigma_c} \sigma k(\sigma)\exp\left[-\frac{1}{G\dot{\varepsilon}}\int_0^{\sigma} k(\sigma')d\sigma'\right]d\sigma}{\int_0^{\sigma_c} k(\sigma)\exp\left[-\frac{1}{G\dot{\varepsilon}}\int_0^{\sigma} k(\sigma')d\sigma'\right]d\sigma} \tag{8}$$

In summary, once the dislocation migration barrier profile $E(\sigma)$ is known, the flow stress of the corresponding slip system at arbitrary thermomechanical conditions can be calculated according to Eq. (8). There is then only one parameter in Eq. (8), the attempt frequency k_0, which can be taken to be of the order of $10^{12\sim13}\,\mathrm{s}^{-1}$. Below we will apply the constitutive equations just derived to a specific example of the flow stress in bcc Fe.

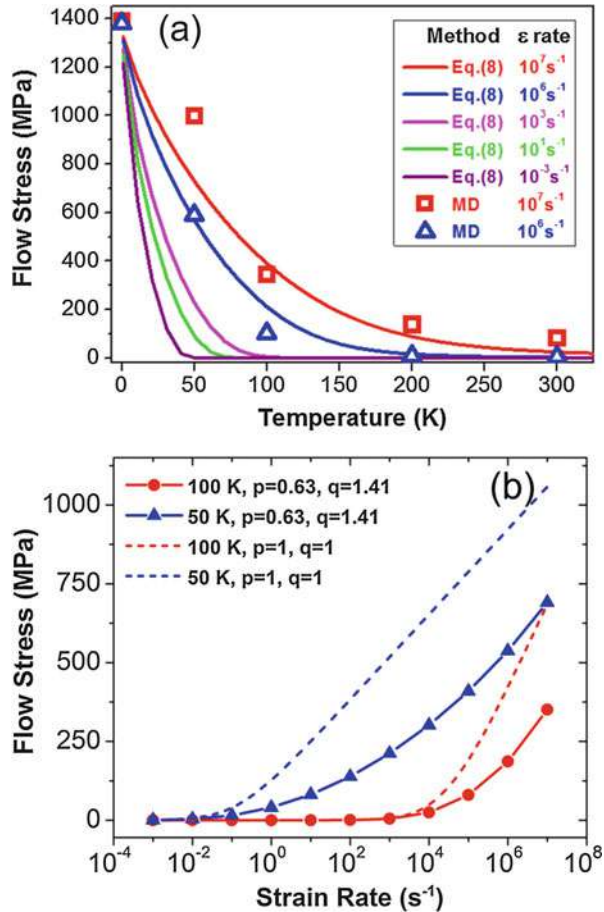
The deformation of bcc metals at low temperature is known to be controlled by the motion of <111> screw dislocations (Domain and Monnet 2005), the flow mechanism being 3D kink nucleation and propagation (Gordon et al. 2010; Rodney and Proville 2009). For the purpose of testing Eq. (8), we examine a short dislocation of length 5b, b being the Burger's vector, which should glide without kink nucleation. Figure 1b above shows the glide barrier for such a dislocation in bcc Fe with an embedded-atom method-type potential developed by Mendelev et al. (2003). Clearly the barrier shows a monotonically decreasing behavior well described by a (p, q) expression $E(\sigma) = E_0\left[1 - (\sigma/\sigma_c)^p\right]^q$ (Rodney and Proville 2009; Kocks et al. 1975), where p = 0.63 and q = 1.41. For the convenience of benchmark discussion below, we also include a dashed line in Fig. 1b denoting p = q = 1, which is the assumption of a linear behavior with a constant activation volume.

Figure 2a shows the thermal behavior of flow stress for strain rates varying over ten orders of magnitude, from $10^7\,\mathrm{s}^{-1}$ down to $10^{-3}\,\mathrm{s}^{-1}$. In the low temperature limit, absence of thermal activation, all flow stresses approach the Peierls stress, which is 1400 MPa for the given potential. As temperature increases, all the
Fig. 1 (**a**) The glide of dislocation corresponds to the hopping between Peierls energy valleys. (**b**) Activation barrier for dislocation glide usually decreases as a function of applied shear stress. Blue squares are the calculated data points by ABC method, and corresponding solid curve is a fit to the realistic (p,q) expression. Dashed line represents a hypothetical linearly decreasing profile

flow stresses monotonically decrease. At a fixed temperature, higher strain-rate loading results in higher flow stress response, suggesting that any quantitative comparison between experimental data and MD simulations must take into account the difference in the strain rate.

The symbols in Fig. 2a represent the corresponding MD results at strain rate of $10^6\,\text{s}^{-1}$ and $10^7\,\text{s}^{-1}$. They are in reasonable agreement with the predictions of Eq. (8) using $k_0 = 1.2*10^{12}\,\text{s}^{-1}$, which matches the Debye frequency satisfactorily. This constitutes a self-consistent test of Eq. (8) with $E(\sigma)$ taken from Fig. 1b (the solid curve) in the range of strain rates where MD is valid. One can see an increasingly sharp drop of flow stress as the strain rate decreases to the range accessible to conventional experiments. The sharp drop has been known as a significant feature of the thermal activation process; this behavior is not well captured by MD simulations at its characteristic strain rates (Domain and Monnet 2005; Zhu et al. 2008). Figure 2a shows that this behavior is at least qualitatively accounted for by the present model.

The variation of flow stress with strain rate is of fundamental interest in experimental studies of crystal plasticity. Figure 2b shows the predicted behavior based on Eq. (8). Under the limit of infinitely high strain rate, the flow stress approaches the Peierls stress. On the other hand, the flow stress is negatively sensitive to the temperature. In the high temperature limit, the flow stress approaches zero regardless of the strain rate. At low $\dot{\varepsilon}$ the flow stress increases only moderately, but as $\dot{\varepsilon}$ increases, above $100\,\text{s}^{-1}$ at 50 K, and $10^4\,\text{s}^{-1}$ at 100 K, it begins to increase much more strongly. This upturn behavior can be analyzed in terms of two factors, stress-dependent activation volume and strain rate-induced non-Arrhenius behavior. Because of the nonlinear stress dependence of the activation barrier (Fig. 1b), the activation volume is very small at high stresses. Such small activation volume leads to a high sensitivity of the flow stress dependence on strain rate (Zhu et al. 2008). In addition, as derived in Eq. (7), there is a non-Arrhenius behavior due to the

Fig. 2 (**a**) Flow stress of the <111> screw dislocation in bcc Fe under different strain-rate and temperature conditions. The solid lines show the calculated results by Eq. (8), and the data points are MD results at high strain rates. (**b**) Predicted flow stress variation at different strain rates. Solid and dashed curves are calculated based on realistic (p,q) barrier profile and hypothetical linear profile shown in Fig. 1b, respectively


strain-rate loading which also contributes to the upturn in Fig. 2b. To decouple the two contributions, we remove the nonlinearity of $E(\sigma)$ by setting p and q equal to unity (dashed line in Fig. 1b). Now the only nonlinear factor comes from the strain rate-induced non-Arrhenius behavior in Eq. (8). As shown in Fig. 2b, under this condition, the flow stress upturn remains, but the stress is now higher beyond the crossover strain rate. Since the assumption of $p = q = 1$ results in a higher effective barrier and correspondingly a longer residence time, it follows that the flow stress response is higher as well. Our analysis therefore shows the onset of flow stress upturn is to be attributed mainly to the non-Arrhenius behavior induced by strain rate, as described by Eqs. (7) and (8).

To compare the predicted upturn behavior quantitatively with experimental data, we adapt the energy profile $E(\sigma)$ for a longer screw dislocation system in bcc Fe

Fig. 3 Variation of reduced flow stress with strain rate at 300 K. (The experimental data on copper and ion are adapted from Armstrong et al. (2009) and references therein)
calculated by Gordon et al. (2010) and use it as the input into Eq. (8). Figure 3 shows the variation of flow stress and strain rate at 300 K, as observed experimentally and predicted by our model. Since the flow stress magnitude is significantly influenced by the defect microstructures in the experimental specimens (Armstrong et al. 2009), the quantitative comparison can only be meaningful after an appropriate normalization. Therefore, in Fig. 3, we show the reduced flow stress, defined as the ratio of flow stress to its value at the highest strain rate $10^7 \, \text{s}^{-1}$, as a function of strain rate. It is seen that both the experiments and our calculation results show a significant flow stress upturn with the critical strain rate in the range of 10^4–$10^5 \, \text{s}^{-1}$. The extent of the agreement suggests Eq. (8) and $E(\sigma)$ have essentially captured the mechanism for the flow stress upturn behavior. On the other hand, it is known that the flow stress magnitude depends on the local defect microstructure in the material. Experimental specimens have a complex defect microstructure leading to appreciably higher flow stresses (due to, e.g., dislocation-obstacle interactions to be discussed in the next section) seen in the experiments compared to the results in Fig. 2b. It is therefore intriguing that the reduced flow stress predicted by our model in Fig. 3 is also quantitatively consistent with experiments from different materials (a ductile one, copper, and, a brittle one, iron). This may be attributed to the fact that the energy barrier for dislocation to climb/glide over the defects/obstacles in the material bears a similar stress-activated behavior as the simple dislocation glide represented by the expression $E(\sigma) = E_0 \left[1 - (\sigma/\sigma_c)^p \right]^q$ that was described above (Remington et al. 2006).

In sum, such example shows that, without invoking any specific mechanism or fitting parameters, the PEL-based approach can naturally capture the nonlinear transition of the flow stress from a classical Arrhenius behavior to a fast upturn over a broad range of strain rates.
Fig. 4 Schematic ABC-TST modeling on dislocation-obstacle interaction at prescribed thermo-mechanical conditions. The detailed iterative procedures are described in the main text

2.2   Dislocation-Obstacle Interaction Mechanism Map

Under complex environments (e.g., irradiation, severe plastic deformation, etc.), a host of non-equilibrium obstacles/precipitates would be present in the system. It therefore becomes particularly important to probe the dislocation-obstacle interaction mechanisms at various conditions since they will determine many important mechanical properties of structural materials, such as hardening, creep, embrittlement, crack nucleation, etc. (Bakó et al. 2006; Bulatov et al. 2006; Jumonji et al. 1996; Van der Giessen et al. 2001; Shin et al. 2005).

The first key challenge that needs to be addressed is to investigate the dislocation-obstacle interactions at much longer timescale, well beyond the range accessible to MD. As introduced above, the ABC method is a robust algorithm that can drive the system out from a trapped deep energy basin and thus probe the microstructural evolution at long timescales. Therefore, by iteratively combining ABC and TST into a dynamic scenario, one could then study the dislocation-obstacle interactions at prescribed strain rate and temperature, as illustrated in Fig. 4.

The consecutive iterations can be described as:

1. Under a given strain condition (including the initial state with no strain), employ ABC to explore the PEL structure, and thus obtain the dominant reaction pathway at this moment.

2. Apply nudged elastic band (NEB) method to accurately calculate the energy barrier E_b between the current and next minimum states in PEL that are identified in step (i).

3. Determine the thermal activation time defined as $\Delta t = [\nu_0 \cdot \exp(-E_b/k_B T)]^{-1}$, where ν_0 is the attempt frequency (of Debye order 10^{13} s^{-1}). For a specified strain rate $\dot{\varepsilon}$, the corresponding strain increment, $\Delta \varepsilon = \dot{\varepsilon} \cdot \Delta t = \dot{\varepsilon} \ [\nu_0 \cdot \exp(-E_b/k_B T)]^{-1}$, is applied to the system. Go back to step (i) under the new strain condition.

Through this algorithm, the coupling between thermal activation and strain rate is treated in the transition state theory framework. To be more specific, because ABC is employed iteratively on-the-fly, the environmental effects on PEL will be naturally captured. Since the atomic arrangements near the defects (e.g., dislocations and obstacles) are off perfect lattice sites and highly disordered, the underlying PEL structures could be rather complex, and each local minimum state in PEL might connect with multiple different transition pathways, corresponding to different evolution mechanisms. If these transition pathways show different sensitivities to surrounding environments (e.g., strain rate, temperature, stress state, etc.), then a crossover between their relative importance at different conditions might occur, which would then lead to different deformation mechanisms and mechanical behavior.

Figure 5 shows an example on the interaction mechanisms between a $< 11\bar{2}0 >$ $\{10\bar{1}0\}$ dislocation and a self-interstitial atom (SIA) cluster in HCP Zr over a wide range of thermomechanical environments (Fan et al. 2013). Starting from the initial state in Fig. 5a, the PEL-based iterative ABC-TST procedure enables one to uncover the interaction mechanisms over 15 orders of magnitude in timescales, from 10^7 s^{-1} down to 10^{-7} s^{-1}, far beyond the MD's range but appropriate for direct comparison with experiments. It is demonstrated in Fig. 5b that even the same unit process could lead to remarkably different mechanisms. Specifically, in the low temperature and high strain-rate regime, the dislocation tends to simply pass by the obstacle, and the system undergoes a stable homogeneous deformation with normal work hardening, while in the higher temperature and lower strain-rate regime, the obstacle is absorbed and swept by the dislocation. The removal of obstacle will result in a defect-free region along the slip plane known as dislocation channel, which is associated with strain localization and heterogeneous deformation, and could further induce mechanical instability.

The reason why the same initial state could give rise to significantly different mechanical behavior can be explained by the environmental effects on the system's underlying PEL structure revealed by the ABC technique. As shown in Fig. 5c, for such unit process in HCP Zr, the initial state connects with two transition pathways that are associated with different microstructural evolution modes. At the beginning, path I (obstacle removal) has a lower activation energy than path II (simple bypass) does. Therefore, if the surrounding environments do not change significantly, say when the driven strain rate is relatively low, then the system would naturally have a higher chance to go through the path I and give rise to the dislocation
Fig. 5 (**a**) Initial state of the unit process of dislocation-SIA cluster interaction in the prismatic slip system in HCP Zr. (**b**) The same initial state could result in remarkably different evolution mechanisms when the timescale is spanning more than 15 orders of magnitude. In the low temperature and high strain-rate regime, the system undergoes a stable homogeneous deformation process because the dislocation simply bypasses the SIA cluster. However, in the higher temperature and lower strain-rate regime, the SIA cluster is absorbed and removed by the gliding dislocation, which then leads to dislocation channeling and mechanical instabilities. It can be seen that the ABC-based modeling technique allows one to probe the microstructural evolution mechanisms from atomic level at realistic timescale far beyond the traditional MD's range (region of blue squares). (**c**) The crossover of two different mechanisms originates from the variation of system's underlying PEL under different environments. As shown in (c1), the initial state connects with two transition pathways that are associated with different microstructural evolution modes. At the beginning, path I (obstacle removal) has a lower activation energy than path II (simple bypass) does. Therefore, if the driven strain rate is relatively low, i.e., when the surrounding environments do not change appreciably, then the system would naturally have a higher chance to go through the path I, which leads to obstacle removal. On the other hand, under very high strain-rate scenario, since path II is more sensitive to external loading and its activation barrier under large strain becomes lower than path I does, as seen in (c2), then path II becomes more favorable and a bypass mechanism occurs

channel formations. This is indeed what has been observed by TEM experiment (Onimus et al. 2004) at the condition of 600 K and 10^{-4} s^{-1}. However, as shown in Fig. 5c1–c2, the responses of two pathways to external stimuli are different. Path II is more sensitive to the applied shear loading, and its activation barrier becomes

lower at large strain condition. Therefore, under very high strain-rate scenario, path II becomes favorable very quickly, and a different deformation mechanism would occur.

To validate the diagram just predicted, independent MD simulations have been employed. Although MD studies are limited to the very high strain-rate regime, the results at different temperatures (blue squares in Fig. 5b) show a clear mechanism crossover between dislocation bypass and channeling.

We would like to note that the approach in constructing the mechanism map is based on a general thermal activation theory under prescribed strain rate (Fan et al. 2012, 2013), and is not limited to the defects discussed here in the Zr system. For instance, previous MD simulations in bcc Fe report different interaction mechanisms between a dislocation and a SIA loop as a function of temperature (Terentyev et al. 2010a; Bacon et al. 2009). Specifically, at high temperature, the SIA loop is absorbed by the dislocation, while at low temperature, both dislocation and SIA loop are completely recovered. Despite both being at high strain rate, these two different outcomes in bcc Fe can also be understood as a competition of strain rate and temperature, as explained by the mechanism map in Fig. 5b. In other words, the present framework is quite general and can be applied to study different materials (e.g., glass materials, colloidal system) and responses to different conditions (e.g., annealing rate, irradiation rate).

3   Plasticity in Amorphous Solids

Glassy materials deform and flow in response to external mechanical agitation and internal thermal activation. Due to the lack of well-defined structural defects such as dislocations in their crystalline counterpart, studying the mechanistic details, by which the constituent atoms rearrange themselves under stress and temperature environment, is still not well understood. In particular, the stress and strain-rate effects on plastic deformation and its underlying microscopic processes are in need of further studies.

A number of theoretical models have been proposed to describe the mechanisms of atomistic deformation and flow responsible for plastic deformation in amorphous solids. Spaepen considered the distinction between homogeneous and inhomogeneous flows in metallic glasses (Spaepen 1977) and introduced the concept of the local free volume as an order parameter. In this view local strain production and dissipation are assumed to be associated with individual atomic jumps. Argon proposed a plastic deformation model of metallic glasses based on the notion of local shear transformations driven by stress and in the presence of thermal fluctuations (Argon 1979). The atoms participating in such processes essentially undergo an inelastic shear deformation. Twenty years later, Falk and Langer introduced the term shear transformation zone (STZ) in interpreting simulation results of viscoplastic deformation of amorphous solids (Falk and Langer 1998), and the term STZ has become widely adopted in studies of amorphous materials.

On the other hand, significant attempts to understand amorphous plasticity have been carried out using molecular dynamics (MD) simulations. For instance, MD results revealed that structural disorder-induced softening precedes thermal softening which acts as the origin of the shear banding (Cao et al. 2009). The bottleneck well-known in MD is that simulations of deformation often entails extreme conditions of strain rate which are higher by several orders of magnitude than those studied experimentally (Yamakov et al. 2002; Sentjabrskaja et al. 2015). Because slow thermal activations and relaxations could be suppressed due to the short timescale in MD simulations, direct comparison with experiments cannot be straightforwardly performed.

In this section, we discuss two studies of amorphous plastic deformation under low mechanical stress or slow strain rate using the ABC-based PEL sampling technique: (1) constant stress-driven amorphous creep and (2) strain rate-dependent slip avalanches in amorphous plasticity.

3.1   Creep: Deformation and Flow at Constant Mechanical Stress

Creep is a slow deformation phenomenon occurring in materials typically subjected to constant mechanical stress and temperature. Creep deformation has been studied in various amorphous materials such as metallic glasses and colloidal systems (Krisponeit et al. 2014; Huang et al. 2009; Siebenbürger et al. 2012; Schuh et al. 2007; Lu et al. 2003). To identify the elementary processes of deformation and flow in amorphous creep, we implement a meta-dynamic formulation (Cao et al. 2017) that allows transition state trajectories to be generated on timescale of seconds. In the simulation, we apply a prescribed uniaxial tensile stress to the system and execute the following steps:

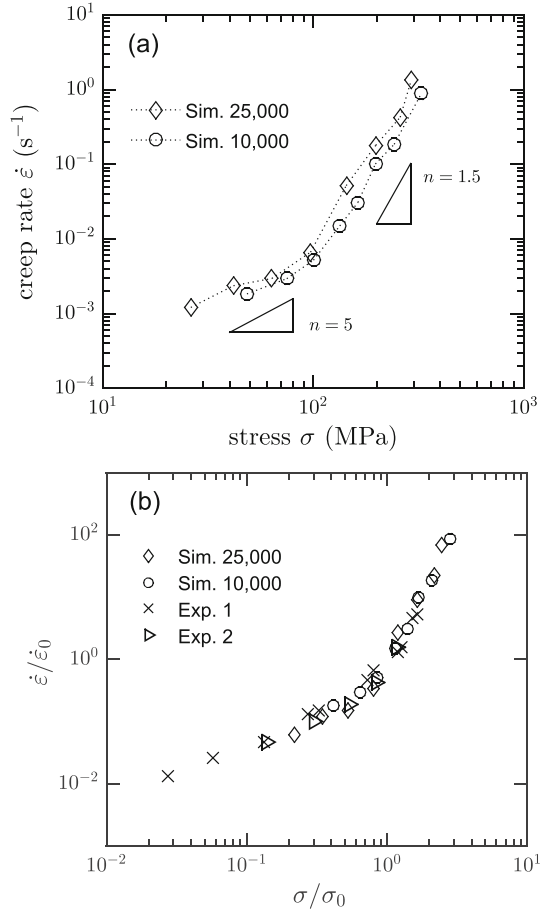
1. Perform energy minimization on the relaxed system to bring it to the nearest local energy minimum.
2. Apply the autonomous basin climbing (ABC) algorithm (Kushima et al. 2009a; Cao et al. 2012) to obtain the transition state pathway and determine the neighboring local energy minimum state.
3. Compare the internal stress of the new state with the prescribed tensile stress. If the two stresses deviate by more than 1%, perform step (d); otherwise go back to step (b).
4. Perform cell relaxation in the presence of the external stress. The atoms are rescaled to new positions whenever the size of simulation cell is changed, and the final configuration converges to a new local minimum.

The system evolution is then determined by examining the newly sampled configurations of the local energy minima. The activation time of each evolution step can be estimated through transition state theory, $\Delta t_i = \left[v_0 \exp(-\frac{\Delta E_i}{k_B T}) \right]^{-1}$, with attempt frequency v_0 typically taken to be 10^{12} s^{-1}, ΔE_i is the energy barrier of activation path i.
Fig. 6 Simulated creep curve: time evolution of system strain ε at stress 198 MPa and temperature $0.68T_{\mathrm{g}}$. The creep rate $\dot{\varepsilon}$ of the secondary stage is essentially constant and at a minimum. The background colors are drawn schematically to denote the creep rate

Figure 6 shows the simulation result of time development of the system strain. The creep curve shows the classical behavior of three stages of strain evolution. The initial period of strain buildup, consisting of a steep increase followed by a gradual approach to saturation, is known as primary or transient creep. The secondary stage of steady-state creep is a period of linear strain increase in time. The extent of this stage depends on the combination of applied stress and system temperature. For relatively low stresses, the secondary stage may have a considerable extent before the onset of tertiary creep, where strain rate increases without apparent limit. In the case of Fig. 6, the onset of structural instability at a strain level of ∼2.5% is readily observed.

In the present discussion, our interest lies in the mechanisms sustaining the steady-state creep (secondary stage). By varying the value of applied stress, one can determine the creep rate, and its variation with stress is shown in Fig. 7a. We can see a bimodal behavior in the monotonic variation of creep rate $\dot{\varepsilon}$ with stress σ. At low stress, $\dot{\varepsilon}$ is characterized by a creep-rate slope of $n \sim 1.5$, where n is known as the stress exponent. At high stress n increases to ∼5. Notice the stress value for the change in index n. The transition in creep rate behavior is well-known in experiments on different materials (see Fig. 7b for comparison with experiments) (Boyle and Spence 2013; Nieh and Wadsworth 2006; Klueh 2005). It is generally understood to signify thermal activation processes at low stress, changing over to stress activation for reasons that have not been resolved heretofore, particularly regarding the roles of atomic diffusion and shear deformation.

Figure 8 shows the spatial distributions of nonaffine displacement and of deviatoric strain at low and high stresses. At the low stress of 64 MPa, the features of

Fig. 7 (**a**) Stress dependence of creep rate from simulations with two different system sizes of 25,000 and 10,000 atoms. (**b**) Stress variation of creep rate, the two sets of experimental data 1 (crosses) and data 2 (triangles) are adapted from Lu et al. (2003) and Nieh and Wadsworth (2006), respectively. σ_0 and $\dot{\varepsilon}_0$ are threshold values in the creep rate-stress curve


the nonaffine displacement and local strain can be essentially attributed to thermally processes. As shown in Fig. 7c, the thermally activated atomic diffusion produces little local strain burst (local rupture) event. At high stress of 258 MPa indicated by Fig. 8b, the displacement magnitude of the sites of high mobility is about a factor of three larger than the displacements at low stress. Moreover, when looking at Fig. 7d, we see the presence of bi-directional deformation which corresponds to local strain bursts, a striking effect of stress-induced deformation.

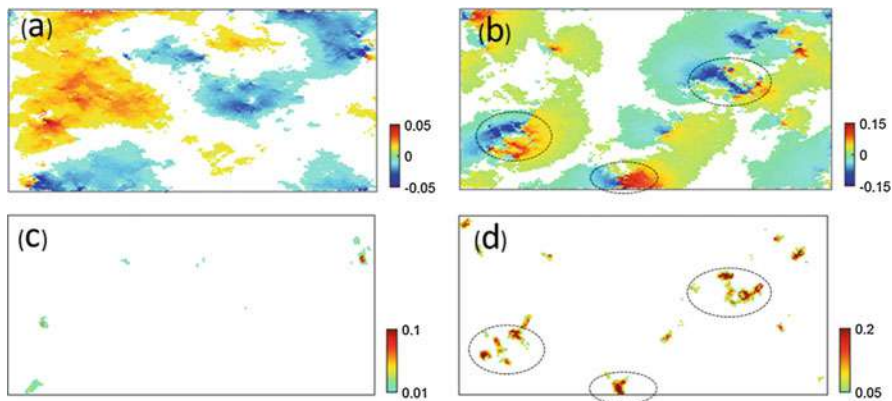
We believe the creep rate upturn delineates a regime of nonlinear response in the rheological behavior of amorphous materials, a consequence of the nonlinear coupling between atomic diffusion and shear-induced deformation. More generally, it indicates an interplay between thermal and stress-activated processes, involving loading effects, thermal noise, and stress-induced fluctuations.


Fig. 8 Spatial distributions of nonaffine displacement (**a**) and (**b**) and of deviatoric strain (**c**) and (**d**). All measures are time incremental, taken over a time interval of 0.01 s. Atoms are colored according to magnitude of their displacements or strains. At each level the left and right panels denote low stress (64 MPa) and high stress (258 MPa), respectively

3.2 Slip Avalanches of Amorphous Plasticity Under Constant Strain Rates

Discrete stress relaxations (slip avalanches), the serrations in stress-strain responses to mechanical deformation are ubiquitous in the dynamics of amorphous plasticity (Schuh et al. 2007; Antonaglia et al. 2014a). A common characteristic of slip avalanches is the strain-rate sensitivity which becomes more pronounced as the rate is lowered (Schuh et al. 2002, 2007; Antonaglia et al. 2014b; Harris et al. 2016). To understand the atomistic mechanisms of stress relaxation at a wide range of strain rate, we implement an atomistic simulation algorithm (Cao et al. 2014a, 2018) that can reach timescales in the range of experiments. To model constant strain-rate simulation, we first select a strain-rate value and use the transition state theory expression $\dot{\varepsilon} = \dot{\gamma}_0 \exp(-E_b/k_B T)$ to determine a value for the activation barrier E_b, where γ_0 is the attempt frequency prefactor and k_B is the Boltzmann constant. After determination of the activation barrier E_b for a strain rate $\dot{\varepsilon}$, we perform the following steps:

1. Perform energy minimization to bring the system to the nearest local energy minimum state.
2. Run the autonomous basin climbing (ABC) algorithm (Cao et al. 2012) to generate a transition state pathway (TSP) trajectory consisting of local energy minima and saddle points, stopping the ABC simulation when an activation energy barrier greater than E_b is found.
3. Examine the local energy minima explored by the ABC algorithm, and perform a standard Monte Carlo (MC) run to pick the most likely state according to

the probability $p = \exp\left(\Delta E_{(i,j)}/k_\text{B}T\right)$, where $\Delta E_{(i,j)}$ is the energy difference between local minima i and j. Save the associated atomic configurations.

4. Apply a small strain increment $\Delta\varepsilon = 10^{-4}$ to the system, perform energy minimization, and repeat steps 1, 2, and 3. Each step thus contributes a strain increment $\Delta\varepsilon$ to the overall imposed strain ε. The associated atomic configurations stored in the process can be used to calculate the corresponding single-atom displacement and the local deviatoric strain. The iteration continues until the strain ε reaches 18%.

5. For quasistatic (QS) simulation, $E_b = 0$, so there is no need to run steps 2 an 3. The simulation thus consists of iterating on steps 1 and 4, performing energy minimization after each strain increment.

In Fig. 9a we show the simulated responses of system-level stress to uniaxial compression at three distinct values of strain rates. The curve QS (quasistatic) (Falk and Maloney 2010) is obtained by potential energy minimization, which is effectively the limit of high strain rate (Fan et al. 2013; Cao et al. 2014b). The other two curves correspond, respectively, to constant strain rates of $2.2 \times 10^7\,\text{s}^{-1}$ and $4.6 \times 10^{-2}\,\text{s}^{-1}$, which are typical of conventional MD simulations and laboratory mechanical testing, respectively.

The overall response at each strain rate shows initially elastic loading up to a yield point, followed by a series of stress drops of varying magnitudes. The effects of strain rate are first a lowering of the entire stress-strain curve as the strain rate decreases from QS to MD to laboratory testing. Secondly, a significant sharpening of the serrations occurs in this progression of strain rates. The variation of the peak (yield) stress with strain rate, known as the stress overshoot, is also evident. In Fig. 9b portions of the flow curve at the three strain rates are shown in greater detail to illustrate the significant sharpening in avalanche response as the strain rate is lowered (Maaß et al. 2011; Antonaglia et al. 2014b). At the lowest strain rate, we see well-resolved intermittent minor relaxations interspersed between large events throughout the entire flow regime. Similar behavior, suggesting a distinction between small and large avalanches, is observed experimentally (Antonaglia et al. 2014a; Wright et al. 2013; Maaß et al. 2011).

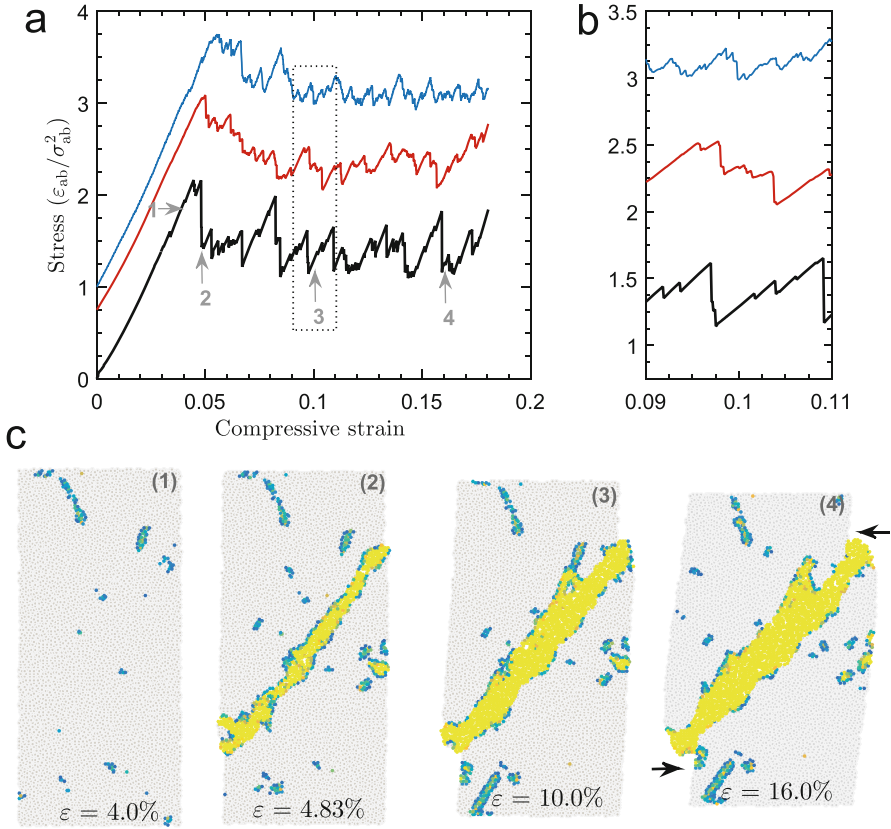
In Fig. 9c we show the corresponding deformations at the lowest strain rate associated with the onset of yielding and subsequent flow. In the four panels, one sees the spatial distributions of atomic sites with high deviatoric strain, color coded to indicate the magnitude of D^2_min. The distributions are cumulative strains (with reference to the initial undeformed configuration) during compression at the four numbered stages labeled in Fig. 9a: during elastic loading (point 1), after yielding (2), and during serrated flow (3–4). At 4% strain, we see only a few high-strain sites distributed rather randomly. Immediately after the onset of yielding, at 4.83% strain, a band of high-strain sites spanning the system has clearly formed. Notice also the appearance of a surface step. After the appearance of the shear band, the subsequent plastic flow is essentially dominated by this shear localized region, involving sliding and thickening. For example, with further compression through 10% to 16% strain,


Fig. 9 (**a**) Stress-strain response obtained at three strain rates: QS (top), $2.2 \times 10^7 \, \mathrm{s}^{-1}$ (middle), and $4.6 \times 10^{-2} \, \mathrm{s}^{-1}$ (bottom). The two upper curves have been shifted vertically by 1.0 and 0.75, respectively, to facilitate visual inspection. Arrows indicate the four stages of deformation corresponding to the four panels shown in (**c**). (**b**) Enlarged view of dotted box in (**a**). (**c**) Deviatoric strain distributions in the elastic response regime, after yielding and during the flow stage at a strain rate of $4.6 \times 10^{-2} \, \mathrm{s}^{-1}$. The red spheres indicate atoms subjected to large deviatoric strain, and atoms with strain $D_{\mathrm{min}}^2 < 1$ are colored gray. The arrows point to surface steps at strain of 16.0%. (Images modified from Cao et al. 2018)

the shear band has expanded in thickness as shown in the third and fourth panels of Fig. 9c. Correspondingly, the edge steps have become larger to accommodate the increased strain in the system (Shan et al. 2008).

To probe the nanoscale deformation and flow processes associated with an avalanche, we examine the deviatoric strain D_{min}^2 and the nonaffine atomic displacement. Figure 10 shows the spatial maps of D_{min}^2 for small and large avalanches at the steady-state flow stage of deformation. In Fig. 10a, which pertains to small avalanches, one sees a few local sites of significant strain magnitude. This indicates that during a minor stress drop, there is relatively little activity involving
Fig. 10 Visualization of local plastic strains associated with two typical avalanches, small (**a**) and large (**b**). Atoms are color coded by the magnitude of $D^2_{\min}$. The imposed strains in the two cases are 8.3% and 9.7%, respectively. Visualization of nonaffine displacement associated with small (**a**) and large (**b**) avalanches. Arrows are color coded by the nonaffine displacement magnitude. Note that the color scale is different for (**a**) and (**b**). The imposed strains in the two cases are 8.3%

localized shear transformations, and the few activated sites are spread out along the established shear band. In contrast, as seen in Fig. 10b, major stress relaxations involve a large number of activated sites at high strain magnitudes, clustered along a characteristic band-like region. Comparing Fig. 10a, b, one has a clear picture of the different roles that small and large avalanches play in maintaining serrated flow. Through the nonaffine displacements, we can assess atomic motions associated with internal relaxation during system flow. In Fig. 10c–d, we again see the distinction between small and large avalanches now visualized through the non-affine atom displacement. Comparing these results with the distributions of plastic strain production, we have a consistent picture of the molecular processes associated with serrated flow, resolved between small and large avalanches and between the single-particle (diffusion) and collective (cluster deformation) degrees of freedom. The processes are clearly spatially heterogeneous and temporally intermittent. Such details provide meaningful complements to current studies of the mechanisms of amorphous plasticity, based on combining theoretical modeling (Antonaglia et al. 2014a) with high temporal resolution mechanical testing (Wright et al. 2016).

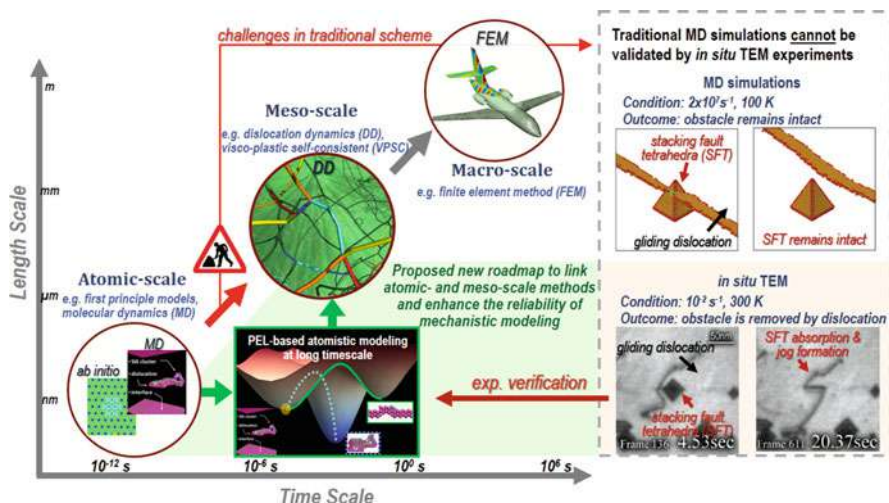
The fact that the system response is different in avalanche sizes implies the existence of two response regimes. The actual evolution of avalanche size suggests the small avalanches can be regarded as precursor events or an incubation stage leading up to the occasional major relaxation event. We see the large avalanches as a form of nonlinear response involving the concerted action of thermally activated atomic diffusion and stress-activated shear of local clusters of atoms. Such responses are characterized by spatial and temporal fluctuations that have been referred to as dynamical heterogeneities. Recognition of this kind of response can stimulate further theoretical work in modeling the weakening mechanism that underlies the onset of avalanches.


Fig. 11 Typical paradigm of multiscale modeling on dislocation-related problems consists of three different levels. At atomic scale, first principle calculation (e.g., ab initio) and molecular dynamics (MD) are widely used. At mesoscale, dislocation dynamics (DD) and visco-plastic self-consistent (VPSC) methods are most popular. And at macroscale, finite element method (FEM) is the dominant technique. It is expected that the outcomes from finer-scale models are fed into higher-level models as input parameters, which would then enable the inclusion of multi-physical processes at different scales. However, such traditional scheme, particularly the interface from MD to DD/VPSC, could be ill-informed. To be more specific, the right box shows the interaction mechanisms between a gliding dislocation and a stacking fault tetrahedra (SFT, a vacancy-type cluster) in FCC metals probed by MD simulation and by in situ TEM experiment, respectively. In MD study the SFT is found intact after cutting by the dislocation. But in real experiment, where the timescale is ten orders of magnitude longer than in MD simulation, the SFT is apparently absorbed and removed by the dislocation. Such discrepancies demonstrate that, due to its intrinsic timescale limitation, traditional MD simulation cannot capture the accurate and complete knowledge needed for the higher-level models. Given recent progress on the long-timescale atomistic simulation techniques, a new path via the PEL-based modeling has shown great promise in probing materials behavior at realistic timescale while still retaining the atomistic details

4   Summary and Outlook

It is widely appreciated that material microstructural evolution is an immensely complicated multi-physics phenomenon involving spatial and temporal scales ranging over many orders of magnitude. To establish a modeling and simulation framework to address the fundamental molecular mechanisms and to transfer such details to the higher-level models at meso- and macroscales is certainly a grand challenge.

As an example, Fig. 11 represents a well-accepted paradigm for the multiscale modeling of dislocation-related problems. At the macroscopic scale or continuum level, the finite element method (FEM) has been regarded as the most appropriate technique (Needleman and Van der Giessen 2005; Zhong and Zhu 2008). The fidelity of FEM calculation largely depends on whether its mesh can be efficiently

handled and whether there are reliable constitutive descriptions for all the nodes. The constitutive equations for dislocation-mediated deformation are usually provided by mesoscale models, such as dislocation dynamics (DD) and visco-plastic self-consistent (VPSC) method, which have been widely applied (Lebensohn et al. 2007; Turner et al. 1999; Schwarz 1999; Zbib and de la Rubia 2002; Arsenlis et al. 2007; El-Awady et al. 2008). On the other hand, both DD and VPSC models rely on many fitting or empirically assigned parameters, such as the dislocation core structures, the critical resolved shear stress for each slip system, the strain hardening exponent, the dislocation jog/junction formation mechanisms, the dislocation climb rate, etc.. As a result, although these mesoscale models can explain many observed experiments by adjusting various parameters, the predictive power of those models remains to be further improved. To reduce the number of empirical parameters, one still needs to employ more fundamental yet computationally more expensive modeling from the atomic levels, such as first principle calculations and MD method. These atomistic simulations can capture the dislocation core structures at equilibrium environments (Dezerald et al. 2016; Chaari et al. 2014; Proville et al. 2012) and provide useful mechanistic insights into the detailed dislocation-obstacle interaction processes (Terentyev et al. 2008, 2010a, b; Osetsky et al. 2006b).

Therefore, to enable a high-fidelity multiscale modeling, the connection between atomic-scale modeling and mesoscale modeling plays a vital role, because the robustness of multiscale modeling largely relies on whether MD simulations can provide accurate and complete mechanisms or not. Unfortunately, there are circumstances where MD simulations at short timescales cannot represent the realistic mechanism in experiments. An example that supports this is a remarkable controversy between the MD prediction and experimental observation over the dislocation-obstacle interaction mechanism in FCC metals. As shown in the right box of Fig. 11, in situ TEM experiments clearly show that a perfect SFT (a vacancy-type defect cluster named stacking fault tetrahedra) is fully absorbed and removed by a single moving dislocation (Osetsky et al. 2006a, b). However, parallel MD simulations show that the same type of obstacle remains intact after cutting by a moving dislocation (Matsukawa and Zinkle 2004). While the geometries and boundary conditions have been regarded as potential factors that might lead to such discrepancy (Osetsky et al. 2006a), the most probable reason, as discussed by Matsukawa and Zinkle (Matsukawa and Zinkle 2004), is the huge gap in timescale between the in situ TEM ($\sim 10^{-2}\,\mathrm{s}^{-1}$) and MD simulations ($\sim 10^{8}\,\mathrm{s}^{-1}$).

In this chapter we have shown several examples in both crystalline and amorphous materials that the PEL-based novel modeling techniques are capable of uncovering the microstructural evolutions over wide range of timescales and directly compare with experimental observations (Fan et al. 2012, 2013). A particularly notable feature of the PEL framework is that it is fundamentally governed by the interatomic potentials between the constituent particles, and thus no phenomenological assumptions or empirical parameters are needed.

Given these advantages, one could propose a "detour" on the conventional multiscale modeling roadmap. As illustrated by the green arrows in Fig. 11, instead of directly connecting MD with mesoscale methods (Yip and Short 2013), one can first

employ the PEL-based modeling to gain a more comprehensive knowledge at longer timescale and then pass the atomistic insights obtained on-the-fly to the higher-level models. Such a modification may be expected to lead to a more predictive modeling and simulation.

Quantized Dislocations for Functional and Quantum Materials

12

Mingda Li and Ricardo Pablo-Pedro

Contents

Abstract

Dislocations have a profound influence on materials' functional properties. In this perspective, we discuss the recent development of quantized dislocations – a theoretical tool that aims to compute the role of dislocations on materials' functionalities, at a full quantum field theoretical level. After a brief discussion of the motivation and a pedagogical introduction of quantization, we focus on a few case studies of dislon theory, to see how dislon can be applied to solve a given materials' functionality problem and lead to new predictions. We conclude by envisioning a few more open questions. With the aid of the powerful quantum field theory, the dislon approach may enable plenty of opportunities to compute multiple functional and quantum properties in a dislocated crystal at a new level of clarity.

1   Introduction

Dislocations affect materials' mechanical properties and functionalities, such as electronic structure, optical properties, thermal transport, magnetic ordering, and superconductivity. For decades, the dislocation research has been centering on mechanical behaviors, such as crystal plasticity (Hirth and Lothe 1992; Nabarro 1967). However, given the flourishing development of novel functional materials in recent years, the proper modeling of dislocation functionalities beyond mechanical aspects is gaining more and more importance, yet faces a series of challenges. As an extended defect with internal structure, a realistic dislocation is not only a quenched disorder composed of a distribution of strain field, but also subject to strong dynamical vibration and material-dependent Coulomb interaction in a complex interaction environment. In this sense, many dislocation studies are only describing a partial feature of a realistic dislocation, where its definition $\oint_L d\mathbf{u} = -\mathbf{b}$ is often not respected. While all these factors are taken into account to fully characterize a realistic dislocation, the calculation on the functionalities poses another level of challenge. On the one hand, due to the long-range nature of a dislocation's stress field, the first-principles calculation with dislocations requires a large supercell – could be as high as $N \sim 1000$ atoms (Wang et al. 2014). To carry out the response calculations, however, the computational complexity $\sim O(N^4)$ using the density functional perturbation theory is simply too high to be realistic (Baroni et al. 2001). On the other hand, since almost all those functionalities can be traced back to a microscopic quantum origin, a classical description of dislocation may simply be incapable to be integrated into a quantum theory in order to describe a complex quantum phenomenon.

In fact, a number of open questions remain in the field of dislocation functionalities. For electronic structure, it is known that the electrical resistivity in dislocated metals can have a particular type of electron-line defect resonance scattering, shown in Fig. 1a (Brown 1977; Karolik and Luhvich 1994). Although the resonance scattering model did explain some experimental data, the origin of such resonance is unclear: "There must be some general mechanism underlying this phenomenon... This is still very much an open question..." (Brown 1977). For optical properties, it is known that dislocation can induce luminescence (Drozdov et al. 1976) with four significant luminescence peaks (called D1 – D4) at low-temperature, which may survive even at room temperature after sample treatment (Fig. 1b). This phenomenon enabled dislocation based light-emitting diode (LED) applications (Kveder et al. 2004). However, even after three-decades-long research, the microscopic origin of these peaks is not yet fully understood, particularly "The origin of the D2-line is still under discussion" (Reiche and Kittler 2016). For the thermal transport, there has been a decades-long debate, arguing whether the dislocation-phonon interaction is static or dynamic in nature. Despite different temperature dependence, that $k_{\text{static}} \propto T^2$ while $k_{\text{dynamic}} \propto T^3$, carefully planned experiments may exhibit a mixed behavior (Fig. 1c). In particular, one recent first-principles calculations of dislocations mentioned that "Because of the break-

down of the Born approximation, earlier literature models fail, even qualitatively" (Wang et al. 2017). As to superconductivity, P.W. Anderson asserted that "The (superconducting) transition temperature (with defects) will always be slightly smaller for the scattered states than they would be in the pure case" (Anderson 1959), yet many experiments show otherwise. The anisotropic superconducting gap explains the transition temperature enhancement effect for point impurities (Markowitz and Kadanoff 1963), but a quantitative comparison for dislocations without using empirical parameter has been missing. These open questions, along with the unbearably high computational cost, indeed call for a much better approach to tackle the dislocation functionality problems at a more fundamental level.

This perspective article is a self-contained introduction on the recent theoretical progress of the so-called dislon theory. Dislon is a quasiparticle that aims to solve the above dislocation functionalities issues by directly quantizing a classical dislocation (Fu and Li 2017; Li 2019; Li et al. 2017a, b, c, 2018; Pablo-Pedro et al. 2018). We believe that there are a number of unique advantages adopting this quantized dislocation approach, mainly formalism simplicity and strong predictive power.

Formalism simplicity: The simplicity has a multifold meaning. First is the procedure to incorporate a dislocation into an existing system. Apparently, there are plenty of existing approaches that can introduce a dislocation. For instance, for electronic property studies, a dislocation is often modeled as a line charge. With a scattering Coulomb potential $V(r)$, its Fourier transformation $V(q)$ gives the scattering strength, from which the electron-dislocation relaxation time can be obtained using Fermi's golden rule (Jena et al. 2000; Look and Sizelove 1999; Weimann et al. 1998). Taking the dislon approach, a dislocation is introduced by adding the dislon Hamiltonian H_D and the interaction Hamiltonian H_I, into the original Hamiltonian H_0 for a pristine system. Given the arbitrary freedom to choose H_0, a dislocation can always be introduced properly. This leads to the second fold of simplicity that the Hamiltonian approach standardizes the procedure to compute all functional properties. With the knowledge of a given H_0, the electrical conductivity, thermal conductivity, thermopower, optical absorption, etc., are all computable using standard quantum many-body approaches, such as linear response theory (Mahan 2000). Now the understanding of the role that dislocations may play is then reduced to a standard linear-response calculation of functionalities, but with the total Hamiltonian $H_0 + H_I + H_D$. The third meaning of simplicity lies in the form of dislon Hamiltonian H_D, which has great mathematical simplicity to tackle, but with all dislocation effects – strain, dynamic, Coulomb – incorporated simultaneously. This comprehensive description of dislocation is in sharp contrast with a potential scattering approach. Taking the popular line charge model of dislocation as an example, we see that the Burgers vector **b** does not even appear explicitly in the expression of relaxation time, which is unphysical to some extent.

Strong predictive power: Besides the formalism simplicity, the main advantage of dislon theory lies in the strong predictive power. This is a natural consequence by adopting a quantum field theoretical approach, since it can seamlessly incorporate all other interactions and correlation effects to an arbitrarily high order. The interaction effects are essential for a realistic scenario, for instance, dislocations may coexist with point defects, phonons, and electrons in a real crystal, and we could always pick up the relevant degrees of freedom that are of interest for a given problem. For instance, if we are interested in phonon-dominant thermal transport, then the Coulomb charge model of dislocation cannot interact with phonon, hence cannot be used for thermal transport study. The dislon theory, on the other hand, is a unified approach. Since it already contains the strain effect in the dislon field, the interaction with phonon becomes straightforward. The correlation effect and higher-order scattering, on the other hand, are both important toward qualitatively novel phenomena (Rammer 1998). This also distinguishes the dislon theory from a semiclassical model. Again taking the line charge model as an example, we will know for sure that Coulomb scattering is guaranteed to happen, but meanwhile, full predictability is lost since there is no information how dynamic and strain effect affects the electronic structure. A quantum field theory, on the other hand, is still ab initio in nature, which retains a full predictive power without loss of information from the starting point.

2   Dislon as Quantized Dislocation

To see how a dislocation can be quantized into a quantized operator form, we noticed that both a dislocation and a phonon are atomic lattice displacement **u**, with the major difference coming from the dislocation's topological constraint $\oint_L d\mathbf{u} = -\mathbf{b}$. Therefore, two major pillars are needed to quantize a dislocation. One is the lesson of quantum procedure, learned from the more familiar phonon quantization; the other is the unique features of a classical dislocation that distinguishes from a classical lattice wave.

The lesson from phonon quantization: We briefly outline the familiar phonon quantization first since the dislocation quantization shares some formalism similarity. A comprehensive procedure for phonon quantization can be found in quantum many-body monographs (Fetter and Walecka 2003; Mahan 2000). For a system with N atoms with mass m, each atom located at coordinate $\mathbf{R}_n$ has its own displacement $\mathbf{u}_n$ and momentum $\mathbf{p}_n (n = 1, 2, \ldots N)$. The total kinetic energy gives

$$K = \sum_{n=1}^{N} \frac{|\mathbf{p}_n|^2}{2m} = \sum_{n=1}^{N} \sum_{i=1}^{3} \frac{(p_{ni})^2}{2m} \tag{1}$$

where p_{ni} is the ith Cartesian component of the vector $\mathbf{p}_n$. The total potential energy can be written as

$$U = \frac{1}{2} \sum_{m,n=1}^{N} \sum_{i,j=1}^{3} u_{mi} V_{ij}^{mn} u_{ni} \tag{2}$$

where u_{ni} is the ith Cartesian component of displacement $\mathbf{u}_n$, V_{ij}^{mn} is a generalized "spring constant" for a harmonic oscillator. To obtain a quantum theory, we promote the classical dynamical variables $\mathbf{u}_n$ and $\mathbf{p}_n$ into first-quantized operators, with the following canonical quantization condition:

$$[u_{ni}, p_{mj}] = i\hbar \delta_{ij} \delta_{mn} \tag{3}$$

i.e., different atomic locations ($m \neq n$) and directions ($i \neq j$) commute with each other.

As we see, the phonons in an N-atom system Eqs. (1) and (2) appear cumbersome in a first-quantized form. However, all these can be simplified using a second quantization approach. To do so, we perform a Fourier transform:

$$\begin{aligned}
\mathbf{u}_n &= \frac{1}{\sqrt{N}} \sum_{\mathbf{k}} \mathbf{u}_{\mathbf{k}} e^{-i\mathbf{k}\cdot\mathbf{R}_n}, \quad \mathbf{u}_{\mathbf{k}} = \frac{1}{\sqrt{N}} \sum_{\mathbf{k}} \mathbf{u}_n e^{i\mathbf{k}\cdot\mathbf{R}_n} \\
\mathbf{p}_n &= \frac{1}{\sqrt{N}} \sum_{\mathbf{k}} \mathbf{p}_{\mathbf{k}} e^{-i\mathbf{k}\cdot\mathbf{R}_n}, \quad \mathbf{p}_{\mathbf{k}} = \frac{1}{\sqrt{N}} \sum_{\mathbf{k}} \mathbf{p}_n e^{i\mathbf{k}\cdot\mathbf{R}_n}
\end{aligned} \tag{4}$$

where $\mathbf{u_k}$ and $\mathbf{p_k}$ are the canonical displacement and momentum operator labeled by quantum number $\mathbf{k}$ (called crystal momentum), respectively. Then, substituting Eq. (4) back to Eqs. (1) and (2), and performing a Fourier transform to the expansion coefficient V_{ij}^{mn},

$$D_{ij}(\mathbf{k}) = \sum_{\mathbf{R} \equiv \mathbf{R}_m - \mathbf{R}_n} V_{ij}^{mn} e^{-i\mathbf{k} \cdot (\mathbf{R}_m - \mathbf{R}_n)} \tag{5}$$

where since a crystalline solid is periodic with translation symmetry, we only need to sum over the position *difference* between two lattice positions $\mathbf{R}_n$ and $\mathbf{R}_m$. Now since $D_{ij}(\mathbf{k}) = D_{ji}(\mathbf{k})$, the $3 \times 3 D(\mathbf{k})$ matrix ($\mathbf{k}$ can be considered as a parameter) can be diagonalized with real eigenvalues. The eigen-equation can be written as

$$D(\mathbf{k}) \varepsilon_{\mathbf{k}\lambda} = m\omega_{\mathbf{k}\lambda}^2 \varepsilon_{\mathbf{k}\lambda} \tag{6}$$

in which $\varepsilon_{\mathbf{k}\lambda}$ is the eigenvector ($\lambda = 1,2,3$) called polarization vector, and $m\omega_{\mathbf{k}\lambda}^2$ is the eigenvalue. The second-quantized form can be defined by the particle occupation number formalism:

$$\begin{aligned} \mathbf{u_k} &= \sum_{\lambda} \sqrt{\frac{\hbar}{2m\omega_{\mathbf{k}\lambda}}} \left(a_{\mathbf{k}\lambda}^+ + a_{\mathbf{k}\lambda} \right) \varepsilon_{\mathbf{k}\lambda} \\ \mathbf{p_k} &= i \sum_{\lambda} \sqrt{\frac{\hbar m\omega_{\mathbf{k}\lambda}}{2}} \left(a_{\mathbf{k}\lambda}^+ - a_{\mathbf{k}\lambda} \right) \varepsilon_{\mathbf{k}\lambda} \end{aligned} \tag{7}$$

where $a_{\mathbf{k}\lambda}$ and $a_{\mathbf{k}\lambda}^+$ annihilate and create a phonon at state $\mathbf{k}\lambda$, respectively, satisfying the following commutation relation:

$$\left[a_{\mathbf{k}\lambda}, a_{\mathbf{k}\lambda}^+ \right] = 1 \tag{8}$$

Now substituting Eqs. (4), (7) and (8) back to Eqs. (1) and (2), we finally obtain a second-quantized Hamiltonian for 3D phonons:

$$H = \sum_{\mathbf{k}\lambda} \hbar\omega_{\mathbf{k}\lambda} \left(a_{\mathbf{k}\lambda}^+ a_{\mathbf{k}\lambda} + \frac{1}{2} \right) \tag{9}$$

which now has a much simpler form and enhanced power to deal with complex interaction problems. Such formalism and power enhancement also happens to a classical dislocation upon second quantization.

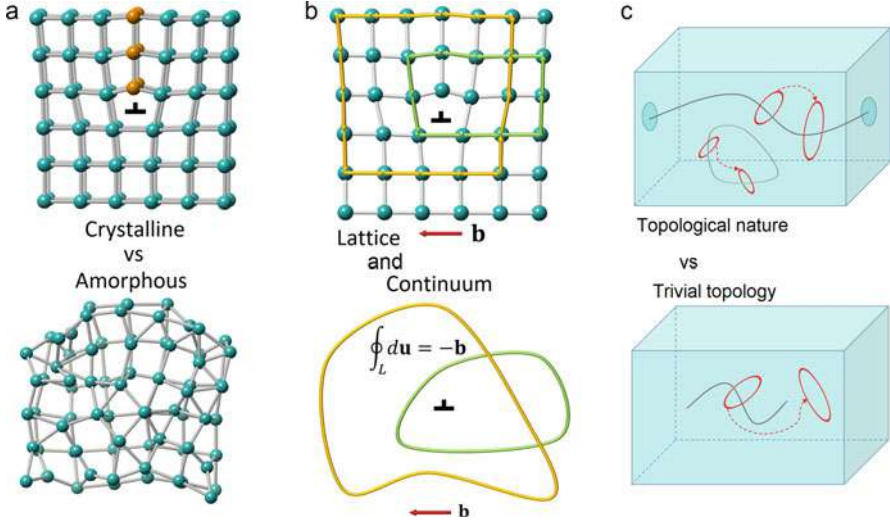
The lesson from Classical Dislocation: Another major pillar that supports the quantized dislocation lies in a few aspects of its classical counterpart (Fig. 2). First, a dislocation exists in a crystalline solid, but not in amorphous materials (Fig. 2a). This greatly facilitates the electron and phonon interaction problems in that the Bloch's theorem is valid. Second, a dislocation not only can be defined in discrete


Fig. 2 A few essential elements for a classical dislocation, including crystalline, continuum compatible, and topological. (Figures from Li (2019))

crystals, but also in a continuous medium $\oint_L d\mathbf{u} = -\mathbf{b}$, where $\mathbf{u} = \mathbf{u}(\mathbf{R})$, and $\mathbf{R}$ is a continuous spatial coordinate (Fig. 2b). This facilitates a treatment to develop a simpler low-energy effective quantum theory. Third, a dislocation's definition $\oint_L d\mathbf{u} = -\mathbf{b}$ indicates a topological invariance and forbids a dislocation to end inside a crystal bulk (Fig. 2c). This facilitates the description of dislocation as a long straight line, without worrying a short or segmented dislocation line, if we leave the complex dislocation loop out of the picture.

With the method of canonical quantization procedure and the concept of topological invariance, the dislon theory can be considered as a natural merge of these two pillars. The detailed dislocation quantization procedure is introduced in a recent review (Li 2019). Briefly speaking, a dislocated lattice system still contains kinetic energy and lattice strain potential energy, just like Eqs. (1) and (2). The dislocation's definition $\oint_L d\mathbf{u} = -\mathbf{b}$ is evolved into a simple boundary condition of the quantized operator. The incorporation of both the kinetic energy and potential energy is a critical move. This is so since many dislocation models contain only the potential energy part (e.g., stress field) in a frozen-lattice configuration. However, for phonon-dislocation scattering, it is well known that the dominant mechanism is the dynamic process, which could be orders-of-magnitude higher than the strain field (Anderson and Malinowski 1972; Maurel et al. 2004). By simultaneously incorporating both the kinetic energy and the potential energy, not only the formalism is greatly simplified in second-quantized form, but also both dynamic and static interactions are taken into account on an equal footing, which is more appropriate for a realistic dislocation.

2.1   The Dislon Hamiltonian

The major difference between the phonon and dislocation quantization lies in the Fourier transform step. Since a dislocation is an extended line defect, we have another generic expansion instead of plane-wave expansion:

$$\mathbf{u}_{dis}\left(\mathbf{R}\right) = \frac{1}{L^2} \sum_{\mathbf{k}} e^{i\mathbf{k}\cdot\mathbf{R}} \mathbf{F}\left(\mathbf{k}\right) u_{\mathbf{k}} \tag{10}$$

where L denotes the system size, that there is one dislocation at present within a square of L^2. For acoustic phonons, we have $\mathbf{F}(\mathbf{k}) = \varepsilon_{\mathbf{k}}$. Moreover, under the long-wavelength limit $\mathbf{k} \to 0$, we have $\lim_{\mathbf{k}\to 0} u_{\mathbf{k}} = 0$ for phonons, i.e., it reduces to a perfect lattice under the static limit without displacement. The situation of dislocation is distinct. The $\mathbf{F}(\mathbf{k})$ is an expansion coefficient with local modes,

$$\mathbf{F}\left(\mathbf{k}\right) = \frac{1}{k_x k^2} \left(\mathbf{n}\left(\mathbf{b}\cdot\mathbf{k}\right) + \mathbf{b}\left(\mathbf{n}\cdot\mathbf{k}\right) - \frac{1}{(1-\nu)} \frac{\mathbf{k}\left(\mathbf{n}\cdot\mathbf{k}\right)\left(\mathbf{b}\cdot\mathbf{k}\right)}{k^2}\right) \tag{11}$$

if we assume xz plane as slip-plane, and ν is the Poisson ratio.

On the other hand, $u_{\mathbf{k}}$ satisfies a different boundary condition $\lim_{k_z \to 0} u_{\mathbf{k}} = 1$ if we assume the dislocation is along the z-direction (Li et al. 2018). This simple boundary condition is a natural result to ensure the compatibility with the definition $\oint_L d\mathbf{u} = -\mathbf{b}$. In the end, the dislon Hamiltonian with dislon excitation $\Omega_{\mathbf{k}}$ in the second quantized form can be written as

$$H_D = \sum_{\mathbf{k}\geq 0} \Omega_{\mathbf{k}} \left(d_{\mathbf{k}}^+ d_{\mathbf{k}} + \frac{1}{2}\right) + \sum_{\mathbf{k}\geq 0} \Omega_{\mathbf{k}} \left(f_{\mathbf{k}}^+ f_{\mathbf{k}} + \frac{1}{2}\right) \tag{12}$$

where the operators satisfy

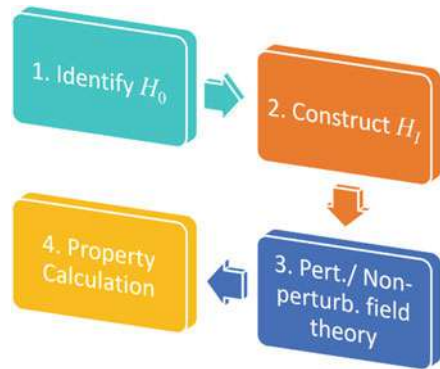
$$\left[d_{\mathbf{k}}, d_{\mathbf{k}'}^+\right] = \delta_{\mathbf{k}\mathbf{k}'}, \quad \left[f_{\mathbf{k}}, f_{\mathbf{k}'}^+\right] = \delta_{\mathbf{k}\mathbf{k}'} \tag{13}$$

with a boundary condition

$$\lim_{k_z \to 0} d_{\mathbf{k}} = \lim_{k_z \to 0} d_{\mathbf{k}}^+ = C_{k_\parallel} \tag{14}$$

in which $C_{k_\parallel}$ is a boundary term taking care of the effects along the in-plane directions perpendicular to the dislocation line, such as Coulomb scattering and strain field scattering. Whenever a classical effect needs to be taken into account, we can generalize $C_{k_\parallel}$ for a specific problem.

To sum up, we need two Bosonic fields to describe a quantized dislocation, which are subject to different boundary conditions, in contrast to the phonon case where one Bosonic field suffices (Fig. 3a). This resembles another topological defect of
Fig. 3 (**a**) Two fields of the dislon. (**b**) A magnetic monopole with two classical vector fields. (Figure adapted Li (2019))

Fig. 4 The general workflow applying the dislon theory


magnetic monopole (Fig. 3b), where two classical fields (magnetic vector potential), A_N and A_S, are needed to capture the intrinsic topology.

Equations (12), (13), and (14) are the central results of a dislon Hamiltonian. Equation (13) takes care of all dynamic effects, while Eq. (14) is responsible for the strain field scattering and the classical Coulomb scattering, where eventually $C_{k_\parallel}$ can be directly related to the classical dislocation-electron scattering amplitude.

2.2   General Workflow to Apply the Dislon Theory

With the dislon Hamiltonian in hand, we are in good shape to introduce the general workflow applying the dislon theory to a general functionality problem, summarized in Fig. 4.

Step 1. Identify the Hamiltonian H_0 that describes the dislocation-free system. If we are interested in electrons in a metal, then H_0 is just non-interacting electrons; if we want to study the phonon transport, H_0 is the free-phonon Hamiltonian Eq. (9). If

we want to study optical and magnetic properties that are influenced by dislocation, then a multi-band Hamiltonian can be applied, for instance, a 2-band model,

$$H_0 = \sum_{\mathbf{k}} \begin{pmatrix} c_{\mathbf{k}a}^+ & c_{\mathbf{k}b}^+ \end{pmatrix} \begin{pmatrix} E_{\mathbf{k}a} - \mu & 0 \\ 0 & E_{\mathbf{k}b} - \mu \end{pmatrix} \begin{pmatrix} c_{\mathbf{k}a} \\ c_{\mathbf{k}b} \end{pmatrix} \qquad (15)$$

where $(a, b) = (\uparrow, \downarrow)$ for a spin-1/2 system, while $(a, b) = (c, v)$ for a 2-band model with conduction and valence band.

Step 2. Identify the interacting Hamiltonian H_I. The non-interacting dislon Hamiltonian H_D itself is not enough to affect H_0, without having an interaction term. As we will see in the next section, in many situations, we need to write down the classical interaction Hamiltonian and then perform the corresponding quantization. Fortunately, Since dislocation contains strain field, dynamic vibration, and Coulomb interaction, the number of such interaction Hamiltonians are finite, some are quantized recently (Li et al. 2018). For instance, for the prototypical deformation potential scattering between dislocation displacement field and the gradient of Coulomb interaction, we have $\mathbf{u}_{dis} \cdot \nabla V_{Coulomb}$; for the velocity-velocity fluttering interaction with phonon, we have $\dot{\mathbf{u}}_{dis} \cdot \dot{\mathbf{u}}_{ph}$; while for the anharmonic dislocation-phonon interaction, we have $\mathbf{u}_{dis}\mathbf{u}_{ph}^2$, etc. The goal is to rewrite these classical interaction Hamiltonians in terms of a combination of creation and annihilation operators from H_0 (electron and phonon operators) and from H_D (dislon operators).

Step 3. Perturbative and Non-perturbative calculations. With the non-interacting and interacting Hamiltonians, we are ready to carry out relevant calculations, by setting up perturbative and non-perturbative calculations. By non-perturbative, we refer to the functional integral approach (Negele and Orland 1988), which is convenient to take into account the constraint Eq. (14). If, on the other hand, we only want to understand the dynamical quantum effect of dislocations, then no constraint is needed.

Step 4. Property calculation. Through step 3, almost all major physical quantities, such as DC and AC electrical conductivity, thermal conductivity, dielectric function, optical absorption, Seebeck coefficient, magnetic susceptibility, superconducting transition temperature, etc., can be computed systematically based on linear response theory, with controllable approximations. An example of DC conductivity workflow is shown in Fig. 5.

3   Cases Studies Using the Dislon Theory

This tribute intends to provide a few concrete examples and see how the dislon theory can be applied in a given interaction scenario. We will provide three examples, including the computation of the electron-dislon relaxation time, the calculation of superconducting transition temperature T_c, and also the phonon energy shift and relaxation time upon dislocation interaction. We elaborate the first example given its simplicity and outline the remaining two by summarizing the main results and major predictions.

Scheme for Computing Electrical Transport with Electron Scattering from Parallel Dislocation Arrays

DC Conductivity

$$\mathrm{Re}[\sigma_{ab}(T)] = -\frac{e^2}{L^3}\sum_{\mathbf{k}}\Gamma_{0,a}(\mathbf{k},\mathbf{k})\left.\frac{\partial n_F(\varepsilon)}{\partial\varepsilon}\right|_{E_{\mathbf{k}}-\mu}$$

$$\times\,\mathrm{Re}[\Gamma_b(\mathbf{k},\mathbf{k};E_{\mathbf{k}}-\mu+i\delta,E_{\mathbf{k}}-\mu-i\delta)]$$

Relaxation Rate

$$\frac{\hbar}{\tau_{\mathbf{k}}} = \frac{2\pi n_{\mathrm{dis}}}{L^2}\sum_{\mathbf{k}'}\left|\frac{A_{\mathbf{k}-\mathbf{k}'}}{\varepsilon(\mathbf{k}-\mathbf{k}')}\right|^2\delta_{kz,k'z}\delta(E_{\mathbf{k}}-E_{\mathbf{k}'})$$

Current Vertex

$$\Gamma_b(\mathbf{k},\mathbf{k};\varepsilon+i\delta,\varepsilon\pm i\delta) = \Gamma_{0,b}(\mathbf{k},\mathbf{k})$$

$$+\frac{n_{\mathrm{dis}}}{L^2}\sum_{\mathbf{k}'}\left|\frac{A(\mathbf{k}'-\mathbf{k})}{\varepsilon(\mathbf{k}'-\mathbf{k})}\right|^2\delta_{kz,k'z}G(\mathbf{k}';\varepsilon+i\delta)$$

$$\times\,G(\mathbf{k}';\varepsilon\pm i\delta)\,\Gamma_b(\mathbf{k}',\mathbf{k}';\varepsilon+i\delta,\varepsilon\pm i\delta)$$

Self-Energy

$$\Sigma(\mathbf{k},\varepsilon\pm i\delta) = \frac{n_{\mathrm{dis}}}{L^2}\sum_{\mathbf{k}'}\frac{|A_{\mathbf{k}-\mathbf{k}'}/\varepsilon(\mathbf{k}-\mathbf{k}')|^2\delta_{kz,k'z}}{\varepsilon-E_{\mathbf{k}'}+\mu\pm i\delta}$$

Green's Function

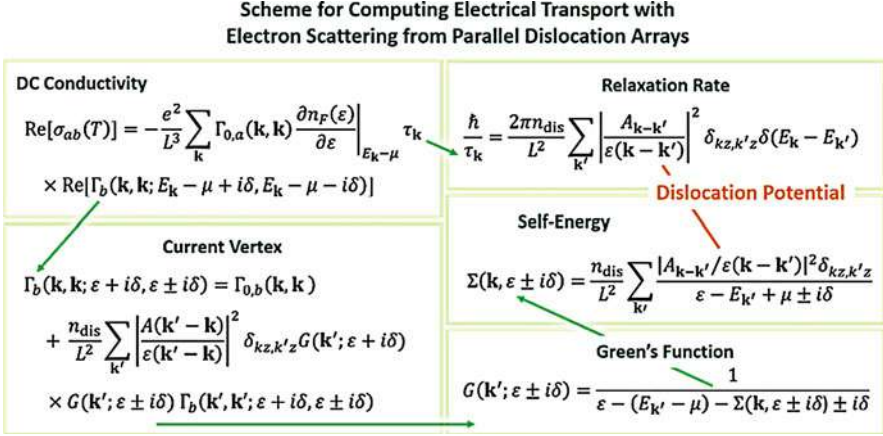
$$G(\mathbf{k}';\varepsilon\pm i\delta) = \frac{1}{\varepsilon-(E_{\mathbf{k}'}-\mu)-\Sigma(\mathbf{k},\varepsilon\pm i\delta)\pm i\delta}$$


Fig. 5 The example workflow of electrical conductivity calculation using a quantum many-body approach with the presence of dislocations

3.1   Computation of Relaxation Time

In the classical dislocation theory, a dislocation is modeled as a scattering potential $V(\mathbf{r})$, and the relaxation rate from state i to f can be computed using Fermi's golden rule:

$$\Gamma_{i\to f} = \frac{2\pi}{\hbar}\left|\int\psi_f^*(\mathbf{r})\,V(\mathbf{r})\,\psi_i(\mathbf{r})\,d\mathbf{r}\right|^2\delta\left(\varepsilon_f-\varepsilon_i\right) \qquad (16)$$

where $\psi_i(\mathbf{r})$ and $\psi_f(\mathbf{r})$ are the initial and final wavefunctions with energy ε_i and ε_f, respectively. If we assume a plane wave wavefunctions $\psi_i(\mathbf{r}) = e^{i\mathbf{k}\cdot\mathbf{r}}/L^{D/2}$ and $\psi_f(\mathbf{r}) = e^{i(\mathbf{k}+\mathbf{q})\cdot\mathbf{r}}/L^{D/2}$, and define a Fourier transform $V(\mathbf{q}) = \int V(\mathbf{r})e^{-i\mathbf{q}\cdot\mathbf{r}}d^D\mathbf{r}$, the relaxation rate for an electron with momentum $\mathbf{k}$ being scattered into $\mathbf{k}+\mathbf{q}$ using Eq. (16) can be written as

$$\Gamma_{\mathbf{k}\to\mathbf{k}+\mathbf{q}} = \frac{1}{L^{2D}}\frac{2\pi}{\hbar}|V(\mathbf{q})|^2\delta\left(\varepsilon(\mathbf{k}+\mathbf{q})-\varepsilon(\mathbf{k})\right) \qquad (17)$$

Since the momentum change $\mathbf{q}$ is arbitrary, if we assume a total number of N_{dis} dislocations, the total relaxation rate as a function of electron momentum $\mathbf{k}$ can be written as

$$\Gamma_{\mathbf{k}} = N_{dis}\sum_{\mathbf{q}}\Gamma_{\mathbf{k}\to\mathbf{k}+\mathbf{q}} = \frac{2\pi}{\hbar}n_{dis}\int\frac{d^D\mathbf{q}}{(2\pi)^D}|V(\mathbf{q})|^2\delta\left(\varepsilon(\mathbf{k}+\mathbf{q})-\varepsilon(\mathbf{k})\right) \qquad (18)$$

where n_{dis} denotes the dislocation density.

Equation (18) is a common approach to link dislocation's potential $V(\mathbf{r})$, electron energy $\varepsilon(\mathbf{k})$ to the relaxation rate $\Gamma_{\mathbf{k}}$. However, problems remain: (a) The relation between $V(\mathbf{q})$ and the definition $\oint_L d\mathbf{u} = -\mathbf{b}$ is obscure. If we model a dislocation as a line charge, where $V(\mathbf{r})$ is Coulomb potential, it has nothing to do with dislocation's definition. (b) When the electrons are under interactions in the solid, the wavefunctions are usually too difficult to obtain. In addition, it seems impossible to incorporate other interactions into this formalism. (c) When dislocation density is high and multiple scattering emerges, it would be nice to have a formalism to treat multiple scattering, especially infinite order where a qualitative change of system such as Anderson localization, emerges (Rammer 1998). (d) Regardless of interaction and high-order effects, many other effects, such as temperature dependence, are also challenging to be incorporated. As we will see, the quantum field approach can solve all these problems instantly in an elegant way.

In a quantum field language, instead of using wavefunctions, the Green's functions, aka propagators, serve as building blocks. We will work with the imaginary-time Green's function

$$G\left(\mathbf{k}, \tau\right) = -\left\langle c_{\mathbf{k}}\left(\tau\right) c_{\mathbf{k}}^{+}(0)\right\rangle \tag{19}$$

which demonstrates a process that an electron with momentum $\mathbf{k}$ is created at time 0 ($c_{\mathbf{k}}^{+}(0)$ term), and then annihilated at time τ ($c_{\mathbf{k}}(\tau)$ term), hence represents the electron propagation probability amplitude under an interacting environment. τ is called imaginary time, $0 < \tau < \beta = 1/k_B T$, whose Fourier transform gives the so-called Matsubara frequency $p_n, p_n = (2n + 1)\pi/\beta, n = 0, \pm 1, \pm 2 \ldots$ for fermions. Such formalism is a convenient approach to solve finite-temperature problems.

For non-interacting spinless electrons with $H_0 = \sum_{\mathbf{k}} (E_{\mathbf{k}} - \mu) c_{\mathbf{k}}^{+} c_{\mathbf{k}}$, the non-interacting Green's function in Matsubara frequency domain is written as

$$G_0\left(\mathbf{k}, ip_n\right) = \frac{1}{ip_n - E_{\mathbf{k}} + \mu} \tag{20}$$

from which the most straightforward process that leads to relaxation time $\tau_{\mathbf{k}}$ can be considered as a virtual process where an electron $\mathbf{k}$ is first scattered into $\mathbf{k} + \mathbf{q}$ by a dislon with momentum $\mathbf{q}$ with interaction strength $g_{\mathbf{q}}$, then the $\mathbf{k} + \mathbf{q}$ electron is scattered back to the original momentum $\mathbf{k}$ through a dislon with momentum $-\mathbf{q}$. Such a process can be diagrammatically represented as:
In above figure, the straight line segment and wavy line denotes the electron and dislon propagator, G_0 and D_0, respectively, in which the part inside the dashed rectangle is the lowest-order self-energy, which can be written as

$$\Sigma^1 \left(\mathbf{k}, i p_n \right) = -\frac{1}{\beta} \sum_{\mathbf{q} m} g_{\mathbf{q}}^2 D^0 \left(\mathbf{q}, i \omega_m \right) G^0 \left(\mathbf{k} - \mathbf{q}, i p_n - i \omega_m \right) \tag{21}$$

where the internal momentum $\mathbf{q}$ and Matsubara frequency $i\omega_m$ are summed over. Finally, the relaxation time $\tau_{\mathbf{k}}$ can be computed from a self-energy calculation:

$$\frac{1}{\tau_{\mathbf{k}}} = -2 \operatorname{Im} \left[\Sigma \left(\mathbf{k}, 0 \right) \right] \tag{22}$$

which can lead to consistent result with Eq. (18). Despite seemingly more cumbersome than a Fermi's golden rule approach, the above quantum field scheme can indeed conquer all difficulties faced by Fermi's golden rule approach.

(a) Dislocation's definition is well respected in the dislon Hamiltonian Eqs. (12), (13) and (14).
(b) If other interaction mechanisms are needed, no matter point defects or phonon interactions with electrons, or even Coulomb interaction between electrons, we only need to rewrite the corresponding electron propagator taking into account the relevant interactions. For instance, the lowest-order correction of point defect or phonon scattering can be diagrammatically represented as:
where the double-line on the left-hand side denotes the dressed electron propagator upon interaction. The total self-energy taking into account other interactions can be represented as:
while the Eq. (22) is still valid by replacing the electron propagator $G_0 \to G$ in the updated self-energy.

(c) Higher-order scattering processes are easily incorporable as well. For instance, the second-order electron-dislon scattering can be written pictorially as:
(d) Other effects can also be incorporated in a systematic way. In particular, temperature effects are fully taken into account within the finite-temperature Matsubara formalism.

3.2   Electron-Dislon Interaction: Explaining T_c

The power of adopting the dislon approach to study the electron-dislon interaction problem is beyond the calculation of relaxation time, but can also be used to study the effects of dislocations on dislocated superconductors. To see this, we notice that the electron-dislocation interaction Hamiltonian can well be described by a deformation potential scattering Hamiltonian:

$$H_{e-ion} = \int d^3\mathbf{R}\rho_e\left(\mathbf{R}\right) \sum_{n=1}^{N} \nabla_\mathbf{R} V_{ei}\left(\mathbf{R} - \mathbf{R}_n^0\right) \cdot \mathbf{u}_{dis}\left(\mathbf{R}_n^0\right) \tag{23}$$

where $\rho_e(\mathbf{R})$ is the electron charge density, V_{ei} is the Coulomb interaction, $\mathbf{R}_n^0$ is the atomic location of atom number n. After quantization, we have

$$H_{e-dis} = \sum_{\mathbf{k}'\sigma;\mathbf{k}\geq 0} g_\mathbf{k} c_{\mathbf{k}'+\mathbf{k}\sigma}^+ c_{\mathbf{k}'\sigma} d_\mathbf{k} + \text{h.c.} \tag{24}$$

where $g_\mathbf{k} \propto \mathbf{k} \cdot \mathbf{F}\left(\mathbf{k}\right) \propto \frac{1-2\nu}{1-\nu} b$ is the electron-dislocation coupling strength, which gives highly consistent result from semiclassical theory (Dexter and Seitz 1952).

In the end, we were able to compute the superconducting transition temperature T_c, quantitatively in a dislocated superconductor, for the first time. The T_c equation can be written as (Li et al. 2017c)

$$\frac{1}{g_{ph} + g_D} = N\left(\mu\right) \int_0^{\theta_D'} d\xi \sum_{s=\pm 1} \tanh\left(\frac{\xi + is\Gamma_D}{2T_c}\right) \bigg/ 2\xi \tag{25}$$

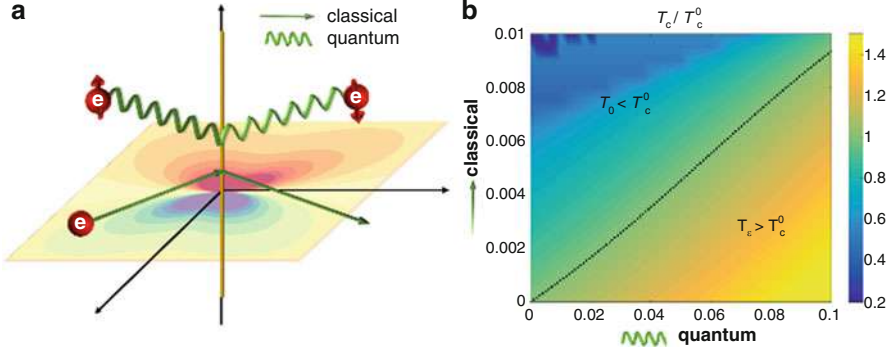
with two major coefficients (classical potential scattering Γ_D and quantum fluctuation g_D):


Fig. 6 (**a**) Schematics of the classical vs quantum type of electron-dislocation interaction, whose competition will determine the T_c in a dislocated superconductor (**b**). (Figure adapted from Li et al. (2017c))

$$\Gamma_D = \frac{\pi m^*}{4\hbar^2 k_F^2 k_{TF}^4} \left(Ze^2 n\right)^2 n_{dis} b^2 \left(\frac{1-2\nu}{1-\nu}\right)^2$$
$$g_D = n_{dis}^{3/2} \frac{\left(4\pi Ze^2 n\right)^2}{2k_{TF}^4 (\lambda + 2\mu)} \tag{26}$$

where g_{ph} is the electron-phonon coupling constant, θ'_D is the renormalized Debye frequency, m^* is the effective mass, k_F is Fermi wavevector, k_{TF} is Thomas-Fermi screening wavevector, n is atomic number density, n_{dis} is dislocation density, b is Burgers vector, ν is Poisson ratio, λ and μ are Lame parameters, which are all common materials parameters that can be looked up in database. The Eq. (25) implies a completion effect between classical scattering and quantum fluctuation, as illustrated in Fig. 6, which shows excellent quantitative agreement comparing with experimental data without free fitting parameter (Li et al. 2017c).

3.3   Phonon-Dislon Interaction: Beyond Perturbation

The general workflow is also applicable to the dislocation-phonon interaction problems. The classical velocity-velocity drag-like fluttering interaction Hamiltonian between dislocation and phonon can be written as

$$H_{flu} = \rho \int \dot{\mathbf{u}}_{ph}\left(\mathbf{R}\right) \cdot \dot{\mathbf{u}}_{dis}\left(\mathbf{R}\right) d^3\mathbf{R} \tag{27}$$

After the second quantization procedure, we have

$$H_{flu} = \sum_{\mathbf{k}>0} g_{\mathbf{k}}^{\text{dyn}} \boldsymbol{\varepsilon}_{\mathbf{k}} \cdot \mathbf{F}\left(\mathbf{k}\right) \left(-a_{\mathbf{k}} + a_{-\mathbf{k}}^+\right) f_{\mathbf{k}} + \text{h.c.} \tag{28}$$

where $g_{\mathbf{k}}^{\mathrm{dyn}}$ is the dislocation-phonon coupling dynamic coefficient that depends on phonon and dislon dispersions $\omega_{\mathbf{k}}$ and $\Omega_{\mathbf{k}}$. The interaction Hamiltonian Eq. (28) turns out to be able to shift phonon dispersion and meanwhile result in a finite phonon lifetime (Li et al. 2017b).

The phonon dispersion changed by dislocation is shown in Fig. 7. In a dislocated crystal (Fig. 7a), the dislon theory predicts anisotropic phonon softening and TA modes splitting (Fig. 7b, yellow lines), which are confirmed by both lattice dynamics simulations (Fig. 7b, blue lines) and ab initio first-principles calculations (Fig. 7c). As to the finite phonon lifetime, the dislon theory reveals a fruitful structure, depending on the dislocation type, phonon type, and phonon polarization.

In particular, a special type of saturation and resonance are predicted (Fig. 8a, b). These go far beyond any classical theory, where the relaxation rate τ^{-1} only contains monotonic dependence with phonon frequency ω:

$$
\begin{aligned}
\tau_{\mathrm{fluttering}}^{-1} &\propto \omega^{-1} \\
\tau_{\mathrm{strain}}^{-1} &\propto \omega \\
\tau_{\mathrm{core}}^{-1} &\propto \omega^3 \\
\tau_{\mathrm{isotope}}^{-1} &\propto \omega^4
\end{aligned}
\tag{29}
$$
Fig. 7 (**a**) A schematic of a dislocated simple cubic crystal. (**b**) An isotropic phonon softening and transverse acoustic (TA) modes splitting with dislocations. (**c**) Verification through *ab initio* calculations. (Figures adapted from Li et al. (2017b) and Wang et al. (2017))
Fig. 8 The dislocation-phonon scattering relaxation rates for a transverse-like (**a**) and a longitudinal-like (**b**) with an edge dislocation. A similar saturation behavior in (**a**) and a resonance behavior in (**b**) are seen in the ab initio calculations in (**c**). (Figures adapted from Li et al. (2017b) and Wang et al. (2017))

where the four terms denote phonon-dislocation dynamic "fluttering" scattering, phonon-dislocation strain-field scattering, phonon-dislocation core scattering, and phonon-isotope point defect scattering, respectively. Both the saturation behavior and the resonance behavior are revealed in the ab initio calculations (Fig. 8c), although the simulation and theory are not precisely computing the same system. The simulation contains a dislocation pair to reduce the system size, while the dislon theory is computed in a simpler system with single dislocation and thus has a slightly different definition on the phonon modes.

4   Outlook and Perspective

Despite some initial success of the dislon theory, as a framework on which new theories can be built upon, the dislon theory is still at its infant stage. Here we sketch a few more examples that appear challenging for a classical dislocation theory, but are expected to be directly computable using the dislon theory:

Electronic bandgap: how dislocations can change the bandgap in semiconductors and insulators. We notice that the multi-band Hamiltonian Eq. (15) contains an energy gap. By introducing an interaction Hamiltonian, such as Eq. (24), the bandstructures will change, $E_{\mathbf{k}a} \rightarrow E'_{\mathbf{k}a}$, which can be obtained from perturbation theory, and will result in a bandgap modulation effect.

Optical absorption: the role of dislocations to the optical absorption coefficient $\alpha(\omega)$. Optical absorption leads to intensity distinction $I(x) = I_0 \exp(-\alpha x)$. To compute $\alpha(\omega)$, we first follow the scheme like Fig. 5 to compute the AC conductivity $\sigma(\omega)$, using the original Hamiltonian H_0 and total Hamiltonian $H_0 + H_I + H_D$. Then, the dielectric function $\varepsilon(\omega)$ can be written as $\varepsilon(\omega) = 1 + 4\pi i\sigma(\omega)/\omega$. Finally, defining an extinction coefficient $k(\omega)$ as $k^2(\omega) \equiv (|\varepsilon(\omega)| - \mathrm{Re}\,[\varepsilon(\omega)])/2$, the optical absorption coefficient can be written as $\alpha(\omega) = 2\omega k(\omega)/c$.

Phase transition: Although challenging to summarize within a few steps, one major application that distinguishes the dislon theory from a classical dislocation model lies in the capability to study dislocation-induced phase transition problems, such as metal-insulator transition. Early experiments reported the dislocation-induced semiconductor-superconductor phase transition (Fogel et al. 2001), which has been explained using the dislon theory, quantitatively (Li et al. 2017c). In a more recent example, a quantum phase transition of phonons is revealed (Pablo-Pedro et al. 2018), caused by a competition effect between the topological protection of dislocation and a topological-breaking inelastic scattering. By understanding the relationship between dislocations and phase transitions, dislocations will gain more importance from materials imperfections to a new dimension to tailor the phase diagram, including unexplored new electronic, phononic, and photonic phases.

Indeed, the dislon theory offers a systematic approach to understand the interplay between crystal dislocations and materials electronic, spintronic, phononic, and photonic degrees of freedom at a microscopic quantum level. However, why the dislon, or say the quantization procedure, could work in the first place? Intuitively, the term "quantum field" contains both the "quantum" part, which deals with the internal dynamics and excitation, and the "field" part, which deals with spatial

extension. This dual nature seems appropriate to describe a dislocation, which contains both internal dynamics, such as dynamic fluttering, and spatial extension that arises naturally as an extended defect. In fact, the spatial extension naturally and unavoidably leads to the internal dynamic structure. This brings up a more general question, that whether any extended defect can, or even should, be described by some quantum field:

$$\text{Large Defects} = \text{Quantum Fields} \tag{30}$$

The answer to this grand question may greatly empower our approach to tackle complex defects problems.

Photovoltaics: First Principles Modeling

Photovoltaics: Advances in First Principles Modeling – Overview

13

Marco Bernardi and Jeffrey C. Grossman

Contents

Abstract

Photovoltaic devices are challenging to model due to their multi-scale physics, which ranges from light absorption to charge carrier generation and transport. This overview chapter outlines recent developments in first-principles modeling of solar cells. Besides the traditional focus on predicting the structure, bandgap, and optical properties of materials, first-principles methods can now also model charge transport and excited carrier dynamics. New materials are breaking the established paradigms of conventional solar cells, leading to exciting discoveries of broad relevance to materials science and physics. We discuss three recent directions in photovoltaics research, including ultrathin solar cells, complex

materials, and ultrafast electron dynamics, and outline future challenges. First-principles calculations are playing a key role in pushing these frontiers of photovoltaics research.

1   Modeling Solar Cells

Photovoltaic (PV) solar cells convert sunlight to electricity through a cascade of physical processes spanning multiple length and timescales (Bernardi and Grossman 2016). In a conventional solar cell, light absorption generates electron and hole carriers, which are then transported through the active layer and extracted at the contacts. In excitonic solar cells, such as those made of organic or nanostructured materials, sunlight generates excitons (bound electron-hole pairs), so that additional exciton transport and dissociation steps are needed for energy conversion. Modeling PV devices entails understanding the energetics and dynamics of the charge carriers, excitons, and photons involved in the energy conversion process.

We recently reviewed the computational methods available for modeling solar cell materials and devices (Bernardi and Grossman 2016). Our chapter identified several open challenges, including modeling from first-principles charge transport, ultrafast electron dynamics, and the impact of defects and impurities on solar cell performance. New trends and computational tools have emerged in the last three years since our review was published. Some of the most notable recent research directions, which are outlined in the next section, can be summarized with three words: *ultrathin, ultrafast, complex*. These ideas pose new challenges to first-principles calculations. New complex PV materials and ultrafast electron dynamics are introduced in Sect. 2 and reviewed in the contributed chapters (see below). Research efforts on atomically thin solar cells are summarized in Sect. 3.

2   New Frontiers: Ultrathin, Ultrafast, Complex

Industry and academia approach solar cell research from complementary angles. In academia, PV is a playground for materials synthesis and for solid state and device physics. First-principles calculations play a key role in understanding energy conversion in new PV materials discovered in academia. By contrast, industry efforts are more practical – they are centered on maximizing device efficiency while reducing module and installation cost per Watt. Conventional semiconductors – mainly silicon, but also GaAs, chalcogenides, and amorphous Si – are still the main focus of industry research, though new materials are also being explored. Equipping solar cells with new functionalities, such as making them bendable and transparent, is also a recent research direction toward making solar cells ubiquitous. We explore recent trends in academic PV research, focusing on three themes – complex materials, ultrafast timescales, and ultrathin solar cells.

Complex materials   Despite the dominant role of conventional semiconductors, there is a renewed focus on structurally and chemically complex materials, which

can enable new engineering paradigms not possible with simple elemental or binary inorganic semiconductors (Jean et al. 2015). Examples are hybrid halide perovskites, which have been a primary focus of recent PV research (Liu et al. 2013; Green et al. 2014). Halide perovskites possess several desirable properties, including easy deposition from solution or vapor, a near-ideal bandgap that can be tuned with composition, and strong sunlight absorption in thin films. Despite the dramatic rise in the power conversion efficiency of halide perovskites, the origin of their exceptional performance and charge transport properties remains the subject of debate, largely due to their complexity. The atomic and electronic structures of halide perovskites are uniquely complex compared to conventional solar cell materials. Their electronic, vibrational, and electron spin degrees of freedom are strongly coupled, and their structure exhibits phase transitions controlled by an interplay between the inorganic framework and the organic ion rotations.

Long carrier lifetimes and diffusion lengths have been recognized early on as a key factor for device performance in halide perovskites; understanding this unusual charge transport constitutes a main challenge for first-principles calculations. Methylammonium lead iodide ($MAPbI_3$) is a key halide perovskite compound. It has been studied extensively, but the mechanisms governing its long carrier lifetimes are not completely understood. A leading hypothesis is that a large bulk Rashba effect (due to spin-orbit coupling) makes the bandgap indirect, thus slowing down carrier recombination. One of us (Bernardi) recently demonstrated that at room temperature, $MAPbI_3$ is centrosymmetric and has only a very small Rashba splitting, thus ruling out the role of bulk Rashba effects (Frohna et al. 2018). This work also established the correct structure and band structure for future ab initio studies of charge transport in $MAPbI_3$. There are important open challenges for theory in halide perovskites besides charge transport; they are outlined in the contributed chapter by Giustino and in a recent review article (Martiradonna 2018).

Ultrafast timescales Ultrafast spectroscopies are able to probe charge carrier dynamics at the femtosecond to nanosecond timescale, over which key PV physical processes occur. These experiments are providing new insights into the microscopic energy conversion mechanisms in solar cells. Among other benefits, understanding the sub-picosecond dynamics of carriers and excitons can lead to more efficient exciton dissociation and to extracting hot carriers. Time-dependent density functional theory (TD-DFT) has so far been the primary method for studying excited electron dynamics. Efforts on understanding charge transfer in model donor-acceptor interfaces using TD-DFT are reviewed in the contributed chapter by Rozzi and Pittalis.

There are also new rigorous methods to compute excited electron dynamics from first principles. One of us (Bernardi) combined electron-phonon scattering calculations (Bernardi 2016) with the real-time Boltzmann transport equation to investigate excited electron dynamics and hot carriers effects in a range of semiconductors and metals (Bernardi et al. 2014, 2015a, b; Jhalani et al. 2017). The time and length scale for hot carrier relaxation and the energy loss mechanisms of the excited electrons can be accurately predicted with these techniques, thus providing valuable information on a regime (sub-picosecond time and nanometer

length scales) that is hard to access experimentally. Using similar techniques, charge transport (e.g., the electron mobility as a function of temperature) can now be accurately computed in materials ranging from simple inorganic to complex organic semiconductors and transition metal oxides (Mustafa et al. 2016; Zhou and Bernardi 2016; Lee et al. 2018; Zhou et al. 2018). These new first-principles methods for investigating carrier dynamics complement the traditional ab initio toolkit employed for studying solar cells – mainly, DFT and GW for bandgaps and interface band alignments and TD-DFT and the Bethe-Salpeter equation (BSE) for computing optical absorption and excitons (Bernardi and Grossman 2016).

Ultrathin solar cells   The last trend we mention here is the recent focus on novel two-dimensional (2D) materials with potential to enable ultrathin (∼10 nm thick) solar cells. The rise of graphene has spurred investigations of 2D materials, which have led to the discovery of a wide range of atomically thin semiconductors. These materials and their potential for solar cells are discussed in the next section as a selected case study from our own research.

3   Ultrathin Solar Cells

Recently discovered atomically thin semiconductors possess yet untapped technological potential. Much research has focused on group-6 transition metal dichalcogenides (TMDs) with a chemical formula of MX_2 (where M is a group-6 transition metal and X a chalcogen atom). This family of semiconductors, which includes MoS_2, WS_2, and related compounds, can be prepared routinely in monolayer and few-layer form and exhibits unique electronic and optical properties (Bernardi et al. 2017). Solar cells based on 2D-TMDs provide an example of how theory can guide the design of new PV devices.

In an article we published in 2013 (Bernardi et al. 2013), we predicted that 2D-TMDs possess an extraordinary sunlight absorption – they absorb as much sunlight in a sub-nm thick monolayer as GaAs (one of the best solar cell materials) can absorb in 10 nm. These ultrathin light absorbers show promise for applications in solar cells, as is seen by analyzing PV devices based on just two stacked monolayers. We investigated a Schottky barrier solar cell between MoS_2 and graphene and an excitonic solar cell based on a MoS_2/WS_2 hetero-bilayer (Bernardi et al. 2013). Our calculations demonstrated that such 1 nm thick active layers can attain power conversion efficiencies of up to ∼1%, which corresponds to power densities (Watts/kg) higher by a factor of 100–1,000 than the best existing thin-film solar cells based on conventional semiconductors (Bernardi et al. 2013).

Several results predicted in our work have now been confirmed experimentally, including the type-II alignment and the presence of interlayer excitons at the MoS_2/WS_2 hetero-bilayer interface. Solar cells consisting of a MoS_2/WS_2 bilayer with close to 1% efficiency have been fabricated (Furchi et al. 2014; Pospischil et al. 2014), confirming our calculations. Note that these nanometer thick devices are perhaps the thinnest solar cells ever made. While the 1% power conversion

efficiency of a TMD bilayer is far too small for PV applications, our work predicted that light absorption and the power conversion efficiency could be increased by an order of magnitude by stacking multiple TMD monolayers and managing light through a back metallic contact (Bernardi et al. 2013). Inspired by our idea, researchers have recently fabricated ~15 nm thick multi-layer stacks of TMDs exhibiting near-unity absorption (Jariwala et al. 2016), in agreement with our predictions.

These results demonstrate the potential of first-principles calculations for designing novel PV materials and devices. The future of atomically thin solar cells is still unclear, mainly because fabricating large-area and high-quality TMDs remains challenging. Yet, first-principles calculations on 2D-TMDs are making significant strides. An example from our research is the accurate prediction of radiative lifetimes in monolayer TMDs (Palummo et al. 2015) and the development of new methods to investigate their anisotropic light emission (Chen et al. 2018). These recent advances are an example of how methods developed to investigate PV materials are also broadly relevant to the materials theory community.

4   Outlook and Perspective

The textbook model of a solar cell is a semiconductor *pn* junction under illumination. This simplified picture is not representative of devices investigated in modern PV research, where *interfaces, defects, impurities, contacts*, and *degradation* play a key role. First-principles calculations able to capture such complexity of real devices are needed for understanding solar cells and improving their efficiency.

Heterojunctions and interfaces are present in nearly all inorganic and organic solar cells. For organic solar cells, the optimization of transport and buffer layers can turn a poor device into a record one, and designing donor/acceptor interfaces is essential to optimizing the efficiency. Defects, impurities, and grain boundaries are particularly important in inorganic solar cells. They are challenging to model from first principles both because they require simulation cells with a large number of atoms and because new theory is needed.

For example, the impact of defects and impurities on charge transport cannot be accurately computed from first principles. Electron-defect scattering and carrier trapping at impurities have received little attention from the first-principles community despite being crucial issues in devices. New methods are emerging to rigorously treat electron-defect scattering; these efforts parallel the recent advances on electron-phonon interactions and will be highly valuable for PV devices. Predicting the stability of materials exposed to sunlight and moisture is also a challenge, though new computational methods (mainly developed in the context of photocatalysis) are advancing this frontier.

Carefully designed experiments are necessary to advance the field. Experiments focusing on deeper understanding of PV materials and devices (rather than merely on increasing their efficiency) could dramatically move the field forward. Recent experiments are moving in this direction, in particular since the advent of complex

perovskites has stimulated experimental studies on the physics of PV materials. By contrast, when a decade ago the community was focusing on organic and dye-sensitized solar cells, the goal of much research was merely improving the efficiency, often by optimizing active layer materials by trial and error.

As discussed above, remarkable progress has been made in the last few years on charge carrier dynamics calculations. Two main challenges need to be addressed to make these methods more broadly applicable. One is computing carrier dynamics in the presence of excitons, which is relevant to solar cells. Since exciton transport is typically understood through heuristic diffusion models, first-principles calculations of exciton dynamics would significantly improve understanding of solar cells. The BSE (and to some extent, TD-DFT) can compute the exciton energy and wave function, but not exciton dynamics; new methods to compute exciton-phonon scattering and exciton dynamics are emerging as a new frontier in the field. Computing charge transport in the polaron regime is the second challenge. In organic semiconductors and oxides, localized carriers can couple strongly with lattice vibrations, forming bound states – called polarons – which can be thought of as electrons moving along with a phonon cloud. In the polaron transport regime, materials typically exhibit a low mobility with a peculiar temperature dependence. Poor charge transport due to polarons is the reason why, in spite of several attempts, oxide solar cells have never emerged as a viable alternative and organic semiconductors still struggle to make double-digit efficiencies. Predicting the properties of polarons is a long-standing challenge due to the strong (non-perturbative) electron-phonon interactions. While empirical models and even DFT calculations of polaron formation and hopping can be found in the literature, rigorous treatments of charge transport in the polaron regime remain an open challenge. In summary, new theory and first-principles methods are needed to advance both practical aspects and the physics of solar cells.

5   Contributions

This short section contains two contributions that discuss recent advances in modeling complex solar cell materials and ultrafast electron dynamics in photovoltaics. The authors use a variety of first-principles approaches beyond density functional theory to investigate the properties of novel materials and to microscopically understand solar energy conversion:

- ▶ Chapter 15, "Prototyping Ultrafast Charge Separation by Means of Time-Dependent Density Functional Methods" by Carlo Andrea Rozzi and Stefano Pittalis. This chapter focuses on charge separation, a key process in bulk heterojunction solar cells. The authors identify prototypical molecular systems for studying charge separation and provide new insights into the ultrafast dynamics of coupled electrons and nuclei using real-time time-dependent density functional theory. Method advances and strategies for improving device performance are also discussed.

- ▶ Chapter 14, "Hybrid Halide Perovskites: Fundamental Theory and Materials Design" by Flip, Volonakis and Giustino. This chapter reviews efforts by the author and his collaborators to model complex hybrid halide perovskites with promising power conversion efficiencies. Density functional theory, GW, and electron-phonon calculations are employed to shed light on the structure-property relations of this fascinating new family of compounds. Materials design efforts to develop novel halide perovskites where Pb is replaced by nontoxic elements are also discussed.

Contents

Abstract

Hybrid organic-inorganic halide perovskites have emerged as a disruptive new class of materials, exhibiting optimum properties for a broad range of opto-electronic applications, most notably for photovoltaics. The first report of highly efficient organic-inorganic perovskite solar cells in 2012 (Lee et al., Science 338:643–647, 2012) marked a new era for photovoltaics research, reporting a power conversion efficiency of over 10% (NREL, National renewable energy laboratory: best research-cell efficiencies. http://www.nrel.gov/ncpv/images/efficiency_chart.jpg, Accessed Nov 2017). Only five years after this

discovery, perovskite photovoltaic devices have reached a certified efficiency of 22.7%, making them the first-solution processable technology to surpass thin film and multi-crystalline silicon solar cells (NREL, National renewable energy laboratory: best research-cell efficiencies. http://www.nrel.gov/ncpv/images/efficiency_chart.jpg, Accessed Nov 2017). The remarkable development of perovskite solar cells is due to the ideal optoelectronic properties of organic-inorganic lead-halide perovskites. The prototypical compound, methylammonium lead iodide, $CH_3NH_3PbI_3$ (Stranks and Snaith, Nat Nanotechnol 10:391–402, 2015), is a direct band gap semiconductor with a band gap in the visible, high charge carrier mobility, long diffusion length, and low excitonic binding energy (Johnston and Herz, Acc Chem Res 49(1):146–154, 2016). Due to these ideal properties, $CH_3NH_3PbI_3$ is also drawing interest across many other applications beyond photovoltaics, such as light-emitting devices (Tan et al., Nat Nanotechnol 9:687–692, 2014), lasers (Wehrenfennig et al., J Phys Chem Lett 5:1300–1306, 2014), photocatalysts (Chen et al., J Am Chem Soc 137(2):974–981, 2015), and transistors (Ward et al., ACS Appl Mater Interf 9(21):18,120–18,126, 2017).

The continued progress of metal-halide perovskite optoelectronics relies not only on a detailed understanding of the electronic and optical properties of materials in this class but also on the development of practical strategies to tune their properties by controlling parameters such as chemical composition. In this context, ab initio computational modelling can play a key role in providing a physical interpretation of experimental measurements and guiding the design of novel halide perovskites with tailored properties.

In this chapter we will present an account of the contributions to this fast-developing field of research from our computational modelling group. The chapter is organized in two sections. The first section focuses on the structural and optoelectronic properties of $CH_3NH_3PbI_3$. Here, we expand on some of the challenging aspects of modelling the electronic and vibrational properties of $CH_3NH_3PbI_3$ and discuss the main theoretical results alongside experimental data. The second section discusses the recent computationally led materials design of novel halide perovskites and the principal challenges in replacing Pb^{2+} in $CH_3NH_3PbI_3$ by nontoxic elements.

1   Methylammonium Lead Iodide

Methylammonium lead iodide, $CH_3NH_3PbI_3$, belongs to the ABX_3 perovskite structural family (Poglitsch and Weber 1987). As shown in Fig. 1, the Pb^{2+} and I^- ions form a three-dimensional network of corner-sharing octahedra. The organic $CH_3NH_3^+$ cations occupy the center of the cuboctahedral cavities enclosed by the inorganic PbI_6 network (Poglitsch and Weber 1987). The crystal structure of $CH_3NH_3PbI_3$ is strongly dependent on temperature and undergoes two phase transitions (Poglitsch and Weber 1987; Baikie et al. 2013; Stoumpos et al. 2013; Weller et al. 2015): from the low-temperature orthorhombic *Pnma* structure to
Fig. 1 **Temperature-dependent crystal structure of CH$_3$NH$_3$PbI$_3$.** Polyhedral representation of the low-temperature orthorhombic *Pnma* structure (**a**), the tetragonal *I*4/*mcm* structure (**b**), and the cubic *Pm*$\bar{3}$*m* structure (**c**). In all three panels, the Pb atoms are represented by the light blue spheres at the center of the octahedra, the I atoms are the red spheres at the corners of the octahedra, and the C, N, and H atoms are represented by the dark grey, dark blue, and white spheres, respectively. The figures were constructed using the lattice parameters and atomic positions reported by Weller et al. (2015)

the tetragonal *I*4/*mcm* structure at 160 K and the cubic *Pm*$\bar{3}$*m* structure at 315–330 K. As shown in Fig. 1, all phases of CH$_3$NH$_3$PbI$_3$ maintain the corner-sharing connectivity of the PbI$_6$ octahedra; however the degree of octahedral tilting is reduced as the temperature increases. In addition, the organic CH$_3$NH$_3^+$ cations exhibit ordered orientations throughout the unit cell only in the orthorhombic phases, while in the tetragonal and cubic phase, the cations are orientationally disordered (Poglitsch and Weber 1987; Baikie et al. 2013; Stoumpos et al. 2013; Weller et al. 2015).

The excited state properties of CH$_3$NH$_3$PbI$_3$ have been intensely investigated over the last 5 years. The optical absorption spectrum of CH$_3$NH$_3$PbI$_3$ is characteristic of a direct band gap semiconductor (Herz 2016), with a sharp absorption onset around 1.6 eV. At low temperature, the optical absorption spectrum exhibits an excitonic peak, with an exciton binding energy of ∼20 meV. This feature becomes less visible as the temperature increases (D'Innocenzo et al. 2014; Miyata et al. 2015; Herz 2016). In addition, the absorption line shape at room temperature exhibits an Urbach tail of 15 meV (De Wolf et al. 2014), unexpectedly low given the disordered character of the CH$_3$NH$_3^+$ cation. The optical band gap of CH$_3$NH$_3$PbI$_3$ increases with temperature from 1.62 eV at 4 K to 1.67 eV at 160 K. At the phase transition temperature between the orthorhombic and tetragonal phase, 160 K, the band gap decreases sharply to approximately 1.58 eV and then continues to increase beyond this temperature, as in the orthorhombic phase (Milot et al. 2015).

Free electrons and holes dominate over bound exciton pairs upon photoexcitation, an ideal characteristic for application in solar energy conversion (D'Innocenzo et al. 2014; Herz 2016). The photogenerated charge carriers are long lived in CH$_3$NH$_3$PbI$_3$ and exhibit charge carrier mobilities of approximately 35 cm$^2(Vs)^{-1}$ (Johnston and Herz 2016) at room temperature. Bimolecular recombination in CH$_3$NH$_3$PbI$_3$ is found to be the predominant mechanism for charge carrier

recombination at standard photovoltaic device operation conditions, exhibiting a highly non-Langevin behavior (Johnston and Herz 2016; Herz 2016). This means that the ratio between the bimolecular recombination rate $k_2 \sim 10^{-10}\,\mathrm{cm^3 s^{-1}}$ and the charge carrier mobility $\mu \sim 10\,\mathrm{cm^2 V^{-1} s^{-1}}$ is four orders of magnitude lower than the value $e/(\epsilon_0 \epsilon_r)$ predicted by the Langevin model (Herz 2016; Wehrenfennig et al. 2014). This effect explains the long charge carrier diffusion lengths ($\sim 1\,\mu\mathrm{m}$) measured for halide perovskites (Herz 2016).

The band gap of $CH_3NH_3PbI_3$ can be tuned via chemical substitution (Herz 2016). The replacement of the $CH_3NH_3^+$ cation with $CH(NH_2)_2^+$ (formamidinium), Cs^+, or Rb^+ leads to a change in the optical band gap over a range of 0.3 eV (Eperon et al. 2014; Filip et al. 2014); the substitution of Pb^{2+} by Sn^{2+} reduces the band gap by approximately 0.4 eV (Hao et al. 2014), and the replacement of I^- by the smaller anions Cl^- and Br^- blue-shifts the optical band gap by up to 0.7 eV (Comin et al. 2015; Noh et al. 2013). In practice, mixed cation, mixed metal, and mixed halide perovskites are currently explored in order to optimize light absorption over the entire visible spectrum, but also to improve the stability of perovskite solar cells (McMeekin et al. 2016; Eperon et al. 2016; Saliba et al. 2016).

Theoretical investigations of the fundamental structural, electronic, and vibrational properties of $CH_3NH_3PbI_3$ have played an important role in the interpretation of the experimental data summarized above. In the following we discuss some of the theoretical results obtained by us and our coworkers in the study of $CH_3NH_3PbI_3$.

1.1   Basic Electronic Structure of $CH_3NH_3PbI_3$

To construct the electronic band structure of $CH_3NH_3PbI_3$, it is necessary to know the lattice parameters and the atomic positions for the perovskite unit cell. For the low-temperature orthorhombic phase, the unit cell was fully resolved for the first time by Baikie et al. (2013). The unit cell contains four PbI_6 octahedra and four $CH_3NH_3^+$ cations, 48 atoms in total, arranged according to the *Pnma* space group.

In the tetragonal and cubic phases, the unit cell contains four and one PbI_6 octahedra, respectively, and the shape of the inorganic octahedral networks are well described (Stoumpos et al. 2013; Weller et al. 2015) by the space groups $I4/mcm$ and $Pm\bar{3}m$, respectively. At variance with the inorganic scaffold, the organic cations have a disordered orientation inside the perovskite cavity, in the tetragonal and cubic phases, and pose difficulties for any electronic structure calculation that employs periodic boundary conditions. For example, structural relaxation of the unit cell starting from arbitrary orientations of the $CH_3NH_3^+$ cations leads to significant distortions of the unit cell and considerable changes to the electronic band structure that are highly dependent on the choice of the orientation (Motta et al. 2015). This effect is purely an artefact of the chosen orientation of the cation and bears no physical meaning.

To ensure that we can obtain meaningful results of the electronic properties of $CH_3NH_3PbI_3$, we have two options. One approach is to simulate the disordered

orientation of the $CH_3NH_3^+$ by averaging over its many possible orientations. This approach is best addressed using molecular dynamics (Carignano and Kachmar 2015; Lahnsteiner et al. 2016) and requires a careful study of the size of the supercell in order to correctly represent the disordered orientations of $CH_3NH_3^+$. The second approach relies on the general property of ABX_3 perovskites by which the A-site cations do not participate in bonds, and as a consequence, they only contribute to electronic states far away from the band edges (Megaw 1973). In this latter approach, we can first calculate the electronic properties of $CH_3NH_3PbI_3$ in the well-known orthorhombic phase. Then we can investigate how the change in the shape of the inorganic octahedral network affects these properties. In the following, we describe the latter strategy.

In Fig. 1a we show the projected density of states of $CH_3NH_3PbI_3$ in the low-temperature orthorhombic *Pnma* case. The valence band top is occupied by I-p and Pb-s electrons, while the conduction band bottom is of I-p and Pb-p character. As expected, the states localized on the $CH_3NH_3^+$ cation are located away from the band edges (approximately 5 eV). Based on Fig. 2a we can construct a tight-binding argument to explain the tunability of the band gap by substitution of I anions or Pb cations. The replacement of I by Cl or Br leads to an increase in the band gap, due to the lower-lying Br-p and Cl-p electronic states that populate the valence band top; similarly, the substitution of Pb by Sn lowers the conduction band bottom and reduces the band gap due to the lower-lying Sn-p states. In addition, from Fig. 2a, it is clear that the $CH_3NH_3^+$ cations do not contribute to the optical absorption, and their role is to act as a structural filler and to ensure the charge neutrality of the unit cell. In practice, the $CH_3NH_3^+$ cation can be replaced by a positive background charge, and the electronic band structure would not change significantly (Filip et al. 2014).

Taking advantage of this property, we can study how the shape of the cuboctahedral cavity influences the electronic structure of the perovskite. Filip et al. (2014) showed that the unit cell of the perovskite lattice can be uniquely described by a "Platonic" model, whereby the PbI_6 octahedra are ideal and identical throughout the lattice, and their orientation within the unit cell is uniquely described by two angles: the equatorial and the apical bond angles (Fig. 2c). Figure 2b depicts the variation of the band gap with the two bond angles of the "Platonic" perovskite lattice. The gap increases as the bond angles decrease.

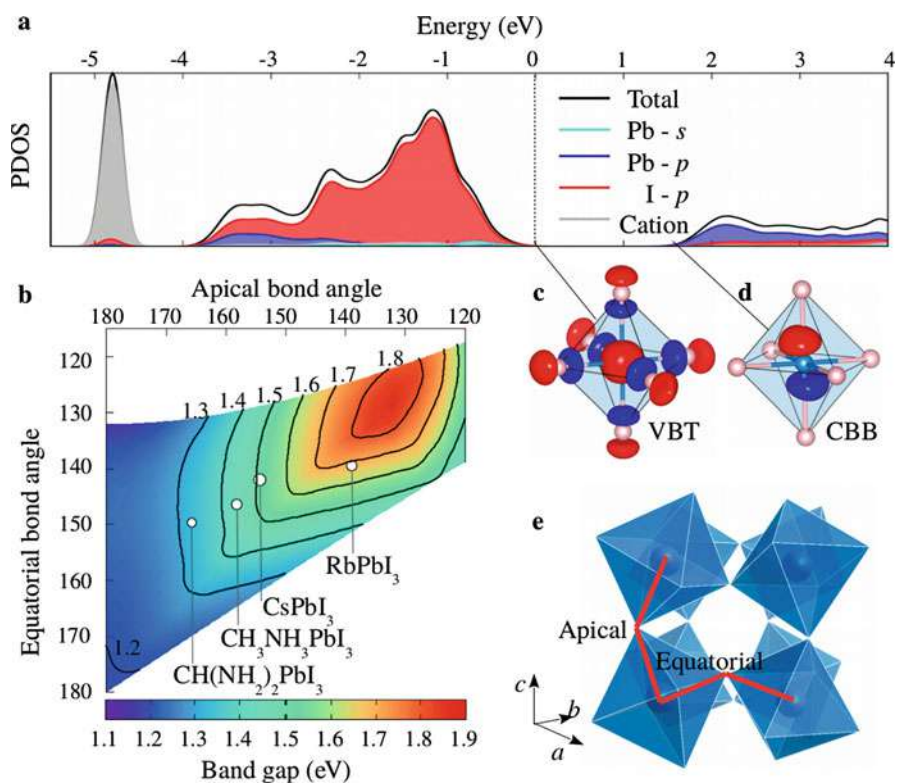
Two observations can be drawn from Fig. 2b. Firstly, the size of the A-site cation in the perovskite lattice influences the shape of the octahedral lattice, by changing the apical and equatorial bond angles, which in turn enables the control of the band gap. This leads to the following simple trend: the smaller the cation, the smaller the bond angles, the larger the band gap. The band gap trend predicted in Fig. 2b is in agreement with the trend observed experimentally and explains the band gap tunability with the substitution of the A-site cation (Eperon et al. 2014; Filip et al. 2014). Secondly, based on Fig. 2b we can explain the discontinuity in the band gap dependence on temperature observed at the transition temperature of 160 K (Milot et al. 2015). When the $CH_3NH_3PbI_3$ transitions from an orthorhombic to


Fig. 2 Electronic structure and band gap tunability of CH₃NH₃PbI₃. (**a**) Projected density of states of CH$_3$NH$_3$PbI$_3$ calculated within the local density approximation to density functional theory (DFT/LDA) without spin-orbit coupling for the orthorhombic crystal structure. The bands are aligned to the valence band top (VBT) represented by the dotted line. (Adapted with permission from Filip et al. (2014), Copyright (2014) Nature Publishing Group). (**b**) Two-dimensional map of the DFT band gap as a function of the apical and equatorial bond angles. The band gaps for each point of the map were calculated for Platonic model structures, as described by Filip et al. (2014), which do not contain the A-site cation, as shown in (**e**). The white disks represent the angular coordinates (apical and equatorial bond angles) of realistic models of CH$_3$NH$_3$PbI$_3$, CH(NH$_2$)$_2$PbI$_3$, CsPbI$_3$ and RbPbI$_3$. (Adapted with permission from Filip et al. (2014), Copyright (2014) Nature Publishing Group). (**c–d**) Wave functions corresponding to the valence band top (**c**) and the conduction band bottom of a lead iodide perovskite (**d**). (**e**) Polyhedral representation of the Platonic model for the orthorhombic perovskite structure. The apical and equatorial bond angles are represented by the red lines in the figure

a tetragonal phase, the apical bond angle increases from 160° to 180°. According to the map in Fig. 2b, the band gap should decrease by up to 0.2 eV, in good agreement with the sudden drop of 0.1 eV measured around 160 K.

The core conclusion that can be drawn from Fig. 2a is that the fundamental roles of the organic cation CH$_3$NH$_3^+$ in the lead iodide perovskite lattice are to balance the charge and to stabilize the shape of the perovskite lattice. Therefore, in order

to ensure that we are studying a physically meaningful crystal structure, in the following discussions, we focus on the low-temperature orthorhombic *Pnma* phase, as refined by Baikie et al. (2013).

1.2   The Quasiparticle Band Structure of $CH_3NH_3PbI_3$

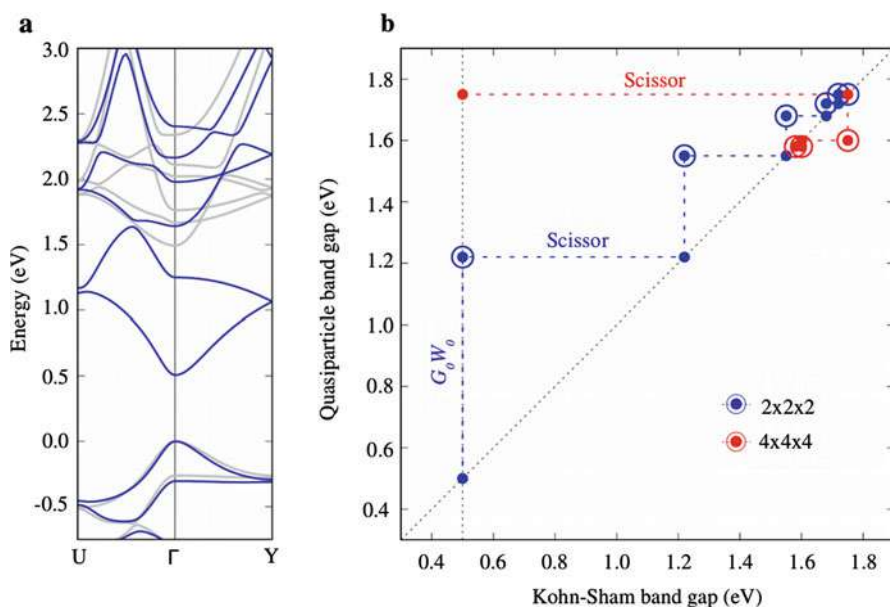
The calculations shown so far in Fig. 2 were obtained within DFT in the scalar-relativistic approximation. However, the presence of Pb in $CH_3NH_3PbI_3$ requires a relativistic treatment. In Fig. 3a we show that the spin-orbit coupling effect is crucial for the correct calculation of the band edge topology. Not only relativistic effects lower the conduction band bottom of $CH_3NH_3PbI_3$ by approximately 1 eV (Even et al. 2013), but also they change the shape of the band edges. In particular, the effective masses become fully isotropic upon inclusion of spin-orbit coupling, by


Fig. 3 Band structure of $CH_3NH_3PbI_3$. (**a**) DFT/LDA band structure of $CH_3NH_3PbI_3$ calculated with (blue line) and without (grey line) including spin-orbit coupling effects. The calculations were performed for the orthorhombic *Pnma* phase using norm-conserving Troullier-Martins pseudopotentials as described by Filip and Giustino (2014). (**b**) Convergence of the self-consistent scissor GW scheme for the quasiparticle band gap of $CH_3NH_3PbI_3$. The self-consistent scissor GW scheme is described in detail by Filip and Giustino (2014). For all quasiparticle calculations, we have used 1000 bands and plane wave cutoffs of 35 Ry and 6 Ry for the exchange and polarizability, respectively. The diagram shows the self-consistent scissor scheme calculated for a Γ-centered $2 \times 2 \times 2$ **k**-point grid (blue) and a $4 \times 4 \times 4$ **k**-point grid (red). All quasiparticle calculations include semicore d electrons for both Pb and I, as discussed by Filip and Giustino (2014)

contrast with those calculated in the scalar-relativistic approach (Menéndez-Proupin et al. 2014). As shown in Table 1, fully relativistic DFT calculations underestimate the band gap by ∼1 eV and the reduced effective mass by a factor of two.

The underestimation of the band gap and effective masses of DFT can be corrected by including quasiparticle effects. The quasiparticle band gap and band structure can be calculated within the GW approximation (Hedin 1965). The quasiparticle eigenvalues $E_{n\mathbf{k}}$ are calculated starting from the single-particle DFT/LDA eigenvalues $\epsilon_{n\mathbf{k}}$ as (Hedin 1965; Hybertsen and Louie 1986):

$$E_{n\mathbf{k}} = \epsilon_{n\mathbf{k}} + Z(\epsilon_{n\mathbf{k}})\langle n\mathbf{k}|\hat{\Sigma}(\epsilon_{n\mathbf{k}}) - V_{xc}|n\mathbf{k}\rangle, \qquad (1)$$

where $|n\mathbf{k}\rangle$ denotes a single-particle eigenstate with band index n and crystal momentum $\mathbf{k}$, $Z(\omega) = (1 - \partial \mathrm{Re}\hat{\Sigma}/\partial\omega)^{-1}$ is the quasiparticle renormalization, V_{xc} is the exchange-correlation potential, and $\hat{\Sigma} = iG_0W_0$ is the quasiparticle self-energy (Hybertsen and Louie 1986). In the expression of $\hat{\Sigma}$, G_0 is the non-interacting Green's function calculated using single-particle eigenvalues and eigenstates as obtained from DFT. The screened Coulomb interaction has the expression $W_0 = \epsilon^{-1}v$, where v is the bare Coulomb interaction and ϵ^{-1} is the inverse dielectric matrix.

In the case of $CH_3NH_3PbI_3$, it has been shown that the one-shot G_0W_0 quasiparticle band gap is underestimated with respect to experiment by up to

Table 1 Calculated values of the band gap, high- and low-frequency dielectric constants, and electron, hole, and reduced effective masses within DFT/LDA and within the GW approximation including the self-consistent scissor correction of Filip and Giustino (2014). The band gaps are expressed in eV, and the effective masses are expressed in the unit of electron masses (m_e). The reduced effective mass is calculated using the following expression: $\mu^* = \frac{m_h^* m_e^*}{m_h^* + m_e^*}$, where m_e^*, m_h^*, and μ^* are the electron, hole, and reduced effective masses, respectively. The exciton binding energy is calculated using the expression $E_b = \mu^*/\epsilon_\infty^2 \times E_{Ry}$ eV, with $E_{Ry} = 13.60565$ eV, the reduced effective mass $\mu^* = 0.11\,m_e$, and the high-frequency dielectric constant $\epsilon_\infty = 5.8$

	DFT	G_0W_0	GW	Exp.

[g]Poglitsch and Weber (1987)
[h]Miyata et al. (2015)

0.4 eV (Brivio et al. 2014; Filip and Giustino 2014), as shown in Table 1. This is primarily due to the underestimated single-particle band gap calculated at the DFT level, which leads to an overestimation of the dielectric screening in W_0 (Brivio et al. 2014; Filip and Giustino 2014). The quasiparticle band gap underestimation at the G_0W_0 level appears irrespective of the exchange-correlation functional employed for the DFT starting point, and it tends to worsen when more core electrons are included in the valence configuration of I (Scherpelz et al. 2016). However, this sensitivity to the DFT starting point can be mitigated by calculating the electron self-energy self-consistently (van Schilfgaarde et al. 2006).

Figure 3b shows an approximate self-consistency scheme introduced by Kioupakis et al. (2008) and applied to the case of $CH_3NH_3PbI_3$ by Filip and Giustino (2014), the self-consistent scissor GW. In this approach the G_0W_0 band gap correction Δ is first calculated, and then a scissor correction of magnitude Δ is applied to all eigenstates in the conduction band. These two steps are repeated until the band gap is converged, as shown in Fig. 3b (Kioupakis et al. 2008; Filip and Giustino 2014). The final converged band gap is of 1.57 eV, within 80 meV of the measured optical band gap of 1.65 eV (Milot et al. 2015; Davies et al. 2018). This small difference is accounted for by the absence of electron-hole interaction effects and electron-phonon effects.

Figure 4a shows the comparison between the GW quasiparticle band structure and the DFT/LDA band structure obtained from Wannier interpolation (Marzari and Vanderbilt 1997; Souza et al. 2001). Qualitatively the band dispersions calculated within DFT/LDA and GW are similar, with the quasiparticle valence band exhibiting a noticeably more pronounced curvature. A more quantitative comparison between the DFT/LDA and GW band dispersions is given by the isotropic effective masses, as shown in Table 1. The effective mass tensor is calculated as the inverse of the second derivatives of the energy with respect to the crystal momentum, $m_{ij}^* = \hbar^2(\partial^2\epsilon/\partial k_i\partial k_j)^{-1}$, and the values reported in Table 1 are the averages of the eigenvalues of the effective mass tensors. From Table 1 we can see that the DFT/LDA and GW effective masses differ by almost a factor of two. In addition, the GW reduced effective mass of $0.11\,m_e$ is in excellent agreement with the experimental value of $0.10\,m_e$ reported by Miyata et al. (2015), thus establishing the accuracy of the quasiparticle band structure calculations.

An important consequence of the quasiparticle effects in the calculation of the band structure of $CH_3NH_3PbI_3$ is the band edge parabolicity. While both DFT/LDA and GW yield isotropic band edges, the DFT/LDA bands are parabolic only in a narrow energy range near the band edges. On the other hand, the quasiparticle valence and conduction band edges exhibit a parabolic profile over a range of 300 meV (Fig. 4b). This observation is most clearly visualized in the joint density of states (JDOS), as shown in Fig 4b, where the parabolic shape of the bands extends over approximately 0.3 eV for the quasiparticle JDOS, while the JDOS calculated from DFT/LDA departs from the parabolic shape within 50 meV from the onset.

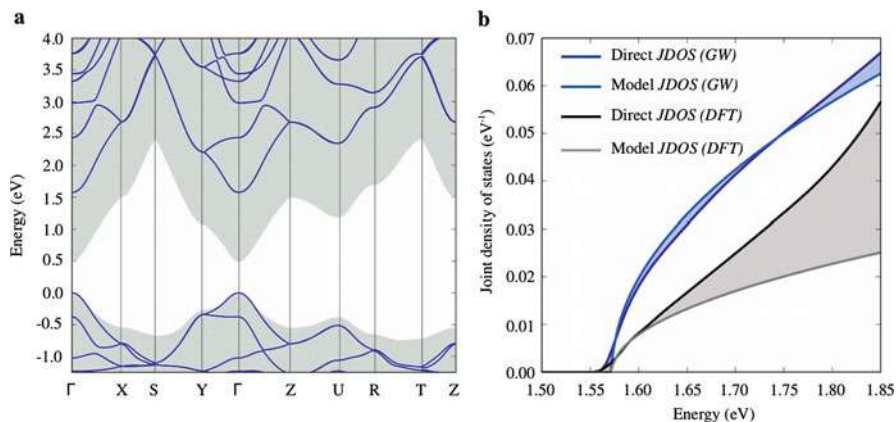
The parabolicity of the conduction and valence band edges has important implications in the understanding of both absorption and recombination mechanisms in $CH_3NH_3PbI_3$. Using a combined experimental and theoretical analysis of the


Fig. 4 Band parabolicity. (**a**) Quasiparticle band structure of $CH_3NH_3PbI_3$. The quasiparticle band structure is represented by the blue lines; the grey background is the DFT/LDA band structure. The quasiparticle band structure was obtained by performing a Wannier interpolation of the quasiparticle eigenvalues calculated for a $4 \times 4 \times 4$ Γ-centered grid, using the GW and the self-consistent scissor scheme (Filip et al. 2015; Davies et al. 2018). (**b**) Joint density of states of $CH_3NH_3PbI_3$ calculated within DFT (black line) and GW (dark blue line). The direct joint densities of states were calculated using the definition $J(\omega) = \sum_{cv\mathbf{k}} \delta(\epsilon_{c\mathbf{k}} - \epsilon_{v\mathbf{k}} - \omega)$, where c and v are the band indices for the conduction and valence band states, respectively, and $\mathbf{k}$ is the crystal momentum. The summation over the crystal momenta is performed by discretizing the Brillouin zone on a Γ-centered grid of $40 \times 40 \times 40$ points. The DFT and GW eigenvalues are obtained on this grid from Wannier interpolation (Filip et al. 2015; Davies et al. 2018). The model joint densities of states (light blue line for GW and grey for DFT) are calculated using the assumption that the bands are parabolic using, $J^{\mathrm{DFT}/GW}(\omega) = 1/4\pi^2 (2\mu^{\mathrm{DFT}/GW}/\hbar^2)^{3/2} (\omega - E_g)^{1/2}$, where μ is the reduced effective mass calculated from DFT ($0.06\,m_e$) or GW ($0.11\,m_e$). Both the model and the direct JDOS calculated from DFT were rigidly shifted in order to match the GW onset, for clarity

optical absorption line shape, Davies et al. (2018) showed that the optical absorption spectrum of $CH_3NH_3PbI_3$ can be modelled using Elliot's theory (Elliott 1957) up to 100 meV above the absorption onset. Within this premise, Davies et al. (2018) decoupled the excitonic and continuum part of the absorption spectrum and calculated the bimolecular recombination rate using the van Roosbroeck-Shockley formalism (van Roosbroeck and Shockley 1954). By comparing this model to direct transient spectroscopic measurements, Davies et al. (2018) demonstrated that bimolecular recombination in $CH_3NH_3PbI_3$ is an inverse absorption process. This result reinforces the conclusion that $CH_3NH_3PbI_3$ is in many respects very similar to conventional semiconductors, such as GaAs (Herz 2016).

1.3   Vibrational Properties of $CH_3NH_3PbI_3$

The vibrational spectrum is a key piece of information in the study of the optoelectronic properties of $CH_3NH_3PbI_3$. Lattice vibrations can be analyzed experimentally from IR (Pérez-Osorio et al. 2015) and Raman (Ledinský et al. 2015) spectroscopy,

as well as inelastic neutron scattering (Druzbicki et al. 2016), and can be directly compared with ab initio calculations. Compared to the latter two techniques, IR spectroscopy is most accessible, as high-resolution measurements can be achieved in a short time frame over a wide range of frequencies (Pérez-Osorio et al. 2015).

The vibrational properties of $CH_3NH_3PbI_3$ can be calculated within density functional perturbation theory (DFPT). The vibrational spectrum of $CH_3NH_3PbI_3$ in the orthorhombic *Pnma* phase consists of 144 normal modes at the Γ point, with frequencies extending up to $3100\,cm^{-1}$ (Pérez-Osorio et al. 2015). The vibrational modes of $CH_3NH_3PbI_3$ can be classified into three main categories: vibrations of the $CH_3NH_3^+$ cations, vibrations of the inorganic PbI_3 network, and mixed modes. In addition, the vibrations of the $CH_3NH_3^+$ cations ca be decomposed into rigid translations, spinning vibrations around the C-N axis, librations around the center of mass of the cation, and internal vibrations. Up to $60\,cm^{-1}$, the main contribution to the vibrational phonon modes comes from the internal vibrations of the inorganic network, while above $60\,cm^{-1}$, the vibrational phonon modes are almost exclusively due to the vibrations of the organic cations (Pérez-Osorio et al. 2015). Pérez-Osorio et al. (2015) describes the precise contribution of these three categories of vibrations to each of the vibrational modes. These contributions were calculated by a systematic decomposition of each mode followed by a factor-group analysis of their symmetries.

Using the calculated vibrational frequencies of $CH_3NH_3PbI_3$, the IR spectrum is obtained by calculating the absorption spectrum in the IR frequency range as (Pérez-Osorio et al. 2015):

$$I(\omega) = \frac{e^2}{M_0} \sum_{\alpha v} |Z_{\alpha v}^*|^2 \delta(\omega - \omega_v), \tag{2}$$

where M_0 is the average mass over the unit cell, e is the electronic charge, ω_v are the vibrational eigenfrequencies at the zone center, and $Z_{\alpha v}^* = \sum_{\kappa \beta} \sqrt{\frac{M_0}{M_\kappa}} e_{\kappa \beta, v} Z_{\kappa, \alpha \beta}^*$, with M_κ being the nuclear mass of atom κ in the unit cell; $e_{\kappa \beta, v}$ the vibrational eigenmode of atom κ in the Cartesian direction β, with vibrational frequency ω_v; and $Z_{\kappa, \alpha \beta}^*$ the Born effective charge (Pérez-Osorio et al. 2015).

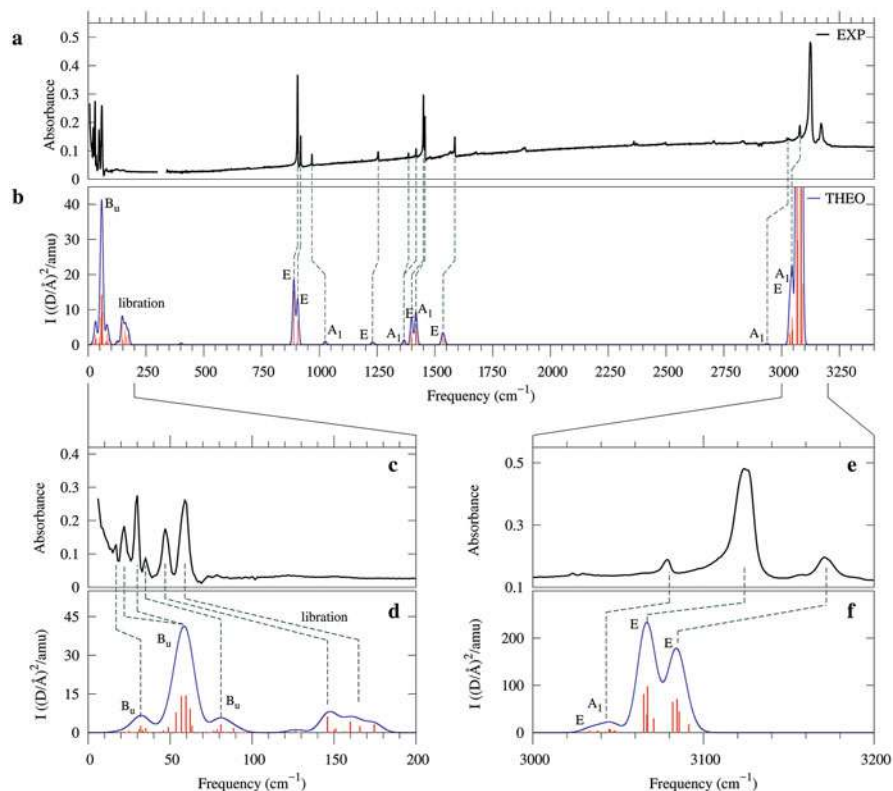
In Fig. 5 we show a comparison between the experimental and theoretical IR spectra of $CH_3NH_3PbI_3$, as measured and calculated by Pérez-Osorio et al. (2015). Each of the features in the experimental IR spectrum is assigned to a peak and a vibrational symmetry in the calculated spectrum. The theoretical and experimental spectra agree well for almost the entire frequency range. The two main discrepancies are shown in Fig. 5c–f. At high frequency, the three peaks are redshifted by approximately $70\,cm^{-1}$. This discrepancy is shown by Pérez-Osorio et al. (2015) to be corrected by the use of the generalized gradient approximation (GGA) instead of LDA for the calculation of the exchange-correlation potential in DFPT. In the low-frequency (Fig. 5c, d) region of the spectrum, DFPT calculations appear to overestimate the vibrational frequencies of the librational modes of $CH_3NH_3^+$ around $150\,cm^{-1}$. This discrepancy (Fig. 5e, f) is consistent with other studies in


Fig. 5 Experimental and theoretical IR spectra of $CH_3NH_3PbI_3$ at low temperature. (a) IR spectrum of CH_3NH_3 measured on thin film at 10 K. The dashed lines indicate the assignment of the most prominent peaks of the spectrum to features in the calculated IR spectrum in (**b**). The IR spectrum is measured at normal incidence, and only TO normal modes can be excited in this geometry. (**b**). Calculated IR spectrum of $CH_3NH_3PbI_3$ in the low-temperature orthorhombic structure. The red sticks are the calculated infrared intensities, and the blue line corresponds to the spectrum calculated by representing each absorption peak with a Gaussian broadening. To be able to compare with the experimental data obtained within the geometry described in (**a**), only TO modes are included in the calculated IR spectrum, as discussed by Pérez-Osorio et al. (2015). (**c, d**). Close-up of the comparison between the experimental (**c**) and theoretical (**d**) IR spectra in the low-frequency region. (**e, f**) Close-up of the comparison between experimental (**e**) and theoretical (**f**) IR spectra in the high-frequency region. (Reprinted with permission from Pérez-Osorio et al. (2015), Copyright (2015) American Chemical Society)

literature (Mosconi et al. 2014; Družbicki et al. 2016), and it appears regardless of the choice of exchange-correlation functional (LDA vs. GGA), inclusion of relativistic spin-orbit coupling effects, van der Waals interactions, or anharmonic effects (Pérez-Osorio et al. 2017). Moreover, Pérez-Osorio et al. (2017) show that the calculated vibrational density of states is in good agreement with inelastic neutron scattering spectra (Družbicki et al. 2016), suggesting that the discrepancy

between the experimental and calculated IR spectra may be related to a mismatch between the experimental and theoretical IR intensities.

Having established both the electronic and vibrational properties of $CH_3NH_3PbI_3$, we have access to the high- and low-frequency dielectric permittivities, ϵ_∞ and ϵ_0, respectively. The high-frequency permittivity does not depend on lattice vibrations, but its value does depend on the calculated band gap. For this reason, the closest agreement with the experimental value $\varepsilon_\infty = 6.5$ (Hirasawa et al. 1994) is obtained from finite-electric field calculations within scalar-relativistic DFT (Pérez-Osorio et al. 2015; Filip et al. 2015) (5.8, see Table 1). The low-frequency permittivity depends on the vibrational frequencies of $CH_3NH_3PbI_3$, with the vibrations of the inorganic PbI_6 network carrying the largest contribution (Pérez-Osorio et al. 2015). Pérez-Osorio et al. (2015) reports a value of $\varepsilon_0 = 25.3$, as calculated from DFPT, in very good agreement with the experimental low-frequency dielectric constant $\varepsilon_0 = 30.5$ (Poglitsch and Weber 1987). As shown by Pérez-Osorio et al. (2015), the large difference between the high- and low-frequency dielectric permittivities is due almost entirely to the vibrations of the inorganic PbI_6 network.

1.4   Electron-Phonon Coupling in $CH_3NH_3PbI_3$

Understanding the interaction between electrons and lattice vibrations is essential in the investigation of the transport properties and charge carrier recombinations in $CH_3NH_3PbI_3$. In particular, electron-phonon coupling manifests itself prominently in the temperature-dependent charge carrier mobility and in the broadening of the photoluminescence spectra (Johnston and Herz 2016). The charge carrier mobility decreases with increasing temperature as T^m, where m takes values between -1.4 and -1.6 (Brenner et al. 2015; Wright et al. 2016). Such behavior is typical of nonpolar semiconductors such as silicon or germanium, where electron-phonon interactions at room temperature are almost exclusively governed by the interaction with acoustic phonons. It is, however, unexpected in the case of $CH_3NH_3PbI_3$, given the polar nature of the this compound.

As shown by Wright et al. (2016), the nature of electron-phonon interactions in $CH_3NH_3PbI_3$ can be investigated by analyzing the photoluminescence linewidth as a function of temperature. In their study, Wright et al. (2016) find that the contribution of acoustic phonons to the broadening of the photoluminescence linewidth is negligible compared to that of the longitudinal-optical (LO) modes. This argument is further corroborated by first principles calculations of the electron-phonon coupling, as shown in Fig. 6 (Wright et al. 2016).

The photoluminescence linewidth can be directly associated with the imaginary part of the electron-phonon self-energy, calculated using the following expression (Wright et al. 2016):

$$\Sigma_{n\mathbf{k}} = \sum_{m\nu\mathbf{q}} |g_{mn}^\nu(\mathbf{k}, \mathbf{q})|^2 \left[\frac{n_{\mathbf{q},\nu} + f_{m\mathbf{k}+\mathbf{q}}}{\varepsilon_{n\mathbf{k}} - \varepsilon_{m\mathbf{k}+\mathbf{q}} - \omega_{\mathbf{q}\nu} - i\eta} + \frac{n_{\mathbf{q},\nu} + 1 - f_{m\mathbf{k}+\mathbf{q}}}{\varepsilon_{n\mathbf{k}} - \varepsilon_{m\mathbf{k}+\mathbf{q}} - \omega_{\mathbf{q}\nu} - i\eta} \right],$$

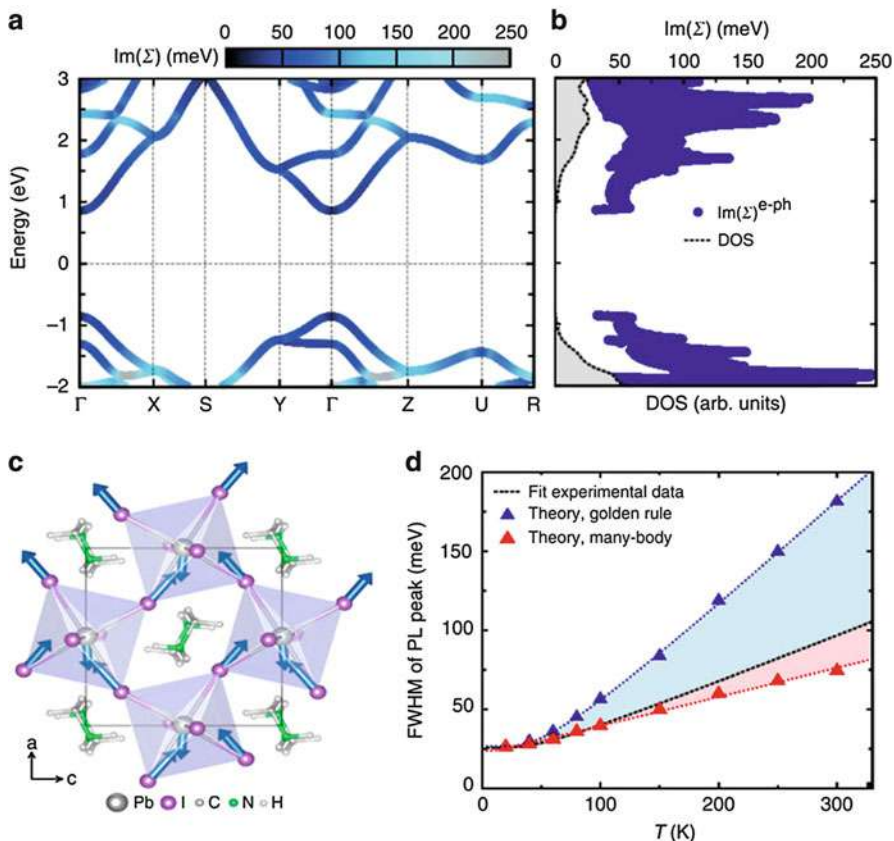
$$(3)$$


Fig. 6 Electron-phonon coupling and PL broadening of $CH_3NH_3PbI_3$. (**a**) GW quasiparticle band structure of the orthorhombic $CH_3NH_3PbI_3$, combined with the heat map of the imaginary part of the electron-phonon self-energy, $Im(\Sigma)$ at T = 200 K. The zero of the energy is placed in the middle of the band gap. (**b**) Imaginary part of the electron-phonon self-energy (dark blue line) and the electronic density of states (dotted black line). $2Im(\Sigma)$ corresponds to the electron-hole linewidth arising from electron-phonon coupling (without the quasiparticle renormalization factor Z). (**c**) Ball-and-stick representation of the LO vibration responsible for the broadening of the PL peaks. (**d**) Temperature dependence of the full width at half maximum (FWHM) of the PL peak in $CH_3NH_3PbI_3$. The dashed black line corresponds to the fit to experimental data, and the blue and red triangles correspond to theoretical calculations using Fermi's golden rule and the Brillouin Wigner perturbation theory (red triangles), respectively. The theoretical broadening is obtained as the sum of $2Im(\Sigma)$ at the valence and conduction band edges, rigidly shifted by a constant inhomogeneous broadening of 26 meV. (Reprinted with permission from Wright et al. (2016), Copyright (2016) Nature Publishing Group)

where $f_{m\mathbf{k}+\mathbf{q}}$ and $n_{\mathbf{q},\nu}$ are the Fermi-Dirac and Bose-Einstein occupations; $\epsilon_{n\mathbf{k}}$ and $\hbar\omega_{\mathbf{q}\nu}$ are the electron and phonon energies, respectively; η is a small broadening parameter; and $g_{mn}^{\nu}(\mathbf{k}, \mathbf{q})$ is the electron-phonon matrix element calculated by taking into account only the interaction with the LO phonons, as discussed by Verdi and Giustino (2015).

Figure 6a shows how the imaginary part of the electron and hole linewidth is distributed across the electronic states in the quasiparticle band structure (Wright et al. 2016). The linewidth increases as the density of states increases (Fig. 6b), because more states become available for electronic transitions. The predominant contribution to the electron-phonon self-energy comes from the LO phonon mode with an energy of 13 meV, which corresponds to the vibrations shown in Fig. 6c. This value is in excellent agreement with the dominant phonon energy of 11 meV determined from the experiments (Wright et al. 2016). Figure 6d shows that the measured and the calculated trend for the PL broadening as a function of temperature is in very good agreement, thereby confirming that the predominant electron-phonon interaction is that between charge carriers and longitudinal optical phonons. In addition, both theoretical and experimental results reported by Wright et al. (2016) show that $CH_3NH_3PbBr_3$ exhibits an electron-phonon coupling which is 40% stronger than for the iodide, pointing to potential directions for controlling such effects through chemical substitution.

1.5 Desirable Electronic Structure Properties and the Basis for Materials Design

Experimental and theoretical studies of the electronic and optical properties of $CH_3NH_3PbI_3$ have so far elucidated many of its fundamental properties. Perhaps the most striking finding is that $CH_3NH_3PbI_3$ exhibits optoelectronic properties which are remarkably similar to the best inorganic semiconductors such as GaAs. Despite much progress on the understanding of the fundamental properties of $CH_3NH_3PbI_3$ and related compounds, several important questions remain to be addressed. For example, it would be important to investigate charge carrier transport and recombination processes (Herz 2016), degradation mechanisms (Leijtens et al. 2017), and defect physics (Ball and Petrozza 2017). All these topics are active areas of current research in this field.

Much of the current success of halide perovskites owes to the continued in-depth investigation of their fundamental optoelectronic properties, but also to the development of practical strategies to control these properties through chemical substitution and to design new materials with targeted functionalities. For example, chemical substitution has been systematically explored as a means to tune the optical absorption properties (Filip et al. 2014; Eperon et al. 2016), improve the stability (McMeekin et al. 2016), and reduce the toxicity (Giustino and Snaith 2016) of lead-halide perovskites.

In particular, there is currently an ongoing search for alternative lead-free halide perovskites which retain the optoelectronic properties of $CH_3NH_3PbI_3$ and remove any potential environmental concerns due to the presence of lead. The nearly ideal optoelectronic properties of lead-halide perovskites set a very high bar for potential lead-free candidates: new compounds must exhibit a band gap in the visible range, long carrier lifetimes, good charge carrier mobilities, low exciton binding energies,

and shallow or electrically inactive defects. In the next section, we review our efforts in the search for novel halide perovskites that might exhibit this unique combination of optoelectronic properties.

2   Design of Lead-Free Perovskites

The presence of lead in lead-halide perovskites has raised questions on the environmental impact of perovskite solar cells. While the content of lead by weight in these devices is well below the limits set by governmental agencies, the prospect of developing lead-free perovskites is very attractive. Until now a lead-free material that can compete with $CH_3NH_3PbI_3$ and related compounds has not been found, but substantial progress has been made in the development of new lead-free perovskites.

   Among the different approaches to develop new lead-free perovskites, first-principles computational design has emerged as a powerful tool for screening new materials and identifying promising candidates. In fact, over the last two years, several new lead-free halide double perovskites have been first proposed by theoretical studies and subsequently synthesized in the lab. In the next sections, representative examples in this area are discussed.

2.1   Homovalent Pb Replacement

In order to replace lead in the $APbX_3$ structure, the simplest starting point is to search for alternative cations in the +2 oxidation state. Hypothetical new perovskites should be stable toward air, moisture, illumination, and heat and should exhibit band gap and carrier effective masses similar to those of $CH_3NH_3PbI_3$. The most obvious choice would be to replace Pb^{2+} with another atom of Group IV, such as Sn^{2+}. Indeed Sn-based perovskites were shown to exhibit ideal band gaps for photovoltaics applications, as well as good charge carrier mobilities (Stoumpos et al. 2013). However, perovskites containing Sn^{2+} tend to degrade rapidly due to the oxidation of the cation to Sn^{4+}. This limitation was recently overcome by developing mixed Sn/Pb halide perovskites, and the first applications to tandem device architectures are very promising (McMeekin et al. 2016; Eperon et al. 2016).

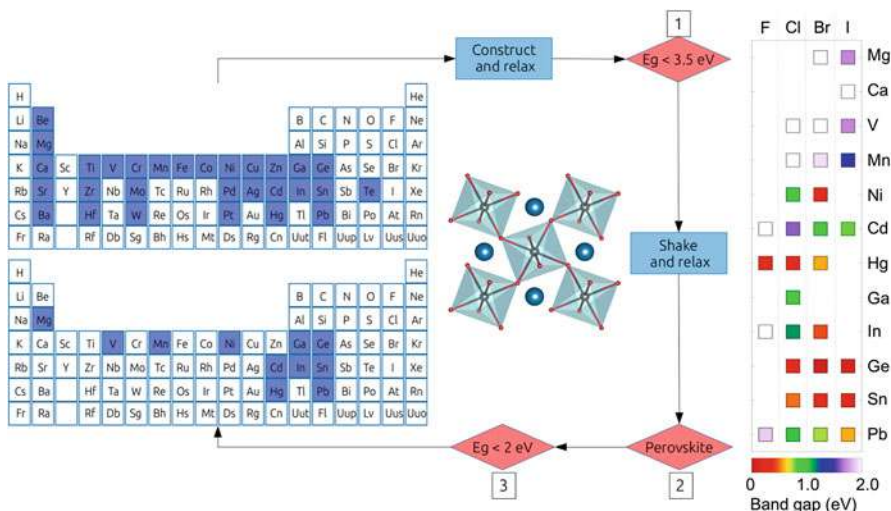
   A comprehensive search for other +2 B-site cations was performed by Filip and Giustino (2016). In this work the Periodic Table was screened by means of DFT calculations, using the procedure illustrated in Fig. 7. The candidate cations include metals which exhibit a stable +2 oxidation state and which form BX_2 salts with $X = Cl$, Br, or I. This choice leads to 116 hypothetical compounds for which the electronic structure was calculated using DFT/LDA, using the same orthorhombic perovskite structure as for $CH_3NH_3PbI_3$. The calculated band structures were then used to reduce the materials space, and only those insulating compounds with a band gap smaller than 3.5 eV were retained, leaving 40 potential candidates. These compounds were tested for dynamic stability using a "shake-and-relax" approach, meaning that the structures are randomly distorted and subsequently re-optimized.


Fig. 7 Homovalent replacement of lead. Schematic illustration of the methodology and the selection criteria (in red triangles) employed for screening the Periodic Table for stable lead-free ABX_3 halide perovskites. At first, all perovskite structures with a DFT/LDA band gap larger than 3.5 eV were eliminated. The remaining compounds were randomly distorted ("shake-and-relax") to probe their dynamic stability, and only compounds which retained the perovskite structure and exhibited a band gap of less than 2.0 eV were considered for the final GW calculations. These compounds are marked with the blue squares in the lower Periodic Table. The DFT/LDA band gaps for all the halide perovskites which satisfied all selection criteria are summarized at the left side of the figure. (Adapted with permission from Filip and Giustino (2016), Copyright (2016) American Chemical Society)

Only structures that preserve the perovskite connectivity are retained in this step. For the 32 compounds that pass this test, more refined calculations including spin-orbit coupling effects were performed, and 25 hypothetical perovskites with band gaps smaller than 2 eV were identified. For the compounds with the most promising electronic properties, Filip and Giustino (2016) performed additional calculations at the GW level. However in all the cases considered, the quasiparticle band gaps were too wide for solar cell applications. This result suggests that homovalent Pb replacement may not be the best option for eliminating Pb in halide perovskites. A possible promising exception is the use of Sn^{2+}, provided the stability issues can be resolved. Similar conclusions were reached by an extensive, high-throughput search of novel ABX_3 perovskites by Korbel et al. (2016).

2.2   Heterovalent Pb Replacement

In the previous section, we considered the possibility of replacing Pb with another divalent cation. In order to broaden the search space, several authors considered the potential replacement of Pb^{2+} by cations in their +3 or +4 formal oxidation

states. This choice leads to the formation of perovskite-related structures such as $Cs_3Sb(III)_2I_9$ and $Cs_3Bi_2I_9$ (Saparov et al. 2015; Park et al. 2015), $Cs_2Sn(IV)I_6$, and Cs_2PdBr_6 (Lee et al. 2014; Sakai et al. 2017). In all these structures, the three-dimensional corner-sharing connectivity of the octahedra is disrupted. In particular, A_2BX_6 compounds can be described as vacancy-ordered double perovskites, where the B-sites of the perovskite lattice are replaced alternatively by the $+4$ cation and by a vacancy. In this structure the BX_6 octahedra are structurally disconnected. Similarly $A_3B_2X_9$ compounds can be thought of as if obtained from the perovskite lattice by removing one layer of octahedra. In both cases the resulting compounds behave electronically as low-dimensional systems (zero-dimensional and two-dimensional, respectively), and as a consequence, the optoelectronic properties are not ideal (Xiao et al. 2017b).

Another potential strategy for lead replacement is the split-cation approach. This consists of replacing pairs of Pb^{2+} cations by pairs of $+1$ and $+3$ cations, so as to preserve the average oxidation state on the B-site. When the $+1$ and $+3$ cations are arranged in a rock-salt sublattice, the structure is an ordered double perovskite, also known as elpasolite, as shown in Fig. 8. In this case the three-dimensional connectivity of the octahedra is maintained.

Double perovskites are well known in the literature on oxide perovskites (Vasala and Karppinen 2015). Halide double perovskites are less known, but are commonly employed in radiation detectors as scintillators (van Loef et al. 2002; Biswas and Du 2012). Common elpasolites exhibit wide band gaps; therefore they are unsuitable for photovoltaics applications. In the following three sections, we review recent findings on three new classes of halide elpasolites: halide double perovskites based on pnictogens and noble metals (Volonakis et al. 2016; Filip et al. 2016; Slavney et al. 2016; McClure et al. 2016); indium-silver halide double perovskites (Volonakis et al. 2017a; Zhao et al. 2017a); and indium-bismuth double perovskites (Volonakis et al. 2017b; Xiao et al. 2017a; Zhao et al. 2017b).
Fig. 8 The double perovskite structure. Two divalent cations at the B-site of the $AB(II)X_3$ perovskite structure (left) are replaced with a monovalent and a trivalent cation to form the double perovskite $A_2B(I)B'(III)X_6$ structure (right). The two types of octahedra in the double perovskite remain corner-sharing. When the B(I) and B′(III) cations are ordered in a rock-salt sublattice, these compounds are called elpasolites (Morss et al. 1970; Meyer and Gaebell 1978; Meyer 1980)

2.2.1   Double Perovskites Based on Pnictogens and Noble Metals

In order to design new lead-free halide double perovskites, Volonakis et al. (2016) started from the known elpasolite $Cs_2NaBiCl_6$ (Morss and Robinson 1972) and considered the replacement of monovalent Na by a noble metal. The rationale behind this strategy is that noble metals are known to be good electrical conductors due to their s^1 electrons. Volonakis et al. (2016) performed DFT calculations for hypothetical compounds Cs_2NmPnX_6, where Nm = Cu, Ag, Au, Pn = Bi, Sb, and X = Cl, Br, I. The calculated band gaps and carrier effective masses for the Bi-based hypothetical perovskites are shown in Fig. 9. All band gaps fall below 2.7 eV, and the effective masses do not exceed $0.4\,m_e$. These results indicate that pnictogen/noble metal halide double perovskites might indeed be promising for optoelectronic applications.

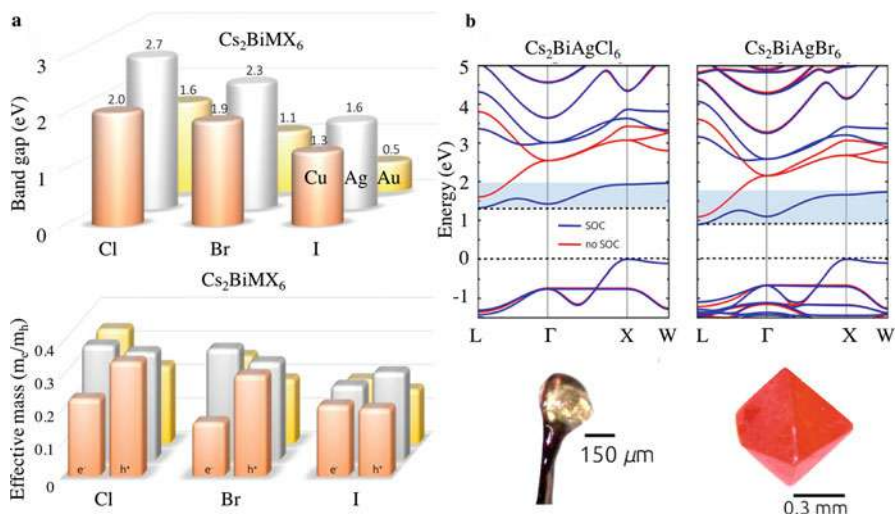
Volonakis et al. (2016) reported the synthesis of $Cs_2AgBiCl_6$. The compound was synthesized by following the same route as for $Cs_2NaBiCl_6$ (Morss and Robinson 1972) and replacing AgCl for NaCl. The structure of this compound was characterized by powder and single crystal X-ray diffraction (XRD) measurements. The authors obtained an ordered double perovskite structure with the $Fm\overline{3}m$ face-centered cubic space group (no. 255) at room temperature. The reported lattice


Fig. 9 Electronic properties of the pnictogen/noble metal double perovskites. (**a**) Calculated electronic band gaps (top left) and effective masses (bottom left) of all the hypothetical $Cs_2BiB'X_6$ lead-free halide double perovskites, with B' = Cu, Ag, Au and X = Cl, Br, I. All the band gaps are calculated by employing the PBE0 hybrid functional and are found to be indirect and below 2.7 eV. The effective masses are low ($<0.4\,m_e$), as calculated from the DFT/LDA at the valence band top and the conduction band bottom for the holes and electrons, respectively. (**b**) The DFT/LDA electronic band structure for the synthesized $Cs_2AgBiCl_6$ and $Cs_2AgBiBr_6$ compounds. Calculations with (without) spin-orbit coupling are shown in blue (red), and the shaded area highlights the lowest unoccupied band. The synthesized $Cs_2AgBiCl_6$ and $Cs_2AgBiBr_6$ single crystals are shown below. (Adapted with permission from Volonakis et al. (2016) and Filip et al. (2016), Copyright (2016) American Chemical Society)

constant is 10.78 Å, in good agreement with the predicted DFT/LDA value of 10.50 Å. Following the same synthetic route, Filip et al. (2016) reported the new double perovskites $Cs_2AgBiBr_6$. Also in this case, the XRD measurements confirmed the formation of an elpasolite structure, with a lattice constant of 11.26 Å. This value is slightly larger than for $Cs_2AgBiCl_6$, as expected based on the ionic radii of the halides. The synthesis of these compounds via solution and via solid-state synthesis was also reported independently (and a few weeks earlier) by two other groups (Slavney et al. 2016; McClure et al. 2016).

The electronic band structures of the new double perovskites are shown in Fig. 9. In both cases the band gap is indirect, with the valence band top at the X point of the Brillouin zone and the conduction band bottom at the L point. The band gaps calculated using the PBE0 hybrid functional are 2.7 and 2.3 eV for $Cs_2AgBiCl_6$ and $Cs_2AgBiBr_6$, respectively (Volonakis et al. 2016). Quasiparticle GW calculations yield slightly smaller gaps, namely, 2.4 and 1.8 eV, respectively (Filip et al. 2016). The calculated band gaps are broadly in agreement with the measured optical gaps, which range between 2.2–2.8 eV and 1.9–2.2 eV for $Cs_2AgBiCl_6$ and $Cs_2AgBiBr_6$, respectively (Filip et al. 2016).

More recently Filip et al. (2017) performed a systematic DFT investigation of the thermodynamic stability of the entire family of Cs_2NmPnX_6 compounds. The calculations involve the comparison between the total energy of each perovskite and the total energies of all possible decomposition products. This study predicted that only three double perovskites should be stable, namely, $Cs_2AgBiCl_6$, $Cs_2AgBiBr_6$, $Cs_2AgSbCl_6$, in line with experimental observations (Slavney et al. 2016; McClure et al. 2016; Volonakis et al. 2016; Tran et al. 2017).

Among these new compounds, the double perovskite $Cs_2AgBiBr_6$ attracted considerable interest as a potential new material for photovoltaics and optoelectronic applications. In fact, solar cells using $Cs_2AgBiBr_6$ as the active layer were demonstrated by Greul et al. (2017), and power conversion efficiencies of 2.5% were reported. Furthermore, the possibility of mixing $Cs_2AgBiBr_6$ with $CH_3NH_3PbI_3$ in order to reduce the Pb content of perovskite solar cells (as opposed to completely replace Pb) is also under investigation (Du et al. 2017a, b). Finally, Pan et al. (2017) showed that single crystals of $Cs_2AgBiBr_6$ can be employed to realize X-ray detectors with low detection thresholds (Pan et al. 2017).

2.2.2 Double Perovskites Based on In(III) and Ag(I)

Following up on the successful design and synthesis of lead-free halide double perovskites based on pnictogen/noble metals combinations, several groups set to improve the design by targeting double perovskites with a direct band gap. Volonakis et al. (2017a) reasoned that the origin of the indirect band gap of $Cs_2AgBiBr_6$ lies in the hybridization between Bi s-states and Ag d-states near the valence band top. In order to demonstrate this effect, the authors artificially lowered the energy of the Bi s-states in $Cs_2AgBiBr_6$ using an effective Hubbard potential in the DFT calculations. This strategy led to the appearance of a direct band gap at the zone center, in line with expectations. In order to exploit this finding, Volonakis

et al. (2017a) proposed to replace Bi with a +3 cation with the outermost *s*-shell unoccupied. This proposal, combined with the observation that the synthetic route to prepare $Cs_2InNaCl_6$ via solution was already known (Morss and Robinson 1972; Meyer and Gaebell 1978), motivated the consideration of hypothetical compounds of the type Cs_2InAgX_6 with X = Cl or Br (Volonakis et al. 2017a).

The calculated band structure of $Cs_2InAgCl_6$ is shown in Fig. 10a. As expected the system exhibits a direct gap at the Γ point, and the top of the valence band is comprised of Ag and In *d*-orbitals, hybridized with the halogen *p*-orbitals. The band gap of $Cs_2InAgCl_6$ was predicted to be in the range 2.7±0.6 eV, with the error bar reflecting the spread in band gaps obtained from calculations based on different exchange and correlation functionals. This compound was successfully synthesized via an acidic solution synthesis route by mixing stoichiometric amounts of $InCl_3$, AgCl, and CsCl. Powder XRD measurements confirmed the formation of a double perovskite with a face-centered cubic crystal ($Fm\overline{3}m$ space group) and a lattice constant of 10.47 Å, in good agreement with the DFT predictions (Volonakis et al. 2017a).

The nature of In/Ag cation ordering in $Cs_2InAgCl_6$ is not firmly established yet. The characteristic fingerprints of cation ordering in the XRD spectra of double perovskites are two doublets arising from reflections at the planes containing each cation (Fig. 10b). In contrast to the cases of $Cs_2AgBiCl_6$ and $Cs_2AgBiBr_6$, where such doublets have clearly been identified (Volonakis et al. 2016), the assignment proved more difficult for $Cs_2InAgCl_6$. Volonakis et al. (2017a) calculated the XRD patterns for structures with ordered or disordered cations and compared these results to measured spectra, as shown in Fig. 10b. From this comparison it is clear that the difference between the two structures is too subtle to be resolved by the measurements. More refined XRD data from Zhou et al. (2017), taken on single crystal samples, show a clear doublet at low angle. This supports the notion that $Cs_2InAgCl_6$ is a fully ordered elpasolite, although further investigations would be desirable to settle this question.

The calculated electron and hole effective masses of $Cs_2InAgCl_6$ are relatively light, $0.29\,m_e$ and $0.28\,m_e$, respectively. These values refer to the parabolic bands that can be seen in Fig. 10a. The non-dispersive band that is seen along the ΓX direction in the same figure arises from two-dimensional wave functions comprising of In $4d_{x^2-y^2}$ states and Cl $3p_{x,y}$-states. These states are expected to hinder hole transport along the six equivalent [001] directions, as well as to favor the formation of deep traps.

The nature of the band gap of $Cs_2InAgCl_6$ remains an open question. The absorption data reported by Volonakis et al. (2017a) indicate an absorption onset around 3.3 eV, which is consistent with the upper range obtained from DFT calculations. However the photoluminescence data by Volonakis et al. (2017a) also indicate emission near 2.0 eV, indicating the presence of optically active defects within the gap. Luo et al. (2017) proposed an alternative explanation for these effects, involving parity-forbidden band-to-band transitions.

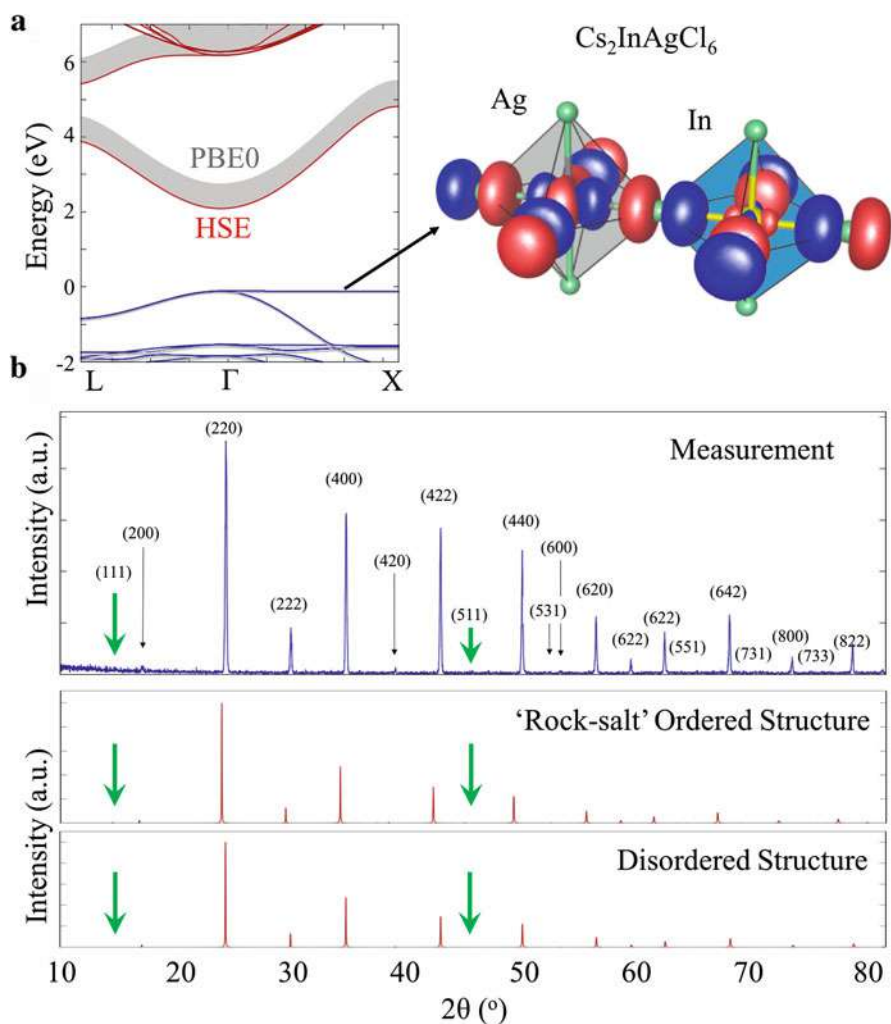
While the band gap of $Cs_2InAgCl_6$ is too wide for applications in photovoltaics, this new double perovskites is attracting attention for applications in UV detectors


Fig. 10 Electronic and structural properties of $Cs_2InAgCl_6$. (**a**) Electronic band structure of $Cs_2InAgCl_6$ within the DFT/PBE0 and the DFT/HSE hybrid functionals. Square moduli of the electronic wave functions for the highest (top) and second highest (bottom) occupied state along the ΓX direction. (**b**) Measured powder XRD pattern of $Cs_2InAgCl_6$ (top), XRD pattern calculated by assuming ideal rock-salt ordering of the In and Ag cations (middle), and XRD pattern calculated by assuming a fully disordered cation sublattice (bottom). The green arrows show the fingerprints of the cation ordering. The difference between the calculated ordered and disordered patterns is within the noise level of the measured spectrum; therefore it is not possible to unambiguously confirm cation ordering in this case. (Adapted with permission from Volonakis et al. (2017a), Copyright (2017) American Chemical Society)

due to its excellent stability and nontoxicity. In particular Luo et al. (2017) and Zhou et al. (2017) succeeded in growing mm-sized single crystals, and Luo et al. (2017) fabricated UV detectors with high on/off ratios, fast photoresponse, low dark current, and high sensitivity.

2.2.3 Double Perovskites Based on Bi(III) and In(I)

The new double perovskites described in the preceding sections exhibit either indirect band gaps or non-dispersive bands at the band extrema. In order to move a step closer to realizing high-quality semiconducting halide perovskites without lead, Volonakis et al. (2017b) revisited the general design principles of the split-cation approach based on +1 and +3 cations.

The authors argued that an ideal double perovskite should contain cations with the same valence configuration as Pb^{2+}. This implies that candidate elements should have (i) occupied s-orbitals, (ii) unoccupied p-orbitals, and (iii) a filled d shell far from the band edge. The candidates for the monovalent cation are limited to the alkali metals, the noble metals, and the Group III elements (boron group). Among these options only the latter have occupied s-orbitals and unoccupied p-orbitals in their formal +1 oxidation state. However, only two members of this group, In and Tl, are stable as +1 cations, and Tl is to be excluded due to its toxicity. This leaves In^+ as the sole candidate for the monovalent B-site cation. For the trivalent B-site cation, the choice is between pnictogens; some transition metals such as Sc, Y, Cu, and Au that were previously reported to form elpasolites (Giustino and Snaith 2016); and elements of the boron group in the +3 oxidation state, lanthanides and actinides. Among these elements only the pnictogens satisfy the criteria (i)–(iii) above. In this group N and P are too small to coordinate six halogens in an octahedral arrangement, and As is toxic; therefore the only options left are Sb^{3+} and Bi^{3+}. Based on this simple reasoning, Volonakis et al. (2017b) concluded that the best option for replacing Pb, from the electronic structure viewpoint, is to consider In(I)/Sb(III) and In(I)/Bi(III) double perovskites.

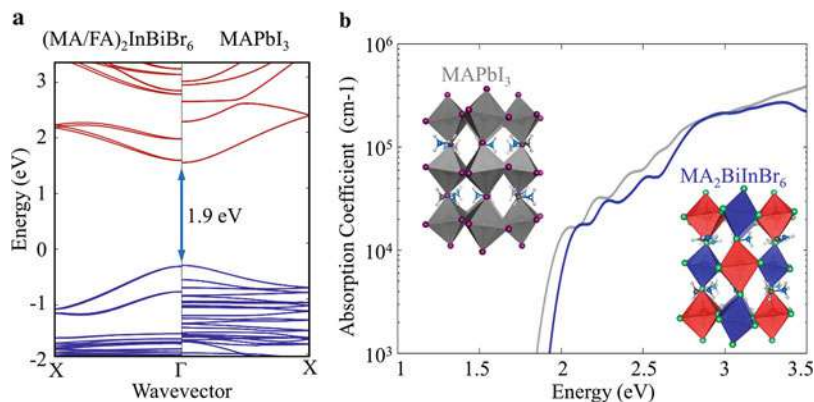
Building on this insight, Volonakis et al. (2017b) evaluated the stability of the hypothetical compounds A_2InPnX_6 with A = K, Rb, Cs, Pn = Sb, Bi, and X = F, Cl, Br, I, using both the Goldschmidt tolerance analysis and DFT calculations of decomposition energies in conjunction with the Materials Project Database (Jain et al. 2013). The outcome of this study was that all compounds are unstable with respect to decomposition, in line with the work of Xiao et al. (2017a). However $Cs_2InBiBr_6$ was found to be only marginally unstable, as the calculated decomposition energy of 1 meV per formula unit falls within the uncertainty of the computational method. This finding raises the hope that $Cs_2InBiBr_6$ or a closely related compound might be amenable to synthesis. Volonakis et al. (2017b) also noted that the decomposition energy correlates with the size of the A-site cation and that double perovskites with larger A-site cations tend to be less prone to decomposition. Based on this observation, the authors proposed that In(I)/Bi(III) halide double perovskites might be amenable for synthesis by using large organic cations such as $CH_3NH_3^+$ and $CH(NH_2)_2^+$.


Fig. 11 Indium/Bismuth halide double perovskites. (**a**) Comparison between the electronic band structures of the hypothetical lead-free double perovskite $(MA/FA)_2InBiBr_6$ and the lead halide perovskite $MAPbI_3$. MA stands for methylammonium (CH_3NH_3) and FA for formamidinium [$CH(NH_2)_2$]. Calculations were performed by employing the PBE0 hybrid functional. The double perovskite structures were fully optimized starting from the low-temperature *Pnma* phase of $MAPbI_3$ and by replacing two Pb atoms with In and Bi. (**b**) Calculated absorption coefficients for $MA_2InBiBr_6$ (blue line) and $MAPbI_3$ (grey line). (Adapted with permission from Volonakis et al. (2017b), Copyright (2017) American Chemical Society)

The electronic band structure of the hypothetical $(CH_3NH_3/CH(NH_2)_2)_2InBiBr_6$ double perovskites along with the band structure of $CH_3NH_3PbI_3$ is shown in Fig. 11a. As anticipated, owing to the similar electronic configuration of Pb^{2+}, In^+ and Bi^{3+}, the two compounds exhibit very similar band structures. The band gaps are direct in both cases and of the same magnitude. Similarly the calculated optical absorption spectra for these compounds are very similar, as shown in Fig. 11b. These findings highlight the potential of hybrid In/Bi halide double perovskites for photovoltaics and optoelectronics.

At the time of writing this chapter, synthetic attempts at making In(I)/Bi(III) halide double perovskites have not been successful. The key challenge appears to be the tendency of In(I) to be oxidized to the more stable form In(III); therefore future synthesis studies should devise strategies for maintaining In in its +1 state long enough to enable its incorporation in the double perovskite lattice.

2.3 Conclusions

In this chapter we have presented a detailed account of the contributions made by our materials modelling group to the study of the fundamental properties and design principles of metal-halide perovskites. The results reviewed in this chapter were obtained by employing techniques ranging from standard density functional theory and density functional perturbation theory to many-body perturbation theory treatments of electronic excitations and electron-phonon coupling phenomena. Our studies so far have been directed at two principal goals: understanding the

fundamental properties of lead-halide perovskites and developing design principles to guide the discovery of novel lead-free metal-halide perovskite semiconductors.

The current understanding of the fundamental properties of lead-halide perovskites is due to a complementary effort combining state-of-the art predictive computational modelling and experimental measurements which have allowed us to rationalize the optoelectronic properties of these materials from the perspective of atomistic modelling. In addition, we have shown that the predictive power of computational modelling can be directed at designing new lead-free halide perovskites, which led most notably to the computational discovery of a new family of lead-free halide double perovskites. During the last year more than eight novel lead-free double perovskite compounds have been successfully synthesized (Volonakis et al. 2016, 2017a; Slavney et al. 2016; McClure et al. 2016; Filip et al. 2016; Tran et al. 2017; Wei et al. 2016; Deng et al. 2016; Wei et al. 2017). Among these, compounds such as $Cs_2AgBiCl_6$, $Cs_2AgBiBr_6$, $Cs_2InAgCl_6$, and $Cs_2AgSbCl_6$ were first proposed by us in silico.

Despite the tremendous popularity of halide perovskites, there are still fundamental open questions and technological challenges that remain unresolved. A non-exhaustive list includes the fundamental understanding of charge transport and excitonic properties, elucidating the physics of defects and their impact on the degradation of these materials under standard solar cell operating conditions, and developing a practical solution for reducing the Pb content without impacting the device performance. All of these problems are currently active areas for both experimental and theoretical research.

In a broader context, the rapid rise of hybrid halide perovskites can be seen as a true success story for experimental and theoretical materials design. As the race for ever higher-performing and cost-efficient optoelectronic devices continues, there is an increasing demand for the discovery of new functional materials. Thanks to the continued development of highly accurate ab initio methods, computational materials modelling can now directly guide discovery, by designing materials and predicting their properties in silico ahead of synthesis. These developments place ab initio modelling in a central role in modern materials science and engineering, as an accelerator for the discovery and deployment of new technologies.

Prototyping Ultrafast Charge Separation by Means of Time-Dependent Density Functional Methods

15

Carlo Andrea Rozzi and Stefano Pittalis

Contents

Abstract

We discuss applications of time-dependent density functional theory (TDDFT) to simulate ultrafast charge separation in organic photovoltaic materials. We first outline both the targeted physics and the employed computational methods with particular regard to the real-time propagation framework. Then, we review some recent successful case studies in which TDDFT-based simulations have helped identify prototypical systems useful both for the basic understanding of the charge separation phenomena and for the systematic improvement of photovoltaic device performances.

1   Introduction

The concept of joining a p-doped and an n-doped semiconductor (typically silicon) in a single crystal is at the heart of traditional inorganic photovoltaics (IPV). In IPV, the charge carriers in a thin volume around the p-n junction diffuse at equilibrium

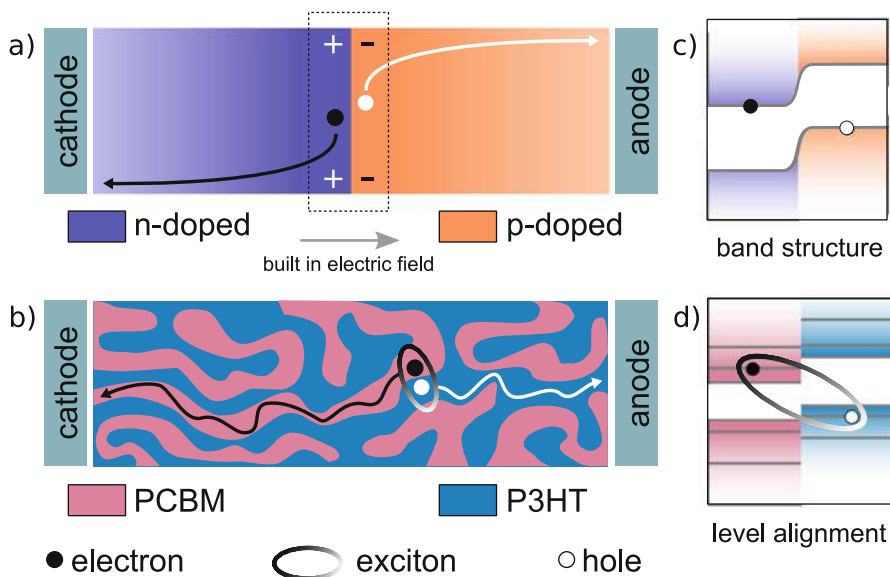

Fig. 1 Comparison between inorganic (first generation) and organic bulk heterojunction photovoltaic cells. Electrons (black), holes (white), and excitons are highlighted. (**a**) Junction between a p- and an n-doped crystalline semiconductor. At the junction, the depletion zone creates an intrinsic electric field that separates the photogenerated carriers. (**b**) Interpenetrating paths in a section of a polymer-acceptor blend (such as P3HT:PCBM). Once the interfacial excitons are dissociated, each type of carriers moves in a distinct phase. (**c**) Band structure of a crystalline p-n junction. Free carriers are directly injected in the conduction and valence bands. (**d**) Energy levels in an organic heterojunction. A strongly bound exciton is formed before the charges are separated

toward neighbor volumes following the gradient of carriers' concentration. At equilibrium, the migrated charges leave behind a depletion zone in which an intrinsic electric field balances the surface charge across the junction. The intrinsic electric field is ultimately responsible for separating electrons and holes when solar light reaches the junction (see Fig. 1a).

The operating principle of solar cells changed dramatically with the advent of the era of organic photovoltaics (OPV) based on dye-sensitized solar cells (DSC) and bulk heterojunctions (BHJ).

In DSC, organic dye molecules are employed to enhance the absorbance of an underlying nanostructured semiconductor (such as TiO_2). The dye is the photoactive material. Electrons are injected from the photoexcited dye to the TiO_2 due to the energy offset between the molecular levels and the valence band of the semiconductor. Electrons are then replaced in the dye by the action of a liquid electrolyte. The process is made unidirectional by the kinetic competition between the (fast) electron injection and the (slower) regeneration by the electrolyte.

In BHJ, the electron donors and acceptors are blended into a solid phase. No liquids appear in the final product, and the material can be printed on a flexible plastic support. Although some variants have been proposed, typically the donor

is a semiconducting polymer or small organic molecules, and the acceptor is a fullerene molecule (Sariciftci et al. 1992). Suitable chemical functionalization of both moieties is performed in order to enhance their mutual mixing and phase separation. The tight interleaving of the donor and acceptor phases increases the charge-separating interfacial area with respect to the film thickness and keeps the surface between the phases within a distance comparable to the exciton diffusion length (see Fig. 1b).

The charge separation induced by light in OPV is fundamentally different from that in IPV in several respects. In traditional p-n junctions, excitation and charge separation occur in the same material. Excitons may be equally created on both sides of the junction. Those formed within the bulk semiconductor can reach the junction if this is within the exciton diffusion length. Otherwise they will recombine with high probability.

Excitons are quite delocalized throughout the crystal lattice (Wannier-type excitons) and have binding energies smaller than the thermal energy at room temperature (of the order of 10 meV for bulk semiconductors (Green 2013). Therefore light excitation is able to directly inject free electrons into the conduction and holes into the valence band. Since the concentration gradient for the two species would drive them back toward the junction, the intrinsic field is the key factor to separate them.

In OPV, instead, two distinct phases exist, but only one of them can efficiently absorb visible light. It is the dye molecule in DSC and the polymer in BHJ. The intermolecular coupling between the components of each phase is weaker than for covalently linked units or bulk solids and the dielectric constant much lower (about 4 in organic (Li et al. 2012) instead of about 15 in bulk semiconductors (Dunlap and Watters 1953)). Therefore excitons typically have Frankel character in the bulk donor phase, i.e., they are localized and have a binding energy (of the order of tenths of an eV (Alvarado et al. 1998). An exothermic pathway to overcome this binding energy and separate the carriers is available provided that the bands of the donor and the acceptor have a suitable offset, namely, with the donor excited state higher in energy than the charge-separated state (see Fig. 1). If this is the case, an exciton can be dissociated at the interface, and the two carriers of opposite sign can be spatially dislocated: electrons move to the acceptor phase, while holes remain in the donor phase. No intrinsic field is needed to keep electrons apart from holes.

Photoexcitation produces free carriers in IPV, but a driving force is needed to avoid their recombination with the holes; in OPV a driving force is necessary to dissociate excitons, but charge carriers remain separated in the appropriate phases. Further important details, however, must be accounted for in order to obtain an accurate description of the charge separation dynamics and, eventually, to gain insight into the actual material performance for OPV. For instance, while the structure of p-n junctions is simply controlled by the crystal purity and the precision of doping, the device morphology of nanostructured blends can be quite intricate and process-dependent. Besides, since the charge separation occurs at the interface, while the carrier transport occurs in each phase separately, morphology affects both stages of the photovoltaic conversion in an interdependent way (Zhong et al. 2015; Jakowetz et al. 2016).

Most importantly, the scheme outlined above does not include the dynamics of exciton dissociation and charge separation. While in IPV the scattering of charge carriers by lattice phonons basically acts as an energy loss channel cooling down electrons toward the bottom of the conduction band, in OPV the role of nuclear motion is significantly more complex. Both low- and high-frequency modes can be strongly coupled to the photoexcited states and may take an active role in driving exciton dissociation. Even assuming that the structure is perfectly known and under control, the description of the aforementioned processes from first principles poses formidable challenges.

In the following sections, we discuss some examples of how the ultrafast regime of charge separation can be successfully analyzed by combining time-dependent density functional theory and suitable schemes for molecular dynamics. After an overview of the theoretical methods, we will review some cases in which the interplay between electronic and nuclear degrees of freedom dramatically affects the behavior of OPV materials. We will show that simple nonempirical calculations can reach a very good agreement with transient spectroscopy experiments and the corresponding simulations offer us important clarifications of the underlying mechanisms.

2 Simulations: Setting Up the Stage

The challenge of computing electronic properties at the nanoscale of even quite sizable systems can be considerably simplified by admitting a reduced description, such as that offered by density functional methods (Hohenberg and Kohn 1964; Kohn and Sham 1965; Runge and Gross 1984). In (time-dependent) density functional theory [(TD)DFT], the basic variable is the (TD) particle density: a real-valued function of the position, which represents the distribution of electrons in space. Crucially, the interacting many-body system can be mapped onto an auxiliary noninteracting many-body system: i.e., the (TD) Kohn-Sham (KS) system. The electrons of the KS system move in an effective potential of which the exchange-correlation (XC) potential is the only component to be approximated. The particle density can be obtained in terms of the contributions due to occupied single-particle orbitals, and thus, the relevant properties of the real system can be computed if they can be practically expressed as functionals of the particle density. The ground state and the excitation energies are among the typical properties which can be determined efficiently and rather accurately. For an extended account on TDDFT, the reader is referred to the contribution of Gross et al. in the Volume 1.

The first and simplest approximation in DFT is the local density approximation (LDA) (Kohn and Sham 1965). The LDA assumes that the XC energy density – and, thus, also the corresponding XC potential – can be approximated locally with that of the uniform gas. The LDA forms the base of a hierarchy of improved approximations: the "Jacobs' ladder" of DFT (Perdew and Schmidt 2001). An approximate time-dependent XC potential can be readily obtained by evaluating an approximation originally designed for ground-state DFT on the instantaneous

particle density (or, more in general, on the corresponding instantaneous KS orbitals). This is the popular adiabatic approximation of TDDFT, which, for example, when applied to the LDA, yields the adiabatic LDA (ALDA). Adiabatic TDDFT functionals neglect the time non-localities of their implicit dependency on particle density. In the Born-Oppenheimer (BO) sense, instead, adiabaticity refers to the possibility of decoupling the dynamics of the nuclear and electronic degrees of freedoms. In the BO approximation, the electronic wave function is restricted to the ground-state manifold at each given nuclear configuration. The cases reported in the remainder of this chapter will demonstrate the usefulness of ALDA when used in a scheme that goes beyond the BO approximation.

Most of the applications of TDDFT are carried out in the linear response regime. The common way of proceeding does not involve a RT propagation but the solution of a (pseudo) eigenvalue problem, from which it is possible to determine the absorption oscillation strengths and the mean polarizability using ground-state KS quantities as an input (Casida 1995). The information obtained in this way identifies the sets of KS transitions which represent the relevant excitations. In the cases presented below, for example, the solutions of the Casida's equations are used to identify the KS states that can mimic the initial excited states, as obtained at the onset of the photoexcitation, to be considered in subsequent RT propagations.

While the linear response of a system is independent of the (small) perturbation, the nonlinear response can vary both quantitatively and qualitatively with the intensity of the perturbation. Nonlinear perturbations are particularly relevant in experimental study of photoinduced charge transfer and include, for example, high-intensity laser pulses such as those employed in transient absorption and 2D spectroscopy experiments (Jonas 2003), suited to highlight emerging coherences.

The response function of the particle density can be accessed by means of real-time (RT) propagation of the TDDFT equations both in the linear and nonlinear regime (Yabana et al. 2006). In the linear response regime, the method based on RT propagation scales better than the method based on the perturbation approach in the frequency space: while the former only involves occupied single-particle orbitals, the latter requires the inclusion of unoccupied orbitals. Moreover, since the propagation in a single-time step of each KS state is independent of the others, the real-time approach is prone to a natural parallelization scheme which is ideally suited to deal with sizable systems. The inter-process communications are only required once per time step to calculate quantities that depend on a sum over states.

An efficient implementation of RT-TDDFT is freely available to users with the `octopus` code (http://octopus-code.org). `octopus` uses a real space grid representation combined with the finite difference approximation for the calculation of derivatives. Describing systems at the atomic level on such a grid ultimately demands the use of pseudo-potentials (Nogueira et al. 2003). The code implements several propagator schemes (Castro et al. 2004); it can handle mixed periodic boundaries and is highly suitable for massively parallel applications (Castro et al. 2006; Andrade et al. 2015). `octopus` is the main computational tool that has been used in the applications reviewed in the next section.

In the remainder of this chapter, we shall consider charge separation occurring after photoexcitation being driven by the vibrational motion of the nuclei. These kind of charge separation should not be confused with the, more commonly analyzed, charge-transfer excitations that can occur at fixed nuclear configurations within the linear regime (Dreuw and Head-Gordon 2004; Hieringer and Görling 2006). The processes we will focus on do not necessarily involve the presence of conical intersections and develop before any thermal equilibration. Therefore, under the assumption of a factorization of the electron-nuclear wave function, relevant dynamical couplings between the electrons and the nuclei can be described by resorting to the Ehrenfest molecular dynamics (EMD). In such a scheme, electrons are evolved according to the TD-KS equations along the trajectory of the instantaneous nuclear positions, while the nuclei are evolved according to Newtonian equations which account for the electron-nuclear interaction as mediated by the instantaneous electron density. The resulting TDDFT+Ehrenfest scheme may be regarded as a dynamical mean-field method. Crucially, the overall dynamics can be started from a KS state which corresponds to either the ground state of the system or to an excited (Tavernelli et al. 2005) or ionized (Gaigeot et al. 2010) configuration.

The time step required in EMD is determined by the maximum electronic frequencies, which means about three orders of magnitude less than the time step required to follow the nuclei by using the adiabatic Born-Oppenheimer approximation. Thus, to enable the application of EMD to realistic systems, efficient numerical implementations are essential. In the remainder of this chapter, we review a few applications of this technique that rest on a highly scalable implementation of a modified EMD (Andrade et al. 2009) included in the `octopus` code.

For the necessary details on the aforementioned theoretical aspects, we refer the reader to the first volume in the MTM set of this handbook and especially to Chap. 6, "TDDFT and Quantum-Classical Dynamics: A Universal Tool Describing the Dynamics of Matter" by Agostini et al. Other pedagogical textbooks discussing the fundamental aspects of TDDFT together with interesting applications are (Ullrich 2012; Marques et al. 2012). A recent review of the state of the art of capturing various types of charge-transfer processes by means of TDDFT approximations is available in Maitra (2017).

3   Charge Separation in Supramolecular Assemblies

The idea of mimicking natural light-harvesting and charge separation processes such as those which occur in photosynthesis is quite an old one (Ciamician 1912). Among the main tasks, two very important ones are to determine the relevant degrees of freedom and to understand the driving forces involved in the processes. The overwhelming complexity of the real systems, however, demands that simplified artificial systems should be made available by molecular self-assembling or more traditional chemical synthesis.

Supramolecular assemblies are ideal playgrounds to investigate the relationships between structure and function. They contain simple units, which can be tailored

to perform a specific task, as it happens in natural photosynthetic complexes. The performance of a device based on supramolecular systems can be optimized both at the molecular and at the supramolecular level (Gust 2015). For example, the Förster energy transfer rate between nearby moieties strongly depends on the spectral overlap and strength of specific electronic transitions in the donor and in the acceptor and on the relative transition dipoles. These properties can be tailored by a wise choice of the molecular components and by organizing the moieties in a suitable spatial arrangement. Their mutual distances and orientations will also affect the intermolecular electronic coupling, which, in turn, controls triplet-triplet energy transfer via the Dexter mechanism. Marcus' theory (1993) highlights the importance of the overlap of electronic orbitals in the donor and the acceptor for electron transfer reactions. Such overlap depends not only on the distance and the orientation of the moieties but also on the nature of their linker groups and on the presence of covalent bonding.

Nano-sized compounds able to provide sufficient thermodynamic driving force to promote photoinduced electron transfer have been obtained by combining porphyrins and fullerenes into covalently linked structures (Imahori 2004). The rationale behind this strategy, as outlined in Sect. 1, is to design each individual moiety to perform a specific action. Furthermore such ensembles display self-assembling properties that can be exploited to ease the fabrication of nano-devices (Umeyama and Imahori 2006), also useful for dye-sensitized solar cells (Planells et al. 2011). The basic donor-acceptor skeleton can be further engineered by adding one or more bridge units to reduce the recombination rate (see below). Other modifications include functionalizing the component moieties to improve their solubility or self-assembling properties, joining together other molecules such as carotenoids to elongate the chain (Liddell et al. 1994), building superstructures to scale up toward the size of natural light-harvesting complexes, yet resorting on simpler components and higher symmetry (Astruc et al. 2010).

As a prototypical case, we examine first a carotene-porphyrin-fullerene triad (CPF) about which a body of photochemical and photophysical studies exists (Kodis et al. 2004, and references therein). The molecule has a donor-bridge-acceptor structure. The porphyrin bridge acts also as the main chromophore. The linear absorption of the CPF is well described as the superposition of the absorption of each moiety (Kuciauskas et al. 2000), which suggests that the moieties are nearly uncoupled in the ground state (Spallanzani et al. 2009). Picosecond transient absorption experiments, however, reveal that upon visible light absorption, the excitation is transferred from the porphyrin to the fullerene. After about 120 ps, a strong new absorption band appears corresponding to the formation of the carotenoid radical cation of the final charge-separated state (i.e., a state having a hole localized on the carotenoid and an electron on the C_{60}).

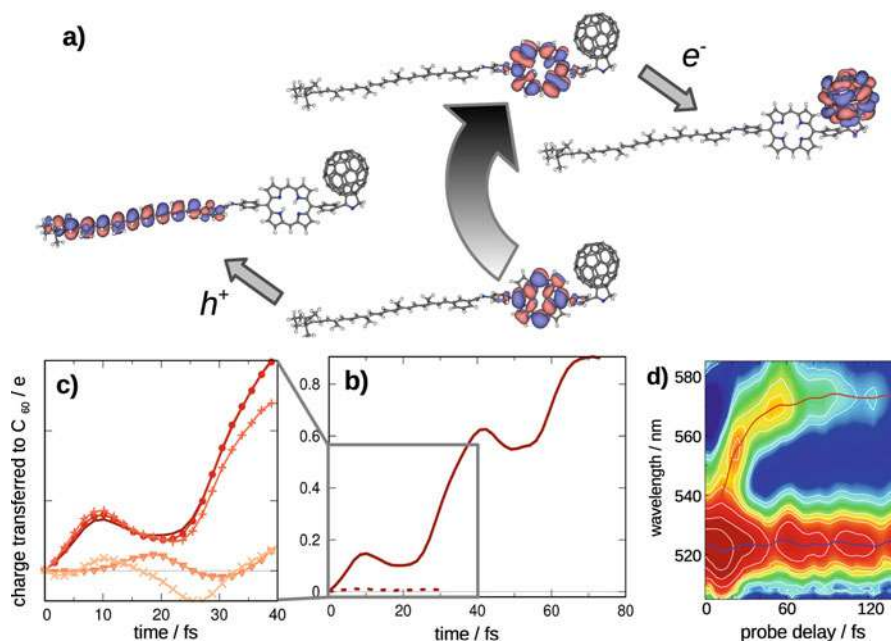
Here, we focus on the early onset of the charge separation: in particular, we show that mixed quantum-classical simulations can reveal coherent wavelike electronic-charge motions which are driven by nuclear vibrations. The system can be reduced to a smaller molecule with 207 atoms (see Fig. 2a), and its dynamics is studied in the sub-ps regime. Previous studies about the CPF geometry in liquid solvents


Fig. 2 (**a**) Kohn-Sham states involved in the porphyrin excitation (middle) and the final charge-separated states (sides). (**b**) Net charge flow from the carotene-porphyrin to the C_{60} in the ultrafast regime: no charge is transferred when all of the nuclei are clamped (dashed line); wavelike charge accumulation appears when the nuclei are free to move and their dynamics is coupled to the electronic one (solid line). (**c**) Lines from darker to lighter colors correspond to lower charge-transfer rates in this order: clamped carotene (circles almost on top of the free nuclei line); clamped C_{60} (plus sign); clamped porphyrin (triangles); clamped aryl ring connecting the porphyrin to the C_{60}. (**d**) Experimental result: differential transmission following impulsive excitation at 550 nm (the scale from blue to red corresponds to a signal from -0.05 to 0.12). The marked feature at 520 nm corresponds to ground-state photobleaching. An increased transmission band drifts toward lower energy. This is the footprint of a transient state, which has the same temporal behavior as the simulated charge-transfer signal. (Data from Rozzi et al. 2013)

have shown that the triad is structurally flexible under ambient conditions. Baruah and Pederson (2009), by combining DFT at the generalized gradient approximation level and kinetic Monte Carlo, have shown that the solvent polarization contributes to the reordering the excited-state energies and have identified a stable bent configuration in vacuo. Su et al. (2012) have investigated the impact of thermal fluctuation on both the triad and solvent. They have probed the conformational distribution of the CPF ground state and have found that the energy landscape of an ensemble of the triad is characterized by a very shallow barrier separating local minima ($<1k_BT$). Manna et al. (2015) employed linear response TDDFT with the BNL range-separated hybrid functional (Baer and Neuhauser 2005; Livshits and Baer 2007) and a polarizable continuum model for the solvent to calculate the energy of solvated charge-transfer states. They also estimate the kinetics of electron transfer in various configurations by means of molecular

dynamics and conclude that a linear configuration of the molecule is the most favorable for the charge separation process. In the linear configuration, the states involved in the photon absorption are strongly localized on the porphyrin, with virtually no overlap with donor and acceptor states (see Fig. 2a). In this case the electron dynamics with no nuclear motion is unable to explain the observed charge separation. RT-TDDFT and EMD together provide, instead, valuable insight into the process. Under the condition that the atoms are free to move, simulations show that the excited electronic wave packet undergoes an oscillatory dynamics, while at the same time charge is being accumulated on the acceptor. These facts reveal that the coupled motion of electrons and nuclei drives the charge separation in the ultrafast window. The simulated charge transfer depicted in Fig. 2b provides two quantitative predictions: (1) that the electron charge oscillations occur with a period of about 30 fs; (2) one electron can be transferred from the carotene-porphyrin to the fullerene moiety in about 70 fs. These results (Rozzi et al. 2013) are in remarkable agreement with high time-resolution observations of the transient absorption spectrum, which shows oscillations in the intensity of the porphyrin Q-band absorption at 523 nm, and also a peculiar stimulated emission band, whose intensity *and resonant wavelength* oscillate at the same frequency as the ground-state one, but in phase opposition with it. The latter band is strongly red-shifted and it disappears after about 70 fs (see Fig. 2d). These features make it impossible to associate the stimulated emission signal with the ballistic motion of the excited wave packet from the donor to the acceptor, and they are compatible with the scenario of coherent charge oscillations devised in the simulations.

It is also possible to perform numerical experiments by clamping different groups of atoms and therefore predict different charge-transfer scenarios. The simulated charge signals in Fig. 2c confirm that while the C_{60} moiety and the carotenoid have little or no influence on the ultrafast regime, impairing the movement of the porphyrin or the linker group between the porphyrin and C_{60} can completely quench the transfer while still leaving the vibrational sloshing-type motion of the wave packet active (see Fig. 2c). These insights would not be easily available without running numerical simulations and can be exploited to manipulate the vibrational properties of the molecule. Vibronic couplings can affect the electron transfer rates since they can transform individual donor-acceptor electronic states into new manifolds of states, which can reduce the transfer energy barrier or open up alternative transfer paths through resonance. Delor et al. (2014) provide a specific example of vibronic manipulation. They show that the efficiency of electron transfer in a covalently bonded donor-bridge-acceptor triad can be controlled by means of narrow-band infrared laser pulses affecting the vibrations of the bridge unit. Moreover, when the system reorganization energy is small, vibronic states become delocalized throughout the moieties. Delocalization, in turn, provides a robust protection against environmental fluctuations due to noise or disorder, and it makes extended coherent states available. The observation of long-lasting coherent oscillations in 2D electronic spectroscopy (Engel et al. 2007) has stimulated an extensive debate about the possible role of quantum coherence in charge and energy

transfer phenomena. A more extensive overview of these aspects can be found in Brédas et al. (2016) and Scholes et al. (2017).

3.1   From Triads to Dyads

The rationale behind building triads instead of dyads is that having a longer charge-separating chain is a way to effectively decrease the coupling between the electron and the hole collectors, thereby reducing the exciton recombination rate. Moreover, the presence of a long sequence of conjugated bonds in the bridge connecting donor and acceptor can enhance the spectral absorption of the complex at longer wavelengths – a beneficial effect. In the case of the CPF triad, transient absorption experiments reveal pronounced long-lived oscillatory modulations in the range between 510 and 580 nm due to the wave packet oscillations in the ground state of the carotene. All this action, however, is not relevant to the interesting part of the ultrafast photoinduced dynamics. Besides, the synthesis of triads is more complex than the synthesis of dyads.

One way to simplify both synthesis and analysis is to build a dyad by using a component that can be easily attached to a variety of other molecules. For example, the diaminoterephthalate unit – which was originally designed for combinatorial chemistry (see Fig. 3a) – can be easily attached to a C_{60} acceptor by a pyrrolidine linker (Freimuth et al. 2015). The resulting system (simply named as dyad hereafter) is much smaller than the CPF, and yet it may support similar charge separation mechanisms.

This dyad is significantly less flexible than the CPF triad, but it may undergo free rotations around the C-C bond connecting the chromophore to the benzyl group and around the contiguous C-O single bond. This produces *syn* and *anti* conformers energetically interchangeable at room temperature (see Fig. 3a). As we will shortly see, these conformers imply different absorption properties.

Although the overall shape of the absorption spectra for the two conformers is expected to be very similar, linear response-level calculations show that there are indeed significant differences (see Fig. 3b). The *syn* conformer displays a weak absorption band at very low energy having charge-transfer character. The donor and acceptor are closely facing in this conformer, and there is a non-zero tunneling probability for an electron to move between the two. An interesting region of the spectrum is the green-yellow band around 2.5 eV. In this spectral region, a chromophore excitation is optically active in both conformers. However, while the excitation is very well localized on the diaminoterephtalate in the *anti* configuration, in the *syn* configuration, the transition has a more delocalized character as it involves also the functionalized C_{60} acceptor. As a consequence, it is expected that the *syn* conformer should more favorably support charge displacements along the molecule than the *anti* conformer. However, the absorption in the visible is not particularly strong.

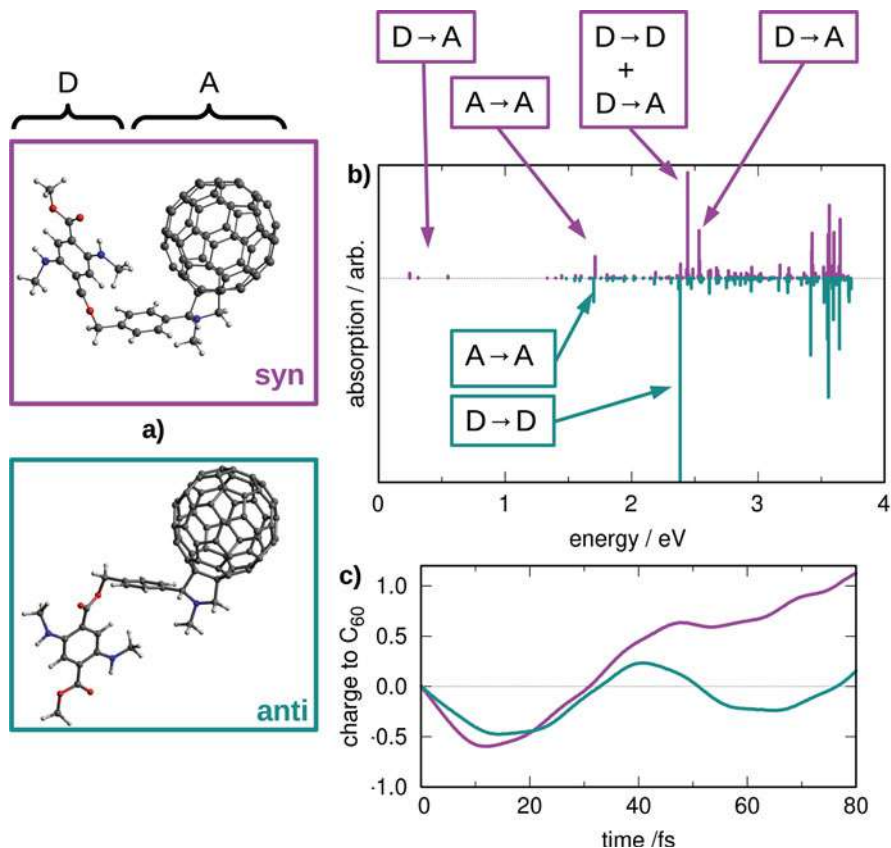
The aforementioned trends suggested by the inspection of the absorption cross section can be confirmed by performing RT propagations of the coupled electron-


Fig. 3 (**a**) Energetically quasi degenerate conformers of the diaminoterephtalate-C_{60} molecule. D and A indicate the donor and the acceptor, respectively. (**b**) Linear response UV-Vis absorption: the upper part refers to the *syn* conformer and the lower part to the *anti* conformer. (**c**) Real-time simulation of the charge flow from the chromophore to the C_{60}. (Copyright Wiley 2015, adapted with permission)

nuclei system using TDDFT and EMD. As an initial state, we may take the single-particle excitation from the chromophore HOMO to the chromophore LUMO. While this choice is realistic for the *anti* conformer, it is less appropriate for the *syn* conformer as it overestimates the localization of the initial excitation. For a comparison, however, it is useful to start with similar initial conditions. The RT propagations yield two clearly distinct scenarios (Pittalis et al. 2015). By tracking the charge motion by numerical integration of the particle density in a volume including the acceptor moiety, it is evident that the *syn* conformer has a substantially larger charge separation power than the *anti* conformer (see Fig. 3c). In other words, the dynamics is not robust with respect to the choice of the initial nuclear configuration. As a common feature with the CPF case, it is observed that the

charge oscillations disappear by suppressing the electron-nuclei coupling, thereby confirming the prominent role of intramolecular vibrations.

These simulations help identify the possible channels which drive the path of the photoexcited charge in the dyad. While in the *syn* conformer both through-bonds and through-space transfer mechanisms could be active (Pettersson et al. 2006), in the *anti* conformer the direct hopping probability of an electron through space tunneling from the chromophore to the acceptor is strongly suppressed. Due to the competition of different transmission channels and considering that a solution should contain both conformers in equal parts at room temperature, it is not expected that a coherent signal can be easily observable in pump-probe experiments on this compound. We remark that the simulations shown in Fig. 3c are from single trajectory run – not from a statistical sampling.

In summary, the considered dyad exhibits some desired features. But to become useful in applications, the system needs to be further engineered, improving the light-harvesting efficiency and enhancing more favorable charge separation pathways.

4   Ultrafast Charge Separation in Bulk Heterojunctions: The Case of P3HT:PCBM

In 1992, Sariciftci et al. reported that when a semiconducting polymer is mixed with an electron acceptor (C_{60}), a quenching of the polymer photoluminescence is observed. This is a clear evidence for the charge-separating properties of the mixture. The luminescence decreases in time because the polymer's S1 excited state, initially populated by solar light, is being depleted, as the electrons transfer to the acceptor before they recombine back to the S0 ground state. This observation provides an upper bound of the order of 1 ps for the charge separation time scale in this material (Lee et al. 1993). Radiative and non-radiative recombination channels are two orders of magnitude slower, which makes quantum efficiency close to unity. The same happens in many other combinations of organic electron donors and acceptors. Time-resolved photoluminescence however has a rather low time resolution, and the estimate of the upper boundary of the time scale does not disclose the details of the electron dynamics in the material.

Using transient absorption spectroscopy with high time resolution (about 10 fs), Brabec et al. (2001) reported that some features in the differential transmission spectra change on a much shorter time scale. In particular, the polymer stimulated emission band turns into a photoinduced absorption band in about 100 fs after pumping the sample with a broadband laser pulse. The photoinduced absorption band is a property of the excited state assigned to the polymer cation radical. This observation was later confirmed by many groups in similar blends, such as P3HT:PCBM (Hwang et al. 2007; Cook et al. 2009; Piris et al. 2009; Howard et al. 2010; Kaake et al. 2012).

These experiments highlight the existence of a sub-100 fs dynamics connected to charge transfer, despite the fact that the production of *free* charges is a much

slower process (which goes from few ps to hundreds of ps) (Hwang et al. 2008). One might argue that the direct excitation of charge-transfer states – which is possible, albeit, with a small cross section – might explain early time dynamics. However, by comparing photoluminescence to photocurrent, it turns out that the contribution of the below-gap radiation is negligible with respect to that of the above-gap exciton (Drori et al. 2010). This clearly indicates that direct charge transfer is not a charge generation mechanism of relevance in these materials. Moreover, Gelinas et al. (2014) reported that the Coulomb binding attraction can be overcome on a time scale as short as 40 fs, suggesting that delocalization may be a crucial factor affecting the system dynamics.

This is a case in which RT-TDDFT simulations, can help clarify the situation and provide information complementing high time-resolution pump-probe spectroscopic data. In order to make the system tractable, suitable simplifications should be admitted. If the photoinduced charge dynamics is an interfacial phenomenon, it can be studied by reducing the P3HT:PCBM to its smallest unit: a single polymer chain (including four thiol rings per unit cell) facing a single C_{60} molecule. The structure optimization of this cell yields an equilibrium distance between the donor and the acceptor of 3.2 Å, corresponding to $\pi - \pi$ stacking of fullerene and polymer rings. Also suitable initial conditions must be set on the electronic wave packet. Real-time simulations can be performed by including explicitly a classical pulsed laser field. A simpler starting point consists in assuming that the first excited state corresponds to a sudden vertical excitation of the polymer in the Franck-Condon framework. Adiabatic (semi-)local functionals describe this transition by predominantly involving the HOMO and LUMO of the polymer. Therefore, the initial state in our subsequent RT propagation can be set by modifying the occupations of these two levels at time zero; i.e., by depopulating the polymer HOMO while populating the polymer LUMO.

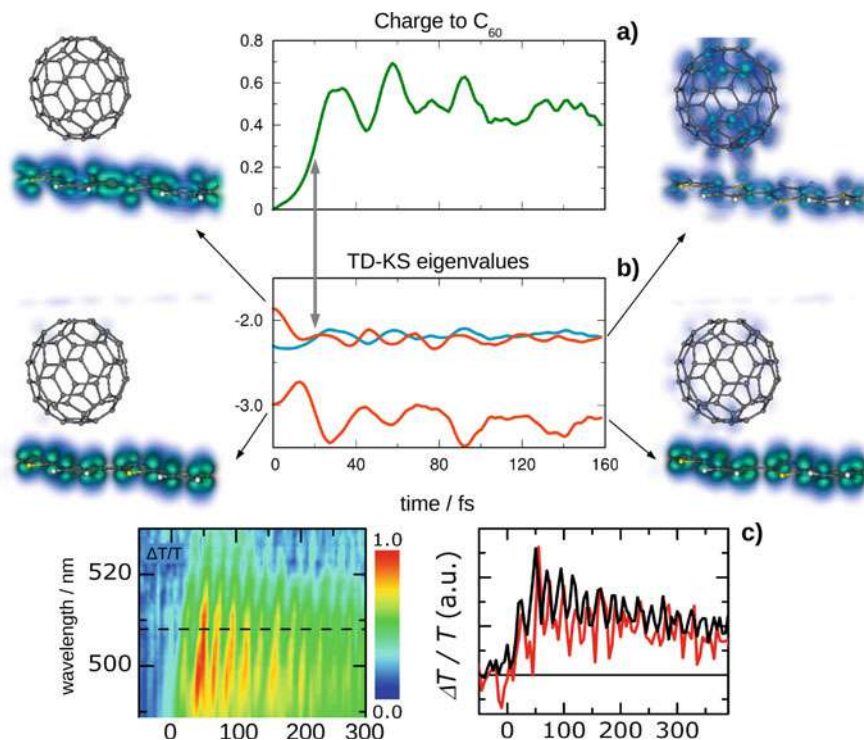
Free RT propagation of the electronic wave packet from the aforementioned initial condition reveals the crossover of the singlet exciton to the charge-transfer state (Falke et al. 2014). This can be rationalized by examining the spatial localization of the HOMO of the polymer and the LUMO of the fullerene. A periodic crossover between the corresponding KS energy levels emerges when nonadiabatic coupling is enabled in the system Hamiltonian (see Fig. 4b). The excited state described by the HOMO of the polymer is free to delocalize over one of the fullerene unoccupied states as soon as the two become isoenergetic. The change in localization provides a net current flowing from P3HT to C_{60}. Driven by the vibrations of the polymer backbone, a wavelike charge movement occurs. Because of the nuclear motion, it progressively gets stabilized to a self-trapping charge-separated state. Looking at (a) and (b) in Fig. 4, it is easy to match the crossing points of the excited donor and the unoccupied acceptor states to times at which the charge-transfer instantaneous rate is maximum. The dynamics clearly proceeds on three different time scales. At times earlier than 23 fs, the dynamics is purely electronic, and it is driven by a fast stabilization of the polymer excited state. After about 23 fs, the first crossing point is reached and the oscillatory motion kicks in. Its frequency is compatible with the polymer C=C stretch frequency. This motion, in combination with a slower


Fig. 4 Snapshots of the simulated joint electronic and nuclear dynamics of a P3HT:PCBM blend. (**a**) Probability of charge transfer from the polymer chain to the fullerene cage as a function of time. (**b**) Kohn-Sham energy levels mainly involved in the charge displacement. Red line: the time-evolved KS eigenvalues starting from the polymer HOMO and LUMO. Blue line: the average of the three lowest unoccupied levels on the C_{60} (almost degenerate in the ground state). When the red and blue lines cross, the flow of the current from the P3HT to the C_{60} is maximal. Left and right panels show the localization of the corresponding Kohn-Sham single-particle orbitals soon after the photon absorption (time 0) and after about 100 fs. During this interval, the highest occupied state in the system delocalizes from the donor to the acceptor. (**c**) Left: differential transmission ($\Delta T/T$) map, which shows coherent oscillations. Right: a section corresponding to the dashed line in the $\Delta T/T$ map (black line) compared to the signal in the pristine polymer (red line). (Data from Falke et al. 2014)

adjustment in the nuclear configuration, leads to a maximum charge transfer of about 0.7 e after approximately 50 fs. Up to this point both the computed vibrational frequency and the electron transfer time constant are in quantitative agreement with the observed ones. At the same time, however, the combination of the adiabatic LDA functional and EMD becomes inaccurate. The excited donor is eventually stabilized to a maximally delocalized state as higher-frequency vibrational modes are progressively engaged and the charge accumulation falls back to about 0.5 e. In reality, inelastic scattering channels (especially vibrational ones) damp the oscillatory motion at later times. Simulating such relaxation processes, however,

would entail a substantial extension of the theoretical approach described in this chapter.

In summary, we have seen that important features of the coherent charge motion following photoexcitation in the P3HT:PCBM bulk heterojunction can be accurately described by employing RT-TDDFT and Ehrenfest-path molecular dynamics. In order to capture more phenomenology, additional capabilities should be added to the employed computational tools. For example, it was recently shown by adopting a non-equilibrium Green's function approach that space-time non-local correlations may explain the decay of the charge-transfer exciton into a charge-separated state in terms of correlation-induced decoherence, provided that the corresponding electronic levels are suitably aligned, nicely complementing our picture (Boström et al. 2018).

5   Conclusions

The challenging quest for developing efficient, reliable, and cheap organic photovoltaic materials also with the help of computational methods based on first principles is undergoing a fast evolution (Rozzi et al. 2018). Prototyping simple functional systems is an important step toward the understanding of the fundamental physics underlying ultrafast phenomena in photovoltaics. This line of research will stimulate the development of more advanced theoretical and computational methods.

In this chapter, we have examined a few paradigmatic cases for which even simple density-functional approximations lead to a description of the ultrafast, coherent components of photoinduced charge dynamics in quantitative agreement with high-resolution transient spectroscopy experiments. For the considered cases, a pivotal role was played by the dynamical coupling of the nuclei with the electrons. Modeling the nuclear dynamics semiclassically on the Ehrenfest mean-field path permits simulations up to about 100 fs, when the actual quantum nature of the nuclei can be neglected. Hence, we have seen that the information gained from time-resolved experiments and RT-TDDFT simulations, when combined, provide more useful information than the sum of their parts taken independently.

Part IV
Modeling Applications to Magnetism, Magnetic Materials, and Spintronics

Applications of Materials Modeling to Magnetism, Magnetic Materials, and Spintronics: Overview

16

Stefano Sanvito

Contents

Abstract

Magnetism underpins many applications in modern technology, where either its static or dynamical properties are exploited. This chapter discusses some of these applications, in particular focussing on three main aspects. Firstly, it will review how modern electronic structure theory can contribute to the discovery and design of novel magnetic materials with multiple functionalities. Secondly, it will address the phenomena related to magnetization dynamics for both spintronics and data-storage applications. Finally, it will look at the interplay between electrical currents and spins. Throughout the chapter special attention will be devoted to present both the necessary theoretical background and discuss how theory may underpin the development of applications.

1 Open issues in Magnetic Materials and Spintronics

The love affair between mankind and magnetic materials has been continuing for 2,000 years and does not show any sign of losing steam. From the invention of the compass, which enabled the eleventh-century Chinese dynasty of Song to embark

on long-distance navigation, magnetic materials have been key for developments in human technology. Today magnets are everywhere in our life. The hard disk of our computer is composed by billions of tiny magnets and it is read by a sensor, whose main component is a complex magnetic nanostructure. Wind turbines are made of strong permanent magnets, as are the electrical motors in our cars, in our kitchen blenders, and in our lawn mowers.

Yet, nature is stingy when it comes to magnets. The first report of a magnetic material dates back to 79 AD, and it is contained in what was probably the first scientific encyclopedia ever, the *Naturalis Historia* (Natural History) from the Roman natural philosopher Plinius the Elder. In the Historia, Plinius, who perished in the eruption of the Vesuvio in 79 AD, reports the legend of "Magnes the shepherd," who discovered two metallic stones attracting each other. These were likely made of magnetite, Fe_3O_4, a mineral abundant in the earth crust and one of the main iron ores. It took about 2,000 years to understand the microscopic origin of magnetism, which was possible only after the formulation of quantum mechanics. During all this time, we have discovered about 4,000 materials, which behave as magnets. In other words, our discovery speed is two magnets per year. Interestingly, only a handful of them are used in mainstream applications.

This section reviews the most recent applications of magnetism and the theoretical methods most suitable for describing them. It does not pretend to be a comprehensive review but to cover some of the most modern and fascinating aspects. In particular it will touch upon three main aspects, namely, the discovery and design of new magnets, the description of macroscopic magnetization dynamics for both spintronics and data-storage applications, and the interplay between electrical currents and spins at the atomic level.

From the materials point of view, magnetism is a relatively rare occurrence in the materials world. In fact, it requires the presence of magnetic ions (the formation of local moments) and a mechanism to make them interacting to each other (the exchange interaction). Thus, among the 100,000 inorganic materials documented to date, only about 4,000 are magnetic. An accelerated strategy to find new magnets is then reviewed and discussed by Sanvito and coworkers (▶ Chap. 17, "Machine Learning and High-Throughput Approaches to Magnetism"). This involves a combination of high-throughput electronic structure theory and machine learning techniques. The methods have been proved to be successful at least for relatively simple magnets (metals) and magnetic orders (ferromagnetic and antiferromagnetic). When the materials properties become more complex large-scale materials prediction becomes more difficult, and one has to use all the tools available for a limited number of cases. This is the situation with multiferroic compounds and Rashba semiconductors. In the first case, the compounds present subtle interplays between magnetic and structural degrees of freedom, and in the second, the spin-orbit interaction produces a band structure with spin-dependent features, even in absence of the moment formation. These classes are reviewed by Picozzi (▶ Chap. 18, "Multiferroic and Ferroelectric Rashba Semiconductors").

Magnetic data storage, the hard-disk drive industry, and spintronics, the use of spins for logic operations, are two main drivers behind the development of modern magnetism. In both cases, magnetization dynamics is crucial. This is an

intrinsic multi-scale problem, where the microscopic interactions (Hund's coupling, exchange interaction, and magneto-crystalline anisotropy) determine the macroscopic behavior. Such multi-scale approach is described here by Hertel (▶ Chap. 19, "Applications of Multi-Scale Modeling to Spin Dynamics in Spintronics Devices"), with a particular focus on how the various levels of theory are connected to each other. A crucial aspect of the multi-scale description concerns the mechanisms with which the energy is distributed between spins and vibrations. This provides an important channel for dissipation, allowing the description of relaxation effects and long-time dynamics. A microscopic approach to spin dynamics is provided in the chapter of Evans (▶ Chap. 20, "Atomistic Spin Dynamics"), while Greaves (▶ Chap. 21, "Ultra-fast Dynamics for Heat-Assisted Magnetic Recording") overviews the computation approach to investigate heat-assisted magnetic recording, where heat fluxes are used to manipulate the local magnetization of a thin film.

A second channel for energy dissipation is provided by the interaction between spins and electrical currents. This occurs mainly through exchange interaction and so it pertains fast dynamics. At the atomic scale, current-to-spin interaction can be used to investigate elementary magnetic excitations and the very nature of the magnetic interaction. The main experimental tool here is scanning electron microscopy, while theoretically a master equation approach, sometime informed by electronic structure theory, is the method of choice. Choi and Lorente (▶ Chap. 22, "Magnetic Impurities on Surfaces: Kondo and Inelastic Scattering") provide a complete view of these aspects. Finally, when a current is driven through a nano- and/or meso-scaled magnet, macroscopic magnetization dynamics can be induced. This can be generated by passing the current through a ferromagnet in a vertical geometry (spin-transfer torque) or through materials with strong spin-orbit interaction in a planar configuration (spin-orbit torque). These aspects and their microscopic description are overviewed by Nikolic and coworkers (▶ Chap. 23, "First-Principles Quantum Transport Modeling of Spin-Transfer and Spin-Orbit Torques in Magnetic Multilayers").

2   Conclusion

Magnetism underpins many technologies, which support our modern way of life. These range from magnetic-data storage devices to electrical motors and turbines to nonvolatile memories. Intriguingly, the different technologies exploit different aspects of magnetism, such as the dynamics of the magnetization or the interaction between electrical currents and the spins. The description of these requires a range of theoretical tools spanning over length and time scales and constructed at different level of approximation. This chapter reviews some of the theoretical attempts to understand the magnetic order and provides an overview of how theory and modelling can facilitate, and sometime drive, the development of high-end applications.

Machine Learning and High-Throughput Approaches to Magnetism

from data storage, to energy production and delivery, to sensing. Such great diversity, associated to the fact that only a limited number of elements can sustain a magnetic order, makes magnetism rare and fascinating. The discovery of a new high-performance magnet is often a complex process, where serendipity plays an important role. Here we present a range of novel approaches to the discovery and design of new magnetic materials, which is rooted in high-throughput electronic structure theory and machine learning models. Such combination of methods has already demonstrated the ability of discovering ferromagnets with high Curie temperature at an unprecedented speed.

1   Why New Magnets?

Magnetism is one of the most fascinating macroscopic orders of matter, and it is deeply rooted in quantum mechanics. The Hund's coupling is responsible for the formation of local magnetic moments, m, often localized close to the atomic nuclei, while the exchange interaction, J, makes the moments interacting to each other. This is the m-J paradigm that, together with spin-orbit interaction, generates a multitude of magnetic orders and phenomena.

The formation of the magnetic moment in the solid state is a relatively rare event among the elements of the periodic table. It is possible in $3d$ transition metals and in $4f$ rare-earths, both with an open shell configuration. It is also found, although more rarely, in some $4d$ ions. Light elements, presenting $2p$ valence orbitals, form close shell compounds. Therefore, despite presenting large Hund's coupling, they can sustain a moment only in their radical form, and the possibility of long-range magnetic order remains associated to extremely defective compounds, and it is surrounded by skepticism and debate (Magda et al. 2014). Finally, for heavier elements the valence shell is too delocalized, and m does not form (Janak 1977), with the exception of some low-dimensional structures (Moruzzi and Marcus 1989; Requist et al. 2016).

Once the moments are formed, there are many possible mechanisms to couple them to each other, depending on the details of any given material and in particular on its position with respect to the metal/insulator boundary (Coey 2009). Magnetic moments in metals usually couple by mean of interactions mediated by itinerant electrons, such as the RKKY or the double-exchange ones. These lead to a ferromagnetic order. At the same time, there are mechanisms, such as magnetic super-exchange, which are mostly active in the insulating regime and may produce an antiferromagnetic order. Such rules, however, are not general and the actual magnetic coupling is very sensitive to details. The local chemical environment, the crystal structure, the density of magnetic ions, etc. all may play a critical role so that it is not uncommon to find also ferromagnetic insulators (Wohlfarth 1980) and antiferromagnetic metals (Wadley et al. 2013). In general, however, it is a fact that magnetism is relatively rare in the materials world, with only about 4,000 inorganic compounds among the 100,000 known to date (ICSD 2018) presenting a magnetic order of some kind.

There are several good technological reasons to extend the available menu of magnetic materials. Firstly, there is a growing number of applications that rely on high-performing magnets for which the ideal compound is yet to be discovered or needs to be "rediscovered." Room-temperature applications, of any kind, require a magnetic ordering temperature in excess of 300 °C, a value that ensures stable operation in the temperature range $-50°/+120$ °C. Only about 400 magnets meet such criterion. Furthermore, specific applications dictate several other conditions. For instance, permanent magnets should maximize the magneto-crystalline anisotropy, K_1, and the total magnetization, M_S, so that energy product is large. At the same time, they should be made of elements abundant in the earth crust. In contrast, element criticality is less problematic for the magnets employed by the data storage industry (e.g., Pt is used), but these need to be grown on desired substrates; their grain structure needs to be highly optimized and so does their magnetic hysteresis. Furthermore, changes in technology may generate novel requirements. For instance, it is likely that the advent of heat-assisted magnetic recording may add constrains on the thermal properties of the magnetic recording media.

Sometimes the demand for a new magnet is not dictated by a new technological need. For instance, $Nd_2Fe_{14}B$-based magnets currently cover about 90% of the permanent magnets market, with the remaining share also being largely occupied by rare-earth-containing compounds (e.g., Sm-Co alloys). The average price of a kilogram of neodymium metal was US$8 in 2006, US$56 at the end of 2010, US$450 in 2011, and then fell to US$125 in September 2012. Price volatility is a significant issue for all those applications requiring large volumes of raw elements (an electric vehicle requires about 3 kg of Nd-Fe-B, a direct-drive wind generator about 250 kg), where steady supply is key. Importantly, the rare-earth prize volatility is not associated to fluctuations in the mining production but to commercial strategies between producers and retailers. Such economical geopolitical constraint is the main driver toward a worldwide effort in developing rare-earth-free permanent magnets.

Finally, in addition of being rare and technologically important, magnetism is complex and often defies our physical/chemical intuition. A good example is given by $SrTcO_3$ (Rodriguez et al. 2011). This is a distorted cubic perovskite displaying a G-type antiferromagnetic order with the remarkably high Néel temperature of $T_N = 750$ °C. $SrTcO_3$ is unusual from several points of view. Tc is the magnetic element, one of the few displaying a local moment among the $4d$ transition metal series and highly radioactive. The Néel temperature is exceptionally high with only a handful antiferromagnets having T_N above 500 °C. Finally, the chemical substitution of Tc with elements in its neighborhood in the periodic table produces only low-temperature antiferromagnets ($SrCrO_3$, $SrMnO_3$ and $SrFeO_3$), one low-temperature ferromagnet ($SrRuO_3$), and a diamagnetic compound ($SrMoO_3$). As such, the strong antiferromagnetism of $SrTcO_3$, which is due to a subtle interplay between p-d hybridization and Jahn-Teller distortion (Franchini et al. 2011), appears as a singularity in our magnetic materials landscape.

Given magnetism complexity, the variety of microscopic mechanisms at play, and the subtle sensitivity to details, it is not surprising that the "traditional" trial and error approach to the discovery/design of new magnets has a pretty low throughput. This

has been recently challenged by two completely new approaches to materials discovery, namely, high-throughput electronic structure theory (HTEST) and machine learning (ML) methods. In this new framework, one aims at accelerating the discovery process by performing an extremely large volume of ab initio calculations, which are directed by astute ways for navigating large datasets and identifying patterns among the data. Here we will review such new materials discovery strategy with a particular emphasis on the problems and requirements associated with the magnetic interaction. We will take the discovery of novel magnetic Heusler alloys as prototype, since this is the materials class where most of the work has focused to date (Sanvito et al. 2017). A large part of the methodology described here is based on the AFLOW project, which is discussed in detail in a chapter of the MTM set (volume 3) of this handbook (Chap. 82, "The AFLOW Fleet for Materials Discovery").

2 The High-Throughput Approach to Materials Discovery

2.1 General Principles

In general there are three steps common to all the attempts at HTEST (Curtarolo et al. 2013): (1) the creation of large dataset of computed materials properties, (2) the organization of such calculations in easy-to-access databases, and (3) the screening of the databases in the search of new materials with desired properties or of new rules for designing novel compounds. Let us discuss these three steps in some detail.

Creating large datasets of computed materials properties imposes a number of choices, which somehow determine the further capability of the entire scheme. One strategy consists in producing highly standardized and curated data. Here one decides the level of theory to use and no data are accepted unless they satisfy some stringent criteria. A rather popular choice is that of using density functional theory (DFT) in either the local density or the generalized gradient approximation (LDA and GGA). These ensure enough accuracy, in particular in terms of total energies and elementary linear-response properties, and most importantly the possibility of a high throughput. The convergence parameters (cutoff energies, k-point sampling, force tolerance, etc.) are also highly standardized, so that total energies can be computed across different chemical compositions, structures, and unit cell sizes. Almost all the most popular databases are produced in this way. These include AFLOW.org (Curtarolo et al. 2012b), Materials Project (Jain et al. 2013), OQMD (Kirklin et al. 2015), and 2D (Rasmussen and Thygesen 2015). A second strategy consists in accepting all possible data, regardless of the source (the particular electronic structure theory code used) and the level of theory (e.g., different exchange correlation functionals). The convergence criteria are usually monitored, but stringent tests making different computational platforms compatible with each other are still under development. Typically the data are much more difficult to compare, but the database volume can grow significantly larger than in the case of highly curated data, since it benefits from a large user base. Examples of

this strategy are the Harvard Clean Energy (Hachmann et al. 2011) and the NoMaD projects (Ghiringhelli et al. 2017).

Common to all the strategies is the necessity to deal with large volumes of calculations produced by several users, often with a rather diverse geographical distribution, and the necessity to store the data in easy-to-access databases. This requires efficient managers to run the calculations, check for convergence, create the appropriate entries for the database, and analyze the data. Again one can adopt different strategies for performing this task. On the one hand, there are examples of a single software platform that performs all these tasks, as, for instance, the AFLOW code (Curtarolo et al. 2012a). On the other hand, one can construct a suit of tools (often written in python), which handle the different tasks, as, for instance, the Aiida platform (Pizzi et al. 2016). The main advantage of the first strategy is the efficiency and the high level of curation, while that of the second is the flexibility of the platform. In both cases the databases are usually accessible through a graphical web interface and a back end suitable for data processing.

Creating large datasets of computational data strictly speaking is not a necessity. In principle one can replace those with experimental data and navigate them with a variety of machine learning tools (see the second part of this chapter). However, although the materials science community produces annually an enormous volume of data, these are communicated via scientific publications in a rather narrative form. As such the experimental data are extremely fragmented and difficult to harvest. There is also a multitude of curated databases, but most of them are proprietary and typically focused only on a limited number of properties (e.g., crystal structure, thermochemistry, etc.). Crystallographic databases are probably the only exception, and projects like ICSD (2018) and the crystallographic open database (Grazulis et al. 2009) currently enjoy a great popularity.

Finally, one needs to develop tools to navigate the databases. Here the central role is played by the *descriptors*. A descriptor is an easy-to-calculate property that defines a material. This can be a direct observable (e.g., the quasiparticle gap, the bulk modulus, etc.) or a quantity that acts as a proxy for a given property, such as the effective mass as a proxy for the mobility of a semiconductor. Descriptors are constructed directly from the elementary electronic properties computed with the chosen electronic structure theory. Their definition usually reflects the understanding of a property from a given community. Examples of descriptors are the *high-throughput topological insulator robustness* for the discovery topological insulators (Yang et al. 2012), the *GIBBS* method for thermal conductivity (Toher et al. 2014), the *spectroscopic limited maximum efficiency* of light-harvesting materials (Yu and Zunger 2012), etc.

2.2 Constructing Magnetic Libraries: Heusler Compounds

In short the HTEST strategy to the discovery of new materials consists in generating large libraries of hypothetical compounds and then in evaluating their properties, including the likelihood of these compounds to be made. Again, the criteria used to generate such initial libraries vary significantly depending on the targeted
Fig. 1 Critical ordering temperature, either Curie or Néel, for known (**a**) ferromagnets and (**b**) antiferromagnets as a function of the materials space group. Note that magnetic order seems to be more favorable for high space group numbers, namely, for high-symmetry cubic crystals. This is the region in the space group space where we find the magnets with the highest critical temperatures

properties. For instance, one can select a specific crystal structure and try all possible chemical compositions compatible with that structure, sometimes imposing additional constraints such as the total valence electron count (Yan et al. 2015). Magnetic compounds are distributed over a broad range of space groups (see Fig. 1) and, in addition to the limited number of magnetic ions, contain a large variety of nonmagnetic elements. As such establishing a stringent criterion for generating a library of magnetic prototypes is not straightforward. One possible criterion is to look at classes of compounds where the incidence of magnetism is high, as, for instance, in transition metals/rare-earth intermetallics (Dam et al. 2017).

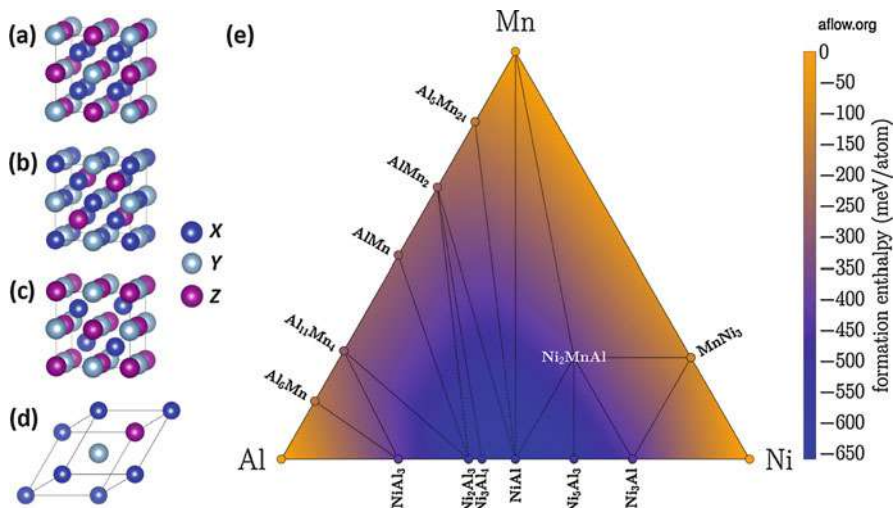
Here we will describe a less selective criterion, namely, a library of Heusler alloys (Sanvito et al. 2017), a prototypical family of ternary compounds populated with several high-performance magnets (Graf et al. 2011). In their most common form, Heusler alloys are cubic compounds consisting of four interpenetrating *fcc* lattices. The so-called *regular* Heusler alloy, X_2YZ (Cu$_2$MnAl-type), crystallizes in the $Fm\bar{3}m$ cubic space group (No. 225), with the X atoms occupying the 8c Wyckoff position (1/4, 1/4, 1/4) and the Y and Z atoms being, respectively, at 4a (0, 0, 0) and 4b (1/2, 1/2, 1/2). The Y and Z elements form an octahedral-coordinated rock-salt structure, while the X atoms occupy the tetrahedral voids


Fig. 2 Possible Heusler alloys: (**a**) regular Heusler, (**b**) inverse Heusler, and (**c**) half Heusler. In panel (**d**) we show the tetrahedral $F\bar{4}3m$ cell used to construct the electronic structure database. (**e**) Ternary convex hull diagram for Al-Mn-Ni. Note the presence of the stable HA, Ni$_2$MnAl. (Figure from Sanvito et al. 2017)

(see Fig. 2a). Alternatively, in the *inverse* Heusler structure, $(XY)XZ$ (Hg$_2$CuTi-type), now X and Z form the rock-salt lattice, while the remaining X and Y atoms fill the tetrahedral sites (Fig. 2b), so that one X atom presents sixfold octahedral coordination, while the other has fourfold tetrahedral coordination. Finally, one can also have the so-called *half* Heusler alloy, XYZ (MgCuSb-type). This is obtained by removing one of the X atoms from the regular type, thus leaving a vacancy at one of the tetrahedral sites (Fig. 2c). The Wyckoff positions are now $4a$ (0, 0, 0), $4b$ (1/2, 1/2, 1/2), and $4c$ (1/4, 1/4, 1/4), respectively, for X, Y, and Z. The minimal unit cell describing all three types can be constructed as a tetrahedral $F\bar{4}3m$ cell, containing four (three for the case of the half Heusler) atoms (Fig. 2d). Such a cell allows for a ferromagnetic spin configuration and for a limited number of antiferromagnetic and ferrimagnetic ones.

Note that it is not uncommon for Heusler alloys to have a significant amount of site-occupation disorder. In this case there is a special classification depending on the particular sites where the disorder takes place, as illustrated in Table 1 for the complete Heusler alloys and in Table 2 for the inverse ones. Modeling site-occupation disorder is a notoriously challenging problem in ab initio studies due to computational costs, although recent developments look promising for future investigations (Yang et al. 2016). Finally, it is worth mentioning that there exist a number of Heusler alloys presenting significant tetragonal distortion. These are usually associated to Mn-containing compounds, in particular with the Mn$_2YZ$ composition (Faleev et al. 2017), and they are interesting since they can potentially display large magneto-crystalline anisotropy.

Table 1 Site occupancy and general formula for different atomic orders of Heusler compounds. The notations according to the Inorganic Crystal Structure Database (ICSD), the Strukturberichte (SB), the Pearson database, as well the space group are given. (Table adapted from Graf et al. 2011)

Site occupancy	Formula	Type (ICSD)	SB	Pearson	Space group
X, X', Y, Z	$XX'YZ$	LiMgPdSn	Y	cF16	$F\bar{4}3m$ (No. 216)

$4a = 4b = 4c = 4d$	X	W	A2	cI2	$Im\bar{3}m$ (No. 229)

We have constructed a library of potential Heusler alloys by considering all possible combinations of three elements chosen from the $3d$, $4d$, and $5d$ periods and from the groups III, IV, V, and VI. These include Ag, Al, As, Au, B, Ba, Be, Bi, Br, Ca, Cd, Cl, Co, Cr, Cu, Fe, Ga, Ge, Hf, Hg, In, Ir, K, La, Li, Mg, Mn, Mo, Na, Nb, Ni, Os, P, Pb, Pd, Pt, Re, Rh, Ru, Sb, Sc, Se, Si, Sn, Sr, Ta, Tc, Te, Ti, Tl, V, W, Y, Zn, and Zr. We have thus avoided rare-earth elements, since in the last decade their price has been volatile on the market, so that the search for rare-earth-free magnets has become a sought-after target. If one considers all the possible stoichiometry compatible with the elements chosen and all the available crystal structures (regular, inverse, and half Heusler), a total number of 236,115 prototypes will be reached. Their electronic structure has been computed at the AFLOW standard, namely, by DFT with the GGA parameterized by Perdew et al. (1996). The DFT platform is VASP (Kresse and Furthmuller 1996), and the convergence criteria is quite stringent, namely, the convergence tolerance is 1 meV/atom and the typical Brillouin zone sampling is over a dense grid of 6,000–10,000 k-points per reciprocal atom (Calderon et al. 2015). The structures are fully relaxed, and in general the electronic structure is initialized in such a way to have the maximum possible spin. This gives a unit-cell ferromagnetic initial configuration whenever

the unit cell contains more than one magnetic ion. The calculations are performed without spin-orbit interaction. More details about the computational method are reported in Calderon et al. (2015).

2.3   The Descriptors

2.3.1   Energy-Related Descriptors

The very first property that one usually wishes to monitor in the HTEST protocol is the likelihood that a particular compound can be grown. The appropriate descriptor is then the Gibbs free energy, $G = H - ST$, where H is the enthalpy, S the entropy, and T the temperature. If G can be calculated, then all thermodynamically stable compounds can be identified, leaving out only those possible in the form of long-living metastable phases. However, the calculation of the Gibbs free energy is too demanding to be carried out in a high-throughput framework, so that in general one chooses to evaluate quantities related only to the DFT total energy.

A very crude but yet selective criterion is given by the enthalpy of formation. For the Heusler X_2YZ one has to check that its enthalpy, H_{X_2YZ}, is lower than the sum of the enthalpies of formation of its elementary constituents, namely, $\Delta H = H_{X_2YZ} - (2H_X + H_Y + H_Z) < 0$. For instance, for Ni$_2$MnAl, a now well-established magnetic shape memory alloy (Ziebeckt and Webster 1975), one has to check that $H_{\text{Ni}_2\text{MnAl}}$ is lower than the sum of the enthalpies of formation of *fcc* Ni, Mn, and Al, their energy-lowest structures. As a further approximation, the enthalpy of formation is replaced by the DFT total energy.

A second, much more stringent, stability criterion is obtained by constructing for every three elements the convex hull diagram of the associated ternary compounds (Lukas et al. 2007), *Descriptor 1*. This essentially consists in establishing whether the enthalpy of formation of X_2YZ is lower than that of all the possible binary and elementary decompositions, for instance, $XY + XZ$, $X_2Y + Z$, $XYZ + X$, etc. Again by taking the example of Ni$_2$MnAl, we find that it is stable against all possible decompositions along the Al-Mn-Ni convex hull diagram, which is presented in Fig. 2e. The most stable structure is the regular Heusler with a formation energy of -404 meV/atom, but there are also three unstable ones with $\Delta H < 0$, namely, Mn$_2$NiAl ($\Delta H = -209$, 121 meV/atom above tie-plane), NiMnAl ($\Delta H = -39$, 400 meV/atom above tie-plane), and Al$_2$MnNi ($\Delta H = -379$, 100 meV/atom above tie-plane). Such three unstable structure, all with $\Delta H < 0$, clearly prove that the enthalpy of formation alone says little about the stability of a given compound. It is also worth to mention that even the convex hull, as calculated so far, provides only an incomplete descriptor for the thermodynamical stability. In fact, in principle one has also to check possible decompositions involving alternative ternary compounds. Furthermore, once a ternary material is predicted stable, there is still the possibility that the ground state crystal structure is not a Heusler type. As such, once a stoichiometry has been predicted stable against decomposition, one should perform further crystal structure prediction calculations. Possible methods

include random sampling (Pickard and Needs 2011), genetic algorithms (Oganov and Glass 2006), or targeted sampling (d'Avezac et al. 2012).

One has to consider that the probability of finding new ground states per alloy reduces with increasing the number of species. This can be seen by performing a phase stability experiment in the thermodynamic data available in the AFLOW.org repository (Curtarolo et al. 2012b), which is performed by calculating all the available binary, ternary, quaternary, etc. convex hulls (Lukas et al. 2007). The enthalpies can then be analyzed, and the average gain in enthalpy with respect to the number of species N, $\delta H(N) \equiv H(N) \rightarrow (N + 1)$, decreases with N. This quantity competes against the disorder state, unavoidably promoted by configurational entropy going as $\approx \log(N)$. If follows that, in our case ternary case, the existence/absence of a ternary compound depends *mostly* on decomposition in binaries than in competition by other ternaries. As such, a first-order stability analysis, based on simply checking binaries, will be an appropriate approach capable to weed out most of the uninteresting compositions.

Additional energy-related descriptors can be defined, depending on the properties and materials class that one wants to investigate. In general, it is useful to have an idea on how robust is the thermodynamical stability of a compounds. This can be estimated by calculating the enthalpy of formation relative to that of the most stable balanced decomposition. If such difference is around $k_B T$ at room temperature (k_B is the Boltzmann constant, $k_B T_{RT} = 25$ meV), then one usually defines the material as robustly stable (Sanvito et al. 2017). This descriptor, *Descriptor 2*, is denoted as Δ^{kT}.

Finally, considering that Heusler alloys are often prone to site-occupation misplacement, it is useful to define a descriptor, *Descriptor 3*, which identifies the tendency to disorder. This is the entropic temperature (Curtarolo et al. 2013; Hart et al. 2013; Yong et al. 2014), T_S, which is defined for a binary XY alloy as

$$T_S = \max_i \left[\frac{\Delta H(X_{x_i} Y_{1-x_i})}{k_B [x_i \log x_i + (1 - x_i) \log(1 - x_i)]} \right], \tag{1}$$

where i counts all the stable compounds in the XY binary system. In practice T_S measures the ability of an ordered phase to resist deterioration into a temperature-driven, entropically promoted, disordered mixture. This is quantified by the concentration-maximized formation enthalpy weighted by the inverse of its ideal entropic contribution (random alloy). By convention we choose the sign of T_S so that a positive temperature is needed for competing against the compound stability ($T_S < 0$ if $\Delta H > 0$), and one expects $T_S \rightarrow 0$ for a compound spontaneously decomposing into a disordered mixture.

In Eq. (1), the curvature of the iso-max ideal-latent heat locus can be seen as a descriptor of the (ideal) entropy that a system can absorb upon nucleation in a single phase and internal reorganization containing ideal disorder. As such, it is a viable descriptor to tackle the unavoidable entropy stabilization happening in half Heuslers (entropy of vacancies) or in full Heuslers (entropy of species permutations). In these

systems, disorder might overcome enthalpy stabilization and lead to stable solid solutions unobtainable with prediction algorithms mentioned above.

2.3.2   Magnetic Descriptors

A magnet can be defined as "high-performing," when it presents a range of electronic and magnetic properties particularly suitable for a given application. Thus, for instance, a high-performing permanent magnet will need to score high against descriptors different from those of a magnet designed for magnetocaloric applications (Coey 2009). Some magnetic descriptors are observables and can be extracted directly from the DFT calculations. This is, for instance, the case of the magnetic moment, *m* (*Descriptor 4*), which can be directly compared with the experimental saturation magnetization. In the case the magnet is screened for spintronics applications (for magneto-transport), it is important to assess its spin polarization at the Fermi level. This is defined as (*Descriptor 5*)

$$P_{\mathrm{F}}^{\alpha} = \frac{n_{\mathrm{F}}^{\uparrow}(v_{\mathrm{F}}^{\uparrow})^{\alpha} - n_{\mathrm{F}}^{\downarrow}(v_{\mathrm{F}}^{\downarrow})^{\alpha}}{n_{\mathrm{F}}^{\uparrow}(v_{\mathrm{F}}^{\uparrow})^{\alpha} + n_{\mathrm{F}}^{\downarrow}(v_{\mathrm{F}}^{\downarrow})^{\alpha}} \ , \tag{2}$$

where n_{F}^{σ} and v_{F}^{σ} are, respectively, the density of states (DOS) at the Fermi level and the Fermi velocity for the spin-σ sub-band. In general, P_{F}^{α} describes the degree of spin polarization of the current that the material can sustain in different transport conditions (Mazin 1999). Here $P = 1$ indicates that only one spin species is responsible for the electron transport (Coey and Sanvito 2004). Note that different values of α characterize different transport experiments. For instance, $\alpha = 0$ is for tunneling, $\alpha = 1$ for ballistic transport, and $\alpha = 2$ for diffusive. Note also that P_{F}^{α} is a direct observable only for $\alpha = 0$ (e.g., with a spectroscopical measurement).

There are also magnetic descriptors, whose definition requires additional DFT calculations, possibly combined with other theories. This is, for instance, the case of the magneto-crystalline anisotropy (MCA – *Descriptor 6*), which measures the ability of a magnet to maintain the magnetization direction fixed in space. The MCA contributes to the hysteresis of a magnet, but it is difficult to isolate from other contributions to the total anisotropy (e.g., shape anisotropy). Computing the MCA is in general involved as it requires highly accurate total energy or perturbation theory calculations including spin-orbit interaction (Błoński and Hafner 2009).

Finally, common to all magnets is the critical ordering temperature, T_{C} (Curie or Néel), *Descriptor 7*. This requires knowledge of the compound magnetic excitation spectrum, namely, of the susceptibility, χ. There are several ways to determine such quantity and all require significant additional work. One of such possibilities is that of using time-dependent DFT (Savrasov 1998), which is capable of describing both Stoner excitations and spin waves. In the case the excitation spectrum is dominated by spin waves, a popular choice is that of performing a series of DFT total energy calculations for different magnetic configurations and mapping these onto a Heisenberg model of some kind. There are several different approaches to perform both the mapping and the total energy calculations, including magnetic

force theorem (Oswald et al. 1985), spin spirals (Sandratskii 1986), and collinear multi-configurations (Archer et al. 2011). Finally, usually T_C is computed either by using mean-field theory or with Monte Carlo simulations.

2.4   Analysis

Out of the 236,115 prototypes contained in our Heusler alloys library, only 35,602 have a DFT energy lower than the sum of that of their elementary phases, namely, they satisfy the condition $\Delta H < 0$. These 35,602 include 6,778 compounds with a magnetic ground state. Such an estimate can be slightly conservative. In fact we are able to describe only those magnetic phases, where the magnetic cell is the same as the primitive one. This clearly excludes many potential magnetic solutions, in particular complex antiferromagnetic and ferrimagnetic phases, which are often found in some of the magnetic Heuslers (Rode et al. 2013). Furthermore, we may expect that the ferromagnetic DFT initialization may force final ferromagnetic solutions to otherwise antiferromagnetic ground states, i.e., the DFT run may converge to a local minimum. In any case 6,778 potentially new magnets is an extraordinary large number, since only 4,000 magnets are known to date.

The application of *Descriptor 1*, however, reduces drastically such number. Since the construction of the ternary convex hull diagrams requires a significantly large number of calculations, we have initially limited our analysis to intermetallic prototypes, namely, to Heusler structures made of $3d$, $4d$, and $5d$ elements only. These are 36,540 in total, but only 248 are on the convex hull; hence only 248 are predicted stable. Most importantly only 20 have a magnetic ground state, meaning that the incidence of stable magnetism in our Heusler library has to be estimated to be around 0.05%. A close look at the newly predicted magnetic Heusler alloys reveals that, with the exception of Rh_2FeZn, only three families are found, namely, Co_2YZ, Mn_2YZ and X_2MnZ.

The Co_2YZ family is perhaps the most interesting; it contains already 25 known compounds all lying on the Slater-Pauling curve (Graf et al. 2011) and houses several half-metals. Our search found four new stable alloys, namely, Co_2VZn, Co_2NbZn, Co_2TaZn, and Co_2MnTi. The first three have the low valence electron count of 25, while for Co_2MnTi this is large, 29. The numerical regression used to evaluate T_C correctly places these four on the Slater-Pauling curve, as shown in Fig. 3, and predicts Co_2MnTi to have the remarkable T_C of 940 K. The other three new compounds have all a T_C around 200 K, but two of them become nonmagnetic upon tetragonal distortion leaving only Co_2VZn magnetic (predicted $T_C \sim 228$ K).

Five Mn_2YZ compounds populate the second family, namely, Mn_2PtRh, Mn_2PtCo, Mn_2PtPd, Mn_2PtV, and Mn_2CoCr. In general Mn_2YZ alloys are found to crystallize in the regular Heusler structure if the atomic number of the Y ion is smaller than that of Mn, $Z(Y) < Z(Mn)$, and the inverse one for $Z(Y) > Z(Mn)$. This, however, is valid when one element from the main groups occupies the $4c$ position. In our case of intermetallic Heuslers, we find that the regular $Fm\bar{3}m$ structure is always the ground state, regardless of the chemical composition. Furthermore, all the new compounds present some degree of antiferromagnetic
Fig. 3 Slater-Pauling curve for magnetic Heusler alloys of the form Co_2YZ. The magnetic moment per formula unit, m, is plotted against the number of valence electron, N_V, in the left panel, while T_C is displayed on the right. Red symbols correspond to predicted HAs while the black ones to existing materials. For the sake of clarity, several compounds have been named collectively on the picture. Co_2AB 1 (Co_2FeGa, Co_2FeAl, Co_2MnSi, Co_2MnGe, Co_2MnSn), Co_2AB 2 (Co_2TaAl, Co_2ZrAl, Co_2HfAl, Co_2HfGa, Co_2TaGa), Co_2AB 3 (Co_2ZrAl, Co_2HfAl, Co_2HfGa, Co_2TaGa). (Figure from Sanvito et al. 2017)

coupling, which results in either a zero-moment ground state when Mn is the only magnetic ion, and in a ferrimagnetic configuration when other magnetic ions are present. No estimate of T_C is possible in this case since there are no data for regular Mn_2YZ alloys to run the regression against.

Finally, we have found several X_2MnZ compounds (13), most of them including a $4d$ ion (Ru, Rh, and Pd) in the tetrahedral X position. In general, these compounds have a magnetic moment per formula unit ranging between 4 and 5 μ_B, consistent with the nominal 2+ valence of Mn in octahedral coordination. The regression, run against 18 existing compounds of which 13 are with X=Ru, Rh, or Pd, establishes a correlation between the Mn-Mn nearest neighbor distance, d_{Mn-Mn}, and T_C. This effectively reproduces the empirical Castelliz-Kanomata curves (Castelliz 1955; Kanomata et al. 1987) and returns us the prediction that none of the X_2MnZ alloys will display a T_C exceeding 500 K.

The final and ultimate validation of the high-throughput approach must come from an experimental lab. With this in mind, we have attempted the growth of four newly predicted alloys, namely, Co_2MnTi, Mn_2PtPd, Mn_2PtCo, and

Mn$_2$PtV. Co$_2$MnTi is chosen because of its high Curie temperature, while among the Mn$_2$-based alloys, we have selected two presenting a ferrimagnetic ground state (Mn$_2$PtCo and Mn$_2$PtV) and one meeting the stringent robustness criterion (Mn$_2$PtPd). Details of the growth and magnetic characterization can be found in Sanvito et al. (2017).

Two of the four Heusler alloys have been successfully synthesized, Co$_2$MnTi and Mn$_2$PtPd, while the other two, Mn$_2$PtCo and Mn$_2$PtV, decompose into binary compounds (notably in both cases, one of the products of the decomposition was an intermetallic with a very large unit cell, and it was not included in our database). Co$_2$MnTi was found to crystallize in the regular $Fm\bar{3}m$ Heusler structure with a lattice parameter, $a = 5.89$ Å in close agreement to the predicted one, $a = 5.84$ Å. Most strikingly the T_C extrapolated from the zero-field cooled magnetization curve in a field of 1 T is found to be 938 K, essentially identical to that predicted by our regression, 940 K. This is a remarkable result, since to our knowledge it is the first time that a new high-temperature ferromagnet has been discovered by high-throughput means.

Also Mn$_2$PtPd was found to be a single phase without evidence of decomposition. X-ray diffraction reveals that the structure is that of a tetragonally distorted regular Heusler (*I4/mmm* – TiAl$_3$-type) with lattice parameters $a = 4.03$ Å and $c = 7.24$ Å. Magnetization curves at room temperature and 4 K show no hysteresis or spontaneous magnetization indicating that the compound is antiferromagnetic at low temperature.

3   Machine Learning for Materials Discovery

The general concept underpinning machine learning methods for materials science is relatively simple. One wishes to establish relations between known microscopic features, including chemical and perhaps structural information, with a number of physical/chemical properties. In practice the machine learning model, f_{ML}, defined as

$$f_{ML} : \vec{v} = (\{Z_i\}, N_V, \ldots) \rightarrow p, \tag{3}$$

associates to a *feature vector*, $\vec{v}$, the property p. Then, $\vec{v}$ contains information such as the atomic numbers, $\{Z_i\}$, of the elements in a compound; the number of valence electrons, N_V; etc. The machine learning models are purely numerical and do not require any particular physical knowledge of the property under investigation. There is a multitude of algorithms available, going from simple linear regression to complex neural network schemes (Shalev-Shwartz and Ben-David 2014; Hastie et al. 2013). These can deliver a classification, namely, they can sort materials in classes or the continuous value of a given property (e.g., the Curie temperature of a ferromagnet). The standard procedure in creating a machine learning model is to train the model over a given subset of data, the *training set*, and then to evaluate the quality of the learning by predicting the property of data never seen before, the *test set*.

There are a number of issues related to machine learning applied to materials science, which are relatively general to any algorithm and property. The first concerns the many possible ways to represent the feature vector, which should satisfy a number of criteria. In particular the feature vector should be continuous for small variations in the features, with two materials having the same representation only if their target properties are identical. This criterion essentially establishes a notion of similarity across the materials space. For instance, if one seeks at describing a property that strongly depends on the number of valence electrons, elements are represented by their group in the periodic table better then by their atomic number. In fact, Si and Ge will have the same representation when using the group (both in group IV), while they will appear as rather distant if the atomic number is considered (14 for Si and 32 for Ge). The representation of the crystal structure poses particular problems. The space group, for instance, is difficult to use, since tiny distortions from a high-symmetry structure (high space group number) may result in a space group with a rather low number. Furthermore, whatever representation one chooses, it should be both translational and rotational invariant and should be insensitive on the choice of the unit cell (for solids). Note that these criteria associated to the feature vector are not stringent conditions in general. In principle a solid machine learning model based on an extremely large number of data should be able to establish patterns among the data even if the distance between different feature vectors does not follow an intuitive physical/chemical metric. Unfortunately the materials space is not large, so that using feature vectors with the properties described above is highly desirable.

The second issue is related to the so-called curse of dimensionality, which establishes that as the dimension of the feature space gets larger, the number of possible distinct configurations increases exponentially. In other words the density of points needed to extrapolate the data in a multidimensional space grows exponentially with the dimension of the space itself. This essentially means that in order to obtain the same quality of learning, the number of data needed grows exponentially with the dimension of the feature vector, i.e., adding more information to the feature vector may decrease the change to establish patterns in the data. In materials science the curse of dimensionality is a serious issue for two main reasons. Firstly, the chemical materials space is large but not huge. Secondly, the availability of experimental data is limited by the fragmentation of the various databases, and the fact that results are communicated in scientific publications, which are little data oriented. This has two main consequences. Firstly, most of the machine learning studies to date train on theoretical data (as the ones contained in AFLOWLIB.org) (Isayev et al. 2017) and not experimental ones, though predictions show to be consistent with the experimental results. Secondly, one has to design machine learning algorithms, where the dimension of the feature vector remains small (Ghiringhelli et al. 2015).

When applied to magnetism, the use of machine learning models remains very limited. Here we will present two illustrative examples, looking, respectively, at predicting the magnetic moment of Fe-containing Heusler alloys and at sorting tetragonally distorted ones into hard and soft magnets. Other examples of machine learning approaches to magnetism include the identification of novel magnetic
Fig. 4 The local coordination of the atomic sites in a Heusler alloy. The neighbors of the central Fe atom form two shells of different symmetry. Atoms belonging to the nearest neighbor shell, shown in blue, coordinate the central atom tetrahedrally. The next nearest neighbor shell is made out of six (green) atoms and has octahedral symmetry. (Figure adapted from Žic et al. 2017)

phases with enhanced magnetic anisotropy (Kusne et al. 2014), the discovery of intermetallic compounds (Oliynyk and Mar 2018), and the prediction of the Curie temperature of transition-metal rare-earth compounds (Dam et al. 2017).

3.1   Magnetic Moment Predictions

We will now present a machine learning strategy to predict the magnetic moment of $L2_1$ Fe-containing Heusler alloys (Žic et al. 2017) of the $X_2\mathrm{Fe}Z$ type. In general the magnetic moment of $3d$ transition metals is highly localized and can be described as atomic-like. This may get modified by the surrounding ions, which should be then included into the definition of a suitable feature vector. We represent the local structure by constructing clusters centered around the Fe ions as illustrated in Fig. 4. The center of the cluster is occupied by Fe, the first coordination shell is populated by ions X with atomic number Z_1, while the second nearest neighbors are ions Z of atomic number Z_2.

A feature vector can then be defined as the following:

$$\vec{v} = (\{Z_i\}, \{r_{0i}\}, \{N_i\}, a_{\mathrm{lat}}), \tag{4}$$

where $\{Z_i\}$ are the atomic number of the ions in the cluster ($i = 1, 2$), $\{N_i\}$ is their valence, r_{0i} is the distance between the central Fe ion and the i-th one, while a_{lat} is the lattice constant of the relative Heusler compound.
Fig. 5 *Left panel* – Magnetic moment of Fe, m_{Fe} (in μ_B), for a wide range of nearest neighbors at a constant Wigner-Seitz volume ($R_{WS} = 2.7$ bohr). The atomic number of the next nearest neighbor, Z_3, is color coded, while here we plot data as a function of the first nearest neighbor atomic number, Z_1. We can notice a linear increase of the magnetic moment across the transition metal series which does not depend on Z_3. The symbols are the DFT data, while the corresponding machine learning trend is shown with the blue line. *Right panel* – a data sample containing a wider range of main group elements. The data elucidates the origin of the oscillation in the machine learning trend throughout the main group series. (Figure adapted from Žic et al. 2017)

We have then used such feature vector in a random forest regression algorithm trained over a large number of Heusler alloys, whose electronic structure was computed at the level of GGA-DFT (Žic et al. 2017). In fact, we have constructed a number of machine learning models using feature vectors similar to that presented here and capable of predicting the magnetic moment of an atom at the center of the cluster of any type (not just Fe). After having noticed that the Fe magnetic moment is little affected by the choice of Z_2, as long as this crystal position is occupied by an element belonging to one of the main groups, we have focused our attention on the dependence of the Fe moment, m_{Fe}, over the Z_1. In general we have discovered that the valence of X determines m_{Fe}. In fact, if this is smaller than 8, then the moment will decrease; otherwise it will increase. This trend is true for all the elements in the $3d$ and $4d$ periods, as shown in Fig. 5, so that the largest Fe moment is found when $X = $ Ni and Pd.

3.2   Anisotropy Analysis: Saving Computational Time

As a second example of machine learning methods applied to magnetism, we describe here the construction of a classification scheme to sort out hard from soft magnets (Žic 2017). The magnetic hardness of a compound is determined, at

the microscopic level, by the magneto-crystalline anisotropy (Błoński and Hafner 2009). This is a well-defined quantity, which depends on the spin-orbit coupling strength, the crystal structure, and the magnetic ion responsible for the magnetic moment. In general it can be computed either by using perturbation theory or by total energy differences. In both cases the calculation is delicate as it required an extremely accurate evaluation of the Fermi surface. In fact, the anisotropy is very sensitive to the occupation of the various d orbitals so that one needs to determine the position of the Fermi energy at a high degree of accuracy. As a result sampling the k-points over a very fine mesh is mandatory, and the calculations end up to be quite time-consuming. Clearly, if one can construct a machine learning strategy to the calculation of the magneto-crystalline anisotropy, the high-throughput analysis of magnetic materials will become more feasible.

Our dataset was constructed from a Heusler alloys library, from which we have selected about 300 compounds presenting a magnetization exceeding $0.5\,\mu_B$/fu and tetragonal distortion $c/a \neq 1$. In this case the thermodynamical stability was not considered so that the dataset includes both stable and unstable structures. The magnetic anisotropy was then calculated at the level of DFT-GGA using magnetic force theorem. These initial calculations have returned us magneto-crystalline anisotropy values ranging between 0 and $15\,\mathrm{MJm}^{-3}$, although for most of the compounds, the anisotropy is smaller than $8\,\mathrm{MJm}^{-3}$.

We have then constructed a machine learning model based on a ridge classifier (Pedregosa et al. 2011) and different choices of feature vector. In particular the best model uses the following vector:

$$\vec{v} = (\{Z_i\}, \{N_i\}, \{\zeta_i\}, \{M_i\}, V), \tag{5}$$

where Z_i, N_i, and M_i are the atomic number, the number of valence electron, and the local magnetic moment of the different species in X_2YZ, respectively. In addition V is the unit cell volume and ζ_i is a quantity associated to the spin-orbit coupling strength (Dunn 1961). Importantly, the magnetic moments are estimated using a generalization of the machine learning model described in the previous section (the central atom does no longer need to be Fe) (Žic et al. 2017), so that the feature vector does not comprise any quantities computed ab initio. We have then set the magneto-crystalline anisotropy value of $0.8\,\mathrm{MJm}^{-3}$ as the boundary between hard and soft magnets. This choice ensures that the population of hard and soft magnets in our dataset is identical.

Although hard magnets are our target, we have decided to train the machine learning model so to identify the soft ones. The reason behind such decision is primarily related to the fact that hard magnets are scarce and the cost of unintentionally dismissing a viable candidate is high. This means that a very selective machine learning model will be able to predict reliably hard magnets but will likely discharge many of them. We therefore choose a strategy where we maximize the number of correctly identified soft magnets, namely, the true positive rate (TPR), under the constraint that no hard magnet is mistaken for a soft magnet, i.e., we aim to keep the false positive rate (FPR) as small as possible. This will select the soft compounds and discharge both soft and hard.

Fig. 6 Receiver operating curve (ROC) for the two hard magnet classifiers discussed in the text (left). The area under the curve (auc) is indicated in the brackets. The machine learning model described in the text is clf 2, while clf 1 represents a second model with a different choice of feature vector. The dashed red line is for a random classifier
In Fig. 6 we present the receiver operating curve (ROC) for the machine learning model described in the text (clf 2), for a second one constructed with a different feature vector (clf 1) and for a random classifier (dashed red line). One can move along the ROC by changing the decision value cutoff. Ideally one wishes the model to be at the top left corner of the ROC, namely, to have a true positive rate of 100% (all compounds with the desired property are selected) and a false positive rate of 0 (no compounds are misclassified). In a realistic machine learning model, this is not possible and one has to take a compromise. In our case the best solution is that of having a false positive rate of 0 and a true positive rate of around 60%. When applied to soft magnets, this means that 60% of the soft magnets will be found without an error, meaning that 30% of the total compounds in the dataset will be correctly classified as soft (we consider a sample where the soft/hard ratio is 1). For those one will not need to perform any further calculation. Clearly such result becomes important if the dataset is very extended. Let us imagine, for the sake of the argument, that one wishes to compute the magneto-crystalline anisotropy for all the 236,000 Heusler alloys contained in the AFLOWLIB.org database. Our machine learning scheme will then save about 79,000 calculations.

4   Conclusion

In this chapter we have described how high-throughput electronic structure theory and machine learning strategies can accelerate the discovery and the design of new magnets. This indeed is an area of magnetism, which is still in its infancy, but that has already demonstrated a strong potential. At a first look, it appears that the efficiency of the approach is not high and the most skeptical reader may argue that

a more conventional trial and error approach can be more fruitful. This is true only in part. There are, in fact, a few key points to be noted.

Firstly, one has to expect that as the databases grow, the need for further calculations will be reduced. The mapping of the Heusler alloys thermodynamical stability has certainly been a challenging computational undertaking. However, we were able to conduct a first rapid screening of the intermetallic subset simply because the data for binary compounds were already in the AFLOWLIB.org database. It is particularly important to remark that many of these data were generated for research projects completely different from the one described here, meaning that data sharing is a unique asset of any high-throughput initiative.

The opposite argument is also valid, namely, our data have been useful not only to discover new magnets but also for screening materials according to other properties. For instance, the half Heusler library was investigated in the search of compounds presenting low thermal conductivity (Carrete et al. 2014). This concept of "recycling data" is indeed an important one, and certainly the success of the method needs to be evaluated over the entire range of discoveries that a dataset enables.

Finally, even data that do not contribute to a direct discovery (materials that are not thermodynamically stable) still can be used to construct machine learning algorithms to rapidly navigate the data themselves. Most importantly such machine learning models will help us in directing further calculations, so to improve the discovery throughput and identify gaps and opportunities in the materials space.

Contents

Abstract

The coupling of different phenomena, such as ferroelectric or magnetic order, often mediated by spin-orbit interaction, offers a rich playground for emergent phenomena in multifunctional materials. In this chapter, we focus on multiferroics and ferroelectric semiconductors showing a strong Rashba effect, we explain the motivations behind their study, and we discuss a few prototypical highlights (from BiFeO$_3$ to spin-spiral TbMnO$_3$, from E-type manganites to GeTe). Our perspective is focused on the key role that first-principles calculations

played in this field in recent years, in terms of understanding microscopic
mechanisms, quantifying relevant quantities, and guiding the interpretation of
experimental results, in view of possible materials optimization for technological
purposes.

1   Introduction

One of the most common keywords in modern materials science is "multifunc-
tionality," i.e., a material's peculiarity to show at the same time more than one
active degree of freedom (charge, spin, dipole, etc. – possibly coupled) and,
correspondingly, its potential use when exploiting more than one "functionality."
Indeed, several breakthroughs in the last decades were achieved when merging
different subfields of materials science. This was, for example, the case in early 2000
with diluted magnetic semiconductors (Ohno 1999; Jungwirth et al. 2006), aimed
at bridging semiconducting behavior with magnetism, to combine logic and storage
functionalities. Unfortunately, their low operating temperature ($\leq$200 K) hindered a
real impact on technology. Within the race for multifunctionality, one of the grand
challenges in nowadays spintronics is represented by the electrical control of spin
degrees of freedom. Several approaches are being pursued, but natural candidates
appear to be those materials where – below a specified phase-transition critical
temperature – spontaneous dipolar electric and magnetic orders coexist (Schmid
1994), i.e., multiferroics (MF, see Fig. 1). Even more important and intriguing is
the study of compounds where the two relevant order parameters (i.e., ferroelectric
polarization and magnetization) not only coexist but are intimately connected via
the so-called "magnetoelectric" (ME) coupling: one can then induce/control/switch
ferroelectric properties via a magnetic field and, vice versa, magnetic properties
via an electric field. In the same context, an alternative class of emerging materials
is represented by (nonmagnetic) ferroelectrics with strong Rashba effects, the so-
called ferroelectric Rashba semiconductors (FERSC, see Fig. 1) (Picozzi 2014).
In those materials, the spin degrees of freedom become active, due to spin-orbit
coupling (SOC) and not to long-range magnetic order (as straightforward and
conventional in magnetic materials). As detailed below, in FERSC, SOC removes
the spin degeneracy of the band structure and creates an electrically controllable
k-dependent spin polarization in the reciprocal space.

The research on these two materials classes implied, implies, and will imply
progresses in various aspects, from the fundamental physics point of view to mate-
rials science issues to new technological paradigms that could revolutionize future
information technology. Both materials classes are relatively new: multiferroics
have experienced a hype since 2003 (Kimura et al. 2003; Wang et al. 2003), and
ferroelectric Rashba semiconductors were first proposed in 2013 (Di Sante et al.
2013). Materials modeling has therefore played a crucial role in recent years:
computational materials scientists heavily contributed to explain experimental data,
to identify new microscopic mechanisms, and to design new MF or FERSC. A
concerted effort from various modeling approaches was carried out in these fields,
ranging from phenomenological approaches (e.g., the Landau theory of second-
Fig. 1 Pictorial view of the different classes of multifunctional materials discussed in this chapter. Multiferroics (as the overlap between ferroelectrics and (anti-)ferromagnets) and ferroelectric Rashba semiconductors (as the overlap between ferroelectrics and materials showing a bulk Rashba effect). Relevant keywords are reported in the outer circle

order phase transitions (Harris 2007), with symmetry considerations playing a crucial role) to model-Hamiltonian approaches, ranging from many-body to – mostly classical – spin-based Hamiltonians, etc. In this chapter, however, we will mostly concentrate on the results obtained from materials modeling based on density functional theory (DFT). Moreover, since the research efforts on MF were massive on a worldwide and longer time scale, we will mainly focus on multiferroicity and magnetoelectricity, leaving a smaller part at the end of the chapter to the FERSC.

2   Basic Ingredients: Ferroelectrics, Symmetries, and Spin-Orbit Coupling

For the sake of clarity, several ingredients – most of them of relevance for both MF and FERSC – need to be preliminarily introduced, before moving to the main part of the chapter. We don't introduce (anti-)ferromagnets, since this chapter is part of a section fully devoted to magnetism, and we assume the reader to be already familiar with this topic.

Ferroelectrics (FE) (Rabe 2007; Scott 2000): materials where a spontaneous dipolar ordering occurs below a Curie temperature, leading to ferroelectric polarization P switchable via an electric field. Due to the presence of a polar axis, they intrinsically lack inversion symmetry. The phase transition occurs at a critical Curie temperature, T_C, above which the system is "paraelectric." Below T_C, even when removing the external electric field, the FE order is kept. As such, their nonvolatile behavior is at the heart of a worldwide multibillionaire market based on FE sensors, memories, transducers, etc.

Symmetries: in the framework of FE and/or (anti-)ferromagnetic phase transitions, symmetry considerations are undoubtedly helpful. In MF and FERSC, the main relevant symmetries to be considered are space-inversion symmetry (SIS) and time-reversal symmetry (TRS). An electric charge dipole (or the corresponding order parameter, i.e., polarization characterizing ferroelectrics) always breaks SIS, as it includes in its definition the vector position r; however, it preserves TRS. On the other hand, a spin moment (or the corresponding order parameter, i.e., magnetization characterizing ferromagnets) always breaks TRS but keeps SIS (as evident from the analogy with a current loop). The materials modeling of both MF and FERSC greatly benefits from symmetry considerations, in terms of space groups, point groups, time-reversal, mode decompositions, etc. Symmetry represents a precious tool to highlight the mechanism behind ferroelectricity and its coupling to other electronic degrees of freedom (mainly spin-related, but also linked to charge-ordering, orbital-ordering, etc.). Analogously, symmetry dictates allowed terms in k•p Hamiltonian (Yu 2005; Harrison 1989) around relevant high symmetry points in the Brillouin zone. To this end, crystallography software, available, i.e., at the Bilbao Crystallographic Server (Orobengoa et al. 2009) or via the Isotropy Software Suite (Stokes n.d.), is particularly helpful for materials modeling.

Spin-orbit coupling (SOC): relativistic interaction linking the electron spin with its orbital motion in space. For long time neglected due to its generally tiny magnitude for most of the technologically relevant materials, it is nowadays regarded as rich source of exotic physics, manifesting in topological insulators (Hasan and Kane 2010), weak ferromagnetism, spin-induced electrical polarization, etc. Thanks to the "locking" between spin and momentum k, SOC has recently become "functional" (Manchon et al. 2015), i.e., exploited to achieve new functionalities. SOC can be thought of as the source of Rashba effect, as explained in detail in Sect. 4.

3   Bulk Multiferroics

The recent research activity on MF has spanned many aspects, from bulk to heterostructures, from studies on magnetic/ferroelectric domains to domain wall engineering. Moreover, it has focused on many different materials (from oxides to chalcogenides, from inorganic to organic and hybrid metal-organic frameworks, etc.) with different microscopic mechanisms at play. For the sake of brevity, in this chapter we will only discuss three highlights on prototypical MF in the family of transition metal oxides (TMO) with perovskite crystal structure: $BiFeO_3$, $TbMnO_3$, and $(Ho/Y)MnO_3$. For each of them, the main experimental results will be briefly

recalled, along with some of the most representative results obtained via first-principles simulations. Furthermore, we will address the microscopic mechanisms and the related switching behavior. We however caution the reader that a huge literature on different aspects of MF exists, and we refer the reader to several excellent reviews for a deeper understanding (Cheong and Mostovoy 2007; Kimura 2007; Ramesh and Spaldin 2007; Picozzi and Ederer 2009; Dong et al. 2015; Catalan and Scott 2009).

The hype on MF started from an apparent problem: most of the prototypical ferroelectrics are perovskite TMO (such as $BaTiO_3$) where the polar distortion mainly arises from the B-site cation showing an empty d-shell (i.e., Ti is formally d^0). The latter electronic configuration can lead to some degree of covalency when bonding with surrounding oxygens during the FE distortion; this situation tends to off-center the B-site cation toward one (or three) of the octahedral oxygens at the expense of weakening the bonds with other nearby oxygens. Being an empty d-shell clearly incompatible with any magnetism (requiring a partially filled d-shell), there arose the famous question posed by Nicola A. Spaldin, one of the leading figures in the field: "*Why there are so few magnetic ferroelectrics?*" (Hill 2000). People tried therefore to search for alternative routes to reconcile magnetism and ferroelectricity, although the initial "exclusion rule" was later revisited (Bhattacharjee et al. 2009) (i.e., for $CaMnO_3$) (Barone et al. 2011). The three prototypes below describe successful ways of overcoming the obstacle: in $BiFeO_3$, the B-site cation (Fe) gives rise to magnetism and the A-site (Bi) gives rise to (displacive) ferroelectricity, whereas in $TbMnO_3$ and $HoMnO_3$, it is the spin ordering that gives rise to ferroelectricity. Within this context, an important concept established in MF during the last 15 years was the emergence of "improper" ferroelectricity (Cheong and Mostovoy 2007): a primary order parameter of "electronic" origin (such as spin, charge, or orbital order) is responsible for symmetry lowering by breaking SIS. As such, it paves the way to ferroelectric polarization, appearing therefore as a secondary order parameter obtained as a by-product of the electronic transition. The concept of electronic ferroelectricity (Picozzi and Ederer 2009) had a large impact, primarily for two technologically appealing features: (i) since polarization involves electronic degrees of freedom, its FE switching is expected to be much faster than that in conventional polarization switching of displacive ferroelectrics, where ionic degrees of freedom are involved; (ii) especially in the case of spin-driven ferroelectricity (such as $TbMnO_3$ and $HoMnO_3$), the ME coupling is expected to be exceedingly strong, since it is the frustrated magnetic order that induces the polar behavior, magnetism, and ferroelectricity, therefore sharing the same microscopic origin.

3.1   Prototype for Lone-Pair-Driven Polarization: BiFeO₃

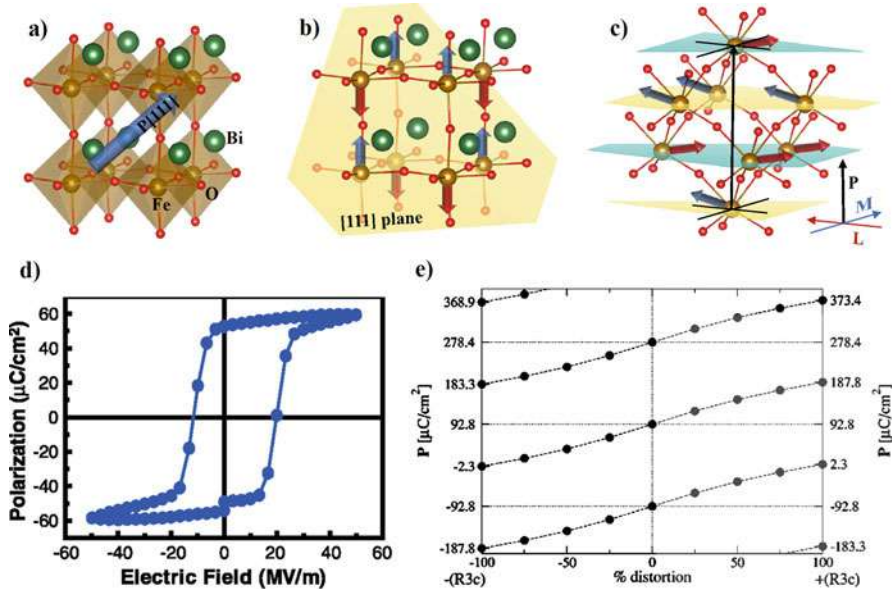
$BiFeO_3$ (Wang et al. 2003) is often considered the "holy grail" of multiferroics and has been thoroughly studied due to the persistence of its multiferroic behavior up to large temperatures. In particular, the so-called "G-type" antiferromagnetic ordering (i.e., AFM coupling of an iron cation with all its nearest neighbors or,


Fig. 2 Multiferroicity in BiFeO$_3$: (**a**) Rhombohedral structure (*R3c* space group), with FE
polarization pointing along the [111] pseudo-cubic axis. FeO$_6$ octahedral cages are highlighted
in brown, whereas Bi, Fe, and O ions are shown with green, brown, and red spheres, respectively.
(**b**) AFM-G-type magnetic ordering, seen as a sequence of FM planes (shown as yellow plane)
antiferromagnetically coupled along the [111] axis. (**c**) Spin canting of the (collinear) AFM-G
magnetic moments on Fe cations (represented by blue and red arrows) in the planes perpendicular
to the polarization direction (see yellow and light blue planes) and giving rise to a small net in-plane
magnetization. The three perpendicular vectors (weak magnetization M, antiferromagnetic order
parameter L, and ferroelectric polarization P) are shown in the lower right part. (**d**) P-E hysteresis
curve for the BiFeO$_3$ FE polarization measured (at room temperature) along the pseudo-cubic
[001] axis (i.e., the observed values are therefore a projection of the polarization vector which is
aligned along the [111] axis). (Reprinted from Catalan and Scott 2009). (**e**) DFT-calculated values
(within LSDA+U method, using $U = 2$ eV) of FE polarization along the FE switching path, going
from the –P state (R3c structure, left side of x-axis) to the centrosymmetric cubic structure to the
+P state (R3c structure, right side of x-axis). We recall that that the spontaneous polarization is
defined as half the difference between two opposite polarization states and that only polarization
differences are physically observable: the calculated values of polarization are therefore shown in
terms of several polarization "branches," differing by the polarization quantum. (Reprinted from
Neaton et al. 2005)

alternatively, seen as a stacking of FM planes antiferromagnetically coupled along
the [111] axis) shows a Néel ordering temperature of 673 K (cfr Fig. 2b). Moreover,
the FE behavior, consistent with a strong rhombohedral distortion of the pseudo-
cubic unit cell with polarization pointing along the [111] direction (cfr Fig. 2a), has
a Curie temperature of 1103 K. Ferroelectricity is driven by the presence of highly
polarizable Bi *6s* "lone-pair" electrons (Seshadri and Hill 2001), which hybridize
with surrounding oxygens in the Fe octahedral cages, therefore leading to strong
displacements of Bi cations along the [111] pseudo-cubic direction and to a related

huge FE polarization of about 90 μC/cm^2 (Wang et al. 2003) (cfr Fig. 2d). The antiferromagnetism is, on the other hand, originated by Fe ions; due to the presence of octahedral counterrotations of the oxygen cage, a non-negligible Dzyaloshinskii-Moriya (DM) interaction is also observed, which leads to a small canting of the magnetic moments in thin films and, via a generalized DM interaction, to a spin-cycloid in bulk samples (Lebeugle et al. 2008; Johnson et al. 2013).

DFT contributed exhaustively from the very beginning to the BiFeO$_3$ understanding, starting from the evaluation (Neaton et al. 2005) within the Berry phase theory of the ferroelectric polarization (King-Smith and Vanderbilt 1993; Resta 1994) (cfr Fig. 2e), directed along the pseudo-cubic [111] axis and of which experiments observe the out-of-plane projection (see Fig. 2d). Another important DFT contribution was the small deviation of the spin moments on Fe ions with respect to the collinear G-type AFM ordering (Ederer and Spaldin 2005), due to spin-orbit coupling and DM interaction (see Fig. 2c): the magnetic easy axis is found to be perpendicular to polarization, and the canting of the spin moments, induced by the (nonpolar) octahedral counterrotation of the oxygen cages, can tilt the iron spin moments. As a result, the net magnetization M, the AFM order parameter L, and the FE polarization P form a Cartesian set. Since the polar distortion is driven by the Bi off-centering and the weak FM is driven by the anti-ferrodistortive mode of oxygens, it follows that P and M are rather decoupled, so that the small net magnetization cannot be controlled via an electric field. Other relevant issues in BiFeO$_3$, both from the modeling and experimental point of view, are (i) the observation of a super-tetragonal phase obtained in BiFeO$_3$ under significant strain (Zeches 2009); (ii) the study of domain walls (Farokhipoor and Noheda 2011), particularly complex due to the rhombohedral setting which gives rise to eight possible directions of domain walls, but with the appealing perspective of a larger conductivity of domain walls with respect to domains; and (iii) the exchange bias observed at the interface with standard ferromagnets, leading, for example, to the electric control of ferromagnetism at the BiFeO$_3$/CoFe interface (Bea et al. 2008; Heron and Trassin 2011).

3.2   Prototype for Spin-Spiral-Driven Polarization: TbMnO₃

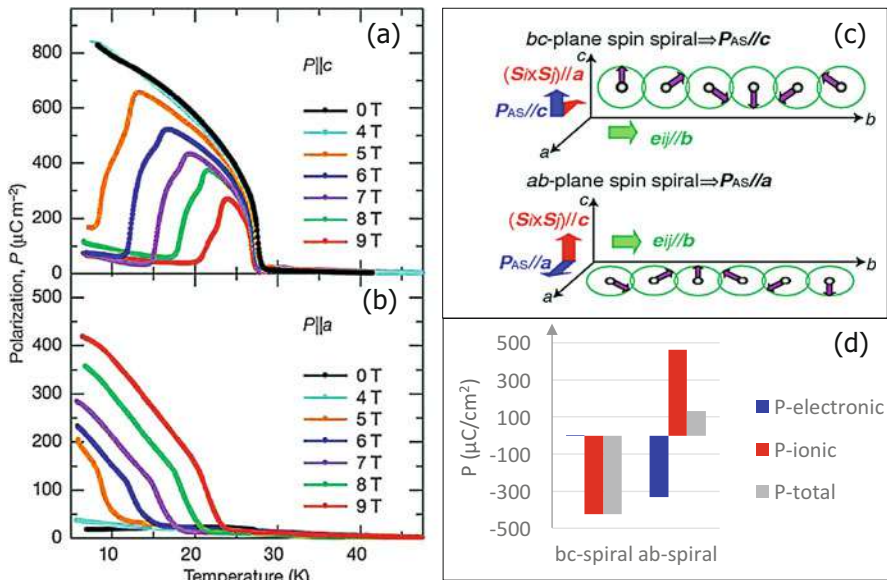
Orthorhombic TbMnO$_3$ is undoubtedly one of the multiferroics with the richest physics phenomenology, the efforts devoted to its understanding leading beyond question to significant fundamental progresses. From the experimental point of view (Kimura et al. 2003), the Mn spins order first at 42 K in a collinear structure with spins along the b-direction to form a longitudinal spin density wave. Moreover, at 28 K, they lock into a non-collinear incommensurate spin arrangement forming a spiral running in the bc plane (the spiral modulation vector depends on the temperature, but it is around $\mathbf{q} = (0,0.28,0)$. At lower temperatures (around 7 K), even the Tb spins order. In a landmark publication (Kimura et al. 2003), Kimura et al. reported a ferroelectric polarization along the c-axis (reaching


Fig. 3 Multiferroicity in orthorhombic TbMnO$_3$ with spiral-spin order. (**a**, **b**) Measured FE polarization along the c- and a-axis (in the *Pbnm* setting), respectively, as a function of temperature and of the magnetic field applied along the b-axis. (Reprinted from Kimura et al. 2003). (**c**) Relationship between the direction of polarization and the spin-spiral plane according to the spin-current model. The magnetic ordering in the upper part shows the ground state and gives polarization P_c (explaining experimental results shown in panel **a**), whereas the magnetic ordering in the lower part shows the spiral reorientation obtained under magnetic field along the b-axis and gives polarization P_a (explaining the results shown in panel **b**). (Reprinted from Mochizuki 2011). (**d**) Results from DFT (values from Malashevic and Vanderbilt 2008; Xiang et al. 2008): polarization (in μC/cm^2) calculated for TbMnO$_3$ (in two different spin-spiral configurations, confined in the *bc* plane and a*b* plane). The total polarization (P-total) is broken down into a purely electronic contribution (P-electronic) for ions fixed in centrosymmetric positions and "ionic" contribution obtained for "relaxed" atomic positions as P-ionic = P-total-P-electronic

a value of 0.08 μC/cm^2) emerging below the spin-spiral ordering temperature, therefore highlighting the intimate coupling between magnetic and dipolar orders (cfr Fig. 3a). Even more intriguingly, it was shown that the electric polarization can be controlled by a magnetic field: upon applying a magnetic field along the b-axis, the spiral flops into the *ab* plane, and, correspondingly, the polarization direction changes into the a-axis (cfr Fig. 3b).

The microscopic origin of polarization will be discussed in Sect. 3.4, but we anticipate here that the spin-spiral breaks SIS and the consequent magnetically driven polarization is explained in terms of the spin-current model (Katsura et al. 2007) (cfr Fig. 3c). From the first-principles point of view, two papers (Xiang et al. 2008; Malashevic and Vanderbilt 2008) (appeared one after the other in Phys. Rev. Lett. 2008) gave important contributions, reaching similar conclusions.

In Malashevic and Vanderbilt (2008) and Xiang et al. (2008), the spiral was modeled within DFT+U by imposing a commensurate magnetic order with rotating spins using a unit cell three times larger (along the *b*-axis) than the *Pbnm* chemical unit cell. In Fig. 3d), we show the results for FE polarization, broken down into different contributions, coming from (1) a "purely electronic" term, i.e., given by the breaking of SIS imposed by the spin spiral, with ions fixed in their centrosymmetric "paramagnetic" positions, and (2) an "ionic" term, arising from exchange-strictive mechanisms, i.e., polar displacements of ions following the spin-driven electronic polarization. While the careful discussion of the microscopic sources of polarization will be deferred to Sect. 3.4, we remark that (i) the sign and the order of magnitude of polarization estimated from DFT are in excellent agreement with experiments, a remarkable achievement for such a complex computational task; (ii) the contribution of ionic vs electronic terms can significantly vary from *bc* to *ab* spirals, being also strongly affected by octahedral distortions (i.e., the purely electronic term is sizeable in the *ab*-plane spiral, but negligible for the *bc* spiral). Moreover, the sign is sensitive to fine magnetic and electronic details: for the *ab* spiral, the ionic and electronic contributions show an opposite sign with comparable magnitude. On the other hand, in the *bc* spiral, the ionic contribution is much greater in magnitude than the electronic term.

3.3   Prototype for Heisenberg-Exchange-Driven Polarization: $RMnO_3$ (R = Ho, Y)

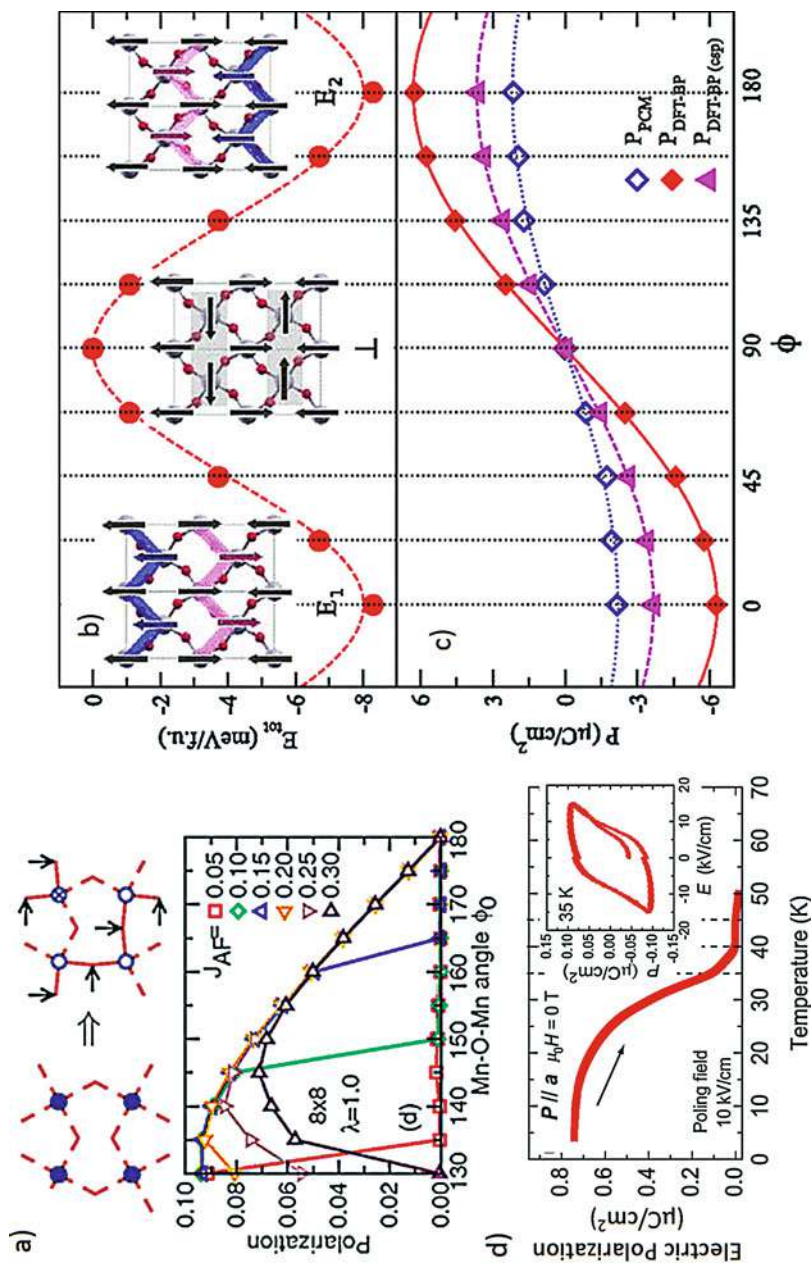
One of the remarkable examples in MF in which materials modeling significantly contributed and helped experiments (Lorentz et al. 2007) was represented by some orthorhombic manganites (*Pbnm* space group) with small rare-earth ions (such as $HoMnO_3$, $YMnO_3$, etc.); these systems show a collinear AFM-E-type order (i.e., in-plane FM zigzag chains antiferromagnetically coupled to nearby chains and with an AFM out-of-plane coupling, or equivalently ↑↑↓↓ Mn chains) below ≈26 K. Sergienko et al. (2006) proposed for the first time a mechanism based on symmetric-exchange striction (or equivalently, spin-lattice coupling) to occur in E-type manganites, where a remarkable role is played by the Mn-O-Mn angle. In closer detail, based on the double-exchange model, hopping was forbidden between opposite $t2_g$ spins but allowed to depend on the Mn-O-Mn angle in the case of parallel spins. As such, the competing contributions given by elastic energy and hopping led to different Mn-O-Mn angles for parallel and antiparallel spins (see Fig. 4a) and, eventually, to a coherent displacement of the O anions with respect to the Mn sublattice, resulting in a net polarization along the a-axis (see results from Monte Carlo simulations shown in Fig. 4a). Although from Sergienko's model one can infer relevant information on the direction of the polarization and its manifest origin in the E-type magnetic configuration, it is clear that one cannot deduce any reliable estimate of polarization. To this end, soon after Sergienko's publication, Picozzi et al. (2007) performed DFT simulations, which also provided a deeper analysis of microscopic effects, in addition to the somewhat simplified


Fig. 4 (continued)

picture provided by double-exchange models. In particular, the "dual nature" of ferroelectric polarization was discussed in Picozzi et al. (2007) (also shown in Fig. 4c): the role of purely electronic contribution to P (i.e., with ionic degrees of freedom frozen in the centrosymmetric structure) compared to magnetostrictive contribution (i.e., allowing ions to move from the centrosymmetric configuration, when subject to the AFM-E spin ordering) was highlighted and found to be of more or less equal size. Moreover, polarization was found to be much larger than in noncollinear MF, as will be more clearly explained in Sect. 3.4. The confirmation from experiments took some time, primarily due to synthesis issues: the ground state for manganites with small rare-earth cations is the hexagonal crystal structure, $P6_3cm$ space group, and the stabilization of orthorhombic phase with *Pnma* space group can only be achieved under pressure, often leading to polycrystalline samples. We report in Fig. 4d the measured ferroelectric polarization for AFM-E $YMnO_3$ (Nakamura et al. 2011), along with a P-E hysteresis loop undoubtedly showing the symmetric-exchange-striction mechanism at play. As for the magnitude of polarization – expected to be much larger than any spin-orbit-driven polarization but still measured to be lower than what is theoretically predicted – the situation is still unclear and requires further studies.

3.4   Microscopic Mechanisms for Polarization

In this subsection we summarize the microscopic mechanisms that were found as most active in multiferroics, along with their corresponding materials modeling. Let us first recall that, as for the sources of ferroelectricity, one has to distinguish two cases (Cheong and Mostovoy 2007): (i) "proper" ferroelectricity, where polarization is the primary order parameter (Bousquet et al. 2008) of the FE transition, and (ii) "improper" ferroelectricity, where – as already mentioned above – polarization is a *secondary* order parameter, whose behavior is controlled by a symmetry-lowering

◄─────────────────────────────────────

(**a**) Left: Mn-O arrangement with Mn-disordered spins (filled blue circles). Right: oxygen displacements (represented by black arrows) occurring with zigzag chains of Mn spins (open and crossed blue circles denote up and down spin, respectively) in the E-AFM spin ordering. Lower part: results (obtained from Monte Carlo method) for FE polarization as a function of the Mn-O-Mn angle for different values of the AFM superexchange constant J_{AF}. (Reprinted from Sergienko et al. 2006). (**b**) Results from DFT of total energy along the ferroelectric switching path. Here the switching path is obtained by changing the orientation of the central spins (cfr gray regions in the central configuration) with respect to the Mn spin in the origin of the unit cell. (**c**) Polarization calculated via the point charge model (empty blue diamonds), via Berry phases within DFT (filled red diamonds), and via Berry phases within DFT for centrosymmetric structure (pink triangles). Panels (**b**, **c**) are reprinted from Picozzi et al. 2007). (**d**) Temperature dependence of the FE polarization along the *a*-axis in orthorhombic YMnO3 in the AFM-E spin configuration. The inset shows the P-E hysteresis curve measured at 35 K. (Reprinted from Nakamura et al. 2011)

primary electronic transition (very often, though not always, of "electronic" origin). $BiFeO_3$ clearly belongs to the first class, its transition being induced by the Bi $6s$ "lone pair." As shown in Fig. 4a), Bi is surrounded by 12 O atoms, 6 of which approximatively lie in the same plane of Bi (with a marginal role for the FE transition), whereas the other 6 oxygens form a prismatic cage. Under FE distortion, the main FE mode involve Bi displacing toward three of them, forming therefore three short and three long bonds, consistently with the lone-pair distribution lying opposite to the short bonds. Since FE requires bistability, it is important to focus also on the configuration showing opposite FE polarization. In the $BiFeO_3$ case, this involves an opposite shift of Bi toward the other three O in the prismatic cage, as shown in Fig. 5a').

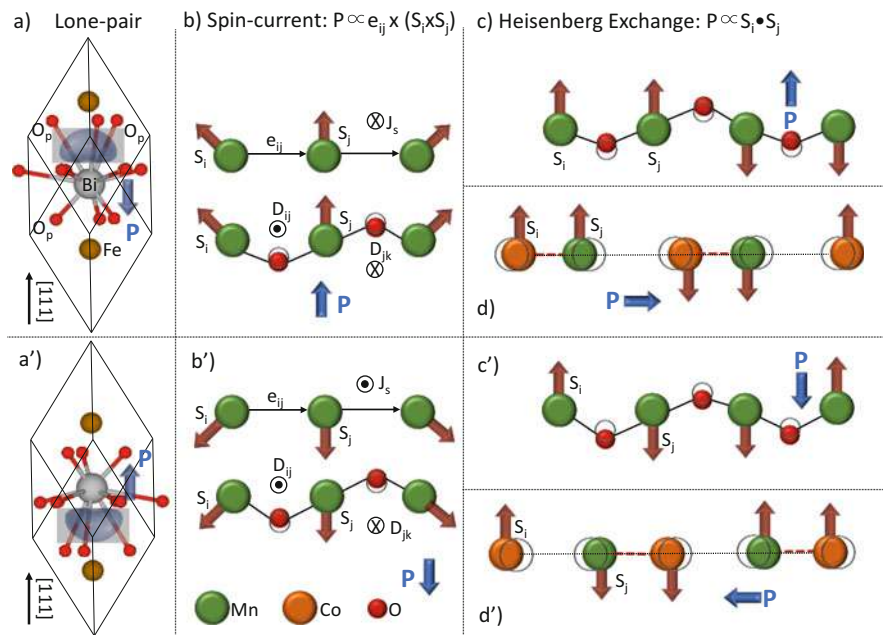
Among MF belonging to the second class, we mention that in both $TbMnO_3$ and $(Ho/Y)MnO_3$, ferroelectricity is spin-induced. At this point, we incidentally mention that another classification exists: Khomskii (2009) proposed to classify as "type II" all those MF where ferroelectricity has a magnetic origin and as "type I" all the others. We remark, however, that no matter which classification one follows, the origin of ferroelectricity constitutes the main ingredient to characterize a specific MF. Within spin-induced ferroelectricity (Dong et al. 2015; Tokura et al. 2014), one often distinguishes P as being originated by two kinds of exchange interactions: (A) symmetric (Heisenberg-like, i.e., of the form $P \propto S_i \cdot S_j$, pictorially represented in Fig. 5c, d) and (B) antisymmetric (Dzyaloshinskii-Moriya-like, i.e., of the form $P \propto e_{ij} \times (S_i \times S_j)$, pictorially represented in Fig. 5b). Since the Heisenberg exchange interaction in *3d*-TMO is usually much stronger than the DM exchange (based on relativistic spin-orbit coupling), the first class of MF usually shows a much larger polarization than the second class (typically, the order of magnitude of *P* are 0.1–1 $\mu C/cm^2$ and 0.01–0.1 $\mu C/cm^2$, for class (A) and (B), respectively). Common to both classes is the observation that polarization is the sum of a purely "electronic" term (i.e., not involving ionic relaxations with respect to ideal centrosymmetric positions) and of an "exchange-striction" term, given by the atomic relaxations according to exchange-energy minimization. It is helpful to discuss first the electronic mechanism and then the exchange-strictive one. In case (B), following Katsura, Nagaosa, and Balatsky (KNB) (Katsura et al. 2007), SOC may induce an electronic charge dipole for a pair of non-collinear spins. The KNB mechanism is also often addressed as driven by "spin current," as the cross product $S_i \times S_j$ is proportional to the spin current j_s, where the DM vector acts as its vector potential. The same mechanism is also often described as "inverse DM": a spin spiral generates a uniform bias of DM, therefore producing a uniform displacement of oxygens, in turn giving rise to P (see Fig. 5b, lower part). The latter mechanism represents therefore the "exchange-strictive" term and was first proposed by Sergienko and Dagotto (2006). On the other hand, in case (A), one deals with Heisenberg-driven polarization, where the latter can even occur for collinear spins. Its most common realization is the up-up-down-down spin chains, observed in AFM-E $HoMnO_3$, Ca_3MnCoO_6 (with spin chains running along the c-axis) (Wu et al. 2009), or even in rare-earth orthoferrites (Tokunaga et al. 2008) (where the two kinds of spins involved in the symmetry-lowering exchange interaction are


Fig. 5 Main mechanisms for multiferroicity. (**a**) Lone-pair driven: displacive ferroelectricity in BiFeO$_3$. Bi displaces toward the three lower oxygens, and correspondingly the lone-pair shifts toward the three upper oxygens. (**a'**) Opposite polarization state with respect to (**a**): Bi displaces toward the three upper oxygens and correspondingly the lone-pair shifts toward the three lower oxygens. (**b**) Spin-current-driven ferroelectricity (e.g., in spin-spiral TbMnO$_3$): polarization according to the KNB model (i.e., electronic term, upper part of the panel) and according to the Sergienko-Dagotto's model (i.e., ionic contribution guided by exchange striction, lower part of the panel). O atoms in paramagnetic (centrosymmetric) configuration are represented with empty black circles, consistent with (magnetic-independent) octahedral tilting. Upon spin-spiral ordering, the O atoms displace downward (see red spheres). (**b'**) Opposite polarization state with respect to (**b**): the spin-spiral rotation is reversed, leading to an opposite spin current (see upper part of the panel). As such, even the O displacements are reversed (O ions displace upward – see difference between black circles and red spheres), leading to an opposite exchange-strictive contribution (lower part of the panel). (**c, d**) Heisenberg-exchange-driven ferroelectricity in (**c**) AFM-E (Ho/Y)MnO$_3$ and (**d**) Ca$_3$CoMnO$_6$ – lower part. In ortho-manganites, with respect to the undistorted structure with centrosymmetric positions (empty black circles), O ions displace to reduce (increase) the Mn-O-Mn angle if the Mn spins are antiparallel (parallel) – see red spheres. In Ca$_3$CoMnO$_6$, with respect to the undistorted structure with centrosymmetric positions (empty black circles), Co and Mn get closer (farther) for parallel (antiparallel) spins. (**c', d'**) Opposite polarization state with half of spins switched. In this case, the exchange-striction mechanism is reversed (due to opposite couple of parallel and antiparallel spins). In all panels, the light blue arrows represent the axis and orientation of FE polarization

3d of iron and *4f* of the rare-earth ion). The purely electronic term contributing to polarization can be understood as follows: (a) in the case of ortho-manganites, by considering that the charge cloud around the O linking two Mn is different depending on whether the two spins are parallel or antiparallel, and (b) in the case

of Co-Mn, by considering that the charge cloud in between Co and Mn is different, depending on whether their spins are parallel or antiparallel. As for the exchange-strictive term in ortho-manganites, as briefly mentioned, the Mn-O-Mn angle is very sensitive to the spins on the two Mn ions: it tends to be closer to (smaller than) 180° for parallel (antiparallel) spins. Similarly, two different spins (say, Co and Mn as in Ca_3MnCoO_6) tend to be closer (farther) in the case of parallel (antiparallel) spins. In both situations (A) and (B), both the exchange-strictive and the purely electronic terms are relevant, and DFT reveals as a precious tool to quantify them (as previously discussed and shown in Figs. 3 and 4).

We remark that, due to lack of space, only few mechanisms were here selected and described in detail. However, several more mechanisms were proposed, and we mention those that were carefully addressed from the first-principles point of view:

(i) the so-called hybrid improper ferroelectricity (HIF) (Perez-Mato et al. 2004), involving a trilinear coupling between two unstable nonpolar modes coupled with a polar mode (which might itself be stable or "hard" when taken alone, but that is softened or "activated," thanks to the coupling with the other two modes). HIF was successfully proposed also for multiferroics and/or magnetoelectrics, for example, in the layered perovskite $Ca_3Mn_2O_7$ (Benedek and Fennie 2011) or in metal-organic frameworks (Stroppa et al. 2013);

(ii) polarization driven by charge-ordering or charge-spin ordering, i.e., polarization arising from a SIS-breaking charge-ordering transition or from a combined spin-charge transition (see, e.g., in magnetite (Alexe 2009; Yamauchi et al. 2009), half-doped manganites (Giovannetti et al. 2009a), or nickelates (Giovannetti et al. 2009b));

(iii) spin-dependent p-d hybridization, requiring relativistic SOC, as discussed in Jia et al. (2007), Xiang et al. (2013b), and Mochizuki (2011).

4   Bulk Ferroelectric Rashba Semiconductors

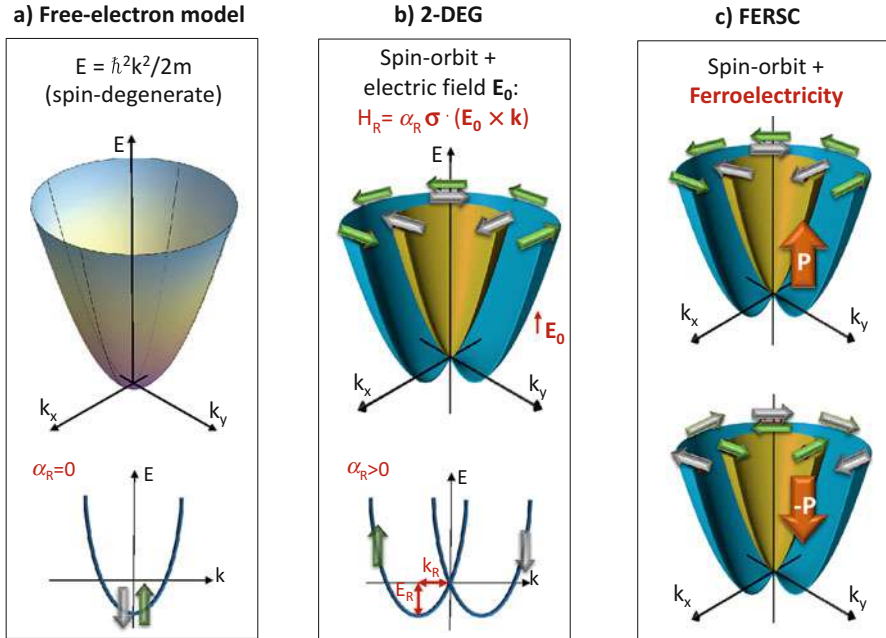
In order to understand the concept behind FERSC, it is necessary to first discuss where the Rashba effect originates from (Rashba 1960; Bihlmayer 2015), by considering the conduction band minimum (or equivalently, valence band maximum) of a conventional semiconductor. In a rough "free electron approximation" and in the presence of both SIS and TRS, the electronic bands are spin doubly degenerated for any $\mathbf{k}$-point in the Brillouin zone (cfr Fig. 6a). On the other hand, when considering the case of a two-dimensional electron gas (2DEG), for example, at the surface of a semiconductor, one can assume an electric field $\mathbf{E_0}$ perpendicular to the 2DEG plane (cfr Fig. 6b), so that SIS is broken. According to relativistic Lorenz transformations, an electron traveling with momentum $\mathbf{p}$ in the 2DEG plane will therefore experience an effective magnetic field $\mathbf{B_{eff}} \sim \mathbf{E_0} \times \mathbf{p}/mc^2$ in its rest frame, which the electron spin couples to via a Zeeman term (i.e., spin-orbit coupling). Carriers will therefore be subject to the so-called Rashba effect (RE), i.e., a $\mathbf{k}$-dependent spin splitting of


Fig. 6 From the free-electron model to the Rashba effect in 2DEG to FERSC. (**a**) Free-electron model, leading to parabolic spin-degenerate bands (both SIS and TRS are present). Upper and lower parts show a 3D view and 2D cut. (**b**) 2DEG model. In the presence of a surface or an interface, SOC + electric field (i.e., broken SIS) lead to the Rashba effect (i.e., a linear-in-k term is used in the Rashba Hamiltonian H_R with a coefficient α_R). Upper and lower parts show a 3D and 2D view. In the latter, the two conventional parameters to quantify the Rashba effect are defined: the difference in reciprocal space between the **k**-point where the minimum of the energy is located with respect to the high-symmetry **k**-point is labeled "k_R," whereas the difference in energies between the minimum of the conduction band and the energy at which the two spin-split bands cross – on the "diabolic" point – is labeled "E_R." The Rashba coefficient is defined as $\alpha_R = 2E_R/k_R$. (**c**) Rashba effect in FERSC (SIS broken): the spin texture is switched when polarization (see orange arrow) is switched. In all panels, green and gray arrows represent spins (i.e., spin-expectation value on the single eigenstate for a certain band index n and wave-vector **k**)

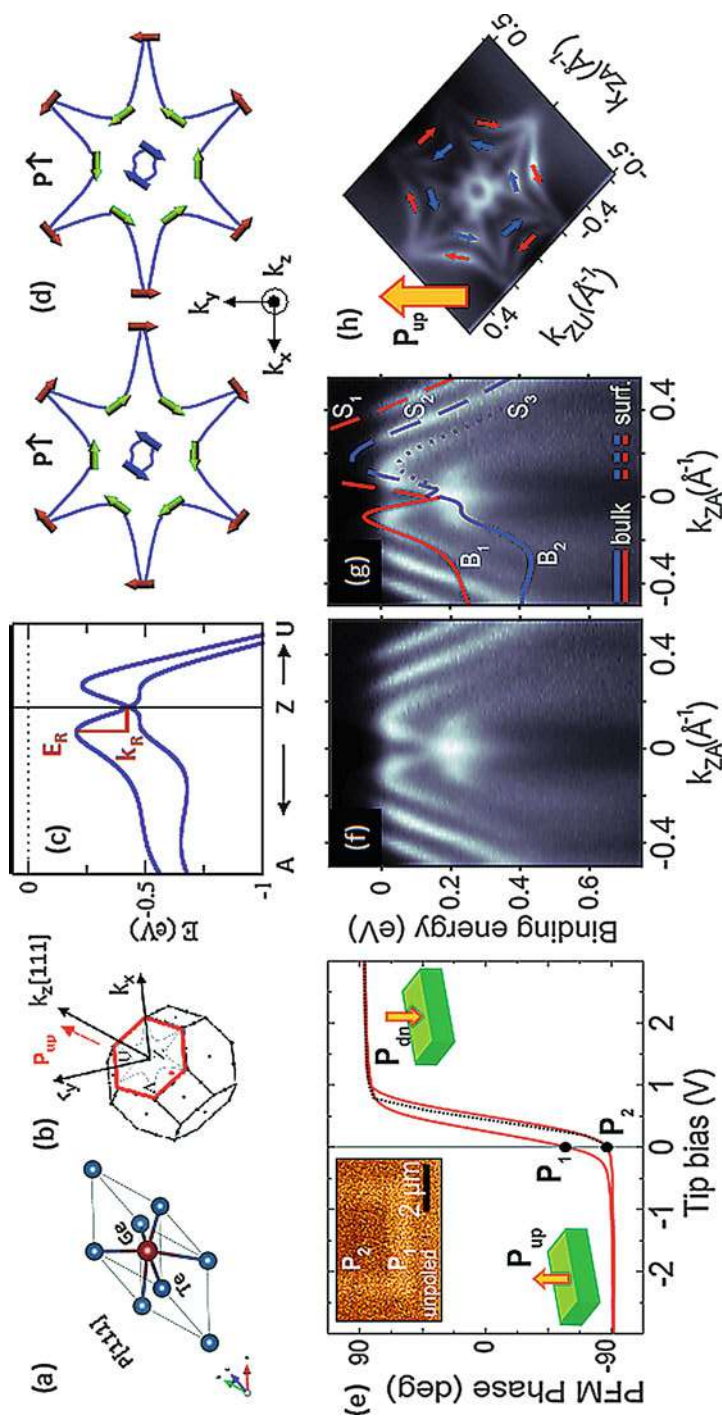
the electronic band structure [even of nonmagnetic compounds, see Fig. 6b). The Rashba Hamiltonian is usually written in terms of a linear-in-momentum term H_R (cfr Fig. 6b), leading to a spin polarization perpendicular to both $\mathbf{E_0}$ and momentum. Going beyond the usual picture of RE occurring at surfaces (or interfaces),there is conceptually nothing preventing the RE to occur in "bulk" materials. In particular, in ferroelectrics, the permanent and switchable polarization along a polar axis renders the compound intrinsically anisotropic, with an "effective Weiss-like" electric field able to generate momentum-dependent Rashba spin splitting in the plane (in reciprocal space) perpendicular to P. In this case, the spin-expectation value for any band with band index n and eigenvalue $\varepsilon_n(\mathbf{k})$ lies predominantly in the plane, i.e., perpendicular to the momentum and tangent to the energy isosurface $\varepsilon = \varepsilon_n(\mathbf{k})$ (see


Fig. 7 (continued)

Fig. 6c). Moreover, an additional functionality brings up the main FERSC feature (Di Sante et al. 2013; Picozzi 2014): as shown in Fig. 6c (upper and lower parts), when switching the polarization direction, the Rashba field also becomes opposite, so that the spin texture is reversed. One therefore achieves a full control of the spin texture with an electric field in a nonvolatile way, i.e., due to bistability, each FE state is permanently kept even when the poling electric field used for switching is turned off.

4.1   The Prototypical FERSC: GeTe

The first example of RE in a "bulk" material was BiTeI, a polar layered material where ab initio predictions and angle-resolved photoemission spectroscopy (ARPES) reported a planar spin texture with huge RE (Ishizaka 2011; Crepaldi 2012). However, BiTeI – despite showing a polar axis – is not FE, i.e., the dipole moment cannot be switched. In 2013, Picozzi's group therefore proposed GeTe (Di Sante et al. 2013), known as a FE semiconductor with high Curie temperature ($T_C = 720$ K), rhombohedrally distorted rock salt structure (space group $R3m$), and ferroelectric P parallel to [111] (Fig. 7a). First-principles predictions showed not only that a gigantic RE is present (see Fig. 7c) but also that a switchable spin texture can be obtained upon polarization switching (i.e., when applying opposite electric fields, Fig. 7d). GeTe was therefore considered the first example of FERSC. While GeTe showed groundbreaking potential from ab initio predictions, its experimental confirmation posed many challenges, due to deviations from the simulated "ideal" crystal: GeTe is usually a highly defective material, with large concentration of Ge vacancies which makes it a degenerate p-type semiconductor. In order to probe the RE and the whole FERSC concept, epitaxial (111) GeTe films were grown on Si(111) using molecular beam epitaxy, and FE properties were confirmed via piezo-force microscopy (PFM): as first discussed in Liebmann (2016), Fig. 7e
Fig. 7 Relevant properties of GeTe. (**a**) Rhombohedral unit cell of GeTe (polarization pointing along the pseudo-cubic [111] axis). (**b**) GeTe Brillouin zone. The direction corresponding to polarization, the related perpendicular plane, and the relevant A-Z-U directions are highlighted. (**c**) DFT-calculated (SOC included) valence maximum bands along ZA and ZU directions. The Rashba splitting is evident, with E_R ($\approx$230 meV) and k_R (≈ 0.09 Å^{-1}) Rashba parameters highlighted ($\alpha_R = 4.8$ eVÅ). (**d**) Theoretical CEM obtained by cutting the band structure in the ZAU plane at a binding energy of around -0.4 eV. The sixfold symmetry of the crystal is evident, while the circulation of the spins (see arrows for the inner and outer branches representing the spin-expectation value in the ZAU plane) is consistent with the RE. A reversal of the FE polarization P completely revers the sense of circulation (cfr left and right part). (**e**) FE hysteresis loop of GeTe(111) measured by piezo-force microscopy, with P pointing outward with respect to the sample surface. Inset: FE domains written by an AFM tip. (**b**) ARPES measured along ZA direction (for photon energy $\mathbf{h}\nu = 20$ eV). (**c**) Comparison between experimental and DFT-calculated surface (S_i) and bulk bands (B_i). (**d**) Measured CEM close to the Fermi level shows the expected "starlike" shape, in excellent agreement with theoretical data. Panels (**a–d**) are adapted from Di Sante et al. (2013); panels (**e–h**) are adapted from Liebmann (2016)

shows a clear FE hysteresis loop along with the possibility to write stable FE domains by applying a voltage bias to the tip of an atomic force microscope. It was also shown that the as-grown surface displays a FE stable state with polarization pointing outward with respect to the sample surface. Spin-ARPES measurements were performed and showed clearly visible Rashba bands along the ZA direction (cfr Fig. 7f, g). When performing a theory-experiment comparison, a remarkably good agreement was achieved, allowing to disentangle surface states and bulk bands and to conclude that the material shows a giant Rashba splitting both for surface and bulk bands. Moreover, Fig. 7h shows a constant energy map (CEM) close to the Fermi level: by probing the spin texture, the spin direction was found to lie predominantly perpendicular to the **k**-vector with a sense of circulation consistent with DFT predictions for an outward polarization, confirming the overall picture of a gigantic RE.

4.2   Additional Results on FERSC and Discussion

Since the first proposal on GeTe in 2013, many different bulk FE materials have been theoretically explored in view of possible switchable RE, ranging from oxides (Davanse da Silveira et al. 2016; Tao et al. 2017), to chalcogenides to small-gap semiconductors (Di Sante et al. 2016; Narayan 2015) and from "fully 3D" compounds to layered systems (Bruyer et al. 2016). In closer detail, a class of materials which has attracted an incredible attention in view of groundbreaking performances for photovoltaics are hybrid organic-inorganic halides, such as methylammonium lead iodide. Due to the presence of heavy elements (like I, Pb, Sn, etc.), SOC effects are relevant. This class of materials was therefore put forward as possible FERSC, in the case of (highly debated (Beilsten-Edmands et al. 2011)) FE ordering of the polar molecular groups (Stroppa et al. 2014; Kepenekian et al. 2015), with an envisaged crucial role of the RE for the excellent photovoltaic performances of these materials (Etienne et al. 2016; Zheng et al. 2015). From the experimental point of view, the research activity of FERSC is much less advanced, and, to our knowledge, GeTe remains the only experimentally studied FERSC so far.

5   Remarks and Conclusions

5.1   Theoretical Considerations

The aim of this subsection is to discuss potentialities and limits and advantages and disadvantages of DFT simulations in the framework of multiferroics and FERSC.

Let us first focus on multiferroics. In addition to the groundbreaking technological perspectives and to experimental synthesis/characterization challenges, from the theoretical point of view, part of the excitement toward this field was driven by the need to find new microscopic mechanisms that could give rise to the coupling between dipolar and spin degrees of freedom. As such, DFT with respect to other

techniques for materials modeling (e.g., devoted to multiscale or time-/temperature-dependent approaches) was particularly important and adequate. With respect to microscopic mechanisms, materials modeling in multiferroics has followed two parallel and complementary approaches, based on the one side on model Hamiltonians and on the other side on first-principles simulations. Undoubtedly, model-Hamiltonian approaches can provide a lot of hints on the microscopic origin of multiferroicity/magnetoelectricity; however, for a quantitative estimate of the different contributions involved, one needs to perform a DFT analysis, the latter being the only approach that can take into account all the different quantum-mechanical degrees of freedom at the same time and within a similar accuracy.

We would like to point out that performing DFT simulations for multiferroics (and complex oxides in general) is extremely challenging and the demands that the physics of multiferroics imposes on theory are extremely high. First, one has to deal with structural complexity: multiferroic oxides often show complicated structures, in presence of Jahn-Teller distortions, octahedral tilting and rotation of the oxygen cages, ferroelectric distortions, etc. Second, simulations need to take into account magnetic complexity: multiferroics often show exotic spin structures, such as non-collinear spin arrangements, like spirals, cycloids, spin canting, etc. Third, complex electronic correlations lead to an intricate interplay between spin, charge, and orbital degrees of freedom. In that case, conventional exchange-correlation functionals (like LDA (Jones and Gunnarsson 1989) or GGA (Perdew et al. 1996)) are generally not accurate enough, so alternative approaches such as the Hubbard-like DFT+U formalism (Anisimov et al. 1997) or hybrid functionals (Heyd 2003) are usually adopted for a better description of d- or f-electrons. However, both techniques are not "fully first principles," as they depend on parameters (the Hubbard-U and exchange-J within DFT+U (Anisimov et al. 1997) and the percentage of local vs Hartree exchange in hybrid functionals), usually provided by the users as external quantities. Finally, delicate relativistic effects have to be properly treated; for example, SOC is the driving mechanism in many electronic multiferroics, and simulations need to include SOC to evaluate the FE polarization in $TbMnO_3$.

As for FERSC, the prediction of the energy band gap is often crucial for a quantitative estimate of the Rashba effect, since the coupling between occupied and unoccupied states is believed to influence the magnitude of the Rashba spin splitting (Bahramy 2011). As is well known, DFT within conventional LDA or GGA exchange-correlation functionals underestimates the size of the gap, due to inaccurate treatment of excited states. Therefore, more rigorous techniques such as GW (Hybertsen 1986) or hybrid functionals (Heyd 2003) need to be used. However, a significant increase in the computational cost arises and makes the simulations accessible only when the unit cells are relatively small (say, of the order of 100 atoms for hybrid functionals).

As a final note, a word of caution to the reader is in order. Quantitative differences can occasionally arise in specific cases when comparing theory and experiments for multiferroics and FERSC, as far as polarization, structural properties, exchange coupling constants, anisotropy axis, energy band gaps, etc. are concerned. We however remark that DFT is very seldom incorrect in predicting *trends* vs strain,

pressure, doping, chemical constituents, etc. As such, DFT remains the technique of first choice when performing systematic studies of classes of materials, thereby including multiferroics and FERSC.

5.2   Outlook

The field of MF, after considerable progress in fundamental understanding in the last 15 years, is now moving forward to applications, especially in view of low-power electronics where exploiting electric fields rather than magnetic fields should bring the highest advantage (Scott 2000; Mundy 2016). Another promising area for ferroelectrics and MF could be related to energy harvesting in terms of light-to-electricity conversion, for example, exploiting dissipationless "shift currents" due to bulk photovoltaic effects in FE materials (Grinberg 2013). Although some progresses have been made specifically from the first-principles point of view (Young and Rappe 2012), this emerging field still requires a lot of fundamental understanding both from phenomenological models and from ab initio approaches. From the modeling point of view (both at the DFT and more phenomenological level), certainly an important field is that of FE/magnetic/MF domain walls, where totally different properties with respect to their corresponding "bulk-like" domains could be expected: different conductivities, different magnetic orders, and different tunability upon applied fields, all at the nanoscale (Seidel 2009; Meier et al. 2012). However, little theoretical work has been done so far, due to severe challenges, ranging from length scales (i.e., very large for first-principles simulations) to choosing appropriate boundary conditions, combined with still too few experimental data to compare with. A certainly exciting topic is the (linear) dynamical ME response, i.e., extending the static response to different frequency ranges (including optical one): $H(\omega)=\alpha(\omega)E(\omega)$. This involves the study of electromagnons (Pimenov 2006; Takahashi et al. 2013), spin wave excitations which are electrically active, where modeling from the first-principles point of view poses several challenges, as for the difficult treatment of excited and correlated states. Furthermore, nowadays topology is more and more commonly accepted as an additional degree of freedom in condensed matter. Little has been done in this respect in the field of MF, even less from the modeling point of view, although some topological FE insulators were addressed from first principles (Di Sante et al. 2016; Plekhanov et al. 2014; Liu et al. 2016). The connection between topology and correlations, gaining an increasing importance, might see MF to play a relevant role in the coming years. Within the same topology-related areas, an intriguing field where MF and ME could play a relevant role is magnetic skyrmions (Skyrme 1961; Roessler et al. 2006). We recall that skyrmions are vortex-like arrangements of spins (with typical size of tens of nanometers) whose spin texture is topologically nontrivial in real space and, being topologically protected macroscopic objects, can be used as nanometer-sized information carriers for high-memory density devices with low driving currents. Experimentally, in the chiral lattice of Cu_2OSeO_3 ferromagnetic oxide (Seki et al. 2012), skyrmions were found to induce FE polarization and could be electrically

controlled. Skyrmions were also observed in MF lacunar spinels, such as GaV_4S_8 (Kézsmarki 2015). From the modeling point of view, an outstanding challenge is the accurate and quantitatively reliable estimate of the DM interaction (Xiang et al. 2013a; Weingart et al. 2012), at the basis of the skyrmion emergence. In correlated materials, tiny quantities such as relativistic DM might show a strong dependence on the (often unknown) Hubbard parameters U and J within the DFT+U formalism, which questions the predictive power of DFT in the field of skyrmions and calls for other approaches to be developed and tested.

As for FERSC, the field is so new that it is hard to envisage how it will evolve. First of all, progress should be made from the experimental point of view. Indeed, GeTe was found (Liebmann 2016) via (spin)-ARPES to show a giant Rashba spin splitting, but the main concept of FERSC, i.e., an opposite spin polarization corresponding to opposite FE polarization, could not be detected yet, due to difficulties in switching ferroelectricity caused by overly conductive samples. In general, FERSC might evolve along three different lines (modeling being crucial in all of them): (i) from the fundamental point of view, it is not clear yet how to optimize/maximize the Rashba spin splitting and which are the main ingredients that influence it. In fact, the situation is more complex than what can be naively thought: the Rashba splitting is not simply proportional to polarization or atomic SOC, but depends on hybridization, orbital character, symmetry constraints, etc. In this context, the role of orbital angular momentum was put forward, leading to an "orbital Rashba" effect as a counterpart of the conventional spin RE (Kim 2013). (ii) From the materials science point of view, there is certainly a large activity to be carried out, as many FE materials exist and could potentially show large RE. More (spin)-ARPES studies on different FE compounds should therefore be performed in order to probe the band structure. (iii) From the technological point of view, FERSC offer intriguing perspectives in semiconductor spintronics, offering the appealing possibility to combine computing/logic and memory functions in a single material and in view of achieving efficient spin-to-charge conversion (Manchon et al. 2015). Many of the devices based on FERSC still have to be designed, with only a first conceptual example of a modified Datta-Das spin transistor reported in Di Sante et al. (2013). The concept of FERSC could also easily branch into neighboring areas: (1) topology, as SOC plays a crucial role in both RE and band inversion leading to nontrivial topological properties. Indeed, SnTe – a prototypical topological crystalline insulator (TCI) – was theoretically explored along this direction (Plekhanov et al. 2014), with the outcome that FERSC and TCI behaviors are not mutually exclusive. (2) Phase change materials (PCM) (Raoux and Wuttig 2009) are compounds which exist in an amorphous phase and in a crystalline phase. By means of optical pulses or electrical Joule heating, PCM can be rapidly and repeatedly switched between the amorphous and crystalline states (with related significant changes of their optical and electronic properties), which eventually allow them to be used for data storage. Being GeTe one of the paradigmatic examples of PCM, the connection between FERSC and PCM physics might be explored in the near future. (3) A plethora of interesting spin-related effects, in addition to the RE, might arise when inversion symmetry is broken in

nonmagnetic compounds; most of them are mediated by SOC and range from spin-valley coupling (Xu et al. 2014; Yamauchi et al. 2015) to electronic nematic phases in correlated metals (Harter et al. 2017). We also mention the theoretically proposed concept of "hidden spin polarization" (HSP) (Zhang et al. 2014), starting from the observation that SOC-induced effects are caused by the *local* rather than by the *global* symmetry of a specific material. Therefore, although in a crystal with SIS, all the bands are enforced by symmetry to be spin degenerate, the electric field is not forced to vanish everywhere (e.g., there might be an inversion asymmetry around a specific atom). As such, it might locally induce a spin polarization in the degenerate bands. A key feature of HSP is that the contributions to such bands are spatially localized on different parts/atoms of the unit cell (i.e., "inversion partners") and show opposite spin textures, so that an overall compensation of the spin polarization is present over the bulk crystal (Slawinska et al. 2016).

We conclude by saying that materials modeling in both FERSC and MF has been, since their birth, absolutely crucial and will likely continue to be so, due to the complexity of the involved phenomena and to the presence of coexisting/competing effects. The latter can be hardly addressed, unless a first-principles approach – which takes into account all the degrees of freedom at the same time – is employed. In this respect, DFT will undoubtedly play a major role for the future development of FERSC and MF and for their prospective scientific and technological impact.

Applications of Multi-scale Modeling to Spin Dynamics in Spintronics Devices

19

Riccardo Hertel

Contents

Abstract

The design of modern spintronic applications relies on the accurate simulation of nanomagnetic structures in realistic situations. Simulations can be particularly challenging when they need to consider effects that unfold on vastly different length scales. Multiscale modeling techniques are a powerful way to treat such cases, especially when the different length scales are coupled, such

R. Hertel (✉)

e-mail: riccardo.hertel@ipcms.unistra.fr

that the coarse length scale cannot be modeled without considering the fine scale or vice versa. This chapter discusses various approaches and features of multiscale simulations of the magnetization in micro- and nanomagnetism. It gives an overview of numerical techniques used in this scientific domain to bridge different length scales and discusses recent multiscale studies in three-dimensional nanomagnetism. The transition to three dimensions that is currently occurring in nanomagnetic research entails new challenges for the modeling of the magnetization. One of the reasons is the occurrence of Bloch points, as three-dimensional magnetic switching processes often involve the nucleation and propagation of these singularities of the magnetization field. Bloch points are three-dimensional magnetization structures that extend over several tens of nanometers and which require an atomistic treatment of their core region. Fully dynamic micromagnetic multiscale simulations with atomistic-continuum coupling have recently been used to simulate the field-driven motion of Bloch points. The transfer of multiscale modeling known from other domains of material science to the simulation of magnetic structures has made it possible to perform numerical studies providing insight into the structure and dynamics of Bloch points and their interaction with the atomic lattice.

1   Introduction

Simulation studies play a central role in the research on magnetic nanostructures and their application in spintronic devices. Modern computer simulations can provide insight into magnetic processes and structures that are often inaccessible by experimental observation, and they can thereby support the design of spintronic applications. To ensure high reliability and ultimately predictive power for such purposes, simulations must be applicable beyond idealized model cases. In order to reproduce realistic situations, simulations often have to take into account processes and effects that occur on disparate length scales. In spite of the ongoing increase of available computational power and the advent of GPU-based supercomputing, which has made it possible to perform micromagnetic simulations of ever larger systems over the past years (Kakay et al. 2010; Li et al. 2010; Lopez-Diaz et al. 2012; Van de Wiele et al. 2012), this progress is, in itself, not sufficient to achieve multiscale functionality that is capable to bridge length scales differing by orders of magnitude. Unlike general-purpose simulation algorithms, which can be applied out-of-the-box to a variety of situations by simply changing the input parameters, multiscale modeling techniques generally require a thorough preparation of the model that is used for the specific situation, such as a spatial subdivision into a fine-scale and a coarse-scale domain. Multiscale modeling tasks are particularly complicated when the fine scale is treated with a different physical model than the coarse scale, as is the case in simulations with atomistic-continuum coupling. This chapter discusses the application of multiscale modeling techniques to micro- and nanomagnetic systems. It is argued that multiscale simulations of the magnetic structure could be particularly helpful to address the new challenges which

arise from the recent trend toward three-dimensional nanomagnetism (Fernández-Pacheco et al. 2017). In particular, a combination of atomistic and continuum models is often necessary to reliably simulate magnetic switching processes which involve the propagation of Bloch points (Arrott et al. 1979). These topological structures, discussed in detail in Sect. 4, are point defects of the magnetization, and they represent a singularity in the continuum model. They require atomistic models to address the features of their core region.

2   Overview of Multiscale Modeling in Magnetism

The literature on multiscale modeling in magnetism comprises a large spectrum of studies, treating a wide variety of situations and often using vastly different numerical methods. Before entering deeper into the subject, it is useful to briefly introduce the main approaches of multiscale simulations in solid-state magnetism. A detailed classification of the numerous multiscale models applied in the broader scope of material science can be found in Miller and Tadmor (2009).

Most multiscale simulations are effectively dual-scale, i.e., they do not include a multitude of different length scales but only two: a coarse scale and a fine scale. In the implementation, the models representing these length scales can be connected to each other in different ways. Multiscale techniques are particularly important in situations where the different length scales are strongly connected, i.e., when an accurate simulation of the coarse or macroscopic scale is not possible without considering microscopic effects unfolding on the fine length scale and vice versa. The usual approach consists in subdividing the problem into distinct regions which are treated with a different degree of accuracy, according to the local requirements. A locally higher accuracy can be achieved in the fine-scale region by refining the discretization cells or by replacing the physical model with a more microscopic one or both. When different physical models are employed, it is important to define suitable coupling mechanisms between the fine-scale and the coarse region. In material modeling, the first multiscale simulations involving an atomistic model embedded into a macroscopic continuum emerged in the 1990s (Kohlhoff et al. 1991). These models were used to investigate the propagation of cracks in brittle materials. More recently, many similar types of multiscale methods have been applied to simulate the spin structure and dynamics in magnetic materials (Jourdan et al. 2008; Andreas et al. 2014b; De Lucia et al. 2016; Poluektov et al. 2018).

Two main branches of multiscale simulations can be distinguished depending on whether or not different physical models are employed to treat the coarse scale and the fine scale, respectively. To emphasize this qualitative difference, the term *multimodel* simulations is sometimes used to describe algorithms that combine distinct modeling paradigms, such as atomistic and continuum.

In simulations involving only one physical model, the main challenge consists in solving the underlying set of equations in a large domain in which strong spatial variations of the accuracy requirements need to be considered while keeping the numerical costs within acceptable limits (Pechstein 2013). This is typically achieved

by employing discretization cells of strongly varying sizes, where a refined mesh is used in the fine-scale region. Sometimes the grid in the fine-scale region is said to be "fully refined," which means that the cell size is refined down to the atomic scale. From a technical perspective, it is usually relatively easy to bridge several length scales by means of local mesh refinement, as long as the underlying equations and the physical model remain the same. Multimodel simulations, on the other hand, are more complex as they require a seamless coupling between the fine-scale and the coarse-scale domains that are governed by different physical models. In the case of simulations with atomistic-continuum coupling, special strategies must be applied at the interface region. The coupling strategies typically involve a hybrid transition region where both models are used and fully refined meshes of the continuum model near the interface.

Another distinguishing feature of multiscale codes is whether the region of interest is spatially defined a priori or whether its location has to be determined automatically by the algorithm. Often the geometrical setup or the physical situation is such that the location of the critical region which requires a fine-scale treatment is known beforehand. In these cases, the model can be prepared accordingly, and the simulation can rely on preprocessed meshes and predefined model parameters. The situation is more complicated if the location of the region of interest needs to be determined dynamically. Such cases require a continuous adaptation of the model during the simulation, controlled by suitable criteria and indicators to identify the regions necessitating a fine-scale treatment. Because of this difference between the simulations, the term "dynamic" can be ambiguous in multiscale modeling, since it may not be immediately clear whether it only refers to the simulation of the magnetization dynamics or also to the spatial dynamics of the multiscale model.

In some cases, multiscale simulations not only combine effects unfolding on vastly different length scales but also on very different time scales. A typical example are the highly complex processes governing the ultrafast laser-induced magnetization dynamics (cf. e.g., Koopmans et al. 2010), which include electronic, phononic, and magnetic effects spanning from the femtosecond to the nanosecond range. Such problems can often be treated in the framework of sequential models (Sect. 2.4). Usually, however, multiscale simulations refer to the simulation of systems that are evolving on a common time scale but on different length scales.

2.1 Multiscale Simulation with Adaptive Meshes

In the modeling of magnetic structures, single-model multiscale simulations with adaptive mesh refinement generally address situations where the domain in which the solution is sought is much larger than the micromagnetic exchange length, discussed in Sect. 3.2. This material-dependent length scale is always in the range of at least several nanometers and is comparable to the extension of fundamental magnetic structures, like the width of domain walls or the size of vortex cores. Micromagnetic simulations generally require that the discretization size does not exceed the exchange length, but in macroscopic samples, it can be prohibitively

expensive to use cell sizes that are everywhere small enough to resolve this fine structure of the magnetization. In these cases adaptive mesh refinement strategies can be used to detect the regions which require a local refinement while using comparatively coarse cells where the magnetic structure is sufficiently smooth (Forster et al. 2002; Hertel and Kronmüller 1998; Hertel et al. 2005). In micromagnetism, the gain in computational resources obtained by adaptive mesh refinement methods has become much less important since the advent of GPU-based high-performance computing (Kakay et al. 2010; Li et al. 2010) which allows for rapid large-scale computations with desktop computers (Van de Wiele et al. 2012; Gliga et al. 2013). Moreover, data compression techniques by means of hierarchical matrix methods (Hackbusch 2015; Börm and Grasedyck 2004) have contributed significantly to the reduction of numerical costs in micromagnetic finite element modeling, thereby enabling their application to large-scale simulations (Knittel et al. 2009; Popović and Praetorius 2005).

In continuum simulations, the size of the discretization cells is merely a numerical parameter without physical meaning. While a decrease of the cell size generally reduces the discretization error due to the discrete numerical representation of the continuum equations, it does not affect the nature of the physical problem. Accordingly, there is no lower limit concerning the admissible cell size, which can be chosen even smaller than the atomistic scale. In fact, early micromagnetic simulation studies attempted to eliminate discretization errors by extrapolating the results to zero cell size (infinite discretization density) (Rave and Hubert 2000; Hertel and Kronmüller 2002). Choosing too small discretization cells is normally a waste of computational resources since the results tend to converge rapidly below a certain cell size and remain unaffected by further refinement, but there is no fundamental criterion that would prevent an infinitely fine discretization.

A transition toward an atomistic model is required when the continuum model ceases to be sufficiently accurate. In such situations, coarse-grained models may fail to capture essential physical features that can only be described on a more fine-grained level. The need for a transition from the continuum to an atomistic model results from physical considerations, which will be discussed in Sect. 3.4.

2.2 Atomistic-Continuum Coupling: Finite Differences

While finite element models are prominent in the continuum modeling of materials in general, finite difference formulations are widespread in micromagnetic continuum simulations because they provide a convenient framework for the computation of the long-range magnetostatic interaction. One way to achieve a combination of atomistic and continuum model in magnetic multiscale simulations based on finite differences consists in refining the discretization grid down to the atomistic level and connecting the surrounding continuum region by means of a coarse-graining procedure. Such models have been applied successfully, e.g., in the simulations of skyrmions (De Lucia et al. 2017) and grain boundaries (Garcia-Sanchez et al. 2005). In these models, the discretization cells in the atomically refined region are
Fig. 1 Example of a finite difference multiscale simulation with atomistic resolution in a domain wall. The cell size is gradually reduced to the atomic scale as the domain wall is approached. Reprinted figure with permission from (Jourdan et al. 2008) Copyright 2008 by the American Physical Society

interpreted as atomistic magnetic moments. The interface between the continuum and the atomistic region can either be sharp (De Lucia et al. 2016) or gradual (Jourdan et al. 2008) (Fig. 1).

Unlike finite element methods, where a continuous variation of the cell size is unproblematic, a local change of the discretization size in finite difference formulations involves averaging procedures and assumptions that connect the smaller cells to the larger ones. In micromagnetic modeling, such coarse-graining procedures can play the role of an atomistic-continuum interface, where the discretization cells belonging to the continuum adjacent to the atomistic region effectively represent coarse-grained atomistic moments. The atomistic cells, on the other hand, can be coupled to the larger cells by means of "ghost" nodes, i.e., magnetic moments located inside the continuum cell, thereby creating an overlap between atomistic and continuum region. This technique can be applied to any level of refinement and coarsening and is not limited to the atomistic-continuum transition.

In micromagnetic finite difference formulations, the equations applied to the atomistic region are often very similar to those used in the continuum region, with the only qualitative difference being the number of interacting neighbors. This similarity arises from the fact that the discretized version of the continuum term of the exchange energy takes the same form as the atomistic Heisenberg exchange model (Donahue and McMichael 1997). Also, the dipolar field can be computed with the same summation scheme for micromagnetic and atomistic cells (Jourdan et al. 2008). These types of multiscale formulations therefore share similarities with mesh refinement techniques (Garcia-Cervera and Roma 2006) applied within a single modeling paradigm. They can nevertheless be regarded as models with genuine atomistic-continuum coupling, since the refinement of the cells down to the atomic scale introduces numerical entities that share sufficient similarities with a Heisenberg model so that the refined part can be interpreted as an atomistic region. While a local cell refinement down to the atomic scale provides an acceptable

model for the atomic part, it should be noted that the atomic cells in this type of multiscale simulations are located on a regular cubic grid defined by the discretization scheme. From a crystallographic perspective, such an arrangement is unrealistic for magnetic materials, and thus one drawback of this method is that the cells representing the atomic moments are not placed at realistic atomic positions of a crystal lattice.

2.3   Atomistic-Continuum Coupling: Finite Elements

In other domains of material modeling, multimodel simulations with atomistic-continuum coupling often provide a more realistic representation of the atomistic structure in the fine-scale region (Tadmor and Miller 2012; Zamora et al. 2012). In these simulations, atomically small cells of the continuum model are used as an ingredient of the interface region but are not directly identified as parts of an atomistic model. By using the finite element method for the continuum and finite difference formulation for the atomistic part, they combine qualitatively different models, which are adapted to the modeling of the respective scales (Fig. 2, right).

In magnetism, a simulation concept with such atomistic-continuum coupling was suggested a long time ago by Kronmüller et al. (1997) as a possibility to treat grain boundaries in composite permanent magnets (Fig. 2, left). The grain boundary problem has later been treated within a sequential atomistic-continuum multiscale approach (Hrkac et al. 2010) (cf. Sect. 2.4) and by using finite difference multiscale simulations with atomistic discretization (Garcia-Sanchez et al. 2005). Finite element implementations of multimodel/multiscale simulations with atomistic-continuum coupling have been reported only recently in micro- and

nanomagnetism (Poluektov et al. 2018; Andreas et al. 2014b). In such models, the coupling mechanism between the atomistic fine-scale domain and an adjacent continuum domain is usually the most complicated aspect. This connection is typically achieved by means of some kind of overlap of the atomistic region extending into the continuum domain, which can contain a "handshake" region where both models are evaluated. The handshake region includes contributions from the atomistic and the continuum model, which are weighted depending on the distance from the interface, thereby achieving a smooth transition from purely continuum to fully atomistic. In addition to these strategies, the continuum domain is often fully refined at the interface region, such that the cell size is compatible to the atomic lattice constant. Due to the complexity of the underlying meshes and their connection within an overlapping region, it is challenging to apply these models to situations in which the location of the atomistic-continuum interfaces changes dynamically. Fully dynamic three-dimensional micromagnetic multiscale code with atomistic-continuum coupling has recently been reported by Andreas et al. (2014b). In their algorithm, atomistic fine-scale regions are inserted and displaced automatically according to the peculiarities of the magnetic structure that develops during the simulation.

2.4   Sequential Models

In micro- and nanomagnetic simulations, the term multiscale modeling is also used occasionally to describe models that connect different length scales in a sequential way. Unlike the previously discussed cases, where coarse and fine scale are solved concurrently, sequential models take the results obtained from the modeling on one length scale and transfer them as input for subsequent simulations on a different scale. The classical case of sequential models consists in calculating material parameters on a microscopic scale and to use them for simulations on a coarser scale, which is employed to address larger problems. There are several examples of this type in magnetism, where electronic calculations provide input parameters for micromagnetic simulations (Schweflinghaus et al. 2016) or where information is passed from the atomistic scale to the continuum (Kazantseva et al. 2008a; Hrkac et al. 2010). The opposite situation is also possible, where continuum models yield information on the magnetic structure, which is then used as an input for electronic calculations (Seemann et al. 2012). Such sequential multiscale simulations are mentioned here only for completeness. The rest of this chapter will deal with concurrent multiscale simulations.

3   Micromagnetic Continuum Theory

Micromagnetic theory (Brown 1963; Aharoni 2000; Hubert and Schäfer 2012; Kronmüller and Fähnle 2003) plays a central role in the modeling of ferromagnetic nanostructures since it provides a theoretical framework to describe

ferromagnetic solids at mesoscopic length scales. This continuum theory bridges the gap between the macroscopic Maxwell theory of electromagnetic fields and the atomistic treatment of condensed matter based on quantum theory. Instead of using macroscopic effective quantities such as the magnetic permeability or susceptibility, micromagnetic theory describes the properties of a ferromagnet (like, e.g., its response to an external field) by analyzing in detail the internal structure of the magnetization. Micromagnetism is the method of choice to study the properties of magnetic domains, domain walls, vortices, and other fundamental structures of the magnetization which are essential in spintronic devices (Zhu and Zheng 2002).

3.1   Basic Assumptions and Fundamental Equations

The range of validity of micromagnetic theory spans over a broad range of length scales, ranging between a few nanometers and several microns. On the large scale, the validity is limited mostly by practical considerations and by the resources that are available for computer simulations. If the problem size is too large, a micromagnetic treatment is either prohibitive or unnecessary. On the lower scale, the limits of validity can be reached in cases when the spin structure displays important features on the atomic scale that cannot be captured within a continuum model. These situations are rather exceptional in magnetic nanostructures, but they deserve particular attention. In micromagnetic modeling, situations that require a multiscale approach are typically located at the boundaries of the validity of micromagnetic theory. As a continuum theory, micromagnetism traditionally takes the role of the coarse-scale model in multiscale simulations, with atomistic models being used for the fine scale. There are however also opposite situations, where the micromagnetic model represents the fine-scale part of the simulation, while in the macroscopic part, the ferromagnet is described by effective quantities, such as the magnetic susceptibility (Bruckner et al. 2013, 2014; Schrefl et al. 2005).

In micromagnetic theory, the magnetic structure is represented as a smooth vector field of the magnetization $M(r, t)$, which is generally a function of space and time. The magnetization, defined as the density of magnetic moments, is a directional field with constant magnitude. Its magnitude is the spontaneous magnetization $M_s = |M|$, which is a material-specific constant. Besides the constraint of constant magnitude $|M|$, micromagnetic theory relies on the assumption that the magnetic structure of a ferromagnet remains mostly homogeneous on the atomic scale. This assumption is justified qualitatively by the dominant influence of the exchange interaction on short length scales, which tends to avoid strong inhomogeneities, and it is confirmed quantitatively by the value of the exchange length discussed in Sect. 3.2, which is much larger than the interatomic distance. The near homogeneity of the spin structure at the atomic scale allows to introduce the magnetization as a meaningful spatial average of the magnetic moments and thus to use a continuum model to describe the magnetic structure.

The fundamental equation of motion of the magnetization is the Landau-Lifshitz-Gilbert equation (Landau and Lifshitz 1935; Gilbert 2004)

$$\frac{d\boldsymbol{M}}{dt} = -\gamma \boldsymbol{M} \times \boldsymbol{H}_{\text{eff}} + \frac{\alpha}{M_s} \left(\boldsymbol{M} \times \frac{d\boldsymbol{M}}{dt} \right) \qquad (1)$$

where γ is the gyromagnetic ratio, α is a phenomenological damping constant, and $\boldsymbol{H}_{\text{eff}}$ is the effective field acting on the local magnetization. The effective field

$$\boldsymbol{H}_{\text{eff}} = -\frac{1}{\mu_0} \frac{\delta e}{\delta \boldsymbol{M}} \qquad (2)$$

(μ_0 is the vacuum permeability) comprises all micromagnetic energy contributions to the local energy density e, the most important of which are usually the ferromagnetic exchange, the magnetocrystalline anisotropy, the Zeeman term, and the nonlocal magnetostatic interaction energy. A detailed description of the micromagnetic energy terms and the corresponding effective fields entering the Landau-Lifshitz-Gilbert equation can be found in, e.g., Refs. (Brown 1963; Hubert and Schäfer 2012; Aharoni 2000; Kronmüller and Parkin 2012).

Given an initial magnetic structure, the standard task of micromagnetic simulations consists in numerically integrating this equation of motion of the vector field $\boldsymbol{M}$ in time until a converged state is obtained.

3.2   Exchange Lengths: Intrinsic Length Scale

The problem of different interacting length scales is ubiquitous in micromagnetism, even in situations which do not require multiscale modeling techniques. At the nanoscale, the magnetic structure in nanoelements consists of basic topological entities like domain walls or vortices that are often much smaller than the magnet itself. In spite of their small size, these fundamental structures generally have a great impact on the magnetic properties of elements used in spintronic devices, and it is necessary to use sufficiently fine discretization grids in order to ensure that these structures are resolved numerically. Vortices and domain walls have a characteristic extension that results from a balance between the long-range magnetostatic interaction and the short-range exchange interaction. This interplay of energy terms acting on different scales leads to a characteristic length scale, the exchange length,

$$l_s = \sqrt{2A/(\mu_0 M_s^2)} \qquad (3)$$

where A is the exchange constant, a material-specific parameter. The exchange length provides an intrinsic length scale that serves as an estimate of the extension of micromagnetic structures, like domain walls or vortices (Hubert and Schäfer 2012). In all known ferromagnetic materials, the exchange length is larger than at least several nanometers (Kronmüller and Fähnle 2003). This is also true for another type of micromagnetic exchange length that can be defined for magnetic

materials with strong magnetocrystalline anisotropy (Kronmüller 1962). Magnetic inhomogeneities in a ferromagnet therefore extend over a range that is much larger than the atomic lattice constant. Accordingly, atomistic models are unnecessary to simulate ordinary topological structures like vortices or domain walls. There may nevertheless be exceptional situations where the magnetic structure in a ferromagnet develops strong inhomogeneities on atomistic distances. In these cases the continuum model becomes inaccurate and should be replaced by an atomistic model that could be combined with a continuum model in a multiscale simulation. Multiscale micromagnetic simulations with atomistic-continuum coupling are typically employed in cases where pronounced inhomogeneities of the magnetization develop only in certain parts of the domain, while most regions of the nanomagnet can be safely described by means of traditional micromagnetic theory.

Another situation that requires multiscale modeling occurs on the opposite spectrum of length scales, when the magnetic structure needs to be modeled in an environment that is of a macroscopic size, i.e., a domain which is by orders of magnitude larger than the exchange length. This is often the case in the modeling of recording processes, where the micromagnetic model of the magnetic layer on a hard disk has to be embedded into macroscopic simulations of the magnetic field generated by the write head and its macroscopic coil (Schrefl et al. 2005). Sometimes it is also necessary to include thermal effects in the model, a task which may involve a description on different length scales if the heat flow is modeled on a macroscopic scale, while temperature also has an impact on the microscopic spin dynamics. The latter can be described by the stochastic version of the Landau-Lifshitz-Gilbert equation (Lyberatos et al. 1993).

3.3   Connection Between Atomistic and Continuum Theory

In the hierarchy of physical theories of ferromagnetic materials, atomistic models with classical magnetic moments provide the framework with next finer granularity following micromagnetic theory. This more fine-grained approach is not constrained by the assumptions that are used in micromagnetic theory: the direction of magnetic moments at neighboring atomic lattice sites can enclose arbitrarily large angles, and it is straightforward to extend the model to account for situations where the magnetic moment is not constant. The latter feature is implemented in the Landau-Lifshitz-Bloch equation (Chubykalo-Fesenko et al. 2006), which generalizes the Landau-Lifshitz-Gilbert equation by allowing for temporal and spatial variations of the magnitude of the magnetic moment. Accounting for a temporal collapse of the magnetic moment is particularly important in the case of ultrafast, laser-induced magnetization dynamics (Kazantseva et al. 2008b). In spite of qualitative differences, atomistic models share many similarities with micromagnetic theory. In particular, the description of the spin dynamics is governed by an atomistic version of the Landau-Lifshitz-Gilbert equation which has the same form, with effective field terms accounting for the various energy terms. The atomistic and the continuum model differ mainly in the form of two energy representations, the exchange

term and the dipolar (magnetostatic) term, and their respective effective field terms. Local energy terms like the magnetocrystalline anisotropy or the Zeeman term remain unaffected by the transition from a discrete to a continuum model.

The continuum form of the energy terms in micromagnetic theory is formally derived from microscopic principles and is obtained by means of a transition from a discrete representation to a continuum form. This is achieved by a spatial averaging procedure through which an ensemble of magnetic moments and magnetic dipoles is transformed into a continuous magnetization and into a distribution of magnetostatic volume and surface charges (Brown 1962). Atomistic models, on the other hand, are located at an intermediate level between the fundamental electronic theory that provides the basis of the material's magnetic properties and the continuum model which removes all granularity by introducing averaged quantities. They are fine-scaled with respect to the continuum model but large-scaled compared to the electronic level. Due to this intermediate position, some heuristics is used for the calculation of the dipolar field in atomistic models. In atomistic models the magnetostatic field is usually represented by a sum of point dipoles attributed to the lattice sites, while in the continuum model, the field is typically calculated by solving the Poisson equation $\Delta U = \nabla \cdot \boldsymbol{M}$ for the magnetostatic potential U, from which the demagnetizing field is obtained as a gradient field $\boldsymbol{H} = -\nabla U$. By choosing atomistic dipole moments, the atomic model introduces a coarse-grained representation of the sources of the magnetostatic fields which are of electronic origin and could in principle be represented by a continuous spin density on the atomistic scale. However, if the goal is to simulate nontrivial three-dimensional spin structures that extend beyond a size of several nanometers, a self-consistent calculation of the electronic spin density is prohibitive, and dipole sums are a natural and practical solution in view of the granularity of the model. Moreover, since the impact of the magnetostatic term is almost negligible on short distances, a possible loss of accuracy introduced by the point dipole model on the atomic scale can be considered to be insignificant.

The most important difference between the micromagnetic and the atomistic models concerns the exchange term. In the atomistic case, a Heisenberg model replaces the continuum expression. The latter considers gradients in the vector field of the magnetization, while the former contains a sum describing the interaction between neighboring magnetic moments.

$$e_{\text{exc}}^{\text{atomistic}} = -J_{ij} \sum_{i \neq j} \hat{\boldsymbol{\mu}}_i \cdot \hat{\boldsymbol{\mu}}_j \quad . \tag{4}$$

Here $\hat{\mu}_i$ is the normalized magnetic moment at the lattice site i, the sum extends over nearest neighbor sites, and J_{ij} is the Heisenberg exchange constant, while the continuum representation is

$$e_{\text{exc}}^{\text{continuum}} = \frac{A}{M_s^2} \left[\left(\nabla M_x\right)^2 + \left(\nabla M_y\right)^2 + \left(\nabla M_z\right)^2 \right] \quad . \tag{5}$$

These two energy forms are connected since the continuum form (5) can be derived from the atomistic Heisenberg term (4) by means of a Taylor expansion by assuming small angles between neighboring magnetic moments (Kittel 1949), i.e.,

$$\left| \hat{\boldsymbol{\mu}}_i - \hat{\boldsymbol{\mu}}_j \right| \ll 1 \quad . \tag{6}$$

The validity of the continuum model is challenged whenever this assumption does not hold. When particularly strong magnetic inhomogeneities develop, the continuum term should be replaced by the atomistic term.

3.4   Strongly Inhomogeneous Spin Structures

The micromagnetic exchange lengths cease to be suitable a measure when the assumption of near homogeneity of the spin structure on the atomic scale is not fulfilled. This can occur, e.g., in heterogeneous, nanocrystalline magnets, where the spin structure can be strongly inhomogeneous at the grain boundaries. Moreover, the exchange lengths are derived assuming an energetic balance resulting from a static energy minimization. Therefore, the scale described by the exchange length is not meaningful in systems that are far out of equilibrium, like in the case of laser-induced magnetic switching (Kazantseva et al. 2008b). A further case in which the magnetization becomes inhomogeneous on length scales that are much smaller than the exchange length are Bloch points, a special type of three-dimensional topological structures (Döring 1968; Feldtkeller 1965). Bloch points can form in homogeneous magnetic material and without thermal excitation. Whenever the criterion (6) is not fulfilled and the exchange lengths lose their meaning, the continuum term of the exchange energy (5) cannot be applied reliably. In such situations the fundamental assumptions of micromagnetic theory are violated, and it becomes necessary to treat the magnetic structure with a more fine-scaled, atomistic theory.

Having established that micromagnetic continuum theory is not an accurate framework to describe microscopic spin structures with inhomogeneities that are too strong to be negligible on an atomistic scale, a quantitative measure is needed to determine the degree of inhomogeneity up to which it is acceptable to apply the continuum theory. Such a measure is an important metric for dynamic multiscale simulations as it allows to identify regions which contain spin structures that require an atomistic treatment. To address this question, Andreas et al. have quantified (Andreas et al. 2014a) the degree of magnetic inhomogeneity beyond which the continuum form of the exchange energy should be replaced by a Heisenberg term. Using a one-dimensional spin spiral as a test system, the local error due to the continuum approximation was calculated as a function of the strength of the magnetic inhomogeneity. This was achieved by comparing the exchange energy computed with the continuum expression with the value obtained from the Heisenberg term. It was found that the local error remains below 0.1% if the spins rotate by 360° within a distance of at least 15 unit cells (Fig. 3).

4   Bloch Point Structures

Over the past years, research in spintronics and nanomagnetism has mostly focused on the properties of flat magnetic thin film elements. Owing to advances in synthesis methods, recent research in nanomagnetism has expanded into three dimensions (Fernández-Pacheco et al. 2017). This development has been further encouraged by theoretical works predicting new magnetic effects in three-dimensional nano-magnets (Yan et al. 2012, 2011) which could result in new functionalities (Staňo et al. 2018; Sanz-Hernández et al. 2017). A transition toward three-dimensional nanomagnets is accompanied by qualitative changes in the magnetic structure. One type of fundamental spin structures developing specifically in three-dimensional nanomagnetism are Bloch points. These complex spin structures display a number of unusual properties which make it impossible to simulate them accurately with usual micromagnetic algorithms. They rather represent archetypal examples of spin structures that can only be modeled reliably by means of multiscale modeling techniques.

4.1   Characteristic Properties and Importance of Bloch Points

Contrary to what their name suggests, Bloch points are not point-like entities but genuinely three-dimensional spin structures (Feldtkeller 1965; Döring 1968). Bloch point structures have a unique combination of topological, structural, and magnetostatic properties which distinguishes them from usual fundamental micro-magnetic structures. The terminology originates from the fact that they contain a point singularity in the continuum picture. Although this point can be regarded as a zero-dimensional entity, its position cannot be defined without the characteristic three-dimensional magnetic environment that surrounds it. There is a large family
Fig. 4 Two different versions of Bloch point structures: (**a**) vortex and (**b**) antivortex type. There exist several further categories (Malozemoff and Slonczewski 1979). Reprinted from (Hertel 2016), Copyright 2016, with permission from IOP publishing

of possible Bloch point structures, which are discussed in detail in the book by Malozemoff and Slonczewski (1979). Bloch point structures are characterized by a circulation of the magnetization around a central point, such that the entire spin space is covered (Fig. 4). Insofar, they can be considered as three-dimensional variants of magnetic vortices or antivortices. One of their defining micromagnetic properties is that any magnetization direction can be found at least once on the surface of any sphere that contains a Bloch point (Hubert and Schäfer 2012). The structurally simplest version of a Bloch point is a hedgehog structure, where the magnetization points radially away from a central point. In the continuum model, the exchange energy density of such a structure diverges at the central point, although the total exchange energy remains finite. The core of the Bloch point represents a topological defect at which the magnetization direction is undefined. In the continuum model, the singularity describes a region at which the magnetization is maximally inhomogeneous, i.e., where the magnetization direction changes by 180° on an arbitrarily small distance. The occurrence of such divergences and singularities is obviously not a physical reality, but rather indicates that the approximations of the continuum model cease to be valid. In fact, there are no singularities when Bloch point structures are treated within the framework of discrete, atomistic models.

Concerning their magnetostatic properties, Bloch points are magnetic monopoles of the magnetic field $\boldsymbol{H}$. Note that, since Bloch points are not isolated entities, their monopolar magnetostatic charge is a real physical feature which does not represent a violation of fundamental laws of physics ($\nabla \cdot \boldsymbol{B} = 0$ remains valid).

In addition to their magnetostatic charge, Bloch points carry a topological charge Q, which is similar to that of skyrmions. In a two-dimensional spin skyrmion

structure, the topological charge is determined by means of a projection of the planar magnetic structure onto a unit sphere, followed by an integration over the surface of the sphere (Pfleiderer 2011). The magnetic structure of a skyrmion projected onto a unit sphere has the same topological property as the magnetization on a unit sphere that encloses a Bloch point (without performing any projection). Therefore, like in the case of skyrmions, a nonzero, integer topological charge can be assigned to Bloch points.

In spite of their topological similarity with skyrmions, Bloch points may also be regarded as three-dimensional counterparts of magnetic vortex and antivortex structures in thin films. This is because of the role that they can play in the dynamics of three-dimensional magnetic structures, which is in many ways analogous to that of vortices in two-dimensional magnetic thin films. For example, magnetic switching processes in thin film elements are often mediated by the nucleation, propagation, and expulsion of magnetic vortices. Similarly, three-dimensional reversal processes can be accomplished by Bloch points entering, traversing, and exiting the sample. A classical example thereof is the magnetization reversal of a soft magnetic cylindrical wire (Arrott et al. 1979). Another similarity between vortices and Bloch points is that they do not occur below a critical sample size, which in the case of a vortex is known as the single-domain limit; otherwise these spin structures would dissolve in order to reduce the ferromagnetic exchange energy. In ferromagnets, these structures can only exist when they are embedded into a sufficiently large volume, so that the cumulative impact of the long-range magnetostatic interaction is sufficiently strong to stabilize them.

4.2   Micromagnetic Modeling of Bloch Points

Accurately simulating Bloch point structures and their dynamics represents a major challenge for micromagnetic simulations, since two characteristic features of Bloch points violate the basic assumptions of micromagnetic theory. Firstly, the topological defect at the center of the Bloch point is in contradiction to the assumption of a smooth and continuous vector field of the magnetization, and it is also in disagreement with the constraint $|\boldsymbol{M}| = $ const. More importantly, the assumption of small variations of the magnetization on the atomic scale is not valid in the vicinity of a Bloch point. In numerical simulations, this results in important local errors of the exchange energy density and of the corresponding effective field, as well as in an artificial pinning of the Bloch point at the discretization grid.

First attempts to address these problems within the framework of micromagnetic theory consisted in using adaptively refined meshes with a high discretization density near the Bloch point (Thiaville et al. 2003; Hertel and Kronmüller 2002). A more sophisticated approach was later presented which consists in extending the continuum model by adding a degree of freedom that, similar to the LLB equation, relaxes the constraint of constant magnitude of the magnetization (Elías and Verga 2011; Galkina et al. 1993; Lebecki et al. 2012). In these models, the singularity in the core is removed by gradually reducing $|\boldsymbol{M}|$ to zero as the center of the Bloch

point is approached. Although the validity of this phenomenological approach to reduce the magnitude of the magnetization near the Bloch point center is not firmly established, these models succeed in removing the difficulties connected with the micromagnetic simulation of Bloch points and thereby provide a description that is more reliable than ordinary micromagnetic simulations with local mesh refinement.

Simulating Bloch points in ferromagnets is generally a task of intrinsically multiscale nature. While standard micromagnetic theory fails to describe the features in the vicinity of the core region, purely atomistic models, on the other hand, cannot describe the formation and motion of Bloch points. Unless specific boundary conditions of the magnetic structure are enforced (Reinhardt 1973), a Bloch point that is not embedded into a larger micromagnetic continuum dissolves in atomistic models due to its high energy density. Bloch points are usually stabilized by the cumulative effect of the long-range magnetostatic interaction within a volume that is too large to be treated atomistically. Exceptions to this are more exotic materials with a strong antisymmetric exchange, where the short-range Dzyaloshinskii-Moriya interaction can stabilize Bloch points (Milde et al. 2013; Rybakov et al. 2015). In these situations purely atomistic models can be sufficient.

Recently, fully dynamical multiscale micromagnetic simulations with atomistic-continuum coupling have been employed to study Bloch points in an ordinary ferromagnet. This has provided quite detailed insight into the dynamics of Bloch points and their interaction with the atomic lattice structure.

4.3 Dynamic Multiscale Model with Atomistic-Continuum Coupling

Since the core region of a Bloch point structure cannot be described reliably with continuum micromagnetism, computer simulations of these magnetic structures should aim at applying an atomistic model in this part of the structure. The magnetic structure surrounding the central region can be simulated safely with continuum theory, and it would thus be unnecessarily expensive (and in practice not feasible) to simulate the entire three-dimensional Bloch point structure atomistically. Purely atomistic simulations could be used to study artificial situations, where the Bloch point structure is stabilized by imposing particular boundary conditions of the magnetization (Reinhardt 1973), but it would currently not be possible to perform fully atomistic simulations of realistic cases of Bloch point structures propagating in mesoscopic ferromagnets. Arguably the best strategy to address these situations is to apply the atomistic model only selectively, i.e., in the regions of the sample where an atomistic resolution is needed, and to enclose this atomistic part into a continuum model that describes the overall, mesoscopic magnetic structure. With such a multiscale approach, it is possible to achieve the required atomistic resolution in Bloch point cores while keeping the total number of degrees of freedom in the simulation within acceptable limits.

If the goal of micromagnetic simulation studies is to investigate the dynamics of Bloch points, the position of the region that is treated atomistically cannot be
Fig. 5 Exploded view of the multiscale sphere used in Andreas et al. (2014b) The core contains an atomistic region, which is connected to a fully refined finite element mesh with cell sizes that gradually increase toward the surface. Reprinted from (Hertel 2016), Copyright 2016, with permission from IOP Publishing

defined a priori. The problem requires a fully dynamic multiscale simulation with adaptively moving atomistic-continuum interface. The first report of a code with these characteristics is due to Andreas et al. (2014b). The authors used GPU-accelerated multiscale modeling techniques to perform dynamic simulations of the magnetic structure and succeeded in bridging several length scales. By adhering to an object-oriented programming approach, the authors encapsulate the multiscale part of the simulation within a numerical object that they called the multiscale sphere (Fig. 5). The multiscale sphere has a diameter of about 50 nm and consists of a core-shell type discretization. It contains a core region that is fully atomistic, enclosed into a spherical shell which is entirely governed by continuum micromagnetics on its outer surface. The spherical shape and the discretization within this multiscale object are optimized for the simulation of Bloch points. To design the multiscale sphere, the size of the region that requires atomistic accuracy in a static Bloch point structure was determined by using the function displayed in Fig. 3 as an error indicator, and the volume of the atomistic core region of the multiscale sphere was chosen accordingly. The transition between this atomistic central region and the surrounding continuum model occurs entirely within the multiscale sphere. By enclosing the atomistic-continuum coupling in a numerical object that can be dynamically generated, displaced, and removed, it becomes possible to adaptively apply multiscale modeling techniques where it is needed. In the simulations, this feature is used to track the position of a Bloch point during its field-driven motion. This ensures that the core of the structure is always simulated with the atomistic model. The code first identifies the positions at which the inhomogeneity is so strong that an atomistic treatment is needed. It then generates or displaces the multiscale sphere as necessary and removes it when it is no longer required. The multiscale sphere can thus be thought of as an "atomistic lens" that follows the region of interest during the simulation. Inserting and displacing the multiscale sphere inside the volume of the sample is achieved without any time-consuming remeshing of

the continuum model in the background. Moreover, several multiscale spheres can operate simultaneously (we used up to 20), with their number being limited by the available numerical resources. When different multimodel spheres intersect, they can generate a larger contiguous atomistic region.

Within the multiscale sphere, the coupling between the atomistic region in the core sphere and the continuum in the outer shell is obtained by means of a hybrid handshake region. In this interface region, both atomistic and continuum model are used. The contributions of the two models are weighted according to their position within the shell, such that the inner part is fully atomistic and the outer part fully micromagnetic. This coupling, combined with a gradual refinement of the mesh down to the atomistic scale near the core region, ensures a seamless transition between the two models. In order to couple the multiscale sphere to the surrounding "background" continuum that provides the larger magnetic structure, the sphere receives the magnetic structure from the background at the surface and transfers the magnetic structure back to the continuum model via the nodes of the unrefined background mesh that are located within the volume of the sphere. More details on the model are described in Andreas et al. (2014b).

4.4   Simulated Bloch Point Dynamics, Interaction with Atomic Lattice

The dynamic multiscale modeling technique described in the previous section has made it possible to simulate in detail the field-driven motion of a Bloch point in a cylindrical nanowire, thereby providing insight into a fundamental magnetization process that was predicted about 40 years ago by Arrott et al. (1979). In cylindrical geometries, Bloch points are part of a special type of head-to-head domain walls. These domain walls, sometimes called Bloch point walls (Da Col et al. 2014), are characterized by an azimuthal vortex structure with the magnetization circulating around the central axis of the cylinder, and they separate two domains with opposite magnetization direction aligned along the cylinder axis. The Bloch point is located in the center of the vortex domain wall and is dragged along the wire as the domain wall is displaced. The simulations revealed that Bloch points driven by moderate magnetic fields (less than 100 mT) can propagate at very high velocities (above 1000 ms^{-1}) without hindering the motion of the domain wall that contains them (Hertel 2016). In spite of its vanishing net magnetization in the core region, the Bloch point structure does not appear to have a significantly inferior mobility than the domain wall. Moreover, the simulations predict that, under specific circumstances, the motion of a field-driven Bloch point in a magnetic nanocylinder can change from a linear displacement along the cylinder axis to a complex spiraling orbit. As a Fourier analysis shows, this spiraling motion can be decomposed into two circulations with opposite sign and different amplitudes. This particular gyrating motion is probably due to the impact of the topological charge of the dynamics, as described by the Thiele equation (Thiele 1973). This is corroborated by the fact that a similarly complex motion was also reported for skyrmions, which have the same

topological charge as Bloch points. In the case of skyrmions, numerical studies have shown that the topological charge leads to a motion along a hypocycloid trajectory (Moutafis et al. 2009; Moon et al. 2014; Shiino et al. 2017), which is very similar to the complex, spiraling motion that occurs for the Bloch point.

In addition to this complex Bloch point dynamics, the studies have brought into evidence an interaction between the atomic lattice and the Bloch point. In the low-field dynamics, the relative orientation of the atomic crystal with respect to the propagation direction can significantly affect the magnetic structure and the propagation velocity of Bloch points. Note that the simulation was performed assuming vanishing magnetocrystalline anisotropy. Therefore, any interaction between the lattice and the Bloch point obtained in the simulation is not of relativistic nature, but a direct consequence of the spatial arrangement of the atomic magnetic moments in the lattice. The interaction between the crystal lattice and the Bloch point is also responsible for the occurrence of a depinning field, i.e., a minimal field strength which is necessary to initiate the motion of a Bloch point. Such a pinning of Bloch points at preferential sites within the atomic lattice was predicted already in 1973 (Reinhardt 1973) and is largely confirmed by the multiscale simulations, which moreover show that the precise value of the depinning field depends on the orientation of the crystal lattice.

Owing to the atomistic resolution provided by the multiscale simulations, it is possible to identify the position of the Bloch point within the atomic lattice, in the static case, as well as in dynamic processes. At any time step of the simulation, the position can be determined by spatially interpolating the magnetic moments of the atomic lattice, since the location of the Bloch point can be uniquely defined as the point at which the interpolated magnetic moment is equal to zero. Using this definition, one can reconstruct precisely the trajectory of the Bloch point during its motion through the crystal lattice. If the instantaneous position of the Bloch point, taken at many different time steps, is projected into a unit cell, a pattern develops which displays a discrete version of the spatial probability distribution of the Bloch point in a unit cell (Fig. 6). The set of points that is thereby obtained assembles in the form of the Wigner-Seitz cell of the crystal lattice of the magnet, thereby showing that the Bloch point is located on a midplane between two atomic lattice sites. Further inspection shows that the probability density distribution is not uniform on the Wigner-Seitz cell. Preferential facets and edges can be clearly recognized, as well as high-energy facets that the Bloch point tends to avoid during its motion.

The interaction between the Bloch point and the crystal lattice is also evidenced by adding information on the local velocity to the high-resolution data of the Bloch point position. A useful representation of the data describing the trajectory of a Bloch point moving through the crystal lattice is obtained by following the previously described principle of projecting the current position into a unit cell. This allows to correlate the local Bloch point velocity and its position within the unit cell. The result emphasizes the strong tendency of the Bloch point to avoid high-energy facets: during its motion, the Bloch point may occasionally enter a high-energy facet of the Wigner-Seitz cell. When this occurs, the Bloch point tends to leave this unfavorable region very quickly, as it immediately experiences a drastic acceleration that increases the local velocity temporarily by almost a factor of two.
Fig. 6 Left: Ensemble of the Bloch positions (displayed in orange) in an atomistic unit cell taken at different time steps during the field-driven propagation of a Bloch point. Preferred locations of the Bloch point are the edges and the square facets of the Wigner-Seitz cell. Right: Trajectory of a Bloch point moving through the crystal lattice, projected into a single unit cell. The color code displays the local velocity. Strong accelerations occur when the Bloch point enters an energetically unfavorable facet of the Wigner-Seitz cell

It should be kept in mind that, although it is possible to ascribe a position and a local velocity to a Bloch point, the analysis of its dynamics is not comparable to the motion of a particle through the crystal lattice. The position of the Bloch point is merely a point in space that is geometrically constructed according to the surrounding spin structure. It is not an isolated entity, but represents the center of a large, three-dimensional magnetic structure. Remarkably, the relatively large micromagnetic Bloch point structure is sensitive to the fine structure of the atomic lattice not only as far as the pinning in the static case is concerned but also during its high-velocity motion through the crystal.

5   Conclusions

Multiscale modeling techniques are tailored to bridge length scales that differ by several orders of magnitude. This is achieved by simulating different parts of the computational region with different degrees of accuracy. In most cases only two length scales are involved, a fine scale and a coarse scale, which may be represented by different physical models. Carefully connecting the coarse-scale and the fine-scale model makes it possible to perform large-scale simulations with high accuracy. In micro- and nanomagnetism, dynamic multiscale simulations have recently been applied to combine atomistic and continuum models. Algorithms with such capabilities could be employed to simulate the spin dynamics in future spintronic devices. These features are particularly useful in view of the ongoing technological transition toward three dimensions in nanomagnetism, where Bloch points often play a central role in magnetic switching processes. Due to their

inherent multiscale character, Bloch point structures cannot be treated reliably with traditional micromagnetic simulations. While multiscale simulations with dynamic atomistic-continuum modeling have long been applied in other domains of material modeling, they have been developed only recently in magnetic modeling. The success of these multiscale simulations in providing insight into the dynamics of Bloch points and their interaction with the crystal lattice makes them a promising starting point for future investigations of complex, three-dimensional magnetic structures.

Atomistic Spin Dynamics

20

Richard F. L. Evans

Contents

Abstract

Atomistic spin models describe a class of models which approach a discrete limit of magnetic materials, where each atom is ascribed a localized atomistic magnetic moment or *spin*. These atomic spins interact principally by the Heisenberg exchange interaction, leading to long-range magnetic order and resulting in macroscopic magnetic properties. Here we review the theoretical foundations and recent developments of atomistic spin dynamics and their application to advanced magnetic materials, thermal and ultrafast spin dynamics.

1   Introduction

The theoretical foundations of spin models were established early in the twentieth century through the discovery of the quantum mechanical property of spin (Gerlach and Stern 1924) and the formulation of the Heisenberg exchange interaction (Heisenberg 1928) giving a microscopic origin of the Weiss field (Weiss 1907). Atomistic spin models were first realized in the model of Ernst Ising (1925) which was the first attempt to formulate a description of macroscopic magnetic order from a microscopic level, which was solvable analytically. Spin models only became practically useful tools with the advent of computational physics, where the finite size properties of magnets could be studied numerically using Metropolis Monte Carlo (Metropolis et al. 1953; Binder 1969). A limitation of the Ising model is the imposition of an infinite anisotropy due to quantization of the spin direction, making it inapplicable to real magnetic materials. A generalization of the Ising model is to remove the quantization of spin and treat the atomic spins as purely classical objects, allowing them to vary freely in 3D space. This allows for more realistic simulation of magnetic materials with finite anisotropies and more complex interactions than described by a simple nearest neighbor exchange interaction, enabling Monte Carlo simulations of equilibrium properties for more realistic systems than the Ising model could describe.

With the development of general purpose computers and programming languages such as FORTRAN and C, it became possible to develop more complex algorithms and software capable of performing numerical micromagnetics. Within the micromagnetic formalism, the atomic magnetic properties are averaged over a small volume of space typically $(2–10\,\text{nm})^3$ by assuming that the magnetization direction within the cell varies continuously. This approximation is known as a continuum approximation and allows the translation of the electronic properties to equivalent large scale micromagnetic equations (Fidler and Schrefl 2000). This first allowed the solution of the ground state magnetic configuration of complex magnetic structures through energy minimization and then the development of simulated magnetization dynamics by numerical solution of the Landau-Lifshitz-Gilbert equation (Fidler and Schrefl 2000). Today micromagnetics is a standard research tool due to the availability of user friendly software packages such as OOMMF and MUMAX3 and the ability to simulate relatively large structures accessible experimentally.

Despite the ubiquity of micromagnetic simulations, they are fundamentally constrained by the continuum formulation which requires that the magnetization direction varies *slowly* in space and time. This limitation means that the dynamics of ferrimagnets and antiferromagnets cannot be properly simulated since the intrinsic magnetization direction varies strongly on the atomic scale. At high temperatures the same problem exists since the thermal fluctuations lead to atomic scale spin disorder. Many technologically important materials and devices rely on ultrathin films and structures where the material properties themselves vary on the atomic length scale and cannot be properly described by the continuum approximation. Thus, the limited applicability of the micromagnetic formalism presents a barrier to understanding the dynamics of many magnetic materials and devices.

A major innovation came with the implementation of atomistic spin dynamics, where the time-dependent behavior of atomic spins is simulated using the Landau-Lifshitz-Gilbert (LLG) equation (Landau and Lifshitz 1935; Gilbert 1955). Although pioneered in the late twentieth century (Antropov et al. 1995; Krech et al. 1998), atomistic spin dynamics simulations were too computationally expensive to be practically useful until the turn of the twenty first century. The theoretical framework with an assumed classical equation of motion allowed the natural consideration of antiferromagnets and ferrimagnets (Nowak 2007), as well as atomic level defects found in nanoparticles, surfaces, and interfaces where the magnetization direction can change significantly at the atomic scale. Atomistic spin dynamics also enables the natural study of high temperature magnetization dynamics near and above the Curie temperature where the spins are paramagnetic and also spin excitations and the spin wave density of states (DOS) (Skubic et al. 2008). All of these features avoid the fundamental continuum limitation of micromagnetics and has led to a renaissance of magnetic materials modeling where the macroscopic properties of magnetic materials can be simulated using a microscopic model with a direct link to the underlying electronic properties responsible for the emergence of magnetic interactions.

2   Atomistic Spin Models

The basis of the atomistic spin model is a discrete description of magnetism, where each atom possess a localized magnetic moment or *spin*. The validity of localized spin models is often a topic of historical debate since it seems to conflict with the Stoner model of magnetism, which explains the existence of non-integer magnetic moments in metals due to the band structure. The development of first principles calculations of the spin polarized electron density revealed that in Fe and Co the electrons responsible for the magnetic moment are well localized to the nucleus and the bonding electrons tend to have only a small net spin. This supports the localized moment picture for elemental Fe and Co, while the small moment in Ni suggests that longitudinal Stoner spin fluctuations are important (Pan et al. 2017). The local moment approximation is also not well justified for induced magnetic moments such as those found in Pt and Rh in close proximity to a $3d$ magnetic metal where the spin density is distributed over the unit cell volume.

The interactions between atomistic spins are encapsulated in the spin Hamiltonian: the full Hamiltonian of the electron system with all spin-independent terms removed. A typical spin Hamiltonian $\mathscr{H}$ consisting of Heisenberg exchange, uniaxial anisotropy, and coupling to an external applied magnetic field is given by

$$\mathscr{H} = -\sum_{i<j} J_{ij}\mathbf{S}_i \cdot \mathbf{S}_j - \sum_i k_{\mathrm{u}}\left(\mathbf{S}_i \cdot \mathbf{e}_i\right)^2 - \sum_i \boldsymbol{\mu}_i\mathbf{S}_i \cdot \mathbf{B}_{\mathrm{app}}, \qquad (1)$$

where i is the local atomic site, J_{ij} is the exchange interaction between spins, $\mathbf{S}_i$ is a unit vector giving the spin direction on atomic site i, $\mathbf{S}_j$ is a unit vector giving

the spin direction on a neighboring atomic site j, k_u is the uniaxial anisotropy constant on site i, $\mathbf{e}_i$ is a unit vector giving the magnetic easy axis for site i, $\boldsymbol{\mu}_i$ is the magnitude of the local atomic spin moment on site i, and $\mathbf{B}_\mathrm{app}$ is a vector describing the external applied magnetic (Zeeman) field.

In atomistic spin models, the exchange interaction is typically the strongest interaction by 2–4 orders of magnitude and is responsible for the alignment of atomic spins. In ferromagnets where $J_{ij} > 0$ this is apparent from the formation of magnetic domains which give rise to classic macroscopic magnetic behavior. In antiferromagnets where $J_{ij} < 0$, the atomic spins are aligned antiparallel, and so in weak external fields, the net magnetization is zero.

For applications the most important factor is often the magnetic stability of the material and its resistance to losing or changing its magnetic state. The stability of the material is determined by its preference for aligning along particular crystallographic orientations, a property usually known as magnetocrystalline anisotropy or magnetic anisotropy energy (MAE). The simplest form of anisotropy is uniaxial, where one magnetic axis is preferred over all others. The common magnets Fe and Ni have cubic anisotropy where the spins prefer to lie along six or eight symmetric crystal directions.

For small systems with a uniform shape such as nanoparticles, the exchange and anisotropy represent the most important interactions in the system. However, for larger systems, thin films, or elongated nanostructures, the dipole field becomes important and can dominate the magnetic structure. For a magnetic sample consisting of point dipoles, the magnetic dipole field $\mathbf{B}_\mathrm{dipole}^i$ at site i can be expressed as

$$\mathbf{B}_\mathrm{dipole}^i = \frac{\mu_0}{4\pi} \left(\sum_{i \neq j} \frac{3(\mathbf{S}_j \cdot \hat{\mathbf{r}})\hat{\mathbf{r}} - \mathbf{S}_j}{r^3} \right), \tag{2}$$

where r is the separation distance between atomic dipoles i and j and $\hat{\mathbf{r}}$ is a unit vector in the direction $i \rightarrow j$. This long-ranged interaction leads to a demagnetizing field which minimizes the surface magnetic charges. The main influence of the dipole field is shape anisotropy, where different shapes have preferred magnetic orientations. For example, thin films prefer an in-plane orientation of the magnetization or elongated nanoparticles prefer to align their magnetization along the long axis of the particle.

Numerically dipole fields represent a challenging problem since each and every dipole interacts with every other, making direct solution of Eq. 2 impossible for all but the smallest systems with a size of around 10,000 atoms or less. Therefore approximate solutions are often used treating the dipole fields with a micromagnetic approximation where the atomic magnetizations are averaged within a small volume of space (Evans et al. 2014). This allows the separation of time and length scales from the atomistic spin dynamics while incorporating the important physical effects of the demagnetizing field.

A realistic spin Hamiltonian for a specific material can invoke a number of more complex interactions, such as two-ion anisotropy (Callen and Callen 1966;

Mryasov et al. 2005), surface anisotropy (Yanes et al. 2007), Dzyaloshinskii-Moriya interactions (Dzyaloshinsky 1958; Moriya 1960), higher-order magnetocrystalline anisotropies (Skomski 2012), and higher-order four-spin terms (Barker and Chantrell 2015). These complex interactions are surprisingly common in most technologically relevant materials, but their application in spin dynamics simulations is a very recent development.

3   Spin Dynamics

While the spin Hamiltonian can describe a plethora of magnetic interactions and properties, by itself it is not especially useful. The many body problem of solving the time evolution of several interacting spins is not solvable analytically and so it is necessary to adopt classical simulations where the spin relaxation is treated adiabatically and without quantum mechanics. It is important to note however that all magnetic interactions are fundamentally quantum mechanical, and these are simply approximated as a classical potential with a classical evolution of the spin states. This allows for classical Monte Carlo simulations to calculate equilibrium thermodynamic properties, but these are unable to capture the time-dependent dynamics of the spin system. At the turn of the twenty first century, atomistic spin dynamics simulations became computationally feasible for the first time and over the past 20 years have evolved to become a standard modeling technique for magnetic materials.

The theoretical basis of spin dynamics is the time evolution of a single atomic spin given by the phenomenological Landau-Lifshitz-Gilbert (LLG) equation, first derived by Landau and Lifshitz (1935) and then extended by Gilbert to include a critical damping (Gilbert 1955). The equation incorporates a precession term which arises from the intrinsic quantum mechanical precession of spins and a relaxation term which aligns the net spin direction with an externally applied magnetic field. The LLG atomistic equation (Ellis et al. 2015) is given by

$$\frac{\partial \mathbf{S}_i}{\partial t} = -\frac{\gamma_i}{(1 + \lambda_i^2)}[\mathbf{S}_i \times \mathbf{B}_i + \lambda_i \mathbf{S}_i \times (\mathbf{S}_i \times \mathbf{B}_i)], \tag{3}$$

where $\mathbf{S}_i$ is the classical spin vector of length $|\mathbf{S}_i| = 1$, $\gamma_i = 1.76 \times 10^{11}$ $\mathrm{T}^{-1}\mathrm{s}^{-1}$ is the gyromagnetic ratio, λ_i is the dimensionless Gilbert damping parameter representing the coupling to the heat bath, and $\mathbf{B}_i$ is the effective magnetic field in units of tesla. At the atomistic level the, Gilbert damping is a coupling of the spin to the electronic system and lattice and as the spin precesses and leads to a loss of energy. Materials containing atoms with strong spin-orbit coupling such as Pt and Ta will typically have a high Gilbert damping (Pan et al. 2016), while insulating materials will typically have low damping. In general the lattice contribution to the Gilbert damping is weak. The effective magnetic field on each atomic spin is given by the derivative of the total spin Hamiltonian with respect to the local spin moment

plus a Langevin thermal term representing the thermal spin fluctuations (Brown 1963) and given by

$$\mathbf{B}_i = \boldsymbol{\zeta}_i(t) - \frac{1}{\mu_i} \frac{\partial \mathcal{H}}{\partial \mathbf{S}_i}, \tag{4}$$

where μ_i is the spin magnetic moment and $\boldsymbol{\zeta}_i(t)$ is a time-dependent random thermal field. The thermal fluctuations are represented by a stochastic Langevin process where the Brownian motion of the spins is simulated by a random thermal magnetic field. The statistical properties of the thermal field in time are described by a white noise process given by

$$\boldsymbol{\zeta}_i = \langle \boldsymbol{\zeta}_i^a(t) \boldsymbol{\zeta}_j^b(t) \rangle = 2\delta_{ij}\delta_{ab}(t - t') \frac{\lambda_i k_B T}{\mu_i \gamma_i}, \tag{5}$$

where

$$\langle \boldsymbol{\zeta}_i^a(t) \rangle = 0. \tag{6}$$

This stochastic Landau-Lifshitz-Gilbert equation of motion, often abbreviated to *sLLG*, describes the fundamental time dependence of classical spins in a Langevin heat bath. This enables the simulation of time-dependent phenomena and phase transitions of complex systems with an almost endless variety of fundamental interactions, properties, and structures. In particular spin waves are modeled explicitly encapsulating the essential physics of many magnetic materials at the atomic level.

The Landau-Lifshitz-Gilbert equation is the essential equation describing magnetization dynamics from atomic to micromagnetic and macroscopic length scales. The development of numerical micromagnetics required numerical solution of the LLG equation and over the years has attracted a wide range of numerical schemes including simple predictor-corrector methods, Runge-Kutta, semi-implicit, midpoint, and symplectic integration schemes. For micromagnetics the effective magnetic fields in the LLG equation are generally small (a few Tesla) and slowly varying and so the integration is essentially limited by the ability to exactly conserve the magnetization length during integration. For atomistic spin dynamics, the requirements are somewhat different since the exchange fields are large (typically 100–1000 T), and the thermal fluctuations are of a similar magnitude at high temperatures due to the atomic values of the spin moment. This firstly requires a numerical integration scheme that leads to the Stratonovich interpretation of the stochastic LLG equation, such as the Heun scheme (García-Palacios and Lázaro 1998). Secondly small time steps around 0.1 fs are required to correctly resolve the dynamics of the spins. This is because spin excitations at elevated temperatures and in ferrimagnets and antiferromagnets are especially large, leading to a rapidly changing effective field in both magnitude and direction. The rapidly changing field means that the fundamental dynamics are not limited by the numerical integration scheme but by the physics of spin dynamics at the atomic scale. Practically this means that there is no value in integration schemes more complex than Heun due to their higher numerical cost. Alternative approaches such as pulsed noise (Garanin

2017) may alleviate some of the problems with large spin excitations and allow larger time steps, but it is not yet clear that this is beneficial for antiferromagnets where the dynamics are intrinsically on the femtosecond timescale.

3.1   Quantum Statistics

In the above classical treatment, all quantum mechanical variables have been replaced with classical variables. The presence of a Langevin thermostat means that infinitesimal changes to spin orientations are allowed. In reality of course spin, transitions are discrete and caused by spin-flip scattering processes induced by incoming photons or electrons interacting with the spins. This means that there is a natural gap in the spectrum where low energy electron and photon excitations are unable to cause a spin flip. This behavior naturally leads to quantum statistics, where there are distinct spin energy levels that are populated. This can be represented in a spin model by considering the intensity of thermal fluctuations and changing their intensity to give the expected magnon distribution (Bergqvist and Bergman 2018) or parametrically by rescaling the effective temperature in the simulation (Evans et al. 2015) to give the experimentally measured temperature-dependent magnetization, which is a direct estimate of the magnon population. However, this still avoids the fundamental nature of the underlying microscopic spin-flip processes. Therefore, the thermodynamic properties of magnetic materials are only approximate and pure classical spin models typically give an incorrect temperature-dependent magnetization curve due to the classical nature of the statistics of the thermal bath.

4   Advanced Models of Magnetic Materials

Simple spin models are based on a straightforward extension of finite difference micromagnetics to atomic resolution, where each cell is the size of an atom and the continuum micromagnetic interactions are replaced with their discrete equivalents with a simple cubic lattice. While these models are qualitatively useful in describing thermal effects and atomic scale magnetism, they suffer from a weak relation to reality where the atomic structure, electronic properties, and magnetism interplay to give a complex range of magnetic phenomena in a wide diversity of magnetic materials. To better understand the magnetic properties with a high degree of specificity, it is necessary to formulate a realistic model of a material including the correct crystal structure and a realistic model of the magnetic interactions. Examples of atomistic spin models of specific materials include FePt (Mryasov et al. 2005), GdFe alloys (Ostler et al. 2011), Fe_3O_4 (Nedelkoski et al. 2017), FeRh (Barker and Chantrell 2015), YIG (Barker and Bauer 2016), $Nd_2Fe_{14}B$ (Toga et al. 2016), and IrMn (Szunyogh et al. 2009; Yanes et al. 2013), where the structure and magnetic interactions are included explicitly in the model. For atomistic spin models, such material-specific models are a relatively recent development, starting

around 20 years ago. In the future such models will be essential to fully understand the fundamental and thermodynamic properties of magnetic materials.

4.1   Amorphous GdFe Alloys

One of the main advantages of atomistic spin models over micromagnetics is the ability to correctly simulate the dynamics of ferrimagnetic and antiferromagnetic materials. In these materials, the localized atomic spins are exchange coupled in an antiparallel state. The partial or complete compensation of the magnetization at the atomic level leads to inertial spin dynamics with a rich variety of behavior making them particularly interesting at the fundamental level as well as practically important. Technologically one of the most important ferrimagnetic materials is GdFe, an amorphous alloy of the rare earth (RE) metal Gd and transition metal (TM) Fe. Here the Gd and Fe atoms form two magnetic sublattices that oppose each other and due to the different origin of the magnetic moments, *4f* and *3d* electrons, respectively. The Fe atoms draw their magnetic moments from the *3d* electrons, and the spin polarized electron density is quite well localized near the nucleus with an effective spin magnetic moment of $1.92\,\mu_B$ per atom. The Gd atoms have a magnetic moment due to the *4f* electron shell, which is lower in energy than the *6s* and *5d* shells and prefers unpaired filling of the orbitals. This leads to a large effective spin moment of $7.63\,\mu_B$ per atom. Since the *4f* electron shell is located away from the *5d* bonding electrons, the exchange coupling is weaker than in the transition metal elements, leading to a lower Curie temperature of 298 K for pure Gd metal. However, when alloyed together as GdFe, the effective Curie temperature is around 500 K which is sufficiently above room temperature to be useful for applications such as magneto-optical recording. This is because the exchange interaction from the Fe sublattice polarizes the Gd spin moments causing an increase in the effective exchange interaction and thus the Curie temperature for the coupled system.

It is possible to model the static and dynamic properties of GdFe alloys using an extended spin model explicitly considering Fe and Gd spin moments and Heisenberg exchange coupling (Ostler et al. 2011). Experimentally GdFe alloys are assumed to be amorphous where the Fe and Gd atoms are almost homogeneously distributed in the material with no short-range or long-range crystallographic order. This would add a significant degree of complexity to the simulations, with a wide range of exchange interaction strengths, coordination number, and density fluctuations. The simplest approach is to consider a magnetically amorphous material where the Gd and Fe sites are randomly distributed within a periodic crystal structure which captures the essence of the magnetic interactions and ferrimagnetic properties. Alloys used for magneto-optical recording applications typically have a composition close to $Gd_{25}Fe_{75}$ to balance the requirement for a low Curie temperature and larger magnetic moment when heating the material to enable recording of information. In thin film form when sandwiched between SiN glass, GdFe films have a strong perpendicular magnetic anisotropy, usually assumed to arise due to interfacial or surface anisotropy. Having defined the interactions in the systems, we can write down the spin Hamiltonian

$$\mathcal{H} = \mathcal{H}_{Gd} + \mathcal{H}_{Fe} \tag{7}$$

$$\mathcal{H}_{Gd} = -\sum_{i<j} J_{Gd}\mathbf{S}_i \cdot \mathbf{S}_j - \sum_{i<\delta} J_{GdFe}\mathbf{S}_i \cdot \mathbf{S}_\delta$$

$$-\sum_i k_u \left(\mathbf{S}_i \cdot \mathbf{e}_i\right)^2 - \boldsymbol{\mu}_{Gd}\sum_i \mathbf{S}_i \cdot \mathbf{B}_{app} \tag{8}$$

$$\mathcal{H}_{Fe} = -\sum_{\nu<\delta} J_{Fe}\mathbf{S}_\nu \cdot \mathbf{S}_\delta - \sum_{\nu<j} J_{GdFe}\mathbf{S}_\nu \cdot \mathbf{S}_j$$

$$-\sum_\nu k_u \left(\mathbf{S}_\nu \cdot \mathbf{e}_\nu\right)^2 - \boldsymbol{\mu}_{Fe}\sum_\nu \mathbf{S}_\nu \cdot \mathbf{B}_{app} \tag{9}$$

which explicitly lists inter-sublattice ($J_{GdFe} = -1.09 \times 10^{-21}$ J/link) and intra-sublattice ($J_{Gd} = 1.26 \times 10^{-21}$ J/link and $J_{Fe} = 2.835 \times 10^{-21}$ J/link) exchange interactions and different couplings to the applied field (Ostler et al. 2011). The anisotropy is assumed to be uniaxial due to the surface effect of SiN capping layers used in experiments with a value of $k_u = 8.07246 \times 10^{-24}$ J/atom. The form given here is encapsulated in the simplified form in Eq. 1 but is more specific in identifying relevant sets of interactions and values in the system.

Having defined the interactions in the system, it is then possible to simulate the equilibrium temperature-dependent properties using atomistic spin dynamics. Figure 1 shows the calculated temperature dependence of the equilibrium sub-lattice and total magnetizations and reproduces the main features of the material seen experimentally: a magnetic compensation point and different temperature-dependent magnetizations of the Fe and Gd sublattices (Ostler et al. 2011). It is important to note that the two magnetic sublattices in GdFe have the same Curie temperature, while their different temperature dependencies come from the different intrinsic exchange interactions, being much weaker for Gd spins compared with Fe. At the compensation point, the net magnetization is close to zero and so macroscopically the system of spins behaves like an antiferromagnet. The existence of a compensation point is only possible due to the different temperature dependences of the Fe and Gd sublattices. This arises because the Gd spins are polarized by the exchange interaction from neighboring Fe spins, which leads to order in the Gd sublattice above its intrinsic Curie temperature of 298 K. However, the spin fluctuations on the Gd sites are larger than the Fe sites due to the lower total exchange, which significantly reduces the Curie temperature of the combined system.

4.2 Magnetite

Magnetite is the oldest known magnetic material, first documented by the ancient Greeks and known in medieval times as lodestone and used as a primitive compass. Despite its long history, the origins of its magnetism are still an active subject of investigation. Magnetite is an oxide of iron with formula unit Fe_3O_4 and has a complex inverse spinel crystal structure, as shown in Fig. 2. The structural
Fig. 1 Plot of the simulated sublattice temperature-dependent magnetization of $Gd_{25}Fe_{75}$ random alloy showing the effect of increased spin fluctuations on the total magnetization. The polarizing effect of the Fe spins on the Gd spins leads to a different temperature dependence of the magnetization as seen from the shape of sublattice magnetization curves. The Fe sublattice exhibits a typical classical $M_s(T)$ curve showing critical behavior near the Curie temperature T_C, while the Gd sublattice shows an almost linear behavior. The ferrimagnetic nature of the exchange coupling between the sublattices and the different temperature-dependent magnetizations naturally leads to a magnetic compensation point where the net magnetization is close to zero. The compensation point leads to a range of complex behaviors due to the inertial magnetization dynamics

Fig. 2 Visualization of the inverse spinel crystal structure of magnetite (Fe_3O_4) showing the different magnetic site symmetries. (Image courtesy of Daniel Meilak)
complexity is typical of the vast majority of magnetic materials and represents a recent development in materials modeling where the structural and magnetic properties are strongly related and must be properly represented in the simulations. In the case of magnetite, the exchange interactions between Fe sites arise due to the double exchange interaction mediated by the oxygen atoms where its strength is determined by the relative overlap of the atomic orbitals. The crystal structure of magnetite contains two distinct sites based on the local oxygen symmetry: tetrahedral and octahedral. The site symmetries define two distinct magnetic sites with different coordination number and localized magnetic moments on the Fe ions due to the different valence states of the Fe. Expanding the spin Hamiltonian into these components we therefore have

$$\mathscr{H} = \mathscr{H}_{\text{Fe}}^{\text{T}} + \mathscr{H}_{\text{Fe}}^{\text{O}} \tag{10}$$

$$\mathscr{H}_{\text{Fe}}^{\text{T}} = -\frac{1}{2} \sum_{i,j} J_{\text{Fe}}^{\text{TT}} \mathbf{S}_i \cdot \mathbf{S}_j - \frac{1}{2} \sum_{i,\delta} J_{\text{Fe}}^{\text{TO}} \mathbf{S}_i \cdot \mathbf{S}_\delta$$

$$-\frac{k_c}{2} \sum_i \left(S_x^4 + S_y^4 + S_z^4 \right) - \mu_{\text{Fe}}^{\text{T}} \sum_i \mathbf{H}_{\text{app}} \cdot \mathbf{S}_i \tag{11}$$

$$\mathscr{H}_{\text{Fe}}^{\text{O}} = -\frac{1}{2} \sum_{v,\delta} J_{\text{Fe}}^{\text{OO}} \mathbf{S}_v \cdot \mathbf{S}_\delta - \frac{1}{2} \sum_{v,j} J_{\text{Fe}}^{\text{TO}} \mathbf{S}_v \cdot \mathbf{S}_j$$

$$-\frac{k_c}{2} \sum_v \left(S_x^4 + S_y^4 + S_z^4 \right) - \mu_{\text{Fe}}^{\text{O}} \sum_v \mathbf{H}_{\text{app}} \cdot \mathbf{S}_v, \tag{12}$$

where T and O indicate tetrahedrally coordinated and octahedrally coordinated Fe ions, respectively. The exchange coupling constants $J_{\text{Fe}}^{\text{TT}} = -2.2 \times 10^{-22}$ J/link, $J_{\text{Fe}}^{\text{TO}} = -5.256 \times 10^{-21}$ J/link, and $J_{\text{Fe}}^{\text{OO}} = -1.0206 \times 10^{-21}$ J/link represent the super exchange interactions between the tetrahedrally and octahedrally coordinated spins. Magnetite exhibits cubic crystal symmetry and so cubic magnetocrystalline anisotropy is included at each Fe site where $k_c = 8.16 \times 10^{-25}$ J/atom is the effective cubic anisotropy at room temperature. Due to the double exchange interaction, the leading term $J_{\text{Fe}}^{\text{TO}}$ is antiferromagnetic which causes magnetite to be ferrimagnetic with opposed tetrahedral and octahedral magnetic sublattices. Unlike GdFe there is no magnetic compensation point in magnetite as the sublattices have a similar temperature dependence.

5   Applications of Spin Dynamics

The core methodology of spin dynamics has been established for over 20 years, but its usefulness at that time was previously limited by a lack of fundamental materials knowledge and the computational expense of modeling reasonably sized systems with simple serial codes. Materials knowledge has advanced considerably

in that time, in particular new capabilities of first principles methods such as the Korringa-Kohn-Rostoker (KKR) method and conventional relativistic density functional theory (rDFT) to determine magnetic properties and parameters and map them to an effective Heisenberg model. The development of parallel spin dynamics codes such as VAMPIRE (https://vampire.york.ac.uk) and UPPASD (http://physics.uu.se/forskning/materialteori/pagaende-forskning/uppasd/) has enabled the simulation of much larger systems than previously possible, using thousands of cores for large-scale simulations at sizes comparable with micromagnetics. These improvements have enabled spin dynamics simulations to address fundamental challenges in magnetic materials modeling in a wide range of applications including heat-assisted magnetic recording (HAMR), magnetic random access memory (MRAM), nanoparticle magnetism, ultrafast magnetism, permanent magnets, and spintronics. It is impossible to cover the full range of applications in the present chapter, but to give a flavor of the capabilities of spin dynamics, we illustrate a few topical examples from slow to ultrafast magnetic processes.

5.1   Calculation of the Effective Gilbert Damping

The Gilbert damping parameter describes the ability of a magnetic material to respond to a magnetic field. The intrinsic damping is mainly electronic in origin (Pan et al. 2016) arising from spin-orbit coupling. However, real materials are often far from ideal and exhibit enhanced damping due to defects and impurities. Another important origin of enhanced damping is caused by thermal spin fluctuations, more commonly known as spin wave scattering. These extrinsic contributions to damping can be modeled directly using spin dynamics by performing a simple magnetic relaxation experiment. The idea is to simulate the relaxation of the net magnetization $\mathbf{M}$ toward a magnetic field $\mathbf{B}_{app}$ after performing an arbitrary rotation of the spin direction by an angle θ. Since the dynamics of the total magnetization follows the Landau-Lifshitz-Gilbert equation which has an analytical solution (Evans et al. 2014), it is possible to extract an effective damping constant from the simulation by fitting to the time-dependent relaxation of the net magnetization.

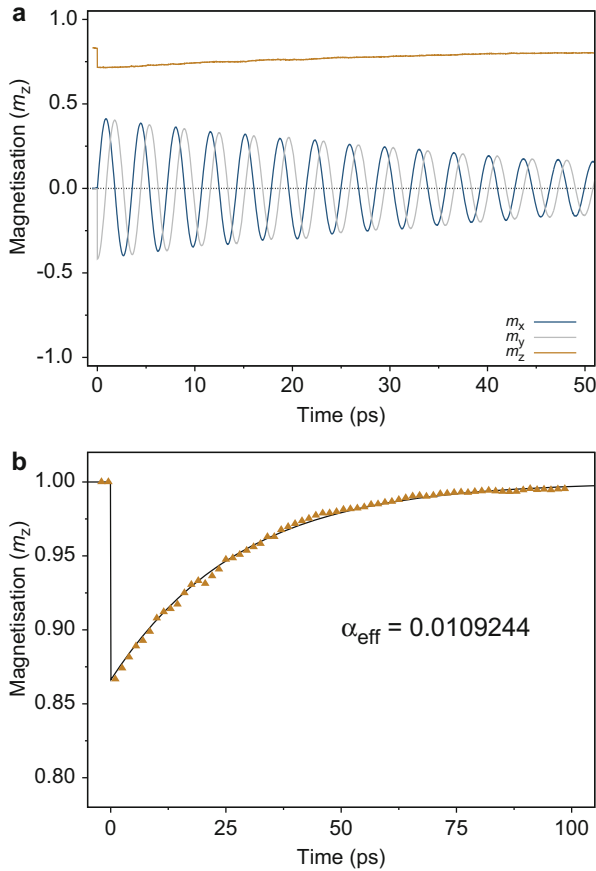
Here we consider a simple ferromagnetic $(10\,\text{nm})^3$ cube of α-Fe with zero magnetocrystalline anisotropy. The effect of spin fluctuations on the damping is calculated by simulating the time-dependent relaxation of a small block of material. The system is first equilibrated at the simulation temperature to thermalize the spins in a strong field. The net magnetization of the system is then instantaneously rotated to an angle of 30 degrees to the applied field direction which causes the net magnetization to precess around the field and gradually relax toward the field direction. Since the microscopic and macroscopic equations of motion are the same, in the absence of spin fluctuations, the input and calculated damping are expected to be the same. The ability to extract the effective Gilbert damping from the simulation requires that applied magnetic field is much larger than the equivalent anisotropy field; otherwise, the spin-dependent fields lead to a large error in the fitting. Zero anisotropy removes any restrictions on the field which can be used,


Fig. 3 (**a**) Plot of the simulated magnetization dynamics of a $(10\,nm)^3$ block of α-Fe at $T = 800\,K$ in a $10\,T$ applied field after an instantaneous rotation of the magnetization to $30°$ from the field direction. The rotation causes the magnetization to precess around the field direction and relax toward the applied field direction. The intrinsic Gilbert damping at $T = 0\,K$ is $\alpha = 0.01$. (**b**) Fitting of the normalized z-component of the magnetization from the analytic solution (Evans et al. 2014). The effective damping shows a small enhancement due to thermal spin fluctuations at elevated temperatures

while for materials with a large anisotropy, much larger fields can be applied. The result of the relaxation simulation for a 10T applied field and intrinsic damping of $\lambda = 0.01$ is shown in Fig. 3 for a temperature of 800 K, a significant fraction of the Curie temperature of 1048 K where spin fluctuations are relatively large. The lines show a fit to the analytic solution incorporating a phase shift due to the initial starting angle of the magnetization of $30°$ from the applied field direction. Here the thermal spin fluctuations lead to a small increase in the effective damping of around 10%. Modeling other contributions to the Gilbert damping is at an early stage, but spin-lattice dynamics offer an enticing route to understanding spin-phonon

interactions, particularly in magnetic oxides such as yttrium iron garnet ($Y_3Fe_5O_{12}$) and magnetite (Fe_3O_4) where the electronic damping is small.

5.2   Magnetization Dynamics in Fe_3O_4 Nanoparticles

An important property of nanoparticles is superparamagnetism, where the thermal fluctuations are sufficiently strong to make the magnetization direction of the particle unstable. The magnetocrystalline anisotropy of magnetite is relatively small, and so superparamagnetism is a common feature of nanoparticles in the 5–15 nm size range typically used for applications in magnetic hyperthermia. Using atomistic spin dynamics, we are able to directly simulate the thermodynamic properties of small magnetite nanoparticles. Using the model of magnetite described earlier, we can build an idealized single-crystal magnetite nanoparticle with an octahedral particle geometry, as shown in Fig. 4. The particle faceting is representative of experimental samples where [111] facets are energetically favorable.

The dynamics of the particle are simulated for a total of 10 ns, but even over this very short timescale, the magnetization is found to be unstable. Due to the cubic magnetocrystalline anisotropy the, minimum energy directions are along the [111] crystal directions. This can be seen from the simulations since the magnetization fluctuates in three dimensions between these eight minima. Extended calculations such as these provide detailed information about the relaxation rates of the particles which is important for other modeling techniques which assume a particular relaxation attempt frequency. Spin dynamics simulations enable this important
Fig. 4 Visualization of a 12 nm Octahedral magnetite nanoparticle (left) and plot of the simulated time-dependent magnetization dynamics at $T = 300$ K (right). The data show fluctuations of the different magnetization components between the 8 minima along the [111] crystal directions due to the cubic magnetocrystalline anisotropy, indicated by the dashed lines

property to be directly simulated for a range of situations such as enhanced surface anisotropy or in the presence of defects such as antiphase boundaries (Nedelkoski et al. 2017).

5.3   Ultrafast Demagnetization of Ni

The dynamics of magnetic materials were once thought to be slow, and limited by the precession frequency of a magnetic spin in a field, given by the Larmor frequency $\omega = -\gamma|\mathbf{B}|$, where $\gamma = 1.76 \times 10^{11}$ T^{-1}s^{-1} is the gyromagnetic ratio and $|\mathbf{B}|$ is the applied magnetic field strength. For everyday magnetic field strengths of around 1 T and where the Gilbert damping is included, this gives a characteristic precession time $\tau_p = -2\pi(1+\alpha^2)/(\gamma|\mathbf{B}|)$ of around 70 picoseconds $(70 \times 10^{-12}$ s). The relaxation time is a multiple of the precession time $\tau_r = \tau_p/\alpha$, where the magnetization has to reorient itself with an external magnetic field. For critical Gilbert damping $\alpha = 1$, the relaxation time is the same as the precession time. However most magnetic materials have much lower damping between 0.001 and 0.1 leading to dynamics on the nanosecond timescale.

In 1996, pioneering experiments showed that metallic Ni responded to a femtosecond laser pulse on the sub-picosecond timescale (Beaurepaire et al. 1996). At the time this was a controversial discovery since it shows magnetic relaxation three orders of magnitude faster than the intrinsic relaxation time from the known properties of magnets. The ultrafast relaxation is caused by thermal spin fluctuations induced through rapid laser heating, though the microscopic mechanism responsible for the transfer of angular momentum from the spins is still debated. At the time the transfer of energy to the spins was described with a simple phenomenological three-temperature (3TM) model (Kirilyuk et al. 2010). The model describes the coupling of electron, lattice, and spin systems as reservoirs for energy. The laser pulse interacts directly with the electrons in the material causing a large increase in their thermal energy. Over the course of a few picoseconds, the hot electrons interact with the lattice causing an increase in the lattice temperature. The heat capacity of the electron system is quite small and so the electron system reaches a much high temperature than the lattice. In a magnetic material, the spins act as another reservoir which can exchange energy with the electrons and lattice. Atomistic spin dynamics is able to simulate this thermal energy transfer directly by calculating the effect of rapid heating, where it can be assumed that the hot electrons interact directly with the 3d spins in the material. In this case one can use the two-temperature model to simulate the dynamic response of the electron and lattice temperatures to the laser pulse. This is expressed by the coupled equations

$$\left(T_e C_e \frac{\partial T_e}{\partial t}\right) = -G_{el}\left(T_e - T_l\right) + P(t) \tag{13}$$

$$C_l \frac{\partial T_l}{\partial t} = G_{el}\left(T_e - T_l\right), \tag{14}$$

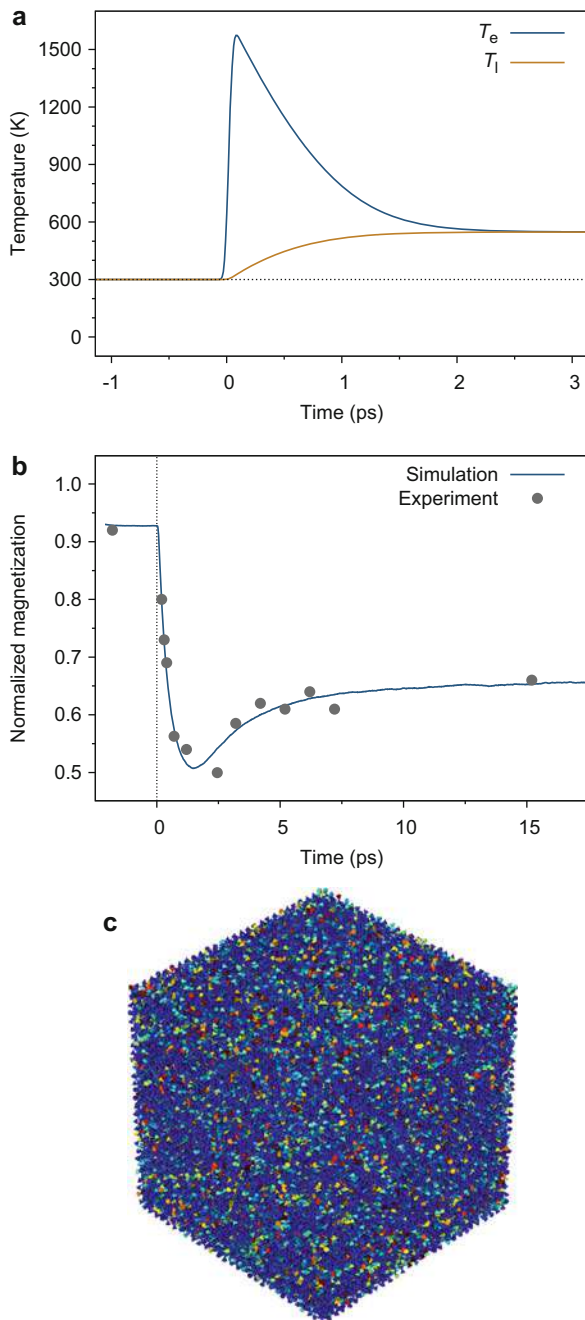
where T_e is the electron temperature, C_e is the electron heat capacity, G_{el} is the electron-lattice coupling, T_l is the lattice temperature, C_l is the lattice heat capacity, and $P(t)$ is a time-dependent energy source from the laser heating. The electron heat capacity is assumed to scale with the electron temperature, known as the free electron approximation. The laser heating is assumed to have a Gaussian profile in time $P(t)$ given by

$$P(t) = \frac{P_0}{\sqrt{2\pi}} \exp\left(\frac{-(t - t_0)}{t_p^2}\right), \tag{15}$$

where P_0 is the laser power, t_p is the pulse width, t is the time, and t_0 is the arrival time of the pulse. These equations can now be solved numerically to determine the response of the electron and lattice temperatures of a Ni surface to a 50 fs laser pulse. A typical time evolution is shown in Fig. 5a. The smaller heat capacity of the electron leads to a large transient increase in the electron temperature caused by the laser energy. After a few hundred femtoseconds, the electron system begins to transfer energy to the lattice which causes a slower increase in the lattice temperature. The final equilibrium temperature of the system is much lower than the peak electron temperature due to the much larger heat capacity of the lattice.

We now simulate the effect of this transient temperature rise caused by the laser pulse on the magnetization of Ni by coupling the $3d$ spins to the electron temperature. We simulate the effect by considering a small segment of the Ni film $(10\,\text{nm})^3$ with periodic boundary conditions in the $x - y$ plane. The response of the z-component of the magnetization is shown in Fig. 5b. Initially before the pulse, the magnetization shows incomplete magnetic order due to the natural thermal spin fluctuations at an ambient temperature of 300 K. When the laser pulse arrives, there is a rapid decrease in the magnetization due to the rapid temperature rise. This causes large thermal spin fluctuations at the atomic level and observed as a transient decrease in magnetic order. A snapshot visualization of the spins during the maximum demagnetization is shown in Fig. 5c. During this process the net angular momentum is transferred to the lattice by electron-lattice interactions. After the pulse has gone, the reduction in the electron temperature leads to a recovery of the magnetization on a longer timescale than the initial demagnetization process. At longer timescales the magnetization reaches a new equilibrium value due to the deposition of heat in the sample by the laser pulse.

Through spin dynamics simulations, we are therefore able to model and understand the basic thermalization process of spins due to laser heating. However, this leaves several outstanding questions. The light matter interactions are complex due to the intensity of the pulse, leading to transient changes of the electronic structure and ultrafast spin currents that are not included within the simple approach above. Also the model completely neglects the underlying spin-flip scattering processes that are responsible for the microscopic spin fluctuations and angular momentum transfer. For the first few fs, the fundamental magnetic parameters are also strongly time and temperature dependent due to the effects of the laser on the underlying

Fig. 5 (**a**) Plot of the simulated time dependence of the electron and lattice temperatures from numerical solution of the two-temperature model. (**b**) Simulated transient magnetization dynamics of a $(10\,\text{nm})^3$ block of Ni excited by a 50 fs laser pulse. The simulations show excellent agreement with experimental measurements (Beaurepaire et al. 1996). (**c**) Visualization of the spin configuration during demagnetization showing thermalization of the spins


electronic structure (Simoni et al. 2017). This makes the field of ultrafast magnetism one of the most exciting areas of the field today and will almost certainly lead to huge advances in our understanding of magnetic processes at the fundamental atomic level.

5.4   Heat-Induced Switching of GdFe

In the previous section, the thermalization of spins described the demagnetization of Ni. More recently the ability to completely control magnetic order just with light was demonstrated in amorphous GdFe (Stanciu et al. 2007). Here pulses of circularly polarized light were able to change the direction of the magnetization, rather than just demagnetization. At the time this was thought to be due to the inverse Faraday effect which induces a net angular moment from the circular polarization of the light. However, further investigation of the sublattice magnetization dynamics with X-ray magnetic circular dichroism (XMCD) and complementary modeling with atomistic spin dynamics (Radu et al. 2011) showed a complex switching mechanism where the Fe and Gd sublattice magnetizations demagnetized at different rates and at some point are aligned in parallel, despite the strong antiferromagnetic coupling between them. These complex dynamics were confirmed by atomistic spin dynamics simulations (Radu et al. 2011) and showed that angular momentum transfer was an important component of the switching process. During the course of this work, the spin dynamics simulations made a startling prediction that the reversal occurred in the absence of a magnetic fields and linearly polarized laser light, essentially *heat* induced magnetic switching. This was possible due to the realistic model of the GdFe material that had been developed, explicitly including the dynamics of Fe and Gd sublattices and their response to an ultrafast heat pulse. This remarkable prediction was confirmed experimentally (Ostler et al. 2012) through laser heating and more recently through pure hot electron transport (Yang et al. 2017), confirming that ultrafast heating alone is sufficient to cause magnetic switching in GdFe.

We will now reproduce this predictive result with a spin dynamics simulation, combining the earlier GdFe model with an ultrafast heat pulse. The model parameters are unchanged apart from a more realistic value of the Gilbert damping of $\lambda = 0.1$ since we are interested in reproducing realistic dynamics rather than equilibrium properties. The response of the system to the heat pulse is shown in Fig. 6. As with the Ni simulation earlier, the initial magnetization shows reduced order before the pulse due to thermal spin fluctuations. When then laser pulse arrives, the transient increase in the electron temperature causes rapid demagnetization of the Fe and Gd sublattices due to the heating. However, due to the different local atomic magnetic moments, the demagnetization times are different for each sublattice. This is because the larger magnetic moments on the Gd sites are less strongly affected by thermal fluctuations responsible for demagnetization. This in turn affects the magnetization dynamics, making the Gd sublattice slow to respond to the laser heating pulse. At the same time, the Fe sublattice fully demagnetizes. After the
Fig. 6 Simulated heat-induced magnetic switching of GdFe be 50 fs laser pulse

pulse is gone, the system attempts to re-magnetize, but the exchange field from the partially demagnetized Gd sublattice causes the Fe sublattice to process rapidly. The Fe precession excites a mutual precession of the Gd sublattice which leads to a dynamic switching process. A fraction of a picosecond later, the magnetization recovers sufficiently to cause the sublattices to align with the magnetic easy axis, completing the switching process (Atxitia et al. 2013). After cooling back to ambient temperature and pulsing again, this process is repeatable and deterministic. This concisely demonstrates the predictive power of atomistic spin dynamics simulations which will only improve over the coming years.

6   The Future

Despite the impressive capabilities of spin dynamics simulations, significant challenges remain in being able to fully understand the dynamics of magnetic materials both in terms of atomic structure and magnetic properties. A new class of model has recently emerged which couples spin and molecular dynamics in a single simulation (Ma et al. 2008; Perera et al. 2016, 2017). This allows an investigation of spin-lattice effects in a direct manner including contributions to the Gilbert damping and magneto volume effects, where the magnetic properties are linked to the lattice parameter. Such models are more computationally expensive than spin models but offer significant improvements in our ability to understand the dynamic properties of magnetic materials.

Another more fundamental limitation of the classical Heisenberg model is the use of classical statistics for the Langevin heat bath. In reality the underlying microscopic mechanisms are discrete electron excitations, causing small jumps in the local spin direction. This process is much better represented by quantum statistics, where infinitesimal spin fluctuations are forbidden. For larger ensembles

of spins, the temperature rescaling method includes an average effect of the lack of infinitesimal spin states by including smaller thermal fluctuations. However, smaller systems such as molecular magnets or isolated spins will require a better treatment of spin fluctuations and single spin dynamics.

Another class of magnetic moment not well treated by a fixed spin approximation induced magnetic moments or moments that are more Stoner-like rather than Heisenberg-like, where their length varies significantly in time. In this case the fixed moment neglects an important degree of freedom in the material and is in most cases a poor approximation. This is most evident in heavy metals such as Pt which has a relatively strong induced moment due to the magnetic proximity effect, where a nearby magnetic atom induces a net moment due to the exchange interaction (Mryasov et al. 2005). Ni also shows some Stoner-like behavior that is not particularly well represented by a fixed spin approximation. However, models of variable spin are much more computationally expensive and so are not currently as widely applicable as standard spin dynamics. In the future models that can better deal with these induced moments will be needed to better understand their behavior.

7   Conclusion

Spin dynamics is becoming a standard research method in the field of magnetism and spintronics due to the ability to model a diverse range of magnetic materials and phenomena, with an increasing ability to be predictive. Through a combination of advanced materials modeling of the structure of materials, their complex magnetic interactions, and spin dynamics simulations, it is now possible to model a wide range of magnetic phenomena which were poorly understood only 20 years ago. This rapidly developing capability will complement ongoing experimental efforts to make devices for a range of practical applications.

Ultra-fast Dynamics for Heat-Assisted Magnetic Recording

21

Simon J. Greaves

Contents

Abstract

This chapter describes models and techniques for the simulation of magnetization dynamics at elevated temperatures. These can be applied to heat-assisted magnetic recording systems, or other systems in which magnetic materials are heated close to or above their Curie temperature. In many cases demagnetization takes place on picosecond time scales as energy is absorbed by the electrons responsible for the magnetic moment. As such, an understanding of ultra-fast magnetization dynamics is important when modelling these systems. Models that can be used to simulate ultra-fast magnetization dynamics are presented, together with an overview of heat sources and other mechanisms that can give rise to ultra-fast dynamics.

1   Introduction

The growth of the information society has resulted in the creation of vast amounts of data that need to be stored and processed. This has led to an insatiable demand for high density, high speed and low cost data storage systems and devices. One candidate technology that may be used in the future is heat assisted magnetic recording, which involves localized heating of a recording medium to reduce the coercivity, allowing information to be stored. If a magnetic material is heated near to its Curie temperature the magnetization dynamics can be quite different from a conventional recording system in which recording takes place at room temperature. Depending on the source and nature of the heating mechanism, the recording medium may become demagnetized on picosecond time scales and the spins, electrons and lattice atoms may need to be described by different temperatures. Hence, models that can account for ultra-fast magnetization dynamics are necessary. This chapter describes micromagnetic and atomistic models that can be used for this task.

2   Heat-Assisted Magnetic Recording

To increase the density of data stored on a magnetic disk medium, the size of the polycrystalline grains comprising the medium should be reduced. For a single-phase grain with volume V and uniaxial anisotropy K_u, the average time, τ, between random, thermally induced changes of the magnetization direction is given by

$$\frac{1}{\tau} = f_0 e^{-K_u V / kT} \tag{1}$$

where T is the temperature, f_0 is the attempt frequency, and k is the Boltzmann's constant. The attempt frequency for high energy barriers ($K_u V \gg kT$) is given by Brown (1963)

$$f_0 = \frac{\gamma \alpha}{1 + \alpha^2} \sqrt{\frac{H_k^3 M_s V}{2\pi kT}} \tag{2}$$

where γ is the gyromagnetic ratio, α the damping constant, M_s the saturation magnetization, and $H_k = 2K_u/M_s$ the anisotropy field.

Suppose the attempt frequency is 10^{10} Hz: if we wish to store data for 10 years at a temperature of 300 K, the ratio $K_u V/kT$ should be about 43 (energy barrier $\Delta E = K_u V \approx 1.78 \times 10^{-12}$ erg) to ensure that at least half of the grains in a medium retain their original magnetization. In reality, higher values of $K_u V/kT$ may be necessary to maintain a sufficiently high signal-to-noise ratio (SNR) as grains may be subjected to magnetostatic fields arising from other medium grains and external magnetic fields. If the grain volume is reduced, K_u, and therefore H_k, must be increased to compensate.

   To record on a magnetic medium, the head field should exceed the anisotropy
field of the medium. However, the recording field that can be generated by a write
head is limited by the saturation magnetization of head materials. The field near the
surface of a magnetic material with magnetization perpendicular to the surface is
$2\pi M_s$. Therefore, the maximum field in-between two parallel planes of the same
material is $4\pi M_s$. In a perpendicular recording system, the air bearing surface
(ABS) of the main pole of the write head generates a field $H_{head} = 2\pi M_s$ and a soft
magnetic underlayer generates an additional field $H_{SUL} < 2\pi M_s$. Some additional
magnetic flux may also be present from the coil driving the write head, but is ignored
here. The maximum M_s of write head materials is around $1910\,\mathrm{emu/cm^3}$ (Yun et al.
1996), giving a maximum write field of 24 kOe.
   The maximum head field places an upper limit on K_u and a lower limit on V.
More complicated media structures, such as composite or exchange spring media,
can be used to reduce the switching field of a grain, but ultimately a limit is reached
and the grain cannot be made any smaller. To overcome this problem, the concept
of heat-assisted magnetic recording (HAMR) was introduced.
   HAMR is a technology that enables recording on media with extremely high
room temperature uniaxial anisotropy. A schematic of a HAMR system is shown in
Fig. 1a. A laser locally heats a portion of the medium during recording, lowering the
anisotropy field below the head field. As the medium cools, the magnetization aligns
with the head field; once the medium returns to room temperature, the anisotropy
field is sufficiently high that the medium is thermally stable. This process is shown

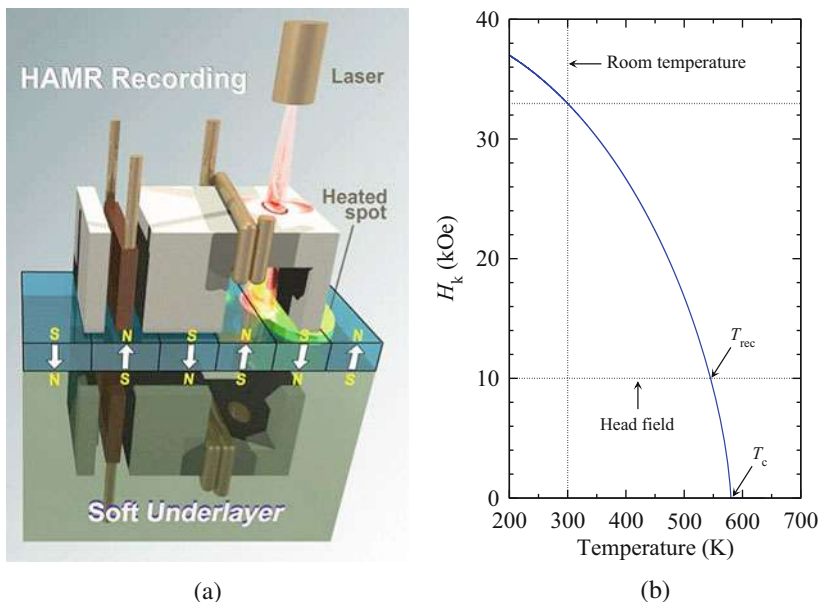
(a)   (b)


Fig. 1 Schematic of a HAMR system (left) (courtesy of Seagate) and recording process (right) (**a**)
HAMR schematic. (**b**) H_k vs. T

in Fig. 1b, in which the temperature dependence of H_k is shown for a medium with an assumed Curie temperature of 580 K. At room temperature, H_k is about 33 kOe, far higher than the assumed head field of 10 kOe. Heating the medium near to, or above, T_c reduces H_k below the head field. As the medium cools, data can be written at temperatures around T_{rec} (545 K in this example), at which point $H_k \approx H_{head}$.

Factors controlling the quality of the recorded bits and the sharpness of transitions in a HAMR system are the thermal gradient in the medium, dT/dy; the rate of change of the anisotropy field in the vicinity of the recording temperature, dH_k/dT; and the head field gradient, dH/dy, where y is the down-track axis. These parameters combine to give an effective head field gradient of

$$\frac{dH_{eff}}{dy} = \frac{dH_k}{dT}\frac{dT}{dy} + \frac{dH}{dy} \tag{3}$$

Head field gradients are limited by geometrical considerations to around 500 Oe/nm, whereas thermal gradients of 5 K/nm and dH_k/dT of 200 Oe/K are easily obtained. As a result the head field gradient becomes less important in a HAMR system and the recording performance is dominated by the thermal gradient and dH_k/dT.

Typical recording media used in HAMR systems are FePt alloys (Weller et al. 2013, 2016). These are favored for their extremely high uniaxial anisotropy, theoretically allowing grains with diameters of 3–4 nm to be thermally stable at room temperature for many years.

The above discussion relates to conventional recording systems, but in recent years, alternative methods of switching the magnetization direction have been proposed which do not rely on an external magnetic field. For example, in all-optical recording, circularly polarized light is used to determine the direction of magnetization switching based on the inverse Faraday effect (Stanciu et al. 2007). In other experiments multiple light pulses were found to have a cumulative effect on the magnetization switching in a process ascribed to magnetic circular dichroism (El Hadri et al. 2016). Electrical pulses may also be used to demagnetize materials on ultrashort time scales (Wilson et al. 2017).

Whatever the nature of the heat source, the approach to modelling the magnetization dynamics is the same: a micromagnetic or atomistic model is used to model the magnetization, with the stimulus provided by the heat included as an additional magnetic field term. The difficulty lies in correctly accounting for the temperature dependence of parameters, such as M_s, K_u, and most other inputs to the model, as well as accurately calculating the temperature itself. The remainder of this section deals with the models used to describe magnetization dynamics, while Sect. 3 considers how to treat the heat absorption.

2.1 The LLG Equation

Standard micromagnetic simulations use the Landau-Lifshitz-Gilbert (LLG) equation to model the change in direction of a magnetization vector **M** when subject to a magnetic field **H**:

$$\frac{d\mathbf{M}}{dt} = -\gamma \left(\mathbf{M} \times \left(\mathbf{H} - \frac{\alpha}{\gamma M_s} \frac{d\mathbf{M}}{dt} \right) \right) \tag{4}$$

$\mathbf{M}$ can represent the magnetization of a single spin or the average magnetization of a discrete volume (cell) containing many spins (a macrospin). When the LLG equation is applied to cells containing many spins, a temperature-dependent function, $M_s(T)$, must be introduced to reflect the reduction of M_s at elevated temperatures and $M_s(T)$ should reach zero at the Curie temperature, T_c.

However, if $M_s(T)$ becomes zero, there would be a singularity in Eq. 4. Strictly speaking, M_s represents the average magnetization of a number of atoms whose magnetic moment is independent of temperature. As such, it could be argued that although the time-averaged magnetization is zero at, or above, the Curie temperature, the instantaneous magnetization is small, but nonzero. Therefore it is sufficient for $M_s(T)$ to be a small, nonzero value at $T \geq T_c$.

The field $\mathbf{H}$ in the LLG equation is not just the external magnetic field applied by the write head; it also includes the magnetostatic, anisotropy, exchange coupling, and thermal fields. A detailed discussion of each of these terms can be found in Greaves (2007). The latter four terms are functions of M_s and are therefore temperature dependent, while the anisotropy field includes a K_u term which also varies with temperature.

The thermal field is used to represent the effect of thermal energy on the magnetization. It is a random value chosen from a Gaussian distribution with an average value of zero and a standard deviation of

$$\sigma = \sqrt{\frac{2k\alpha T}{M_s V \gamma dt}} \tag{5}$$

The thermal field is uncorrelated in space and time, and new values are generated at each point every time the LLG equation is evaluated. The effect of the thermal field is to impart a randomness to the motion of $\mathbf{M}$. If $\mathbf{M}$ represents the magnetization of a single domain particle with uniaxial anisotropy, then at a temperature of zero Kelvin, $\mathbf{M}$ will lie along the easy axis. As the temperature is increased from zero Kelvin, the thermal field will cause $\mathbf{M}$ to fluctuate about the easy axis such that multiple samples of the angle between $\mathbf{M}$ and the easy axis will form a Maxwell-Boltzmann distribution. Interestingly, this also means that at nonzero temperatures, $\mathbf{M}$ can never be perfectly aligned with the easy axis.

2.2 Temperature-Dependent Parameters

The temperature dependence of various physical parameters must be considered in heat-assisted recording models. The form of $M_s(T)$ can be calculated using the Weiss theory and an appropriate value for J (Weiss 1907). The parameter J is used in the Brillouin function $B(\alpha, J)$ to find the value of $x \equiv M_s(T)/M_s(0)$ that satisfies the relation
Fig. 2 Reduced saturation magnetization vs. T/T_c. J is the Brillouin function parameter used in the Weiss theory of ferromagnetism

$$x = B\left(\frac{3JT_c x}{T(J+1)}, J\right).$$ (6)

Figure 2 shows the temperature dependence of M_s calculated using the Weiss theory of ferromagnetism. Materials such as Fe and Co have a temperature dependence of M_s which lies close to the curves with $J = 0.5$ and $J = 1$.

Alternatively, an analytical function for $M_s(T)$ may be used, with the advantage that a better fit to the experimental data may be obtained. For example, Kuzmin (Kuzmin 2005) proposed a function of the form

$$\frac{M_s(T)}{M_s(0)} = \left(1 - s\left(\frac{T}{T_c}\right)^{3/2} - (1-s)\left(\frac{T}{T_c}\right)^p\right)^{1/3}$$ (7)

where s and p are fitting parameters. For many materials, $p = 2.5$ and various values of s were found to give good agreement with experimental data. In the case of Fe, $p = 4$ was better.

Having established the temperature dependence of M_s, the uniaxial anisotropy can often be assumed to follow the relationship

$$\frac{K_u(T)}{K_u(0)} = \left(\frac{M_s(T)}{M_s(0)}\right)^n$$ (8)

where the power n has been measured in experiments to be $n = 2$ for FePt and FeNiPt alloys (Thiele et al. 2002) and $n = 3$ for CoCr alloy thin films (Inaba et al. 2000). For pure ferromagnetic elements, much larger values of n are appropriate (Zener 1954; Carr 1958), but these do not make good recording media.

Exchange coupling is also a temperature-dependent parameter. In a model in which cells are used to represent the magnetization of individual grains in a recording medium, the temperature dependence of the exchange coupling energy density can be described by a linearly decreasing function (Huang and Kryder 2014).

Finally, the damping constant can also vary with temperature. The microscopic origins of damping are not fully understood, and many different mechanisms may contribute in larger or smaller amounts to the overall damping. In general, scattering of conduction electrons by the magnetization and defects are believed to make the largest contributions (Kambersky 2007). The temperature dependence of these effects is difficult to calculate, even for pure metals, and can vary greatly in alloys with different compositions. Examples of measurements on pure ferromagnetic metals such as nickel (Bhagat and Chicklis 1969) and iron (Cochran et al. 1991) show the damping constant decreasing with temperature in the former and increasing with temperature in the latter. Note that the damping constant in these papers, λ, can be related to the damping constant in the LLG equation, α, by $\lambda = \alpha \gamma M_s$. Measurements of the temperature dependence of α can also vary significantly depending on the shape of the sample and the measurement technique used. Given these difficulties, determining the effect of α at high temperatures is perhaps best approached by assuming a simple, linear, temperature-dependent function $\alpha(T)$ which will at least allow the modeller to decide if $\alpha(T)$ has a significant effect on the system being simulated.

2.3   Atomistic Models

If a micromagnetic model is one in which $\mathbf{M}$ represents the average magnetization of a number of atoms, an atomistic model is one in which every (magnetic) atom is represented by an individual magnetic moment or spin $\mathbf{S}$. Because the number of atoms is large in even a small object, e.g., a 4.4 nm cube with a 0.2 nm atomic spacing contains 10,648 atoms, useful calculations are currently limited to single grains, collections of grains, or smaller objects. As computing power increases (and the size of magnetic devices decreases), solving larger problems and modelling of entire devices become more tractable. If the atoms can be assumed to lie on a regular lattice, graphics processing units (GPUs) can be used to accelerate computations, in particular the magnetostatic field calculation.

In an atomistic model, the LLG equation is applied to each spin individually, with $\mathbf{M}$ in Eq. 4 replaced by $\mathbf{S}$ and $M_s V$ replaced by the magnetic moment of the atom. The total magnetization is then given by $\mathbf{M} = \sum_i \mathbf{S_i}$. The exchange coupling calculation may be extended to second and third (or more) nearest neighbors, depending on the nature of the material being modelled.

In atomistic models the magnetic moments are generally assumed to be independent of temperature, with $M_s(T)$ and the Curie temperature being determined by the strength of the exchange coupling interaction and the atomic spacing. At

low temperatures, the exchange coupling field causes the magnetic moments of neighboring atoms in a ferromagnet to align in the same direction. As the temperature is increased, the thermal energy, represented in the model by the thermal field, causes the magnetic moments to become disordered, reducing the spontaneous magnetization. At the Curie temperature, the time-averaged magnetization along any axis reaches zero, although the magnetization at any particular instant is likely to be nonzero as $\sum_i \mathbf{S_i}$ along any particular direction will rarely be exactly zero.

At low temperatures magnetization reversal proceeds via precessional rotation of the magnetization, as in the micromagnetic model. Nearer to the Curie temperature, the reversal mode undergoes a transition to a linear mode. The magnetic moments of individual atoms continue to precess, governed as they are by the LLG equation, but the loss of coherency at high temperatures means that the total magnetization, $\mathbf{M}$, can switch from one direction to the opposite direction without developing a large orthogonal magnetization component (Barker et al. 2010). In this respect the atomistic model behaves quite differently to the micromagnetic model. Linear magnetization reversal can be much faster than precessional reversal, and therefore, where ultra-fast dynamics are concerned, it is important that the model be able to represent the linear reversal mode.

A common problem with atomistic models is that the calculated variation of M_s with temperature follows the $J = \infty$ curve in Fig. 2, which is not representative of materials such as Co or Fe. This discrepancy arises due to the way in which the thermal field is used. As noted in Sect. 2.1, the magnon energies represented by the thermal fields are chosen from a Gaussian distribution and have a constant power spectral density, i.e., the thermal energies form a white noise spectrum. As a result high energy magnon excitations are over represented at low temperatures, leading to lower $M_s(T)$ than in real materials. One solution to this problem is to use colored noise (Woo et al. 2015), although this is nontrivial to generate.

2.4   The LLB Equation

The use of atomistic models is limited by the sheer number of atoms that are present in all but the smallest objects. An alternative way to model high temperature magnetization dynamics is to use the Landau-Lifshitz-Bloch (LLB) equation. First introduced by Garanin (1997), the LLB equation can be used as a replacement for the LLG equation at high temperatures, allowing larger volumes, e.g., polycrystalline grains, to be treated as one discrete object described by an average magnetization vector.

Various forms of the LLB equation exist: Evans et al. (2012), Tzoufras and Grobis (2015), and Xu and Zhang (2012). All of them have in common the fact that at low temperatures, they reduce to the LLG equation, and at high temperatures, an additional term provides for longitudinal magnetization fluctuations. To take an example from the first of these three papers, the LLB equation is given as
Fig. 3 Magnetization reversal of an 8 nm cube at various temperatures. (Data from Greaves et al. 2015)

$$\frac{d\mathbf{m}}{dt} = -\gamma\,(\mathbf{m} \times \mathbf{H}) + \frac{\gamma\alpha_\parallel}{m^2}\,(\mathbf{m} \cdot \mathbf{H})\,\mathbf{m} - \frac{\gamma\alpha_\perp}{m^2}\,(\mathbf{m} \times (\mathbf{m} \times (\mathbf{H} + \boldsymbol{\eta}_\perp))) + \boldsymbol{\eta}_\parallel \qquad (9)$$

where the η terms represent random, thermal fields and the α terms are temperature-dependent damping parameters. At $T = 0\,\mathrm{K}$ $\alpha_\parallel$ is equal to zero and Eq. 9 is basically the same as Eq. 4, albeit expressed in a slightly different form.

Another difference between the LLB and LLG equations is that in the LLB equation, the magnetization vector $\mathbf{m}$ does not have a constant length. The average length of $\mathbf{m}$ is equal to $M_s(T)/M_s(0)$, but the actual length fluctuates from one time step to the next due to the thermal fields. An additional "entropic" field term is added to $\mathbf{H}$ to govern the length of $\mathbf{m}$, such that the entropic field is negative when $|\mathbf{m}| > M_s(T)/M_s(0)$, positive when $|\mathbf{m}| < M_s(T)/M_s(0)$, and zero when $\mathbf{m}$ is the correct length.

The second term on the right hand side of Eq. 9 gives rise to longitudinal magnetization fluctuations at high temperatures, with $\alpha_\parallel = \alpha\frac{2T}{3T_c}$. The effect of these fluctuations can be seen in Fig. 3, which shows how the magnetization of an 8 nm cube reverses from the $+z$ direction to the $-z$ direction during the calculation of a hysteresis loop. At a temperature of $100\,\mathrm{K}$ the magnetization reverses via precessional motion about the z axis, with the magnetization vector lying on the surface of a sphere. Thus, when M_z is small, the in-plane component of M is large. As the temperature is increased, a gradual transformation from precessional to linear reversal takes place (Barker et al. 2010). At 470 K the magnetization changes from $+z$ to $-z$ while expressing only a very small in-plane magnetization component, i.e., the reversal is linear.

The original form of the LLB equation proposed by Garanin supposed that the temperature dependence of M_s followed the $J = \infty$ curve in Fig. 2, and this is

reflected in the formulation of the entropic field equations. To model materials with different values of J, the expressions in Greaves et al. (2015) can be used to resolve the discontinuity in the entropic field at T_c inherent in Garanin's approach when $J \neq \infty$. Alternatively, a quantum LLB equation has been proposed (Nieves et al. 2014) to achieve a similar result. The form of the quantum LLB equation is the same as Eq. 9, with changes to the expressions for the damping constants and entropic field.

One potential problem with the LLB equation is that it cannot be used in an atomistic model as the length of **m** is not constant. Therefore, there must be a certain cell volume below which the LLB equation becomes invalid. However, even a 1 nm^3 cell can contain in excess of 100 atoms, and the use of the LLB equation should not be a problem at these scales, the exception being materials such as dilute magnetic alloys in which the number of magnetic spins in a given volume is relatively small.

2.5 Other Models

Alternative models for high temperature magnetization dynamics should also be mentioned. One approach is to renormalize the temperature-dependent parameters, such as M_s, K_u, α and the exchange coupling constant A, of a block of atoms to match the values obtained from an atomistic model of the same-sized block (Victora and Huang 2013). The block size is typically 1–2 nm, i.e., smaller than the grain size in a recording medium, but allowing much faster calculations than an atomistic model.

3 Heat Transport

The heat flow equation

$$\frac{dT}{dt} = \frac{K}{C}\nabla^2 T + \frac{P(t)}{CV} \tag{10}$$

can be used to calculate the change of temperature of an object over time. Like the LLG and LLB equations, the heat flow equation shares the differential operator d/dt, and temperature distributions can be calculated in parallel with the LLG or LLB equations, although it may be necessary to use a different time step. In Eq. 10 K is the thermal conductivity and C is the specific heat capacity. The last term in the equation is used when heat is added to the medium by an external source, e.g., a laser or near field transducer. In that case $P(t)$ is the energy delivered by the heat source and V the cell volume into which the energy is absorbed. In general $P(t)$ has a spatial distribution, e.g., the laser spot might have a Gaussian intensity profile on the surface of the medium and the laser intensity would decay with depth as the light is absorbed.

   The intensity of light at a depth z within a medium can be calculated using the extinction coefficient of the medium, k_e, as

$$I(z, t) = (1 - R)I(0, t)e^{-4\pi k_e z/\lambda} \tag{11}$$

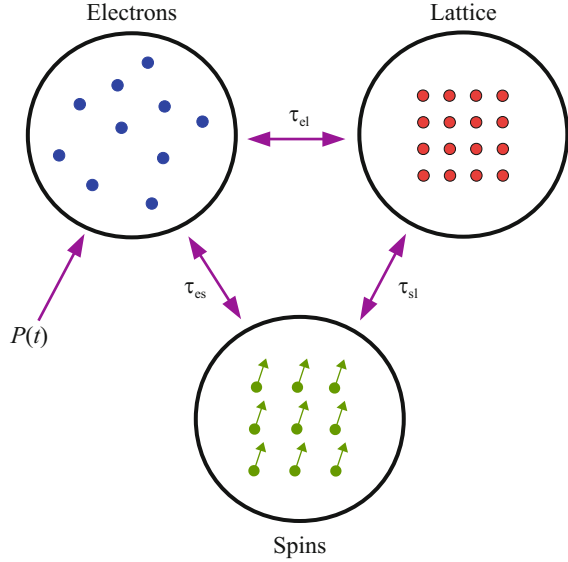
where λ is the wavelength of the light, R is the bulk reflectivity, and $I(0)$ is the intensity of incident light on the surface of the medium. Both R and k_e are functions of λ and k_e is the complex part of the refractive index. Equation 11 can be integrated over the thicknesses of the layers in the model to determine the total energy absorbed by each layer, giving $P(t)$ in Eq. 10. For a commonly used magnetic material such as Co, the extinction coefficient for $\lambda = 600$ nm is about 4, meaning that 55% of incident energy is absorbed within the top 10 nm of a medium and 90% within the top 27 nm. As a result a large vertical temperature gradient can exist within a medium.

   Both the thermal conductivity, K, and the specific heat, C, are functions of temperature. In the case of pure cobalt and iron, the thermal conductivity decreases as the temperature is increased, although in the case of alloys of Co and Fe, the rate of reduction can be much reduced, or even change sign (Terada et al. 2003; Shelton 1934). As data are difficult to obtain, particularly for more complicated alloys, the temperature dependence of bulk thermal conductivity is often omitted from models and the same is true for specific heat capacities. There is some evidence that the specific heat capacity can also depend on the direction of the magnetization and that the temperature dependence of the specific heat capacity is itself related to the uniaxial anisotropy, albeit very weakly (Lanchester et al. 1975).

   Modern, granular recording media consist of magnetic grains segregated by nonmagnetic oxides such as SiO_2 which have a relatively low thermal conductivity. As a result thermal conduction through the depth of the film is likely to be higher than in the film plane, and the model should take account of this anisotropic thermal conductivity. Experiments using FePt, a common material for heat-assisted recording media, have shown that the ratio of the vertical to in-plane thermal conductivities could be as high as 10:1, depending on the FePt grain size (Ho et al. 2013). The use of heat sink layers underneath the recording layer may also increase the ratio of vertical to in-plane thermal conductivity.

3.1 Two- and Three-Temperature Models

For the study of ultra-fast dynamics, it is not sufficient to calculate only the temperature of the bulk, or lattice, as effects such as laser-induced demagnetization take place on a much shorter time scale than changes in the lattice temperature. A two-temperature model can be used to represent the different temperatures of the electrons and lattice (Anisimov et al. 1974). The electrons absorb the heat entering the system, and because they have a much smaller specific heat than the lattice, their temperature increases much more rapidly. Subsequently, heat is transferred from the electrons to the lattice and the two temperatures converge over time. Experimental

Fig. 4 Heat flow between electrons, spins, and lattice atoms in the three-temperature model. $P(t)$ represents the heat from a laser or near field light source


measurements on metals find the two-temperature model gives a good description of the behavior of many metals (Hohlfeld et al. 2000), but in magnetic materials, the temperature of the spins must also be considered.

In the three-temperature model, separate temperatures are ascribed to the electrons, spins, and the lattice atoms (Beaurepaire et al. 1996). Each component has a different (temperature dependent) specific heat, and coupled differential equations describe the heat flow between the three components. A schematic of the model is shown in Fig. 4 with the constants τ_{el}, τ_{es}, and τ_{sl} determining the rate of energy transfer between the three components and $P(t)$ representing the heat entering the system.

Equation 12 shows the equations used to calculate the temperatures of the electrons, spins, and lattice. If necessary, further terms can be added to account for thermal conduction out of the heated region, although such conduction may take place on much longer time scales than the picosecond dynamics of the spins and electrons and could be neglected in many cases:

$$\frac{dT_e}{dt} = \frac{-\tau_{el}(T_e - T_l) - \tau_{es}(T_e - T_s) + P(t)}{C_e(T_e)}$$

$$\frac{dT_l}{dt} = \frac{-\tau_{el}(T_l - T_e) - \tau_{sl}(T_l - T_s)}{C_l(T_l)}$$

$$\frac{dT_s}{dt} = \frac{-\tau_{es}(T_s - T_e) - \tau_{sl}(T_s - T_l)}{C_s(T_s)} \tag{12}$$

Many experiments have shown that energy transfer between electrons and spins can be extremely rapid, such that the spin temperature lags the electron temperature by $\approx$10–100 fs. In such materials Eq. 12 can be simplified to van Kampen (2003)

$$\frac{dT_e}{dt} = \frac{-\tau_{el}(T_e - T_l) + P(t)}{C_e(T_e)}$$

$$\frac{dT_l}{dt} = \frac{-\tau_{el}(T_l - T_e)}{C_l(T_l)}$$

$$\frac{dT_s}{dt} = \frac{(T_e - T_s)}{t_d} \tag{13}$$

where t_d is the delay between the electron and spin temperatures and Eq. 13 is basically the same as the two-temperature model. This approach has been used in an atomistic model of spin dynamics to calculate the evolution of the magnetic moment over femtosecond to nanosecond time scales (Chimata et al. 2012).

Experimental measurements of the specific heat of, e.g., nickel, show a roughly linear variation of specific heat over the temperature range from 300 to 600 K (Grew 1934), with a sharp peak around the Curie temperature at 631 K. To model this behavior, as a first approximation, the specific heat of the lattice can be assumed to be constant, with the electronic specific heat assumed to vary as

$$C_e(T_e) = \gamma T_e \tag{14}$$

and the total specific heat being the sum of the two. The γ parameter can be used as a fitting parameter, with values in the literature for nickel ranging from 1.1×10^3 to 6×10^3 J/m^{3}K^2. Another fitting parameter in the simplified three-temperature model is τ_{el}, which can be of the order 1×10^{18} W/m^{3}K. The parameter controls the rate of decay of the electron temperature. In the full three-temperature model, the other coupling constants were estimated by Beaurepaire et al. (1996) to be $\tau_{es} = 6 \times 10^{17}$ W/m^{3}K and $\tau_{sl} = 0.3 \times 10^{17}$ W/m^{3}K.

3.2 Heat Sources

The nature of the incident energy source used to heat the medium may also need to be considered in the model. In many pump-probe experiments, the medium is heated by an ultra-short laser pulse lasting for less than 100 fs, with the size of the illuminated area measured in tens of microns. Given that micromagnetic models of these experiments are generally limited to simulating regions of $\leq 1\mu$m^2, the model can be simplified by assuming a uniform distribution of the incident laser power $I(0, t)$ over the surface of the medium. The time dependence of the laser pulse intensity on the surface of the medium can be represented by a Gaussian of the form

$$I(0, t) = I_{\max} e^{-(\frac{t - t_{\max}}{t_p})^2} \tag{15}$$

where I_{max} is the maximum intensity, t the time, t_{max} the time at which the pulse reaches its maximum intensity, and t_p the pulse duration. As the laser intensity is uniform over the modelled region, there may be no thermal gradient in the plane of the medium and hence no thermal conduction. A thermal gradient in the vertical direction will still exist and thermal conduction into the air and substrate should be considered.

3.2.1 Near Field Transducers

In modern recording systems, the size of written bits, measured in the tens of nanometers, is much smaller than the minimum (diffraction limited) size of an optical spot that can be obtained using lenses. Instead, near field transducers (NFT) are used to generate the extremely small heat spots used in heat-assisted magnetic recording. Such NFTs usually consist of a thin metallic film, often gold, in which surface plasmons are induced by incident light from a laser or waveguide. Depending on the geometry of the NFT, the plasmon energy can be concentrated into a small area and coupled into an adjacent recording medium.

NFT designs have been studied in detail, with common shapes being "bow tie," "E," "nanobeak," and "lollipop" (Zhou et al. 2014). Of these the most common design reported in the literature as being used in actual HAMR systems is the "lollipop" (Challener et al. 2009). The energy distribution in and around a NFT can be calculated using a finite-difference time-domain (FDTD) model, such as the free software MEEP (Oskooi et al. 2010). As a first approximation, the recording medium can be assumed to consist of homogeneous strata, but a more detailed analysis would also take account of the granular structure of most recording media, with different absorption and thermal conductivity characteristics assigned to the magnetic grains and nonmagnetic grain boundaries (Nakagawa et al. 2007). Such analyses show energy absorption being concentrated in the grains, raising their temperature by more than would be expected from a uniform layer model. There is also recent evidence that the shape of the grains themselves can lead to localized hot spots, for example, in the vicinity of protrusions or locations around the edge of a grain with a smaller radius of curvature relative to the rest of the grain.

3.2.2 Alternative Heating Mechanisms

The three-temperature model provides a good representation of how energy from an incident laser pulse is absorbed by a magnetic material. But in recent years experiments have revealed alternative heating mechanisms that may induce ultra-fast magnetization dynamics, and these are briefly discussed here.

Magnetic circular dichroism is a phenomenon in which the absorption (and reflectivity) of left and right circularly polarized light by a magnetic material differs depending on the orientation of the material's magnetization. This means that if a multi-domain medium with perpendicular anisotropy is subjected to a circularly polarized light pulse, the "up" domains will absorb more energy than

the "down" domains, or vice versa, depending on the polarization of the light. As a result one set of domains will be heated more than the other, creating a temperature difference between the two. The temperature difference creates a higher probability of thermally induced magnetization reversal for one of the magnetization orientations, such that after multiple light pulses, the area or number of the hotter domains will shrink and that of the cooler domains grow. A simple model for this process is described in Gorchon et al. (2016). To include the effect in a dynamic model, a magnetization-dependent absorption term of the form

$$P(t) = A_0 + \Delta A \times m_z/|\mathbf{m}| \tag{16}$$

could be used. Here, A_0 is the light energy absorbed by the medium, obtained by integrating Eq. 11 over the medium thickness; $m_z/|\mathbf{m}|$ is the normalized, vertical component of magnetization; and ΔA represents the magnetic circular dichroism. ΔA is material dependent, but the results in Gorchon et al. (2016) suggest that ΔA of 0.5% is enough to result in all optical switching after a sufficiently large number of light pulses.

The Faraday effect (FE) is the action of a magnetic material in rotating the plane of polarization of light passing through the material. Similarly, the inverse Faraday effect (IFE) is the induction of magnetization in a material by circularly polarized light. Expressions have been derived for the magnitude of the IFE in Battiato et al. (2014) using a quantum mechanical approach. The method has been applied to a model of magnetization switching in FePt media in John et al. (2017). In that model the IFE was implemented as an additional contribution to the magnetization with a characteristic decay time slightly longer than the duration of the light pulse and an initial magnitude of 3–7% of M_s. The initial magnitude of the IFE depends on the light intensity, wavelength, helicity, and the magnetic material.

Finally, electrical pulses can also be used to induce ultra-fast magnetization dynamics. An electric current passing through a resistive material will cause Joule heating, and this may result in demagnetization of a sample if the Curie temperature is reached. But it is also possible to demagnetize a sample using ultra-short duration electric current pulses, where Joule heating of the bulk sample is negligible. The experiments described by Wilson et al. (2017) compare magnetization dynamics in samples subjected to ultra-short (ps) light and electric current pulses of similar energy. In both cases the magnetization dynamics could be described by the three-temperature model, but the rate of energy transfer between the electrons and the lattice, τ_{el}, had to be about twice as large when electric current pulses were used, compared with light pulses, in order to fit the experimental results. The reason for the difference was suggested to be due to how energy is transferred into the medium: an electric current pulse excites many electrons by a small amount, whereas a light pulse excites relatively few electrons by a large amount. The resulting difference in the distribution of electron energies governs the rate of energy transfer τ_{el}.

4   Conclusions

At first glance, creating a model of heat-assisted magnetic recording may appear daunting due to the large number of parameters that must be considered and the fact that nearly all of them are temperature dependent. Indeed, it is often difficult to find appropriate values for many commonly used materials in the literature, and then there is the question as to whether bulk values are representative of thin films. However, on ultra-fast time scales, it is often the case that most of the parameters only have a small influence on the result, meaning that knowledge of their precise values is unnecessary. Magnetization dynamics for macrospin cells can be calculated using the LLB model, while the LLG model is suitable for atomistic calculations. Depending on the size of the illuminated region, thermal conduction calculations may not be needed, and it may be sufficient to assume a uniform temperature distribution. Despite these approximations, many experimental results have been successfully described using micromagnetic and atomistic models, and once a basic model has been implemented, it is not too difficult to add support for more exotic phenomena, such as the inverse Faraday effect, or magnetic circular dichroism, as needed.

Abstract

The scanning tunneling microscope is a unique tool for injecting electrons with great energy and spatial resolution. These electrons can interact with local magnetic moments and reveal the rich phenomena associated with spin-flip dynamics. This chapter is a review of these interesting effects with emphasis on physical concepts and recent results. The Kondo effect is of paramount

importance in condensed matter physics. When Kondo correlations and systems of spins of increasing complexity are used, new phenomena appear such as heavy-fermion phases as recently revealed by quasiparticle-interference experiments. New developments showing the relationship between atomic spin entanglement and appearance of Kondo correlations are reviewed. Non-equilibrium Kondo brings in its own features although in the tunneling regime, the Kondo effect is largely accounted for its equilibrium properties. Kondo peaks, inelastic electron tunneling spectroscopy, electron paramagnetic resonance of single atoms, molecules, and atomic objects are explored.

1   Introduction

Adsorbates on solid surfaces can present localized magnetic moments. The properties of these local magnetic moments give rise to very rich and interesting physics. Recently, it has been shown that the scanning tunneling microscope (STM) is able to measure the spectra of magnetic excitations of these adsorbates (Heinrich et al. 2004; Ternes et al. 2009; Gauyacq et al. 2012; Ternes 2015, 2017), having in this way a probe into the quantum world of atomic adsorbates. Among the rich properties of this quantum world, the Kondo effect has a predominant role revealing the complexity of many-body correlations.

The combination of the just-mentioned magnetic spectroscopy, with the atomic manipulation abilities of the STM, is giving rise to new exciting possibilities. Atoms can be located on a surface in ways that were never thought of before. This permits us to show new properties that only existed in theoretical works. Tantalizing examples are the creation of tailored spin chains with antiferromagnetic ordering (Hirjibehedin et al. 2006; Loth et al. 2012), with ferromagnetic spin waves (Spinelli et al. 2014), with exotic XXZ phases (Toskovic et al. 2016), or with Kondo correlations that did not exist in the isolated components before atom manipulation (Choi et al. 2017b).

Another example of the fast-track evolution of local magnetic moment physics and the STM is the advent of electron paramagnetic resonance (EPR) techniques (Manassen et al. 1989; Komeda and Manassen 2008; Balatsky et al. 2012; Müllegger et al. 2014; Baumann et al. 2015). The measurement of time-resolved signals with the STM opens a new door to hyperfine interactions (Heinrich, 2017, personal communication) and to studying spin lifetimes (T_1) and decoherence times (T_2) (Delgado and Fernández-Rossier 2017). Pure dephasing times (T_2^*) understood as the component of T_2 that deregulate the spin phase via elastic interactions (and not because the population of a given spin state has been quenched after a time T_1) need to be known and understood before any serious coherent manipulation of spins can be successfully undertaken in techniques such as quantum computing (Pla et al. 2012).

In the present chapter, we will make a brief review of the Kondo effect of magnetic adsorbates with special emphasis on developing an understanding of the underlying physics and on exploring recent results. We will also briefly summarize

magnetic inelastic effects at the core of single-atom magnetic spectroscopy. We will show how the study of magnetic impurities can become of increasing complexity by making them mutually interact leading to correlations, entanglement, and new states of matter. In particular, the use of quasiparticle-interference (QPI) analysis in the STM has become a mature technique and is widely used in the study of heavy-fermion systems caused by Kondo correlations (Morr 2017). Due to the exciting new developments of single-molecule EPR, we briefly summarize the developing activities in this area at the end of the chapter.

2   Spin Interaction Between Substrate and Adsorbate

As early as 1930, reports on the behavior of electrical resistivity of noble metals with temperature showed a perplexing upturn of the resistivity as temperature decreased (Meissner and Voigt 1930). This finding was clearly at odds with all the body of knowledge on the electronic and vibrational properties of solids at low temperatures. As temperature is reduced, the resistivity should diminish as $\sim T^5$ due to the quenching of electron-phonon scattering and eventually level off at very low temperatures due to lattice imperfections (van Sciver 2012). It was soon realized that a small concentration of magnetic impurities seemed to be responsible for the anomalous behavior (Kondo 2005). But reports were unclear. In 1964, experimental research was still active in determining when a minimum in the resistivity with dropping temperature was found (Sarachik et al. 1964). The origin of the resistivity upturn became clear the same year, when Jun Kondo computed the resistivity due to scattering off magnetic impurities (Kondo 1964). These calculations proved that magnetic impurities were responsible for the resistivity minimum, and they further showed that coherent spin-flip scattering was the physical process at work. As temperature was reduced, all excitations in the solid were quenched except the ones due to spin-flip scattering that gave rise to an increased scattering rate of conducting electrons. Due to the interaction between the magnetic moments of the electron and the impurity, the spin of an electron can flip at the same time as the magnetic moment of the impurity. The electron can change the magnetic moment in one unit of spin (two Bohr magnetons in magnetic moment units), and the impurity changes in minus one unit, keeping the magnetic moment constant during the electron-impurity scattering.

The calculation by Kondo was based on the s-d exchange model developed by Zener (1951). This model considered the magnetic exchange interaction between itinerant electrons and a quantum impurity. The itinerant electrons were represented by the s-band of a free-electron-like host. The d electrons took into account the localized spin of the impurity. The calculation by Kondo was based on perturbation theory. The result revealed that the second order of perturbation theory gave rise to a logarithmic term on the temperature. This is troublesome for the perturbation scheme because at low temperatures the second order grows as the temperature is reduced and the perturbation expansion is not converging. Nevertheless, the logarithmic behavior turned out to be correct. Kondo fit the experimental data

using an expansion including logarithms, giving very good agreement with experiments (Kondo 1964). In this way, he made a connection between electron scattering off impurity spins and the resistivity minimum.

Logarithmic scaling with interactions is ubiquitous in Kondo systems. They reflect complex many-body processes that cannot be solved with simple techniques. It basically implies that perturbational approaches will fail evaluating the ground state of the system because the new ground state is fundamentally different from the non-interacting one. It further means that all behavior with temperature will be smooth and slow, giving rise to "crossovers" rather than phase transitions.

The new type of ground state is clearly seen by following a renormalization-group (RG) approach (Bulla et al. 2008). The RG approach is based on the observation that to evaluate the ground state, higher-energy degrees of freedom can be effectively considered by a new Hamiltonian. This new Hamiltonian contains the correct ground state if the interactions are changed while removing the higher-energy states. As the higher-energy degrees of freedom are removed, the interactions are renormalized. The evolution or flow of the interactions as the number of available electronic states is reduced gives clear information on the properties of the ground state.

The conditions to have a Kondo ground state are that the magnetic impurity contains internal degrees of freedom that are degenerate and can be switched by an external electron collision where the spin of the electron changes by 1. This is an elastic process where the electron produces a spin flip, thanks to an "effortless" change in the state of the impurity. Kramers theorem (Kramers 1930) warranties that half-integer spin impurities will present a degenerate ground state. In the presence of a positive uniaxial magnetic anisotropy, the ground state of the impurity will be $\pm 1/2$ and the spin-flip ($\Delta s = \pm 1$) becomes possible.

If the uniaxial magnetic anisotropy is negative, the ground state is $\pm S$ and cannot be connected by a spin flip unless $S = 1/2$. The electrons cannot be correlated via scattering with the impurity. However, there can be spin flips with the excited spin degrees of freedom of the impurity. This gives rise to inelastic spin flips. The STM is an excellent tool to reveal all these spin-flip processes (Heinrich et al. 2004; Ternes et al. 2009; Gauyacq et al. 2012; Ternes 2015, 2017). The two types of spin flips, elastic or Kondo and inelastic, can be seen as rapid variations of the differential conductance measured by an STM. Figure 1 shows a typical example for an STM junction where a spin is changing due to elastic spin flips that show as a peak at zero bias or inelastic spin flips that show as sharp steps symmetrically position with respect to zero bias.

The STM consists of a piezoelectrically controlled electrode (the tip) that can be sharpened to be atomically terminated. It is a two-electrode setup as sketched in Fig. 2a. Due to the atomic termination and the sub-Ångström control of the position of the tip, the STM can drive electric currents within the atoms of the other electrode, in general a flat metallic substrate. At low bias, the current proceeds in the tunneling regime because the electrons cannot overcome the vacuum barrier between the electrodes. This tunneling current is extremely localized, both laterally and vertically, which are key for detecting changes in the current under subatomic
Fig. 1 Simulated differential-conductance spectra of an STM over a magnetic adatom displaying spin-flip processes. At zero bias a clear peak appears due to the existence of a Kondo ground state. The peak signals the presence of elastic spin-flip events that lead to a correlated ground state. Symmetrically at positive and negative bias, two steps appear in the differential conductance signaling the onset of inelastic spin-flip processes. When the spin is excited, new conduction channels abruptly open, increasing the conductance of the junction

motions of the tip. Scanning the surface while keeping the tunneling current constant leads to maps of the tip positions that make the usual STM images. Fixing the tip at a location on the surface and ramping the bias allows to record information on the propagation of electrons through the system. Ideally, the tip is not perturbing the substrate and has either a flat electronic structure or a well-known one. In these cases, the STM gives direct information on how electrons are injected or extracted from the sample. A perturbation-like calculation assuming that only the s-wave of the electronic wavefunctions generating at the tip contributes yields that the conductance is proportional to the local density of states evaluated at some tip "center." The local density of states is the number of states per unit energy weighed by the spatial distribution of each electronic state. This is the Tersoff-Hamann approximation that allows us to interpret STM data as due to the electronic spectra of the surface (Tersoff and Hamann 1985). Under the above conditions, the STM is an excellent tool to measure the spectral properties of a conducting solid surface.

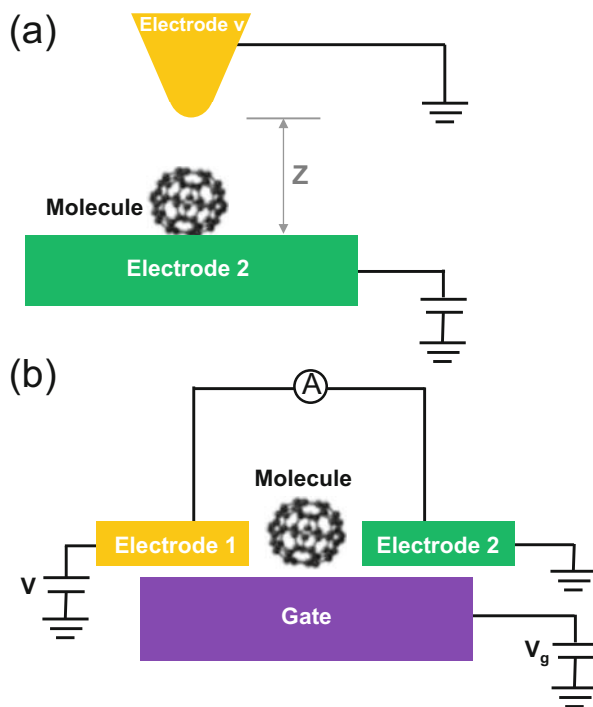
In 1998, the first observations with STM of the Kondo resonance above single magnetic atoms on a metal surface were reported by two groups. Madhavan et al. showed that a narrow asymmetric feature near E_F appeared in the dI/dV of cobalt atoms on a Au(111) surface (Madhavan et al. 1998), while Li et al. observed a characteristic dip around E_F with Ce adatoms on Ag(111) (Li et al. 1998). Both types of spin-flip processes (elastic or Kondo spin-flip and inelastic) can be observed with the STM on a single magnetic impurity. This is due to the peculiar features of the spectral function. In the presence of Kondo physics, the spectral function displays a peak near the Fermi energy (the Abrikosov-Suhl-Kondo or Kondo peak).


Fig. 2 Sketch of electrodes in a STM setup (**a**) and in a molecular break-junction one (**b**). The limitation of two electrodes in the STM is compensated by the scanning ability of the tip electrode yielding sub-Ångström resolution. Break junctions can change their gaps, but they cannot laterally scan. However they can apply a perpendicular electric field that shifts molecular levels and accordingly change the charge state of the molecule

This corresponds to a feature in the conductance at zero bias, sometimes called a zero-bias anomaly (ZBA). Since the conductance is not uniquely determined by the substrate spectral function, the spectral peak can become a general Fano feature (Fano 1961). In contrast, inelastic peaks generally translate into a step in the spectral function and in the conductance. In simple terms, the step is due to the opening of new transmission channels due to the presence of the excitation. At energies or biases below the excitation threshold, the current proceeds through the elastic channel. Above the threshold, inelastic channels open producing a sudden increase of the conductance (Hipps and Mazur 2006). As in the case of the ZBA, the actual electronic transport process can change the profile with bias producing more complex behavior than just a step in the conductance. In the cases of large conductance (generally not in the tunneling regime), the effect of the excitation will be rather detrimental to transport, and instead of an increase of the conductance at threshold bias, there will be a decrease.

The original Kondo effect implies a reduction of conductance at low temperature. However, the STM Kondo effect can be an increase of conductance. At first

perplexing, the conundrum can be solved by realizing that the conductance of an extended system with many impurities means the averaging of the scattering produced by all the impurities. Hence, the increase of conductance over a single impurity actually means an increased scattering rate that leads to a reduction of conductance over many impurities. The STM gives special insight over the behavior of a single magnetic impurity that can be very different from all other techniques based on averaging procedures.

Before closing this section, it is interesting to mention two different techniques where the excitation of individual magnetic moments has also been achieved by electrical means. One of these techniques is the break-junction technique where a small gap (in the nanometer range or smaller) is filled by adsorbates that contain a magnetic moment (Yanson et al. 1995; Park et al. 2002). These magnetic adsorbates interact with the magnetic moment of passing electrons between the junction electrodes. The other technique is the fabrication of quantum dots (QD), where metallic and semiconducting structures blend, creating an electronic potential landscape that can capture individual electrons and thus originate local magnetic moments. The effect of these local moments on the current can be studied by the conductance signals of the device. The common feature of these techniques is that the experimental setup corresponds to a three-terminal junction as sketched in Fig. 2b. The two electrodes drive a current under the applied bias, and the gate is also electrically polarized but uncoupled via some insulating layers from the molecular junction. Its role is to provide an electric field that shifts the molecular levels without injecting extra charge in the system. This allows to have experiments complementary to the ones with the STM setup. The advantage is the possibility to tune electronic states of the junction, while the STM is more precise in the positioning of the electrodes with the great advantage of being able to scan ample sets of electrode positions.

In 1998, the Kondo effect was observed for the first time in a QD by two different groups. A QD is a nanoscale artificial semiconducting box in contact with metallic leads. A two-dimensional electron gas is confined in the dot and produces a DOS with discrete energy levels. The number of electrons in a QD can be adjusted by applying voltage to a gate electrode. The number of confined electrons in the dot can be odd or even. In the case of an odd number of electrons, the net spin of the dot is nonzero. Goldhaber-Gordon et al. observed a Kondo effect in a single-electron transistor containing a GaAs/AlGaAs heterostructure (Goldhaber-Gordon et al. 1998). When an electric field is originated by the gate electrode, the conductance shows peaks periodic in bias, indicating a quantized number of electrons in the dot. For an odd number of electrons, a Kondo resonance is detected near E_F. This indicates that a localized magnetic moment is present in the dot and that it interacts with the free conduction electrons in the leads. The QD therefore closely mimics the Kondo effect of a magnetic impurity embedded in a metal. Goldhaber-Gordon et al. also showed that the Kondo resonance is suppressed when the temperature is increased and that an external magnetic field can produce a Zeeman splitting of the resonance. As we show here after, these effects are both expected for the Kondo effect. Cronenwett et al. also published the study of the Kondo effect in a

QD (Cronenwett et al. 1998). By adjusting the number of electrons in the QD, they switched the Kondo effect on and off. They studied the temperature and the magnetic field dependence and showed the influence of magnetic anisotropy by rotating the external magnetic field.

Break junctions (Yanson et al. 1995; Park et al. 2002) use an actuator to induce pressure on the gate and mechanically increase the distance between the electrodes (Fig. 2b). Hence, a break-junction experiment can map the behavior of the molecular junction under different charging states, like in the above QD setups. Additionally, they can also change the conductance regime from contact to tunneling by varying the distance between electrodes.

The energy needed to destroy the Kondo ground state is usually given in terms of a temperature, T_K (see Eq. (4)), signaling the temperature above which the Kondo effect disappears. The T_K in QD systems is very low, about a few hundred millikelvin, and as a consequence, to observe the Kondo resonance in a QD requires a higher bias resolution than single-molecule devices where $T_K \sim 10$ K. The reason for the lower T_K in QD as compared to atomic and molecular adsorbates is the lower electron confinement, which leads to very small electronic energies as compared with atomic impurities. In this chapter, we focus on the spin-flip physics of atomic systems. Due to the very different energies involved as compared with quantum dots, typical Kondo energies are much higher and easily resolved by low-temperature scanning tunneling microscopes.

3   The Physics of Spin-Flip Scattering

Let us try to give two physical pictures of the processes at hand. The first one is a ground-state picture that simply acknowledges the fact that the Kondo effect is the creation of a new ground state due to the interactions between electrons and a localized magnetic moment. This ground state is many-body and hence difficult to grasp, but a simplified model can shed some interesting facts easily contrastable with what is known of the Kondo effect. The second picture is of a more dynamical aspect. It treats the Kondo effect as due to coherent spin-flip processes, and it is a local picture, where only the variations of the impurity's magnetic moment are followed during the interaction with the substrate electrons. Finally, we will mention the Kondo peak, as a valuable spectroscopical source.

3.1   The Ground State: Simple Picture of the Kondo Effect

The presence of spin-flip scattering off a magnetic impurity leads to a new ground state of the electronic system. The ground state cannot be approximated as a Fermi sea where one-electron states pile up in energy abiding by the Pauli principle. How can we understand this? A simple cartoon-like model is given by P. Fulde in his book on electron correlations (Fulde 1995).

The model assumes a localized electronic state, a, such as we would expect for an atomic impurity on a solid surface. In the limit of very strong intra-atomic Coulomb

(a) V = 0 (b) V ≠ 0
Fig. 3 Energy diagram of the simplified model of Sect. 3.1. Initially we assume just two electrons on two different orbitals. The orbital at energy ε_a is a compact atomic-like orbital, with a large intra-atomic Coulomb repulsion, U, such that double occupancy of the orbital is not permitted. The other orbital corresponds to an extended state, with negligible intra-atomic Coulomb repulsion. When the interaction between the atomic-like and the metallic-like states is zero, $V = 0$, there are four degenerate ground states and one excited state. When a hybridization-like interaction is allowed, $V \neq 0$, a $S = 0$ ground state is generated, leading to the total screening of the otherwise spin-polarized atomic state. The low-energy excitations are magnetic

interaction, $U_a \rightarrow \infty$, this state can only present two occupations, either zero or one electron. This is immediately a magnetic impurity of spin 1/2. To model the metallic surface becomes difficult. Let us assume that it is like an electron in an extended molecular ligand, which is the model that Fulde solves (Fulde 1995). Then our metal will be a single state that is so delocalized that two electrons easily fit in. In other words, $U_{\text{metal}} = 0$. To keep the model simple, we assume we have two electrons in the full system. Furthermore, we assume a nonmagnetic host in the absence of impurities; hence two electrons in the metal will pair antiferromagnetically with spin zero ($S = 0$).

Figure 3a shows the five possible states of these two electrons over the two electronic states (*metal* and *a*) when there is no interaction between impurity and metal. In the absence of impurity-metal hybridization, there are four degenerate states that become the ground state. These corresponds to the four possibilities of putting one electron on the impurity and one electron on the metal. The four possibilities are one singlet state (total spin zero, $S = 0$) and the triplet states (total spin one, $S = 1$). The energy of the ground state is $\varepsilon_a + \varepsilon_{\text{metal}}$ because there is one electron in *a* and one in *metal*. The only excited state is the doubly occupied metal at $2\varepsilon_{\text{metal}}$. The doubly occupied impurity corresponds to an infinite energy ($2\varepsilon_a + U_a$) and is out of our Hilbert space.

When a chemical interaction between impurity and metal is allowed, a one-electron hybridization term allows electrons to flow back and forth the metal from the impurity, which we call $\langle a|V|metal \rangle = V$. This is a one-electron term, so the electron spin is conserved. As a consequence, the new states are still two singlets ($S = 0$) and the three $S = 1$. The interaction couples the two singlets because the hybridization cannot change the spin as we just said. The corresponding Hamiltonian in the $S = 0$ subspace is:

$$\begin{pmatrix} \varepsilon_a + \varepsilon_{metal} & V\sqrt{2} \\ V\sqrt{2} & 2\varepsilon_{metal} \end{pmatrix}. \tag{1}$$

When the hybridization term goes to zero ($V = 0$), we recover the spectrum of the non-interacting case of the $S = 0$ subspace of the previous paragraph. Diagonalizing the new Hamiltonian is simple and yields two states with energies:

$$E_{GS} = \varepsilon_a + \varepsilon_{metal} - \frac{2V^2}{\varepsilon_{metal}}, \qquad (2)$$

and

$$E_{excited} = 2\varepsilon_{metal} + \frac{2V^2}{\varepsilon_{metal}}. \qquad (3)$$

The new spectra are plotted in Fig. 3b, including the invariant $S = 1$ states. We see that the interaction between impurity and metal lifts the degeneracy of the ground state, and the new ground state is stabilized by an energy $-\frac{2V^2}{\varepsilon_{metal}}$. As Fulde shows in his book (Fulde 1995), this simple model contains many features of the complex Kondo physics between an impurity and a true metal substrate.

Features of this simplified model:

- The first startling consequence is magnetic screening of the impurity. Indeed, in the absence of impurity-metal hybridization, the impurity has a local magnetic moment. When the interaction is switched on, the ground state is nonmagnetic and the local moment disappears. This is parallel to the screening of the Kondo effect. In the impurity problem, the magnetic moment of the impurity is screened because the total ground state is nonmagnetic.
- The low-energy excitations are all magnetic. In the simple model, all excitations are singlet-triplet excitations. The excitation energy is $\frac{2V^2}{\varepsilon_{metal}}$. When the system's temperature matches this excitation energy (in the correct units and assuming that we can define thermodynamic quantities), the ground state is destroyed and the system is excited. This temperature would correspond to the Kondo temperature in the correct impurity problem. Obviously the true Kondo temperature is not proportional to the square of the hybridization potential, V^2.
- The ground state is unique, but the first excitation is triply degenerate. Since the ratio $\frac{2V^2}{\varepsilon_{metal}}$ is small because $\varepsilon_{metal} \gg V$, then we have many excited states at very low energies. In the impurity problem, this corresponds to the Kondo peak. Namely, at very low energies (i.e., close to the Fermi energy), there is an enormous density of states due to magnetic excitations. The Kondo peak is a consequence of the low-energy magnetic excitations of the system caused by the hybridization between metal and impurity.
- High-energy excitations correspond to charge transfer from the impurity into the metal. This energy scale is given by ε_{metal}. Excitations are then separated into spin (low-energy, Kondo peak) or charge degrees of freedom.
- As temperature increases, the triplets become populated and the magnetic moment of the impurity is restored.
Fig. 4 Local picture of the Kondo spin fluctuations due to the hybridization of an atomic orbital with metallic orbitals. Due to the intra-atomic Coulomb repulsion and the hybridization with the substrate, the atomic charge fluctuates between zero and one electron. As a consequence of the charge fluctuations, the atomic spin changes

An extension of the above features to the impurity problem can be easily done by using a variational approach to the Anderson model (Fulde 1995; Yosida 1966; Varma and Yafet 1976). In the $U \rightarrow \infty$ simplification, the no-hybridization configurations are, see Fig. 4, (i) a Fermi sea (representing the metal) and an empty impurity (excited state), (ii) a Fermi sea with a missing electron (hole) and a filled impurity (excited state), (iii) and a filled impurity with a hole at the Fermi energy (ground state). Minimizing the expected value of the Anderson Hamiltonian with respect to the coefficients of the three configurations when the hybridization term is allowed, we obtain a new ground state that is stabilized by an energy:

$$k_B T_K = D \, \exp\left(-\frac{\pi |\varepsilon_a|}{\Gamma_a}\right). \tag{4}$$

The electronic bands of the metallic surface are represented by half the bandwidth D. Here Γ_a is the width of the impurity level due to the hybridization with the substrate ($\Gamma_a = 2\pi \sum_k V_k^2 \delta(\varepsilon_a - \varepsilon_k)$). The impurity level energy, ε_a, is now measured from the Fermi energy, which is ε_{metal} in the above simplified model. Then we see that as above, the ingredients determining the strength of the Kondo effect (the ground-state energy) are ε_a and Γ_a.

The behavior of ε_a and Γ_a is actually intrinsically related with the occupation of the impurity level on the metal surface. In the case that $|\varepsilon_a| \gg \Gamma_a$, the level is completely occupied, and the Kondo temperature, Eq. (4), tends to zero. Hence, even if there is a magnetic moment on the impurity with a sizeable coupling to the substrate (large Γ_a) when the level is always full ($|\varepsilon_a| \gg \Gamma_a$), there is no Kondo effect, and the magnetic moment of the impurity remains frozen. This is the local-moment regime. On the other limit, if $|\varepsilon_a| < \Gamma_a$ the level is basically half-filled (or closed to half-filling). This corresponds to a very large Kondo temperature. As a consequence the peak of spin excitations (the Kondo peak) will merge with the peak of charge fluctuations (the resonance derived from the ε_a level). Indeed the charge fluctuations will win over the spin ones, and the Kondo effect will not be well defined. This is the mixed-valence regime. Mixed valence means that the charge in the impurity is fluctuating among several valence states of the impurity. Finally, the

Kondo regime takes place in between, for impurity levels that are largely occupied but allowing charge fluctuations.

The study of charge fluctuations is clearly linked to the study of Kondo physics. We briefly review this in the next section.

3.2   The Dynamical Spin-Flip Picture

Adopting a local picture immediately leads us to charge fluctuations and their role in the Kondo effect. P. W. Anderson (1961) soon realized that the $s - d$ exchange model of Zener and others that Kondo adopted (1964) could be explained in terms of charge fluctuations of the impurity (Schrieffer and Wolff 1966). The occupation of the impurity level will change over time as a consequence of the hybridization with the substrate and the large intra-atomic repulsion ($U \rightarrow \infty$ in the above discussion) if the impurity level is within Γ_a of the Fermi energy following the preceding discussion. If the level is very far from the Fermi energy, the charge state will be frozen and no Kondo effect is possible. But if the average charge state is not zero or one, the level occupation fluctuates between zero and one electron.

Figure 4 shows a simplified scheme of this system. During charge fluctuation the spin is initially in one state, say up. After a certain time, the impurity gets empty. Then it captures another electron with spin up or down with equal probability for nonmagnetic substrates. And this process is repeated over time. As a consequence, the spin on the impurity changes randomly over time. If the average charge state is large, say 90%, then the impurity is 90% of the time occupied, and for a brief 10% of the time, it is empty. An observer would see an impurity that is occupied but that changes randomly its spin due to its hybridization with the metal substrate. Effectively this is a $s - d$ exchange interaction: the spin on the impurity flips by flipping back a spin in the metal. P. W. Anderson (1961) showed that this effective interaction is of the antiferromagnetic exchange type (trending to antialign spins in the impurity and in the metal). Later on Schrieffer and Wolff (Schrieffer and Wolff 1966; Hewson 1993) set a rigorous framework to transform between the Anderson Hamiltonian (describing the impurity hybridization and charge fluctuations) and the $s - d$ exchange or Kondo Hamiltonian.

The difference between the spin-flip picture and the previous ground-state calculation is that the spin-flip picture locally evaluates the physics of the impurity. As a consequence, the construction of the ground state of the full system is simplified to the local fluctuations of the impurity state. The physics is the same, but they offer complementary pictures that help understanding the Kondo effect.

3.3   The Spectroscopic Signature: The Kondo Resonance

The spectroscopic signature of the Kondo effect is the Kondo peak. In the STM this shows as a zero-bias anomaly in the conductance. In photoemission, it is a peak in the spectra. The peak takes place very close to the Fermi energy because it

comes from very low-energy excitations of magnetic origin. When the intra-atomic Coulomb repulsion is finite, hole-like excitations are also allowed and the Kondo peak actually extends below the Fermi energy. In a symmetric case (symmetric Anderson model, $|\varepsilon_a| = U/2$), particle and hole excitations weigh the same in the spectra, and the Kondo peak is centered on the Fermi energy.

As we show in the simplified model above, not only the ground state is shifted due to the hybridization but also the metallic states. If we evaluate the square of the overlap of the metallic state before and after switching on the hybridization, we find that it is $1 - n_a$ for metallic states close to the Fermi energy, where n_a is the occupation of the impurity level. In the Kondo regime, n_a approaches one. This means that the metal states at the Fermi energy before and after connecting the hybridization are virtually orthogonal. The metal states become quasiparticles that actually behave like non-interacting fermions (Hewson 1993).

Actual STM measurements are quite involved, and the complete characterization of the Kondo peak requires several measurements. However, the Kondo peak has some unique features that make it totally different from any other source of ZBA. The Kondo effect disappears with increasing temperature by developing a particular broadening of the Kondo resonance. The broadening can be shown by measuring the corresponding decrease of the conductance amplitude at resonance. Changes in amplitude with temperature can be expressed as (Pustilnik and Glazman 2001):

$$G(T) = \frac{2e^2}{h} t \left[1 + \frac{T^2}{T_K^2} (2^{1/s} - 1) \right]^{-s} + G_{el} \qquad (5)$$

with $s = 0.22$, while G_{el} accounts for a constant background. The free parameters T_K, t, and G_{el} are found by fitting the experiment. As for the broadening, assuming a Lorentzian resonance, the full width at half maximum Δ_K is approximately (Nagaoka et al. 2002; Ternes et al. 2009):

$$\Delta_K = \sqrt{(\alpha k_B T)^2 + (2k_B T_K)^2} \qquad (6)$$

where k_B is the Boltzmann constant, T is the working temperature, and $\alpha = 5.4$ (Ternes et al. 2009). When $T \ll T_K$, then $\Delta_K \simeq 2k_B T_K$.

A second sign that experiments are dealing with the Kondo effect is the peak dependence with external magnetic field, $\vec{B}$. An external magnetic field induces a Zeeman splitting of the impurity's magnetic levels; hence spin-up scattering is not any longer degenerate with spin-down scattering, and the Kondo effect is destroyed. However, its destruction is not complete, because electrons of higher energy can interfere with opposite spin electrons if their energy difference is exactly the Zeeman splitting. Indeed, we are describing an inelastic effect, and at the energy threshold of this inelastic effect, the electrons can spin flip coherently, recovering a Kondo peak, but instead of being centered near the Fermi energy, the new peak is centered at the energy of the excitation. Since electrons above the Fermi energy and below (holes) can produce this inelastic effect, there are two new peaks that

appear, replacing the previous Kondo peak when the magnetic field is applied. For very large fields, coherence cannot be achieved and all peaks disappear, or in other words, the impurity's magnetic moment cannot be screened out at large external magnetic fields.

Both the temperature and magnetic field behaviors permit us to characterize a zero-bias anomaly as due to the Kondo effect. However, experiments are further complicated by the fact that these anomalies are rarely pure peaks. Indeed, they present Fano line shapes that are more difficult to analyze. The origin of the Fano line shape comes from the contribution of many electronic states to the STM conductance other than the impurity's ones. In STM, the line shape of the Kondo resonance depends on the quantum interference, or Fano interference, of the tunneling channels (Fano 1961; Madhavan et al. 2001). One of the tunneling channels takes place between the tip and the Kondo resonance. The second channel is tunneling between the tip and the metal surface through a non-Kondo process. The third channel is directly tunneling into the d-level of the impurity. In this case, the electron eventually has its spin flipped and is located at the Fermi energy in its final state. Channels 1 and 2 preserve the spin orientation and therefore can interfere. This interference is the Fano interference of a localized state with a continuum. Depending on the relative phases of both processes, the interference produces the asymmetric line shape of the ZBA. Several workers have devoted their attention to the appearance of these Fano profiles (Madhavan et al. 2001; Plihal and Gadzuk 2001; Merino and Gunnarsson 2004; Baruselli et al. 2015; Jacob 2015; Frank and Jacob 2015; Fernández et al. 2016). They all model the previous interference mechanism but using different numerical tools. Frank and Jacob (2015) simplify their approach writing a 2×2 matrix for the Hamiltonian, including the above principal scattering channels, and give a very physical account of the leading terms of the interference for the case of Co adatoms. Previously, similar calculations (Merino and Gunnarsson 2004) had shown the importance of particular electronic structure on the continuum states, such as surface states; recently Aligia and co-workers explain the experimental Fano line shape of a Co atom on confined surface states following the same rational (Fernández et al. 2016).

4   Inelastic Spin-Flip Spectroscopy

The excitation of spins using the STM is a mature technique with many well-tested examples and a thorough understanding of its principles. The first IETS was performed by Heinrich and co-workers (Heinrich et al. 2004) studying Mn atoms on an $Al_2O_3/NiAl$ substrate. The oxide layer was proven to be fundamental to increase the lifetime of the excitation and in this way resolve it in the spectra. The spectra were a set of steps that split in smaller steps under an external magnetic field, showing the magnetic origin of the inelastic effect. The steps in the spectra originate when the applied bias is larger than the inelastic thresholds. At this moment a new inelastic channel opens, suddenly increasing the conductance. The reason why

the rise is so abrupt comes from the sharp edge of the Fermi distribution at low temperatures. Indeed, during tunneling the inelastic effect is a close channel if the final electron states correspond to an occupied state or, in other words, to an energy below the Fermi energy. Hence, the Fermi distribution function has a fundamental role in determining when the inelastic effect takes place; as temperature increases, the Fermi distribution function smears out, eventually rendering the opening of the channel, and hence the conductance step, invisible.

Other experiments followed using IETS to characterize magnetic adsorbates and magnetic interactions at surfaces. The assembly of atomic spin chains of Mn on Cu_2N/Cu(100) was an astonishing example of the capability of the STM to create new physical objects not explored before (Hirjibehedin et al. 2006). The atoms were aligned leaving a distance of 3.5 Å between atoms, and they were shown to interact via a spin-spin Heisenberg interaction of the form $J\vec{S}_i \cdot \vec{S}_{i+1}$ between the spins of atoms i and $i + 1$. The experimental data nicely followed the excitation thresholds of the above Heisenberg chain, showing the spectroscopic signature of the spin excitations of each chain.

Single Fe atoms on the same substrate also showed tantalizing magnetic spectra that were correctly identified as due to the magnetic anisotropy created by the surface on the Fe atom (Hirjibehedin et al. 2007). These experiments showed that the strength of the signal, namely, the size of the conductance steps at the inelastic thresholds, followed the modulus square of the matrix element between initial and final spin of the total spin vector. This empirical result was theoretically justified by Mats Persson (2009) and soon after identified with the strong-coupling co-tunneling arguments of Lorente and Gauyacq (Lorente and Gauyacq 2009; Gauyacq et al. 2012). This last work emphasized the experimental fact that the inelastic changes in conductance were outstandingly large, easily becoming larger than the elastic contribution, in contrast to vibrational IETS (Ho 2002; Komeda 2005; Morgenstern et al. 2013) that rarely yields changes above 10% of the elastic conductance. The authors justified the efficiency of the inelastic transitions using the following physical picture (Lorente and Gauyacq 2009; Gauyacq et al. 2012). The tunneling of electrons leads to the temporary formation of a negative-like (or positive-like or both) intermediate ion. When the electron leaves the ion, the final state can have a large probability to be different from the initial one. This is because the co-tunneling process (an electron jumping in and out of the atom) changes the spin by one unit, and the overlap of this state with one of the excited states plus the spin of the outgoing electron is related to Clebsch-Gordan coefficients that are large numbers, many times larger than one. As a consequence, the transition probability can become very large. Indeed, the physical process is the one of angular momentum compositions between the impurity spin and the tunneling electron spin. Angular momentum composition can lead to large spin transfer and hence to an efficient spin torque (Delgado et al. 2010; Novaes et al. 2010; Gauyacq et al. 2012).

The $\vec{S}^2$ theory for spin excitation is simple and permits a quick rationalization of experimental spectra. It has become a standard for inelastic spin transition using ab initio (Hurley et al. 2011a, b) or empirical approaches (Ternes 2015).

Recent experiments (Ormaza et al. 2017) performed on a nickelocene molecule show extremely large changes in conductance. Indeed, the step size is more than six times the elastic conductance. This means that when a current is driven through this type of molecules, the current is basically inelastic, and any type of rationalization of the electronic transport of the molecule in terms of elastic currents (i.e., Landauer approach) will fail. Nickelocene is a $S = 1$ molecule, with an easy plane anisotropy due to its internal ligand field. The large inelastic efficiency is a consequence of the efficient spin transitions due to the actual energy positioning of the conducting molecular orbitals with respect to the Fermi energy (Ormaza et al. 2017).

Many other experiments have been performed together with theoretical work. These works have been recently summarized in different review articles (Gauyacq et al. 2012; Ternes 2015, 2017).

5   Magnetic Molecules in Break-Junction Experiments

A Kondo peak is clearly seen in the differential conductance at different temperatures in a Au-C_{60}-Au mechanical controllable break junction, where the Kondo effect is carried by the C_{60} molecule (Parks et al. 2007). Despite the very nonmagnetic nature of fullerenes, a large fraction of contacted molecules showed Kondo peaks in the conductance measurements. Obviously the difference among the sets of measurements was the way molecules were contacted by the electrodes. Fullerenes are known to display large electron affinities, and in the presence of an electron-rich environment such as metallic electrodes, charge transfer is natural. The experiments can be largely explained by the transfer of a single electron, in the cases where the Kondo peak was seen. The implication of these findings is that the electrode-molecule interface is of great importance determining charge transfer, the chemical stability, and ultimately the system's electronic ground state.

Molecules of increasing sophistication have been also studied in break-junction setups (Gaudenzi et al. 2017). Radical molecules present unpaired electrons which is a nonstandard molecular electronic structure. As such the spin leaves in a molecular orbital associated with a group of atoms, contrary to the usual case of local magnetic moments associated to single magnetic atoms that generally are transition-metal or rare-earth atoms. The experiment uses the gating electrode to change the charge state of the molecule, which is beautifully demonstrated by the magnetic IETS at the different molecular charges. A radical electron in a molecule is very unstable in front of charge transfer from the electrodes, and hence we generally do not expect to find any Kondo evidence in organic molecules without metallic centers. Surprisingly, Kondo peaks in the break-junction traces of these molecules are found. The conclusion is that these molecules are special radicals that preserve their open-shell electronic structures despite of not being in solution and in contact with electrodes (Gaudenzi et al. 2017).

Park et al. (2002) studied the Kondo effect of a molecular break-junction device. They showed that a Co ion bonded to polypyridyl ligands with different lengths of insulating tethers, $[Co(tpy-(CH_2)_5-SH)_2]^{2+}$ and $[Co(tpy-SH)_2]^{2+}$, presented a

Zeeman-split Kondo resonance with an external magnetic field in the dI/dV. The splitting amplitude may be tuned by changing the magnetic moment of the molecule via the gate electrode, while changes of the splitting with external magnetic field yield a gyromagnetic factor close to 2 as expected for a free electron, showing that the intrinsic spin-orbit coupling of Co is small.

Break junctions and molecular systems have a rich set of parameters to tune different Kondo regimes. Work performed in Cornell with theoretical insight from Bariloche (Parks et al. 2010) showed that different regimes of the Kondo ground state of a magnetic molecule can be achieved by playing with the mechanical degrees of freedom of the molecule. Stretching or contracting the molecule shifts electronic states which change the magnetic moment and the coupling of the molecule with the electrodes. The consequence is that the molecule can be driven in a state where the spin is too large for the available number of hybridization channels with the substrate. The substrate electrons cannot screen the local magnetic moment completely, and the Kondo effect takes place in the presence of a surviving local magnetic moment. This underscreened Kondo regime is clearly seen in the splitting of the Kondo peak. Contrary to the screened Kondo that needs an external critical magnetic field to split, the underscreened Kondo displays a split peak as soon as the magnetic field is different from zero (Parks et al. 2010).

6 The Kondo Effect and Interimpurity Interactions

When several local magnetic moments interact on a substrate, they can compose, creating a new object with different magnetic moment, different spin dynamics, and different surface spin screening. Their properties can be utterly different from the initial constituents on the same surface. Here, we briefly review the work performed with the STM, revealing these interesting phenomena.

6.1 The Two-Impurity Problem

Wahl et al. (2007) used atom manipulation to vary the distance between two Co adatoms on Cu(100) and recorded dI/dV spectra. For interatomic distances beyond 6 Å, each Co adatom presented individual and unperturbed Kondo resonances. Below 6 Å, the Kondo ground state of the two Co atoms was perturbed through an exchange interaction. The sign of the exchange interaction depended on the Co-Co distance. At 5.12 Å, the exchange coupling was AFM, and the Kondo resonance splits apart. The resonance splitting was, however, not sufficiently strong to be detected in the dI/dV spectrum. Rather, a broadened line width was observed. At 2.54 Å, the two Co atoms coupled instead ferromagnetically. Since no feature appeared in the dI/dV spectrum, this meant that $T_K^N \ll T$, i.e., the new Kondo ground state was lost at the working temperature T. In a different study by Bork et al. 2011, they picked up a Co atom with the tip and approached the tip into contact

with a Co adatom on a Au(111) surface. By varying the interimpurity distance, the authors were able to map the phase space of different ground states as the impurity-impurity interaction changed the Kondo screening.

Another experiment consisted of $CoCu_nCo$ chains adjusting the distance between two Co atoms (Néel et al. 2011). Depending on the length of the chain, a different exchange interaction is produced. For $n = 1$, the interaction is ferromagnetic; for $n = 2$ the interaction is antiferromagnetic. In this last case, no resonance splitting is observed, but only a broadened feature. An oscillation for T_K was evidenced with n ≥ 3 due to an RKKY interaction mediated by the Cu atoms between two Co atoms.

Electrons in different levels of a nano-object such as a cluster of molecules can also present a complex Kondo effect. This is the case of copper phthalocyanine (CuPc) molecules on Ag (100) (Mugarza et al. 2010, 2012; Korytár and Lorente 2011). As in the case of point-contact and break-junction setups, the presence of the surface can induce charge transfer in the adsorbed systems. In CuPc, experimental and theoretical evidence (Mugarza et al. 2010, 2012; Korytár and Lorente 2011) show that an electron can be captured by the large organic ligands of the molecule. The magnetic situation becomes very interesting; there are two different 1/2 spins, one in the ligand and one in the d^9 configuration of the Cu ion, that are weakly coupled through the molecular structure. Electronic-structure calculations show that the coupling is ferromagnetic, and this is fully consistent with the Kondo structure found in the experimental dI/dV. In the experiment a clear Kondo peak is found, very similar to the one that is found for NiPc. Additionally, the spectra show an electron satellite as well as a hole one around the main Kondo peak; these two smaller peaks are absent from the NiPc case. NiPc basically shares the ligand structure with CuPc, in agreement with the idea that an extra electron is being captured there and this is the origin of the Kondo peak. However in CuPc there is an extra d electron; the ferromagnetic coupling with the ligand electron leads to an overall $S = 1$ that presents an excitation to $S = 0$. Then above the excitation energy of roughly 25 meV, the injected electrons can excite the molecular singlet and end up at the Fermi energy of the substrate that holds the Kondo peak. The corresponding large Kondo density of states leads to a peak at the excitation energy. If the electron is extracted from the sample, a similar peak is detected at -25 meV. The physical picture is of a two-impurity problem where one of the spins is strongly screened by the substrate (Kondo effect), while the other spin is in a compact d orbital with small interaction with the substrate and, thus, no Kondo screening. This is the scenario of an underscreened $S = 1$ Kondo system at present measuring temperatures (few Kelvins).

The combination of molecules in chains also gives rise to interesting Kondo physics. In DiLullo et al. (2012), they show the modulation of the Kondo temperature along the molecular spin chain.

This type of physics turns out to be ubiquitous in molecular adsorbates. The double-decker $TbPc_2$ also shows a prominent Kondo feature (Komeda et al. 2011) due to a ligand electron and so does YPc_2 (Robles et al. 2012). The large magnetic moment of the core f-electron of $TbPc_2$ is largely intact. As a consequence the system is again an underscreened Kondo one.

6.2   Kondo Lattices

When Kondo impurities interact, arranged in an infinite array, new physics takes place (Hewson 1993). Below a coherence temperature, T^*, the Kondo impurities are coherent and create a full new ground state of the many-electron system. It can be proved that the new state behaves like a fermion. Given that this new fermionic state is the result of weakly hybridizing, well-defined Kondo states, we would expect to find a dispersless state. Indeed this is the case and the lack of dispersion of the new fermion can be translated in a very large effective mass, typically thousands of times the electronic mass. Kondo lattices are at the origin of heavy-fermion states.

These states have been achieved (Tsukahara et al. 2011) in arrays of iron phthalocyanine (FePc) molecules on Au (111). Their Kondo states hybridized, giving rise to a small gap at the Fermi energy with two dispersless states. But heavy-fermion compounds are known for a long time (Hewson 1993). The adsorption of undissociated oxygen molecules with their large spins (Alducin et al. 2010) on Ag (110) and Au (110) is suspected to give rise to a Kondo lattice and hence to a heavy-fermion phase as well (Jiang et al. 2011). Another example of a 2-D Kondo lattice has been reported on fluorinated FePc molecules on Au (111) (Girovsky et al. 2017).

A recent review by Morr (2017) shows the extraordinary progress in classical 3-D heavy-fermion systems, thanks to the study of quasiparticle-interference (QPI) patterns with the STM. QPI is very sensitive to the small-energy scale of heavy-fermion excitations about the Fermi energy. Since these excitations originate in the substrate-mediated coupling of Kondo peaks, they carry all relevant information on the heavy-fermion structure. The basic principle in QPI is the interference caused in the extended Fermi states by scattering off defects on the surface of the solid. This permits a mapping of the Fermi surface (without defects but thanks to the defects) following the q-vectors of the surface Brillouin zone. Heavy-fermion superconductivity in compounds, such as $CeCoIn_5$, has been largely attributed to spin fluctuations, thanks to these studies (Morr 2017).

Recent STM experiments on $CeCoIn_5$ achieve outstanding resolution of Co and Ce atoms on cleaved surfaces of this material (Kim et al. 2017). The tunneling measurements show that the STM is only sensitive to the d electrons of the Co atoms; but when the STM reaches close to the surface, the d electrons of the Ce atoms become visible, leading to characteristic patterns on the surface. This study permits to identify the role of the different atoms of the material and give experimental evidence of the effect of spin fluctuations driving superconductivity.

6.3   Impurity Entanglement and New Quantum Objects

The above cases studied the interaction between Kondo systems. The initial magnetic moments, despite of being Kondo screened, managed to interact either via direct exchange interactions or via substrate-mediated interactions. But the Kondo effect was individually operative for each impurity. Here, we mention new

experiments where non-Kondo impurities become a new system that can be Kondo screened. Surprisingly, the individual constituents of the nanostructure are not Kondo screened.

The experiments (Choi et al. 2017b) consisted in assembling a heterogeneous atomic chain on a Cu_2N/Cu (100) substrate via atom manipulation. On this surface, Mn and Fe atoms cannot be Kondo screened at accessible temperatures. The reason of this lies on the anisotropy of these spin systems. Fe is a $S = 2$ system on this substrate with a strong easy-axis anisotropy that leads to a nondegenerate ground state, and Mn is 5/2, also easy-axis (albeit a different direction), and its ground state is degenerate but very inefficiently coupled via spin flips (indeed the weight of allowed $\Delta S = \pm 1$ transitions is tiny). These two types of atoms do not present measurable Kondo peaks. But when they are forced to interact on a surface, they develop the characteristic spectra of a Kondo system. Their Kondo peak is visible from the FeMn system, as soon as two inelastic shoulders also appear in the spectra (Fig. 5). These inelastic shoulders come from the collective spin excitations of the two-atom system and are a direct measurement of the strength of their coupling (Hirjibehedin et al. 2006; Choi et al. 2016b, 2017b). The compound system has a not well-defined total spin, but their ground state is doubly degenerate and can be coupled via a spin flip. However, the S_z component of the spin is a good quantum number, and the ground state is $S_z = \pm 1/2$. This can be flipped by a substrate's electron. As a consequence, Kondo physics develops (Fig. 5a). A simple-minded S_z calculation of the FeMn systems easily yields a $S_z = \pm 1/2$ ground
Fig. 5 Differential conductance (**a**) as a function of the applied bias for $Mn_x Fe$ chains for x going from 1 to 10. The spectra are radically different as the number of Mn atoms, x, increases. However, some common features can be remarked if x is even or odd. For even x no Kondo peak is observed, while it is clear and increasing for increasing odd x. The Kondo peak presents a strong temperature dependence as shown in (**b**) for the Mn_3Fe case

states because the atoms couple antiferromagnetically on this surface (Choi et al. 2016b, 2017b). The ZBA are really Kondo peaks as tested by their behavior with temperature, following Eqs. (5) and (6); see Choi et al. (2017b).

Two very different evolutions of the spectra follow as more Fe or Mn atoms are added to the FeMn system (Fig. 5a). Only if FeMn$_x$ spin chains are assembled with x an odd number, Kondo peaks are experimentally found. The parity of x can be understood from the need to have $S_z = \pm 1/2$ ground states. However, MnFe$_x$ do not show Kondo peaks. The reason for this last behavior is more subtle and has to do with the increasing anisotropy of the spin chain as the number of large-anisotropy Fe atoms increases (Choi et al. 2016b). A larger anisotropy implies less weight of terms that favor spin flip in the ground-state composition. In the limit of very large anisotropy, an Ising-like solution with Néel states is favored, but despite their $S_z = \pm 1/2$ character, these states cannot be toggled by a spin flip. The reason is simple; Néel states are a collection of spin up and down; if we allow one spin flip of the $S_z = 1/2$ Néel ground state, we change one only spin flip of the chain. The resulting state is an excitation orthogonal to the $S_z = -1/2$ Néel ground state. As a result, the excited state cannot de-excite into the "other" Néel ground state without higher-order interactions.

This shows that the actual composition in terms of spin configurations of the ground state is very important. The number of spin configurations in the ground state is a measurement of the entanglement of the system. In a bipartite system (e.g., the Fe atom with the Mn$_x$ chain), the entanglement can be determined using the von Neumann entropy that is an efficient way of computing the amounts of bipartite configurations entering the ground state. In Choi et al. (2017b) a direct correspondence is shown between the von Neumann entropy and the strength of the Kondo peak giving an experimental way of evidencing entanglement in a composite system of spins.

7 Point Contact and High-Conductance Regime

To study the conductance of atomic-sized contacts, a variety of experiments using the tip of STM were performed (Pascual et al. 1993; Agraït et al. 1993; Olesen et al. 1994; Gai et al. 1996). These experiments were carried by bringing the tip into the pristine surface forming a contact. In these experiments, contact formation is monitored by recording the current at a fixed junction voltage. Instead of limiting investigations to tip-surface point contacts, tip contacts can be also performed with single atoms or molecules adsorbed on a metal surface as shown in some STM experiments (Limot et al. 2005; Néel et al. 2007a, b, c, 2008a, b; Kröger et al. 2007; Jensen et al. 2007; Kröger 2008). Tip-adsorbate contacts turn out to be highly reproducible and stable contrary to tip-surface contacts. Single-atom or single-molecule junctions can be formed in this way with an increased control compared to other experimental techniques. The electrodes (the tip and the surface) and the contact constriction (the atom or the molecule) can be in fact characterized prior to and after the contact.

Conductance measurements of a point contact formed by an STM tip on a single atom show surprising stability of the Kondo resonance. The Kondo peak is little affected by structural changes induced by the tip-atom contact (Néel et al. 2007c; Vitali et al. 2008; Bork et al. 2011). However, more recent measurements show that atomic relaxations produced by the tip displacement continuously affect both the Kondo resonance and the conductance prior to and after tip contact (Choi et al. 2012). The experimental results show a reproducible exponential variation of the Kondo width as a function of conductance. The findings demonstrate that the Kondo effect of single atoms adsorbed on a metal surface, and more generally their magnetism, may be tuned via the ballistic conductance of the junction.

Recent experiments using the STM to contact a Co atom on Cu (100) with a sharp nickel tip (Choi et al. 2017b) show a splitting of the ZBA. The ZBA splitting is a sign of strong magnetic polarization of the tip. The authors argue that in spite of the strong polarization of the tip, the atom remains largely unpolarized due to the coupling to the nonmagnetic surface. This leads to the survival of the Kondo effect despite the injection of spin-polarized electrons from the ferromagnetic tip. However, the Kondo effect is influenced by the exchange coupling with the tip, acting like a local magnetic field that effectively splits the Kondo peak. These results are in line with previous studies of the Kondo effect on ferromagnetic point contacts that show the survival of Kondo correlations in the presence of spin-polarized currents (Calvo et al. 2009).

7.1   Non-equilibrium Kondo

Further studies of Co on Cu (100) have been scrutinizing the behavior of the Kondo effect under non-equilibrium (Choi et al. 2017a). This is typically the case when a difference of bias is established, and the drop of bias is not complete at the impurity. In the case of contact experiments, the bias is continuously dropping along the contact region where the impurity is localized. Two major effects signal the presence of non-equilibrium processes in Kondo: (i) there are two nearly equivalent Fermi energies due to the two contacted electrodes; this naturally gives rise to some double peak structure akin to producing a Kondo peak per electrode; (ii) due to the partial drop, the Kondo effect can be established with one electrode producing a Kondo peak well above the other Fermi energy; as a consequence, the scattering electrons can continue into the second electrode, producing some sort of leakage from the Kondo effect; this leads to enhanced decoherence of the Kondo spin flips.

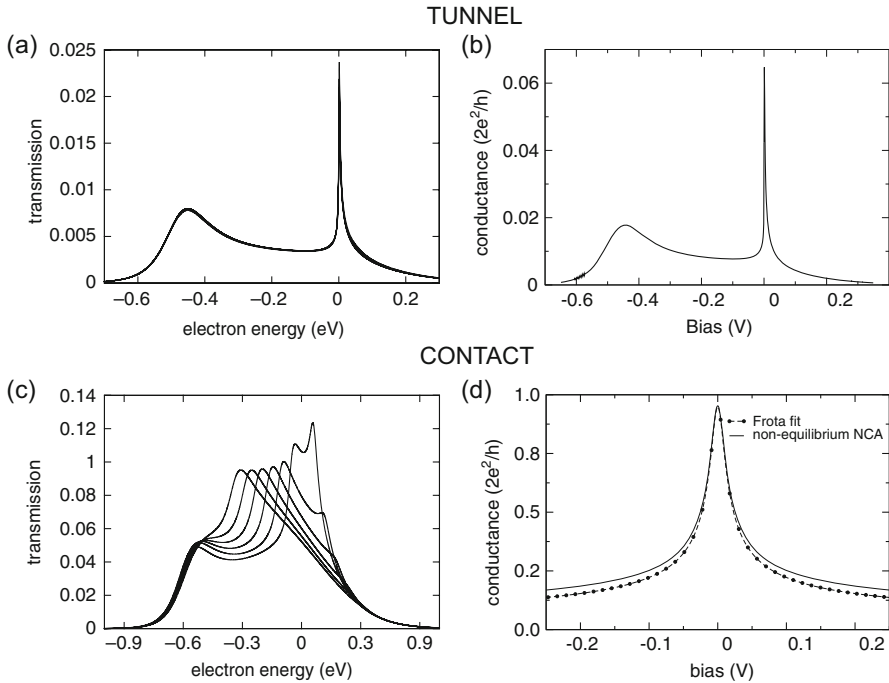
Using DFT and non-equilibrium Green's functions transport calculations, the different channels were identified as well as the magnetic structure of the atomic junction (Choi et al. 2017a). Cobalt maintains its magnetic moment of $2 \mu_B$ regardless of the tip-substrate distance, but the transport properties change as the tip approaches the sample. In tunneling, transport proceeds by the sp electron structure of the adsorbate. When the couplings of the atom to tip and substrate equilibrate, new conduction channels open due to the hybridization of the Co d-electrons to


Fig. 6 Comparison between the transmission function (**a**) and (**c**) (proportional to the spectral function in the present calculations) and the differential conductance (**b**) and (**d**) in tunneling and in contact, respectively. We see that only in tunnel can the differential conductance be directly compared with the spectral function that is independent of the applied bias. In (**a**) ten different values of the bias are plotted from -0.6 to 0.2 V; no difference can be seen. At contact, (**c**), non-equilibrium effects become clearly distinguished in the spectral function, such as splitting of the Kondo peak and increased broadening due to bias-induced decoherence. The spectral function is very different for the six plotted values (from 0.1 to 0.6 V). These effects are however difficult to glean from the differential conductance where the electron transmission contributes for a small energy window for each bias. (Figure modified and adapted from Choi et al. 2017a)

the tip. At contact one single channel dominates with d_{z^2} character. This orbital possesses the largest overlap with the holding substrate, making it responsible for the Kondo signature. Indeed, despite being a $S = 1$ system, Co on Cu(100) is basically a $S = 1/2$ Kondo system due to the single d_{z^2} spin (Choi et al. 2016a; Baruselli et al. 2015; Jacob 2015).

To treat the non-equilibrium Kondo physics when the tip drives the system into the contact regime, Choi et al. (2017a) use the non-equilibrium non-crossing approximation (Hettler et al. 1998). In tunneling, the computed conductance is shown to be proportional to the tunneling spectral function. Figures 6a, c depict the electron transmission (proportional to the spectral function for the plotted case) as a function of electron energy and b and d the differential conductance. Clearly the spectral function is proportional to the differential conductance in tunneling, in

agreement with the Tersoff-Hamann picture (Tersoff and Hamann 1985). This is not true in contact, where the spectral function develops two Kondo peaks when the applied bias is larger than the Kondo temperature and the peaks decay by bias-induced decoherence, cases c and d in Fig. 6.

Despite this very different regime, the width of the ZBA conductance is fixed by the equilibrium spectral function, reflecting the increase of the Kondo temperature due to the larger couplings to electrodes in the contact regime. Hence, the experimentally obtained widths are indeed proportional to the Kondo temperature of the system as the point contact increases its atomic coordination (Choi et al. 2017a).

8 Electron Paramagnetic Resonance

Manassen (1989) and Komeda and Manassen (2008) used GHz excitation frequencies to study single magnetic moments in Si. More recently, other experiments also using STM (Müllegger et al. 2014) showed data that molecular spins could also be addressed in a GHz pulsed STM.

New highly reproducible data with quantitative measurements and explanation recently came available in a low-temperature STM setup (Baumann et al. 2015). Figure 7 shows a simplified scheme of the experiment. Basically, an oscillatory bias is set between tip and sample that matches the energy between two magnetic states of the magnetic atom under study. If the current is spin polarized, they can
Fig. 7 Scheme with the experimental setup to record EPR spectra over a localized magnetic moment. An STM tip is magnetized with magnetic moment $\vec{M}$ following the direction of the external magnetic field $\vec{B}$. An alternating bias is set between tip and substrate, $V_{RF} = V_0\cos(\omega t + \delta)$, with $\omega = 2\pi f$. When the applied frequency, $\hbar\omega$, matches twice the Zeeman energy of the z-component of the B-field, the resonance condition is attained between the two low-energy levels of the local magnetic spin $\vec{S}$ under the influence of the external field. This translates into a change in the tunneling current as a function of the applied frequency ω, roughly following a Lorentzian shape. Fitting the expression Eq. (8), all the parameters characterizing the EPR signal can be extracted

see a change in the current with the frequency of the alternating bias. They showed compelling evidence that Rabi oscillations were established between two Zeeman-split spin states of an iron atom on an MgO surface when a GHz modulation signal was injected on the electron current. Evidence was given that time-dependent electrons can drive the magnetic oscillations. This is a startling fact that is still under debate: what is the actual physical process that makes currents and spins interact? Baumann and co-workers (Baumann et al. 2015) assume that it is the mechanical deformation of the adsorption configuration that leads to the coupling as induced by the pulsed electric field between tip and sample. Lado et al (2017) have argued that it is rather the long-distance dipole-dipole interaction of the tip with the magnetic moment that drives the EPR signal. Recently, Reina et al. (2018, unpublished) have produced a model that explains many of the experimental features of EPR excitation, and it is based on the shifting of the electronic levels of the adsorbate by the oscillating field. When electrons tunnel in and out of the adsorbate, the levels are subjected to the oscillating electric field of the tip. This physical mechanism is the Anderson mechanism for producing the Kondo antiferromagnetic coupling of the s-d exchange Hamiltonian. It is then very efficient in coupling currents and spins.

The density matrix formalism is particularly well adapted for the study of EPR (Delgado and Fernández-Rossier 2017). Let us assume that we have two clear spin states that can be connected via an oscillating driving term (the electric field between tip and sample in the STM setup). Then the density matrix contains three independent terms, namely, the population of each state and a cross term between the two states. This cross term is called *the coherence* because it is a direct measurement of how coherent the two spin states are. When this term goes to zero, the two states are totally disconnected, and there is no connection between the states. The states are then incoherent and their respective phases randomly change in time. If the phase is constant (or almost constant) in time, the density-matrix cross term is not zero, and the two spin states are coherent in time. They will interfere and commonly evolve in time.

Under this situation there are clearly three time-related quantities that contain all the physics of the coherent excitation of spin via an oscillatory driving stimulus. The lifetime of each state is clearly one of the time scales. If we assume we only have one excited state (as we said above), then there is only one lifetime and it is called T_1. The other obvious lifetime is the pure dephasing time, or the time when the relative phase between the two spin states is constant. This is generally called T_2^* (please be aware that in NV centers a different notation is followed). However, the phase can also disappear because the excited state has disappeared. Then the time regulating the evolution will rather be the complete decoherence time, or T_2. Since we are studying the limitation of the phase due to either pure dephasing or population decay, the simple approach is to assume that the inverse times or rates add up linearly:

$$\frac{1}{T_2} = \frac{1}{T_1} + \frac{1}{T_2^*}.$$

(7)

This implies that the rate of disappearance of the phase is the sum of the rates of disappearance due to the destruction of the state T_1 and the destruction of the relative phase T_2^*.

The third magnitude that enters the density matrix dynamics is the Rabi oscillation frequency, Ω. This frequency is a direct measuring of the strength of the coupling between the external driving force and the reaction of the system to that external field. There is a fourth time that we have not mentioned before, because it is self-evident; this is the time associated to the energy scale of the system given by the energy of the excited spin state, f_0 (such that the excitation energy is $E = hf_0$ where h is Planck's constant).

All of the above terms give rise to a particular evolution of the density matrix. The experiments are performed with spin-polarized currents, so the STM can read the change of spin state. Hence, we can assume that the change in current due to the resonant excitation of the spin state will be proportional to the change of density matrix from the equilibrium situation where the spin state is not excited. In this case, the classical Bloch equations for magnetic moments are retrieved, and the line shape with oscillation frequency f, found in the experiments, is reproduced (Delgado and Fernández-Rossier 2017):

$$\frac{\Delta I}{I}(f) = -\frac{\Omega^2 T_1 T_2}{1 + (f - f_0)^2 T_2^2 + \Omega^2 T_1 T_2}. \tag{8}$$

The experimental data are being produced at fast pace and with outstanding quality. Measurement of Cu adsorbates on MgO shows the distinct hyperfine structure of the Cu nuclear magnetic moment. The STM is now capable of looking into the magnetic structure of a single atomic nucleus (Heinrich, 2017, personal communication). More new exciting data are sure to be produced as we write these lines.

9   Conclusions

The study of individual magnetic impurities on surfaces is revolutionizing the field of electron correlations in magnetic impurities, thanks to the advent of scanning probes. The STM permits a complete characterization of the Kondo effect, giving relevant and complementary information on the spectral features of the Kondo resonance, as well as its spatial distribution. The STM is flexible enough to be able to tackle different conductance regimes, permitting us to have new insight on the non-equilibrium Kondo effect. Together with the atomic manipulation abilities of the STM, the Kondo effect is suggesting new possibilities in the creation of nanostructures with specific electronic properties. In this chapter, we have seen how by creating nanostructures with different species we can tune the degree of spin entanglement. This permits us to reach very different Kondo regimes as shown by the tunneling differential conductance.

New techniques are quickly evolving. Recently, the time domain is yielding new capabilities to the STM. As a consequence, we have now EPR signals on localized magnetic moments that will complete our knowledge on the impurity problem. Moreover, pump-and-probe techniques, together with photon excitation, will be very interesting techniques to probe the extraordinary correlations due to magnetic moments.

Abstract

A unified approach for computing (*i*) spin-transfer torque in magnetic trilayers like spin valve and magnetic tunnel junction, where injected charge current flows perpendicularly to interfaces, and (*ii*) spin-orbit torque in magnetic bilayers of the type ferromagnet/spin-orbit-coupled material, where injected charge current flows parallel to the interface, was reviewed. The experimentally explored and technologically relevant spin-orbit-coupled materials include 5*d* heavy metals, topological insulators, Weyl semimetals, and transition metal dichalcogenides. This approach requires to construct the torque operator for a given Hamiltonian of the device and the steady-state nonequilibrium density matrix, where the latter is expressed in terms of the nonequilibrium Green's functions and split into three

contributions. Tracing these contributions with the torque operator automatically yields field-like and damping-like components of spin-transfer torque or spin-orbit torque vector, which is particularly advantageous for spin-orbit torque where the direction of these components depends on the unknown-in-advance orientation of the current-driven nonequilibrium spin density in the presence of spin-orbit coupling. Illustrative examples are provided by computing spin-transfer torque in a one-dimensional toy model of a magnetic tunnel junction and realistic Co/Cu/Co spin valve, both of which are described by first-principles Hamiltonians obtained from noncollinear density functional theory calculations, as well as by computing spin-orbit torque in a ferromagnetic layer described by a tight-binding Hamiltonian which includes spin-orbit proximity effect within ferromagnetic monolayers assumed to be generated by the adjacent monolayer transition metal dichalcogenide. In addition, it is shown here how spin-orbit proximity effect, quantified by computing (via first-principles retarded Green's function) spectral functions and spin textures on monolayers of realistic ferromagnetic material like Co in contact with heavy metal or monolayer transition metal dichalcogenide, can be tailored to enhance the magnitude of spin-orbit torque. Errors made in the calculation of spin-transfer torque are quantified when using Hamiltonian from collinear density functional theory, with rigidly rotated magnetic moments to create noncollinear magnetization configurations, instead of proper (but computationally more expensive) self-consistent Hamiltonian obtained from noncollinear density functional theory.

1   What Is Spin Torque and Why Is It Useful?

The spin-transfer torque (STT) (Ralph and Stiles 2008; Locatelli et al. 2014; Slonczewski 1996; Berger 1996) is a phenomenon in which a spin current of sufficiently large density ($\sim 10^7$ A/cm^2) injected into a ferromagnetic metal (FM) (For easy navigation, provided is a list of abbreviations used throughout the chapter: 1D, one-dimensional; 2D, two-dimensional; 3D, three-dimensional; BZ, Brillouin zone; CD, current-driven; DFT, density functional theory; DL, damping-like; FL, field-like; FM, ferromagnetic metal; GF, Green's function; HM, heavy metal; I, insulator; KS, Kohn-Sham; LCAO, linear combination of atomic orbitals; LLG, Landau-Lifshitz-Gilbert; ML, monolayer; MLWF, maximally localized Wannier function; MRAM, magnetic random access memory; MTJ, magnetic tunnel junction; ncDFT, noncollinear DFT; NEGF, nonequilibrium Green's function; NM, normal metal; PBE, Perdew-Burke-Ernzerhof; scf, self-consistent field; SHE, spin Hall effect; SOC, spin-orbit coupling; SOT, spin-orbit torque; STT, spin-transfer torque; TBH, tight-binding Hamiltonian; TI, topological insulator; TMD, transition metal dichalcogenide; WSM, Weyl semimetal; XC, exchange-correlation.) either switches its magnetization from one static configuration to another or generates a dynamical situation with steady-state precessing magnetization (Locatelli et al. 2014). The origin of STT is the absorption of the itinerant flow of spin angular momentum component normal to the magnetization direction. Figure 1a illustrates a setup with
Fig. 1 Spin-transfer torque basics: (**a**) in a ferromagnet/nonmagnetic-spacer/ferromagnet setup, with noncollinear magnetizations $\mathbf{M}_{\mathrm{fixed}}$ of the fixed FM layer and $\mathbf{M}_{\mathrm{free}}$ of the free FM layer, the transverse spin component of the conduction electrons (red) polarized in the direction of $\mathbf{M}_{\mathrm{fixed}}$ is absorbed as they pass through the free layer, thereby generating a torque on $\mathbf{M}_{\mathrm{free}}$; (**b**) device applications of STT in (**a**) are based on torque-induced magnetization dynamics that is converted into resistance variations via the magnetoresistive effects; (**c**) torques on $\mathbf{M}_{\mathrm{free}}$ where field-like component of current-driven STT, $\mathbf{T}_{\mathrm{FL}}$, is orthogonal to the plane spanned by $\mathbf{M}_{\mathrm{fixed}}$ and $\mathbf{M}_{\mathrm{free}}$ and competes with the effective-field torque $\mathbf{T}_{\mathrm{field}}$ (present also in equilibrium), while damping-like component of current-driven STT, $\mathbf{T}_{\mathrm{DL}}$, is parallel or antiparallel (depending on the current direction) to Gilbert damping torque $\mathbf{T}_{\mathrm{damping}}$ (present also in equilibrium). The illustration in (**c**) assumes particular case where $\mathbf{M}_{\mathrm{fixed}}$ and the effective magnetic field are aligned. (Adapted from Locatelli et al. 2014)

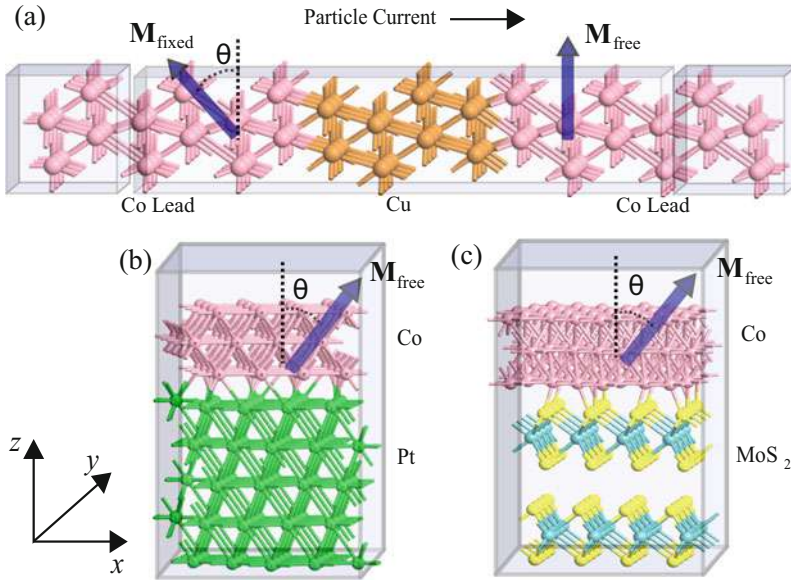
two noncollinear magnetizations which generates STT. This setup can be realized as FM/NM/FM (NM, normal metal) spin valve, exemplified by Co/Cu/Co trilayer in Fig. 2a and employed in early experiments (Tsoi et al. 1998; Myers et al. 1999; Katine et al. 2000), or FM/I/FM (I, insulator) magnetic tunnel junctions (MTJs), exemplified by Fe/MgO/Fe trilayer and employed in later experiments (Sankey et al. 2008; Kubota et al. 2008; Wang et al. 2011) and recent applications (Locatelli et al. 2014; Kent and Worledge 2015). In such magnetic multilayers, injected unpolarized charge current passes through the first thin FM layer to become spin-polarized


Fig. 2 Schematic view of (**a**) FM/NM/FM trilayer for calculations of STT in spin valves, (**b**) FM/HM bilayer for calculations of SOT in the presence of the spin Hall current along the z-axis generated by the HM layer, and (**c**) FM/monolayer-TMD for calculations of SOT in the absence of any spin Hall current. The semi-infinite FM layers in (**a**) are chosen as Co(0001), and the spacer in between consists of l ($l = 4$ in the illustration) monolayers of Cu(111). The trilayer in (**a**) is assumed to be infinite in the transverse directions to the current flow, so that the depicted supercell is periodically repeated within the yz-plane. The bilayer in (**b**) consists of Co(0001) and Pt(111), and in (**c**) it consists of Co(0001) and monolayer MoS_2. The bilayers in (**b**) and (**c**) are assumed to be infinite in the xy-plane but of finite thickness along the z-axis. Small bias voltage V_b is applied to inject electrons along the positive x-axis, so that particle current is perpendicular to interfaces in (**a**) and parallel to the interface in (**b**) and (**c**)

in the direction of its fixed magnetization along the unit vector $\mathbf{M}_{fixed}$, and it is directed into the second thin FM layer with magnetization along the unit vector $\mathbf{M}_{free}$ where transverse (to $\mathbf{M}_{free}$) component of flowing spins is absorbed. The STT-induced magnetization dynamics is converted into resistance variations via the magnetoresistive effect, as illustrated in Fig. 1b, which is much larger in MTJ than in spin valves. The rich nonequilibrium physics arising in the interplay of spin currents carried by fast conduction electrons, described quantum mechanically, and slow collective magnetization dynamics, described by the Landau-Lifshitz-Gilbert (LLG) equation which models magnetization as a classical vector subject to thermal fluctuations (Berkov and Miltat 2008; Evans et al. 2014; Petrović et al. 2018), is also of great fundamental interest. Note that at cryogenic temperatures, where thermal fluctuations are suppressed, quantum-mechanical effects in STT-driven magnetization dynamics can also be observed (Zholud et al. 2017; Mahfouzi and Kioussis 2017; Mahfouzi et al. 2017).

Another setup exhibiting current-induced magnetization dynamics is illustrated in Fig. 2b, c. It utilizes a single FM layer, so that the role of polarizing FM layer with M_{fixed} in Figs. 1a and 2a is taken over by strong spin-orbit coupling (SOC) introduced by heavy metals (HMs) (Miron et al. 2011; Liu et al. 2012) (such as $5d$ metals Pt, W, and Ta) as in Fig. 2b, topological insulators (TIs) (Mellnik et al. 2014; Fan et al. 2014; Han et al. 2017; Wang et al. 2017), Weyl semimetals (WSMs) (MacNeill et al. 2017a, b), and atomically thin transition metal dichalcogenides (TMDs) (Sklenar et al. 2016; Shao et al. 2016; Guimarães et al. 2018; Lv et al. 2018). The TMDs are compounds of the type MX_2 (M = Mo, W, Nb; X = S, Se, Te) where one layer of M atoms is sandwiched between two layers of X atoms, as illustrated by monolayer MoS_2 in Fig. 2c. The SOC is capable of converting charge into spin currents (Vignale 2010; Sinova et al. 2015; Soumyanarayanan et al. 2016), so that their absorption by the FM layer in Fig. 2b, c leads to the so-called spin-orbit torque (SOT) (Manchon et al. 2019) on its free magnetization M_{free}.

The current-driven (CD) STT and SOT vectors are analyzed by decomposing them into two contributions, $T_{CD} = T_{DL} + T_{FL}$, commonly termed (Ralph and Stiles 2008; Manchon et al. 2019) damping-like (DL) and field-like (FL) torque based on how they enter into the LLG equation describing the classical dynamics of magnetization. As illustrated in Fig. 1c, these two torque components provide two different handles to manipulate the dynamics of M_{free}. In the absence of current, displacing M_{free} out of its equilibrium position leads to the effective-field torque T_{field} which drives M_{free} into precession around the effective magnetic field, while Gilbert damping $T_{damping}$ acts to bring it back to its equilibrium position. Under nonequilibrium conditions, brought by injecting steady-state or pulse current (Baumgartner et al. 2017), T_{DL} acts opposite to $T_{damping}$ for "fixed-to-free" current direction, and it enhances $T_{damping}$ for "free-to-fixed" current directions in Fig. 1a. Thus, the former (latter) acts as antidamping (overdamping) torque trying to bring M_{free} antiparallel (parallel) to M_{fixed} (note that at cryogenic temperatures, one finds apparently only antidamping action of T_{DL} for both current directions (Zholud et al. 2017)). The T_{FL} component induces magnetization precession and modifies the energy landscape seen by M_{free}. Although $|T_{FL}|$ is minuscule in metallic spin valves (Wang et al. 2008), it can reach 30–40% of $|T_{DL}|$ in MTJs (Sankey et al. 2008; Kubota et al. 2008), and it can become several times larger than $|T_{DL}|$ in FM/HM bilayers (Kim et al. 2013; Yoon et al. 2017). Thus, T_{FL} component of SOT can play a crucial role (Baumgartner et al. 2017; Yoon et al. 2017) in triggering the reversal process of M_{free} and in enhancing the switching efficiency. In concerted action with T_{DL} and possible other effects brought by interfacial SOC, such as the Dzyaloshinskii-Moriya interaction (Perez et al. 2014), this can also lead to complex inhomogeneous magnetization switching patterns observed in SOT-operated devices (Baumgartner et al. 2017; Yoon et al. 2017; Perez et al. 2014).

By adjusting the ratio $|T_{DL}|/|T_{FL}|$ (Timopheev et al. 2015) via tailoring of material properties and device shape, as well as by tuning the amplitude and duration of the injected pulse current (Baumgartner et al. 2017), both STT- and SOT-operated devices can implement variety of functionalities, such as nonvolatile magnetic random access memories (MRAMs) of almost unlimited endurance,

microwave oscillators, microwave detectors, spin-wave emitters, memristors, and artificial neural networks (Locatelli et al. 2014; Kent and Worledge 2015; Borders et al. 2017). The key goal in all such applications is to actively manipulate magnetization dynamics, without the need for external magnetic fields that are incompatible with downscaling of the device size, while using the smallest possible current [e.g., writing currents $\lesssim 20\,\mu A$ would enable multigigabit MRAM (Kent and Worledge 2015)] and energy consumption. For example, recent experiments (Wang et al. 2017) have demonstrated current-driven magnetization switching at room temperature in FM/TI bilayers using current density $\sim 10^5$ A/cm^2, which is two orders of magnitude smaller than for STT-induced magnetization switching in MTJs or one to two orders of magnitude smaller than for SOT-induced magnetization switching in FM/HM bilayers. The SOT-MRAM is expected to be less affected by damping, which offers flexibility for choosing the FM layer, while it eliminates insulating barrier in the writing process and its possible dielectric breakdown in STT-MRAM based on MTJs (Kent and Worledge 2015). Also, symmetric switching profile of SOT-MRAM evades the asymmetric switching issues in STT-MRAM otherwise requiring additional device/circuit engineering. On the other hand, SOT-MRAM has a disadvantage of being a three-terminal device.

2   How to Model Spin Torque Using Nonequilibrium Density Matrix Combined with Density Functional Theory Calculations

The absorption of the component of flowing spin angular momentum that is transverse to $\mathbf{M}_{\text{free}}$, as illustrated in Fig. 1a, occurs (Stiles and Zangwill 2002; Wang et al. 2008) within a few ferromagnetic monolayers (MLs) near NM/FM or I/FM interface. Since the thickness of this interfacial region is typically shorter (Wang et al. 2008) than any charge or spin dephasing length that would make electronic transport semiclassical, STT *requires* quantum transport modeling (Brataas et al. 2006). The essence of STT can be understood using simple one-dimensional (1D) models solved by matching spin-dependent wave function across the junction, akin to elementary quantum mechanics problems of transmission and reflection through a barrier, as provided in Ralph and Stiles (2008), Manchon et al. (2008) and Xiao et al. (2008). However, to describe details of experiments, such as bias voltage dependence of STT in MTJs (Kubota et al. 2008; Sankey et al. 2008) or complex angular dependence of SOT in FM/HM bilayers (Garello et al. 2013), more involved calculations are needed employing tight-binding or first-principles Hamiltonian as an input. For example, simplistic tight-binding Hamiltonians (TBHs) with single orbital per site have been coupled (Theodonis et al. 2006) to nonequilibrium Green's function (NEGF) formalism (Stefanucci and van Leeuwen 2013) to compute SOT in FM/HM bilayers (Kalitsov et al. 2017) or bias voltage dependence of DL and FL components of STT in MTJs which can describe some features of the experiments by adjusting the tight-binding parameters (Kubota et al. 2008).

However, not all features of STT experiments on MTJs (Wang et al. 2011) can be captured by such NEGF+TBH approach. Furthermore, due to spin-orbit proximity effect, driven by hybridization of wave functions from FM and HM layers (Dolui and Nikolić 2017) or FM and metallic surfaces of three-dimensional (3D) TIs (Marmolejo-Tejada et al. 2017), simplistic Hamiltonians like the Rashba ferromagnetic model (Manchon and Zhang 2008; Haney et al. 2013; Lee et al. 2015; Li et al. 2015; Pesin and MacDonald 2012a; Ado et al. 2017; Kalitsov et al. 2017) or the gapped Dirac model (Ndiaye et al. 2017) are highly inadequate to describe realistic bilayers employed in SOT experiments. This is emphasized by Fig. 3 which shows how spectral function and spin texture on the surface of semi-infinite Co layer can change dramatically as we change the adjacent layer. For example, nonzero in-plane spin texture on the surface of semi-infinite Co layer in contact with vacuum is found in Fig. 3e, despite Co magnetization being perpendicular to that surface. This is the consequence of the Rashba SOC enabled by inversion symmetry breaking (Chantis et al. 2007) where an electrostatic potential gradient can be created by the charge distribution at the metal/vacuum interface to confine wave functions into a Rashba spin-split quasi two-dimensional (2D) electron gas (Bahramy et al. 2012). The surface of semi-infinite Co within the layer embedded into Co/Cu(9 ML)/Co junction illustrated in Fig. 2a does not have any in-plane spin texture in Fig. 3f since the structure is inversion symmetric, but its spectral function in Fig. 3b is quite different from the one on the surface of an isolated semi-infinite Co layer in Fig. 3a. Bringing semi-infinite Co layer in contact with 5 MLs of Pt or 1 ML of MoS_2 transforms its spectral function from Fig. 3a to the ones in Fig. 3c, d, respectively, while inducing the corresponding spin textures in Fig. 3g, h due to spin-orbit proximity effect signified by the "leakage" of SOC from HM or TMD layer into the FM layer.

Note that the spectral function and spin texture at the Co/Pt interface are quite different from those of the ferromagnetic Rashba Hamiltonian in 2D often employed (Manchon and Zhang 2008; Haney et al. 2013; Lee et al. 2015; Li et al. 2015; Pesin and MacDonald 2012a; Ado et al. 2017; Kalitsov et al. 2017) in the calculations of SOT as the putative simplistic description of the FM/HM interface. When charge current flows within FM monolayer hosting spin textures – such as the ones displayed in Fig. 3e, g, h – more forward-going electron states will be occupied and less the backward-going ones which due to spin-momentum locking leads to nonequilibrium spin density (Edelstein 1990; Aronov and Lyanda-Geller 1989) as one of the principal mechanisms behind SOT (Manchon et al. 2019). The direction of the nonequilibrium spin density is easily identified in the case of simple spin textures, such as the one in Fig. 3e or those associated with simplistic models (Pesin and MacDonald 2012b) like the Rashba Hamiltonian or the Dirac Hamiltonian discussed in Sect. 4. Conversely, for complex spin textures within heterostructures of realistic materials, as exemplified by those in Fig. 3g, h, one needs first principles coupled with electronic transport calculations (Chang et al. 2015; Johansson et al. 2018).

Thus, capturing properties of realistic junctions illustrated by Fig. 3 requires first-principles Hamiltonian as offered by the density functional theory (DFT). In the linear-response regime, appropriate for spin valves or SOT-operated bilayers in
Fig. 3 Spectral function $A(E; \mathbf{k}_{\parallel}, x \in \text{ML of Co})$, defined in Eq. (6), plotted along high-symmetry k-path Z-Γ-Y at (**a**) the surface of semi-infinite Co(0001) in contact with vacuum, (**b**) ML of semi-infinite Co(0001) in contact with 9 MLs of Cu(111) within Co/Cu(9 ML)/Co spin valve, (**c**) ML of semi-infinite Co(0001) in contact with 5 MLs of Pt(111), and (**d**) ML of semi-infinite Co(0001) in contact with 1 ML of MoS$_2$. Panels (**e**)–(**h**) plot constant energy contours of $A(E - E_F = 0; \mathbf{k}_{\parallel}, x \in \text{ML of Co})$ and the corresponding spin textures where the out-of-plane S_x component of spin is indicated in color (red for positive and blue for negative). The magnetization of Co is along the x-axis which is perpendicular to the ML of Co over which the spectral functions and spin textures are scanned. The units for k_y and k_z are $2\pi/a$ and $2\pi/b$ where a and b are the lattice constants along the y- and the z-axis, respectively. The horizontal dashed black line in panels (**a**)–(**d**) denotes the position of the Fermi energy E_F. Panels (**a**) and (**e**) are adapted from Marmolejo-Tejada et al. (2017), and panels (**c**) and (**g**) are adapted from Dolui and Nikolić (2017)

Fig. 2, one can also employ first-principles-derived TBH as offered by transforming the DFT Hamiltonian to a basis of orthogonal maximally localized Wannier functions (MLWFs) in a selected energy window around the Fermi energy E_F. This procedure retains faithfully the overlap matrix elements and their phases, orbital character of the bands, and the accuracy of the original DFT calculations (Marzari et al. 2012). Although Wannier TBH has been used to describe infinite-FM-on-infinite-HM bilayers (Freimuth et al. 2014; Mahfouzi and Kioussis (2018)), its accuracy can be compromised by complicated band entanglement in hybridized metallic systems (Marzari et al. 2012). It is also cumbersome to construct Wannier TBH for junctions in other geometries, like the spin valve in Fig. 2a, or when FM/HM bilayer is attached to leads made of different NM material. In such cases, one needs to perform multiple calculations (Shelley et al. 2011; Thygesen and Jacobsen 2005) (such as on periodic leads, supercell composed of the central region of interest attached to buffer layers of the lead material on both sides, etc.) where one can encounter different MLWFs for two similar but nonidentical systems (Thygesen and Jacobsen 2005), nonorthogonal MLWFs belonging to two different regions (Thygesen and Jacobsen 2005), and Fermi energies of distinct calculations that have to be aligned (Shelley et al. 2011). Also, to compute the current or STT in MTJs at finite bias voltage, one needs to recalculate Hamiltonian in order to take into account self-consistent charge redistribution and the corresponding electrostatic potential in the presence of current flow. Otherwise, without computing them across the device, the current-voltage characteristics violates (Christen and Büttiker 1996; Hernández and Lewenkopf 2013) gauge invariance, i.e., invariance with respect to the global shift of electric potential by a constant, $V \to V + V_0$.

The noncollinear DFT (ncDFT) (Capelle et al. 2001; Eich and Gross 2013; Eich et al. 2013; Bulik et al. 2013) coupled to nonequilibrium density matrix (Stefanucci and van Leeuwen 2013) offers an algorithm to compute spin torque in arbitrary device geometry at vanishing or finite bias voltage. The single-particle spin-dependent Kohn-Sham (KS) Hamiltonian in ncDFT takes the form

$$\hat{H}_{\text{KS}} = -\frac{\hbar^2 \nabla^2}{2m} + V_{\text{H}}(\mathbf{r}) + V_{\text{XC}}(\mathbf{r}) + V_{\text{ext}}(\mathbf{r}) - \boldsymbol{\sigma} \cdot \mathbf{B}_{\text{XC}}(\mathbf{r}), \tag{1}$$

where $V_H(\mathbf{r})$, $V_{\text{ext}}(\mathbf{r})$, and $V_{\text{XC}}(\mathbf{r}) = E_{\text{XC}}[n(\mathbf{r}), \mathbf{m}(\mathbf{r})]/\delta n(\mathbf{r})$ are the Hartree, external, and exchange-correlation (XC) potentials, respectively, and $\boldsymbol{\sigma} = (\hat{\sigma}_x, \hat{\sigma}_y, \hat{\sigma}_z)$ is the vector of the Pauli matrices. The extension of DFT to the case of spin-polarized systems is formally derived in terms of total electron density $n(\mathbf{r})$ and vector magnetization density $\mathbf{m}(\mathbf{r})$. In the collinear DFT, $\mathbf{m}(\mathbf{r})$ points in the same direction at all points in space, which is insufficient to study magnetic systems where the direction of the local magnetization is not constrained to a particular axis or systems with SOC. In ncDFT (Capelle et al. 2001), XC functional $E_{\text{XC}}[n(\mathbf{r}), \mathbf{m}(\mathbf{r})]$ depends on $\mathbf{m}(\mathbf{r})$ pointing in arbitrary direction. The XC magnetic field is then given by $\mathbf{B}_{\text{XC}}(\mathbf{r}) = \delta E_{\text{XC}}[n(\mathbf{r}), \mathbf{m}(\mathbf{r})]/\delta \mathbf{m}(\mathbf{r})$.

Once the Hamiltonian of the device is selected, it has to be passed into the formalism of nonequilibrium quantum statistical mechanics. Its central concept is

the density matrix $\boldsymbol{\rho}$ describing quantum many-particle system at finite temperature in equilibrium, or in the presence of external static or time-dependent fields which drive the system out of equilibrium. The knowledge of $\boldsymbol{\rho}$ makes it possible to compute the expectation value of any observable

$$O = \mathrm{Tr}\,[\boldsymbol{\rho}\mathbf{O}], \tag{2}$$

such as the charge density, charge current, spin current, and spin density of interest to spin torque modeling. These require to insert their operators (in some matrix representation) as $\mathbf{O}$ into Eq. (2), where a notation in which bold letters denote matrix representation of an operator in a chosen basis is used. For the KS Hamiltonian in ncDFT in Eq. (1), the torque operator is given by the time derivative of the electronic spin operator (Haney et al. 2007; Carva and Turek 2009)

$$\mathbf{T} = \frac{d\mathbf{S}}{dt} = \frac{1}{2i}[\boldsymbol{\sigma}, \mathbf{H}_{\mathrm{KS}}] = \boldsymbol{\sigma} \times \mathbf{B}_{\mathrm{XC}}. \tag{3}$$

Its trace with $\boldsymbol{\rho}$ yields the spin torque vector while concurrently offering a microscopic picture (Haney et al. 2007) for the origin of torque – misalignment of the nonequilibrium spin density of current carrying quasiparticles with respect to the spins of electrons comprising the magnetic condensate responsible for nonzero $\mathbf{B}_{\mathrm{XC}}$. This causes local torque on individual atoms, which is summed by performing trace in Eq. (2) to find the net effect on the total magnetization $\mathbf{M}_{\mathrm{free}}$ of the free FM layer. Examples of how to evaluate such trace, while using $\mathbf{O} \mapsto \mathbf{T}$ in Eq. (2) in different matrix representations, are given as Eqs. (26) and (27) in Sect. 3.

In equilibrium, $\boldsymbol{\rho}_{\mathrm{eq}}$ is fixed by the Boltzmann-Gibbs prescription, such as $\boldsymbol{\rho}_{\mathrm{eq}} = \sum_n f(E)|\Psi_n\rangle\langle\Psi_n|$ in grand canonical ensemble describing electrons with the Fermi distribution function $f(E)$ due to contact with a macroscopic reservoir at chemical potential μ and temperature T, where E_n and $|\Psi_n\rangle$ are eigenenergies and eigenstates of the Hamiltonian, respectively. Out of equilibrium, the construction of $\boldsymbol{\rho}_{\mathrm{neq}}$ is complicated by the variety of possible driving fields and open nature of a driven quantum system. For example, the Kubo linear-response theory has been used to obtain $\boldsymbol{\rho}_{\mathrm{neq}}$ for small applied electric field in infinite-FM-on-infinite-HM bilayer geometry (Freimuth et al. 2014; Mahfouzi and Kioussis (2018)). However, for arbitrary junction geometry and magnitude of the applied bias voltage V_b or injected pulse current, the most advantageous is to employ the NEGF formalism (Stefanucci and van Leeuwen 2013). This requires to evaluate its two fundamental objects – the retarded GF, $G_{\mathbf{nn}'}^{\sigma\sigma'}(t, t') = -i\Theta(t - t')\langle\{\hat{c}_{\mathbf{n}\sigma}(t), \hat{c}_{\mathbf{n}'\sigma'}^{\dagger}(t')\}\rangle$, and the lesser GF, $G_{\mathbf{nn}'}^{<,\sigma\sigma'}(t, t') = i\langle\hat{c}_{\mathbf{n}'\sigma'}^{\dagger}(t')\hat{c}_{\mathbf{n}\sigma}(t)\rangle$ – describing the density of available quantum states and how electrons occupy those states, respectively. The operator $\hat{c}_{\mathbf{n}\sigma}^{\dagger}$ ($\hat{c}_{\mathbf{n}\sigma}$) creates (annihilates) electron with spin σ at site $\mathbf{n}$ (another index would be required to label more than one orbital present at the site), and $\langle\ldots\rangle$ denotes the nonequilibrium statistical average (Stefanucci and van Leeuwen 2013).

In time-dependent situations, the nonequilibrium density matrix is given by (Petrović et al. 2018; Stefanucci and van Leeuwen 2013)

$$\boldsymbol{\rho}_{\text{neq}}(t) = \mathbf{G}^{<}(t, t)/i. \tag{4}$$

In stationary problems $\mathbf{G}$ and $\mathbf{G}^{<}$ depend only on the time difference $t - t'$ and can, therefore, be Fourier transformed to depend on energy E instead of $t - t'$. The retarded GF in stationary situations is then given by

$$\mathbf{G}(E) = [E - \mathbf{H} - \boldsymbol{\Sigma}_L(E, V_b) - \boldsymbol{\Sigma}_R(E, V_b)]^{-1}, \tag{5}$$

assuming representation in the basis of orthogonal orbitals. In the case of nonorthogonal basis set $|\phi_n\rangle$, one should make a replacement $E \mapsto E\mathbf{D}$ where $\mathbf{D}$ is the overlap matrix composed of elements $\langle \phi_n | \phi_m \rangle$. The self-energies (Velev and Butler 2004; Rungger and Sanvito 2008) $\boldsymbol{\Sigma}_{L,R}(E, V_b)$ describe the semi-infinite leads which guarantee continuous energy spectrum of devices in Fig. 2 required to reach the steady-state transport regime. The leads terminate at infinity into the left (L) and right (R) macroscopic reservoirs with different electrochemical potentials, $\mu_L - \mu_R = eV_L - eV_R = eV_b$. The usual assumption about the leads is that the applied bias voltage V_b induces a rigid shift in their electronic structure(Brandbyge et al. 2002), so that $\boldsymbol{\Sigma}_{L,R}(E, V_b) = \boldsymbol{\Sigma}_{L,R}(E - eV_{L,R})$.

In equilibrium or near equilibrium (i.e., in the linear-response transport regime at small $eV_b \ll E_F$), one needs $\mathbf{G}_0(E)$ obtained from Eq. (5) by setting $V_L = V_R = 0$. The spectral functions shown in Fig. 3a–d can be computed at an arbitrary plane at position x within the junction in Fig. 2a using $\mathbf{G}_0(E)$

$$A(E; \mathbf{k}_{\parallel}, x) = -\frac{1}{\pi} \text{Im} \left[G_0(E; \mathbf{k}_{\parallel}; x, x) \right], \tag{6}$$

where the diagonal matrix elements $G_0(E; \mathbf{k}_{\parallel}; x, x)$ are obtained by transforming the retarded GF from a local orbital to a real-space representation. The spin textures in Fig. 3e–h within the constant energy contours are computed from the spin-resolved spectral function. The equilibrium density matrix can also be expressed in terms of $\mathbf{G}_0(E)$

$$\boldsymbol{\rho}_{\text{eq}} = -\frac{1}{\pi} \int_{-\infty}^{+\infty} dE \, \text{Im} \, \mathbf{G}_0(E) f(E), \tag{7}$$

where $\text{Im} \, \mathbf{O} = (\mathbf{O} - \mathbf{O}^{\dagger})/2i$.

The nonequilibrium density matrix is determined by the lesser GF

$$\boldsymbol{\rho}_{\text{neq}} = \frac{1}{2\pi i} \int_{-\infty}^{+\infty} dE \, \mathbf{G}^{<}(E). \tag{8}$$

In general, if a quantity has nonzero expectation values in equilibrium, that one must be subtracted from the final result since it is *unobservable* in transport experiments. This is exemplified by spin current density in time-reversal invariant systems (Nikolić et al. 2006); spin density, diamagnetic circulating currents, and circulating heat currents in the presence of external magnetic field or spontaneous magnetization breaking time-reversal invariance; and FL component of STT (Theodonis et al. 2006). Thus, the current-driven part of the nonequilibrium density matrix is defined as

$$\boldsymbol{\rho}_{\mathrm{CD}} = \boldsymbol{\rho}_{\mathrm{neq}} - \boldsymbol{\rho}_{\mathrm{eq}}. \tag{9}$$

Although the NEGF formalism can include many-body interactions, such as electron-magnon scattering (Mahfouzi and Nikolić 2014) that can affect STT (Zholud et al. 2017; Levy and Fert 2006; Manchon et al. 2010) and SOT (Yasuda et al. 2017; Okuma and Nomura 2017), here the focus is on the usually considered and conceptually simpler elastic transport regime where the lesser GF of a two-terminal junction

$$\mathbf{G}^{<}(E) = \mathbf{G}(E)\left[if_L(E)\boldsymbol{\Gamma}_L(E) + if_R(E)\boldsymbol{\Gamma}_R(E)\right]\mathbf{G}^{\dagger}(E), \tag{10}$$

is expressed solely in terms of the retarded GF, the level broadening matrices $\boldsymbol{\Gamma}_{L,R}(E) = i[\boldsymbol{\Sigma}_{L,R}(E) - \boldsymbol{\Sigma}_{L,R}^{\dagger}(E)]$ determining the escape rates of electrons into the semi-infinite leads and shifted Fermi functions $f_{L,R}(E) = f(E - eV_{L,R})$.

For purely computational purposes, the integration in Eq. (8) is typically separated [non-uniquely (Xie et al. 2016)] into the apparent "equilibrium" and current-driven "nonequilibrium" terms (Brandbyge et al. 2002; Sanvito 2011)

$$
\begin{aligned}
\boldsymbol{\rho}_{\mathrm{neq}} = &-\frac{1}{\pi} \int\limits_{-\infty}^{+\infty} dE \operatorname{Im} \mathbf{G}(E) f(E - eV_R) \\
&+ \frac{1}{2\pi} \int\limits_{-\infty}^{+\infty} dE \, \mathbf{G}(E) \cdot \boldsymbol{\Gamma}_L(E - eV_L) \cdot \mathbf{G}^{\dagger}(E) \left[f_L(E) - f_R(E)\right].
\end{aligned} \tag{11}
$$

The first "equilibrium" term contains integrand which is analytic in the upper complex plane and can be computed via contour integration (Brandbyge et al. 2002; Areshkin and Nikolić 2010; Ozaki 2007; Karrasch et al. 2010), while the integrand in the second "current-driven" term is a nonanalytic function in the entire complex energy plane so that its integration has to be performed directly along the real axis (Sanvito 2011) between the limits set by the window of nonzero values of $f_L(E) - f_R(E)$. Although the second term in Eq. (11) contains information about the bias voltage [through the difference $f_L(E) - f_R(E)$] and about the lead assumed to be injecting electrons into the device (through $\boldsymbol{\Gamma}_L$), it cannot (Xie et al. 2016; Mahfouzi and Nikolić 2013) be used as the proper $\boldsymbol{\rho}_{\mathrm{CD}}$ defined in Eq. (9). This is due

to the fact that the second term in Eq. (9), expressed in terms of the retarded GF via Eq. (7), does not cancel the gauge-noninvariant first term in Eq. (11) which depends explicitly [through $f(E-eV_R)$] on the arbitrarily chosen reference potential V_R and implicitly on the voltages applied to both reservoirs [through $\mathbf{G}(E)$]. Nevertheless, the second term in Eq. (11), written in the linear-response and zero-temperature limit,

$$\boldsymbol{\rho}_{\mathrm{CD}} \stackrel{?}{=} \frac{eV_b}{2\pi} \mathbf{G}_0(E_F) \cdot \boldsymbol{\Gamma}_L(E_F) \cdot \mathbf{G}_0^{\dagger}(E_F), \qquad (12)$$

has often been used in STT literature (Haney et al. 2007; Heiliger et al. 2008) as the putative but *improper* (due to being gauge-noninvariant, which is marked by "?" on the top of the equality sign) expression for $\boldsymbol{\rho}_{\mathrm{CD}}$. Its usage leads to ambiguous (i.e., dependent on arbitrarily chosen V_R) nonequilibrium expectation values.

The *proper* gauge-invariant expression was derived in Mahfouzi and Nikolić (2013)

$$\boldsymbol{\rho}_{\mathrm{CD}} = \frac{eV_b}{2\pi} \mathbf{G}_0(E_F) \cdot \boldsymbol{\Gamma}_L(E_F) \cdot \mathbf{G}_0^{\dagger}(E_F) - \frac{eV_R}{\pi} \mathrm{Im}\, \mathbf{G}_0(E_F)$$

$$- \frac{1}{\pi} \int\limits_{-\infty}^{+\infty} dE\, \mathrm{Im} \left[\mathbf{G}_0 \left(eU_{\mathbf{n}} - eV_L \frac{\partial \boldsymbol{\Sigma}_L}{\partial E} - eV_R \frac{\partial \boldsymbol{\Sigma}_R}{\partial E} \right) \mathbf{G}_0 \right] f(E), \qquad (13)$$

which is given here at zero temperature so that it can be contrasted with Eq. (12). The second and third term in Eq. (13), whose purpose is to subtract any nonzero expectation value that exists in thermodynamic equilibrium, make it quite different from Eq. (12) while requiring to include also electrostatic potential profile $U_{\mathbf{n}}$ across the active region of the device interpolating between V_L and V_R. For example, the second term in Eq. (13) traced with an operator gives equilibrium expectation value governed by the states at E_F which must be removed. The third term in Eq. (13) ensures the gauge invariance of the nonequilibrium expectation values while making the whole expression non-Fermi-surface property. The third term also renders the usage of Eq. (13) computationally demanding due to the requirement to perform integration from the bottom of the band up to E_F together with sampling of $\mathbf{k}_{\parallel}$ points for the junctions in Fig. 2.

Figure 4 shows an example of a left-right *asymmetric* MTJ, FM/I/FM′, whose FM and FM′ layers are assumed to be made of the same material but have different thicknesses. This setup allows us to demonstrate how application of improper $\boldsymbol{\rho}_{\mathrm{CD}}$ in Eq. (12) yields linear-response $\mathbf{T}_{\mathrm{FL}} \propto V_b$ in Fig. 4b that is *incorrectly* an order of magnitude smaller than the correct result in Fig. 4a. This is due to the fact that $\mathbf{T}_{\mathrm{FL}}$ in MTJs possess both the nonequilibrium CD contribution due to spin reorientation at interfaces, where net spin created at one interface is reflected at the second interface where it briefly precesses in the exchange field of the free FM layer, and equilibrium contribution due to interlayer exchange coupling (Theodonis et al. 2006; Yang et al. 2010). The ambiguity in Fig. 4 arises when this equilibrium contribution
Fig. 4 The angular dependence of the damping-like (i.e., parallel), $|\mathbf{T}_{DL}|$, and field-like (i.e., perpendicular), $|\mathbf{T}_{FL}|$, components of the STT vector in Fig. 1c in an asymmetric (Oh et al. 2009) FM/I/FM′ MTJ computed in the linear-response regime at zero temperature using (**a**) the proper gauge-invariant expression Eq. (13) for ρ_{CD} and (**b**) the improper gauge-noninvariant expression Eq. (12) for ρ_{CD}. The FM/I/FM′ trilayer in Fig. 1a is modeled by TBH (Theodonis et al. 2006) defined on an infinite cubic lattice with a single orbital per site and lattice spacing a. Its insulating barrier has thickness 5 MLs with on-site potential $\varepsilon_{\mathbf{n}} = 6.0$ eV; the left FM layer is semi-infinite, and the right FM′ layer is 20 MLs thick. Both FM layers have the same exchange field $J = 0.5$ eV. The symbol $\square = a^2$ denotes unit interfacial area. (Adapted from Mahfouzi and Nikolić 2013)

is improperly subtracted, so that current-driven $\mathbf{T}_{FL}$ in Fig. 4b is contaminated by a portion of equilibrium contribution added to it when using improper ρ_{CD} in Eq. (12). On the other hand, since $\mathbf{T}_{DL}$ has a zero expectation value in equilibrium, both the proper and improper expressions for ρ_{CD} give the same result in Fig. 4.

Note that in the left-right *symmetric* MTJs, $\mathbf{T}_{FL} \propto V_b$ vanishes. Since this is a rather general result which holds for both MTJs and spin valves in the linear-response regime (Theodonis et al. 2006; Xiao et al. 2008; Heiliger and Stiles 2008) and it has been confirmed in numerous experiments (Wang et al. 2011; Oh et al. 2009), one can use it as a validation test of the computational scheme. For example, the usage of improper ρ_{CD} in Eq. (12), or the proper one in Eq. (13) but with possible software bug, would give nonzero $\mathbf{T}_{FL} \neq 0$ in symmetric junctions at small applied V_b which contradicts experiments (Wang et al. 2011; Oh et al. 2009). In the particular case of symmetric junction, one can actually employ a simpler expression (Mahfouzi and Nikolić 2013; Stamenova et al. 2017) than Eq. (13) which guarantees $\mathbf{T}_{FL} \equiv 0$

$$\rho_{CD} = \frac{eV_b}{4\pi}\mathbf{G}_0(E_F) \cdot [\mathbf{\Gamma}_L(E_F) - \mathbf{\Gamma}_R(E_F)] \cdot \mathbf{G}_0^\dagger(E_F). \tag{14}$$

This expressions is obtained by assuming (Mahfouzi and Nikolić 2013) the particular gauge $V_L = -V_b/2 = -V_R$. Such special gauges and the corresponding Fermi surface expressions for $\boldsymbol{\rho}_{\mathrm{CD}} \propto V_b$ in the linear-response regime do exist also for asymmetric junctions, but one does not know them in advance except for the special case of symmetric junctions (Mahfouzi and Nikolić 2013).

In the calculations in Fig. 4, $(T^x_{\mathrm{CD}}, T^y_{\mathrm{CD}}, T^z_{\mathrm{CD}}) = \mathrm{Tr}\,[\boldsymbol{\rho}_{\mathrm{CD}}\mathbf{T}]$ was first computed using the torque operator $\mathbf{T}$ akin to Eq. (3) but determined by the TBH of the free FM layer. These three numbers are then used to obtain FL (or perpendicular) torque component, $T_{\mathrm{FL}} = T^y_{\mathrm{CD}}$ along the direction $\mathbf{M}_{\mathrm{free}} \times \mathbf{M}_{\mathrm{fixed}}$, and DL (or parallel) torque component, $T_{\mathrm{DL}} = \sqrt{(T^x_{\mathrm{CD}})^2 + (T^z_{\mathrm{CD}})^2}$ in the direction $\mathbf{M}_{\mathrm{free}} \times (\mathbf{M}_{\mathrm{free}} \times \mathbf{M}_{\mathrm{fixed}})$. In MTJs angular dependence of STT components stems only from the cross product, so that $\propto \sin\theta$ dependence (Theodonis et al. 2006; Xiao et al. 2008) for both FL and DL components is obtained in Figs. 4 and 5.
Fig. 5 (**a**) Schematic view of a 1D toy model of MTJ consisting of the left and the right semi-infinite chains of carbon atoms separated by a vacuum gap. (**b**) Comparison of DL component of STT in this MTJ computed via the spin current divergence algorithm (Theodonis et al. 2006; Wang et al. 2008) in Eq. (21) and by using decomposition of the nonequilibrium density matrix into $\boldsymbol{\rho}^{\mu\nu}_{\mathrm{neq}}$ contributions in Eqs. (15), (16), (18), (19), and (20). The DL component of STT, computed in both algorithms in the linear-response regime, acts on the right carbon chain whose magnetic moments comprise the free magnetization $\mathbf{M}_{\mathrm{free}}$ rotated by an angle θ with respect to the fixed magnetization $\mathbf{M}_{\mathrm{fixed}}$ of the left carbon chain. Since MTJ is left-right symmetric, the FL component of the STT vector is zero in the linear-response regime (Wang et al. 2011; Theodonis et al. 2006; Xiao et al. 2008; Oh et al. 2009; Heiliger and Stiles 2008)

In the case of SOT, $\mathbf{T}_{\mathrm{DL}} \propto \mathbf{M}_{\mathrm{free}} \times \mathbf{f}$ and $\mathbf{T}_{\mathrm{DL}} \propto \mathbf{M}_{\mathrm{free}} \times (\mathbf{M}_{\mathrm{free}} \times \mathbf{f})$, where the direction specified by the unit vector $\mathbf{f}$ is determined dynamically once the current flows in the presence of SOC. Therefore, $\mathbf{f}$ is not known in advance (aside from simplistic models like the Rashba ferromagnetic one where $\mathbf{f}$ is along the y-axis for charge current flowing along the x-axis, as illustrated in Fig. 9). Thus, it would be advantageous to decompose $\boldsymbol{\rho}_{\mathrm{CD}}$ into contributions whose trace with the torque operator in Eq. (3) directly yields $\mathbf{T}_{\mathrm{DL}}$ and $\mathbf{T}_{\mathrm{FL}}$. Such decomposition was achieved in Mahfouzi et al. (2016), using adiabatic expansion of Eq. (4) in the powers of $d\mathbf{M}_{\mathrm{free}}/dt$ and symmetry arguments, where $\boldsymbol{\rho}_{\mathrm{neq}} = \boldsymbol{\rho}_{\mathrm{neq}}^{\mathrm{oo}} + \boldsymbol{\rho}_{\mathrm{neq}}^{\mathrm{oe}} + \boldsymbol{\rho}_{\mathrm{neq}}^{\mathrm{eo}} + \boldsymbol{\rho}_{\mathrm{neq}}^{\mathrm{ee}}$ is the sum of the following terms

$$\boldsymbol{\rho}_{\mathrm{neq}}^{\mathrm{oo}} = \frac{1}{8\pi} \int\limits_{-\infty}^{+\infty} dE \, [f_L(E) - f_R(E)] \left(\mathbf{G}\boldsymbol{\Gamma}_L\mathbf{G}^\dagger - \mathbf{G}^\dagger\boldsymbol{\Gamma}_L\mathbf{G} \right.$$

$$\left. - \mathbf{G}\boldsymbol{\Gamma}_R\mathbf{G}^\dagger + \mathbf{G}^\dagger\boldsymbol{\Gamma}_R\mathbf{G} \right), \tag{15}$$

$$\boldsymbol{\rho}_{\mathrm{neq}}^{\mathrm{oe}} = \frac{1}{8\pi} \int\limits_{-\infty}^{+\infty} dE \, [f_L(E) - f_R(E)] \left(\mathbf{G}\boldsymbol{\Gamma}_L\mathbf{G}^\dagger + \mathbf{G}^\dagger\boldsymbol{\Gamma}_L\mathbf{G} - \mathbf{G}\boldsymbol{\Gamma}_R\mathbf{G}^\dagger - \mathbf{G}^\dagger\boldsymbol{\Gamma}_R\mathbf{G} \right),$$

$$\tag{16}$$

$$\boldsymbol{\rho}_{\mathrm{neq}}^{\mathrm{eo}} = \frac{1}{8\pi} \int\limits_{-\infty}^{+\infty} dE \, [f_L(E) + f_R(E)] \left(\mathbf{G}\boldsymbol{\Gamma}_L\mathbf{G}^\dagger - \mathbf{G}^\dagger\boldsymbol{\Gamma}_L\mathbf{G} \right. \tag{17}$$

$$\left. + \mathbf{G}\boldsymbol{\Gamma}_R\mathbf{G}^\dagger - \mathbf{G}^\dagger\boldsymbol{\Gamma}_R\mathbf{G} \right) \equiv 0, \tag{18}$$

$$\boldsymbol{\rho}_{\mathrm{neq}}^{\mathrm{ee}} = \frac{1}{8\pi} \int\limits_{-\infty}^{+\infty} dE \, [f_L(E) + f_R(E)] \left(\mathbf{G}\boldsymbol{\Gamma}_L\mathbf{G}^\dagger + \mathbf{G}^\dagger\boldsymbol{\Gamma}_L\mathbf{G} + \mathbf{G}\boldsymbol{\Gamma}_R\mathbf{G}^\dagger + \mathbf{G}^\dagger\boldsymbol{\Gamma}_R\mathbf{G} \right).$$

$$\tag{19}$$

The four terms are labeled by being odd (o) or even (e) under inverting bias polarity (first index) or time (second index) (Mahfouzi et al. 2016). The terms $\boldsymbol{\rho}_{\mathrm{neq}}^{\mathrm{oo}}$ and $\boldsymbol{\rho}_{\mathrm{neq}}^{\mathrm{oe}}$ depend on $f_L(E) - f_R(E)$ and, therefore, are nonzero only in nonequilibrium generated by the bias voltage $V_b \neq 0$ which drives the steady-state current. Using an identity from the NEGF formalism (Stefanucci and van Leeuwen 2013), $\mathbf{G}(\boldsymbol{\Gamma}_L + \boldsymbol{\Gamma}_R)\mathbf{G}^\dagger = i(\mathbf{G} - \mathbf{G}^\dagger)$, reveals that $\boldsymbol{\rho}_{\mathrm{neq}}^{\mathrm{eo}} \equiv 0$ and

$$\boldsymbol{\rho}_{\mathrm{neq}}^{\mathrm{ee}} = -\frac{1}{2\pi} \int\limits_{-\infty}^{+\infty} dE \, [f_L(E) + f_R(E)] \mathrm{Im}\, \mathbf{G}. \tag{20}$$

Thus, $\rho_{\text{neq}}^{\text{ee}}$ term is nonzero even in equilibrium where it becomes identical to the equilibrium density matrix in Eq. (7), $V_b = 0 \Rightarrow \rho_{\text{neq}}^{\text{ee}} \equiv \rho_{\text{eq}}$. Since $\rho_{\text{neq}}^{\text{oo}}$ is odd under time reversal, its trace with the torque operator in Eq. (3) yields DL component of STT (which depends on three magnetization vectors and it is, therefore, also odd) and FL component of SOT (which depends on one magnetization vector and it is, therefore, also odd). Similarly trace of $\rho_{\text{neq}}^{\text{oe}}$ with the torque operator in Eq. (3) yields FL component of STT and DL component of SOT (Mahfouzi et al. 2016).

In the linear-response regime, pertinent to calculations of STT in spin valves and SOT in FM/spin-orbit-coupled-material bilayers, $f_L(E) - f_R(E) \rightarrow (-\partial f/\partial E) e V_b$. This confines integration in $\rho_{\text{neq}}^{\text{oo}}$ and $\rho_{\text{neq}}^{\text{oe}}$ expressions to a shell of few $k_B T$ around the Fermi energy, or at zero temperature these are just matrix products evaluated at the Fermi energy, akin to Eqs. (12), (13), and (14). Nevertheless, to compute $\rho_{\text{CD}} = \rho_{\text{neq}}^{\text{oo}} + \rho_{\text{neq}}^{\text{oe}} + \rho_{\text{neq}}^{\text{eo}} + \rho_{\text{neq}}^{\text{ee}} - \rho_{\text{eq}}$, one still needs to perform the integration over the Fermi sea in order to obtain $\rho_{\text{neq}}^{\text{ee}} - \rho_{\text{eq}}$, akin to Eq. (13), which can be equivalently computed as $[\rho_{\text{neq}}^{\text{ee}}(V_b) - \rho_{\text{neq}}^{\text{ee}}(-V_b)]/2$ using some small V_b.

To evade singularities on the real axis caused by the poles of the retarded GF in the matrix integral of the type $\int_{-\infty}^{+\infty} dE\, \mathbf{G} f_p(E)$ appearing in Eqs. (7), (13), and (20), such integration can be performed along the contour in the upper half of the complex plane where the retarded GF is analytic. The widely used contour (Brandbyge et al. 2002) consists of a semicircle, a semi-infinite line segment, and a finite number of poles of the Fermi function $f_p(E)$. This contour should be positioned sufficiently far away from the real axis, so that $\mathbf{G}$ is smooth over both of these two segments, while also requiring to select the minimum energy E_{min} (as the starting point of semicircular path) below the bottom of the band edge which is not known in advance in DFT calculations. That is, in self-consistent calculations, incorrectly selected minimum energy causes the charge to erroneously disappear from the system with convergence trivially achieved but to physically incorrect solution. By choosing different types of contours (Areshkin and Nikolić 2010; Ozaki 2007; Karrasch et al. 2010) [such as the "Ozaki contour" (Ozaki 2007; Karrasch et al. 2010) employed in the calculations in Fig. 9] where residue theorem leads to just a sum over a finite set of complex energies, proper positioning of E_{min} and convergence in the number of Fermi poles, as well as selection of sufficient number of contour points along the semicircle and contour points on the line segment, are completely bypassed.

The algorithm based on Eqs. (15), (16), (18), (19), and (20) is compared to often employed spin current divergence algorithm (Theodonis et al. 2006; Wang et al. 2008; Manchon et al. 2008) using a toy model of 1D MTJ, prior to its application to STT calculations in Sect. 3 and SOT calculations in Sect. 4. The model, illustrated in Fig. 5a where the left and right semi-infinite chains of carbon atoms are separated by a vacuum gap, is described by the collinear DFT Hamiltonian implemented in ATK package (Atomistix Toolkit 2017) using single-zeta polarized (Junquera et al. 2001) orbitals on each atom, Ceperley-Alder (Ceperley and Alder 1980) parametrization

of the local spin density approximation for the XC functional (Ceperley and Alder 1980), and norm-conserving pseudopotentials accounting for electron-core interactions. In the absence of spin-flip processes by impurities and magnons or SOC, the STT vector at site n within the right chain can be computed from the divergence (in discrete form) of spin current (Theodonis et al. 2006), $T_n^\alpha = -\nabla I^{S_\alpha} = I_{n-1,n}^{S_\alpha} - I_{n,n+1}^{S_\alpha}$. Its sum over the whole free FM layer gives the total STT as

$$T_{\text{CD}}^\alpha = \sum_{n=1}^{N_{\text{free}}} (I_{n-1,n}^{S_\alpha} - I_{n,n+1}^{S_\alpha}) = I_{0,1}^{S_\alpha} - I_{N_{\text{free}},N_{\text{free}}+1}^{S_\alpha}. \tag{21}$$

Here $I_{0,1}^{S_\alpha}$ is the local spin current, carrying spins pointing in the direction $\alpha \in \{x, y, z\}$, from the last site inside the barrier (which is the last site of the left carbon chain in Fig. 5a) toward the first site of the free FM layer (which is the first site of the right carbon chain in Fig. 5a). Similarly, $I_{N_{\text{free}},N_{\text{free}}+1}$ is the local spin current from the last site inside the free FM layer and the first site of the right lead. Thus, Eq. (21) expresses STT on the free FM layer composed of N_{free} sites as the difference (Wang et al. 2008) between spin currents entering through its left and exiting through its right interface. In the case of semi-infinite free FM layer, $N_{\text{free}} \rightarrow \infty$ and $I_{N_{\text{free}},N_{\text{free}}+1} \rightarrow 0$. The nonequilibrium local spin current can be computed in different ways (Wang et al. 2008), one of which utilizes NEGF expression for ρ_{CD}

$$I_{n,n+1}^{S_\alpha} = \frac{i}{2} \text{Tr} \left[\sigma_\alpha \left(\mathbf{H}_{n,n+1} \rho_{\text{CD}}^{n+1,n} - \rho_{\text{CD}}^{n,n+1} \mathbf{H}_{n+1,n} \right) \right]. \tag{22}$$

Here $\mathbf{H}_{n,n+1}$ and $\rho_{\text{CD}}^{n,n+1}$ are the submatrices of the Hamiltonian and the current-driven part of the nonequilibrium density matrix, respectively, of the size $2N_{\text{orbital}} \times 2N_{\text{orbital}}$ (2 is for spin and N_{orbital} is for the number of orbitals per each atom) which connect sites n and $n + 1$.

Combining Eqs. (14), (21), and (22) yields T_{CD}^x and T_{CD}^z from which we obtain $T_{\text{DL}} = \sqrt{(T_{\text{CD}}^x)^2 + (T_{\text{CD}}^z)^2}$ in the linear-response regime plotted in Fig. 5b as a function of angle θ between $\mathbf{M}_{\text{free}}$ and $\mathbf{M}_{\text{fixed}}$. Alternatively, evaluating the trace of the product of $\rho_{\text{neq}}^{\text{oo}}$ and the torque operator in Eq. (3) yields a vector with two nonzero components, which turn out to be identical to T_{CD}^x and T_{CD}^z computed from the spin current divergence algorithm, as demonstrated in Fig. 5b. The trace of $\rho_{\text{neq}}^{\text{oe}}$ with the torque operator gives a vector with zero x- and z-components and nonzero y-component which, however, is canceled by adding the trace of $\rho_{\text{neq}}^{\text{ee}} - \rho_{\text{eq}}$ with the torque operator to finally produce zero FL component of the STT vector. This is expected because MTJ in Fig. 5a is left-right symmetric.

We emphasize that the algorithm based on the trace of the torque operator with the current-driven part of the nonequilibrium density matrix ρ_{CD} is a *more general approach* than the spin current divergence algorithm since it is valid even in the

presence of spin-flip processes by impurities and magnons or SOC (Haney et al. 2007). In particular, it can be employed to compute SOT (Freimuth et al. 2014; Mahfouzi and Kioussis 2018) in FM/spin-orbit-coupled-material bilayers where spin torque *cannot* (Haney and Stiles 2010) be expressed any more as in Eq. (21).

3 Example: Spin-Transfer Torque in FM/NM/FM Trilayer Spin-Valves

First-principles quantum transport modeling of STT in spin valves (Haney et al. 2007; Wang et al. 2008) and MTJs (Stamenova et al. 2017; Heiliger and Stiles 2008; Jia et al. 2011; Ellis et al. 2017) is typically conducted using an assumption that greatly simplifies computation – noncollinear spins in such systems are described in a *rigid* approximation where one starts from the collinear DFT Hamiltonian and then rotates magnetic moments of either fixed or free FM layer in the spin space in order to generate the relative angle between $\mathbf{M}_{\text{fixed}}$ and $\mathbf{M}_{\text{free}}$ (as it was also done in the calculations of STT in 1D toy model of MTJ in Fig. 5). On the other hand, obtaining true ground state of such system requires noncollinear XC functionals (Capelle et al. 2001; Eich and Gross 2013; Eich et al. 2013; Bulik et al. 2013) and the corresponding self-consistent XC magnetic field $\mathbf{B}_{\text{xc}}$ introduced in Eq. (1). For a given self-consistently converged ncDFT Hamiltonian represented in the linear combination of atomic orbitals (LCAO) basis, we can extract the matrix representation of $\mathbf{B}_{\text{xc}}^{\alpha}$ in the same basis using

$$\mathbf{B}_{\text{XC}}^{x} = 2 \cdot \text{Re} \, \mathbf{H}^{\uparrow\downarrow}, \tag{23}$$

$$\mathbf{B}_{\text{XC}}^{y} = -2 \cdot \text{Im} \, \mathbf{H}^{\uparrow\downarrow}, \tag{24}$$

$$\mathbf{B}_{\text{XC}}^{z} = \mathbf{H}^{\uparrow\uparrow} - \mathbf{H}^{\downarrow\downarrow}. \tag{25}$$

Since LCAO basis sets $|\phi_n\rangle$ are typically nonorthogonal (as is the case of the basis sets (Junquera et al. 2001; Ozaki 2003; Schlipf and Gygi 2015) implemented in ATK (Atomistix Toolkit 2017) and OpenMX (Openmx) packages employed in the calculations of Figs. 5, 6, 7, and 8), the trace leading to the spin torque vector

$$\mathbf{T}_{\text{CD}} = \text{Tr} \, [\boldsymbol{\rho}_{\text{CD}} \boldsymbol{\sigma} \times \mathbf{D}^{-1} \mathbf{B}_{\text{XC}}], \tag{26}$$

requires to use the identity operator $\mathbf{1} = \sum_{ij} |\phi_i\rangle D_{ij}^{-1} \langle \phi_j|$ which inserts $\mathbf{D}^{-1}$ matrix into Eq. (26) where all matrices inside the trace are representations in the LCAO basis. In the real-space basis spanned by the eigenstates $|\mathbf{r}\rangle$ of the position operator, the same trace in Eq. (26) becomes

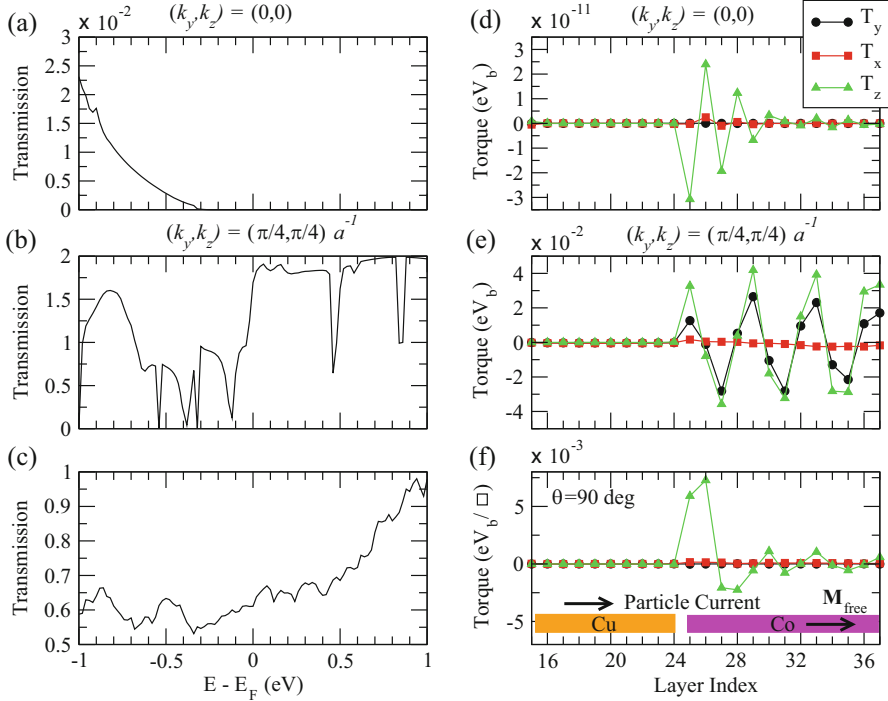
$$\mathbf{T}_{\text{CD}} = \int\limits_{\text{free FM}} d^3\mathbf{r} \, \mathbf{m}_{\text{CD}}(\mathbf{r}) \times \mathbf{B}_{\text{XC}}(\mathbf{r}). \tag{27}$$


Fig. 6 (**a**), (**b**) Transmission function, defined in Eq. (28), for Co/Cu(9 ML)/Co spin valve illustrated in Fig. 2a at two selected transverse wave vectors $\mathbf{k}_\parallel$, as well as (**c**) summed, as in Eq. (29), over all $\mathbf{k}_\parallel$ vectors within the 2D BZ. (**d**)–(**f**) The corresponding layer-resolved Cartesian components of the STT vector at an angle $\theta = 90°$ between the magnetizations $\mathbf{M}_{\text{fixed}}$ of the left Co layer acting as a polarizer and $\mathbf{M}_{\text{free}}$ of the right Co layer receiving the torque. The mesh of $\mathbf{k}_\parallel$ equally spaced points employed in (**c**) is 51×51, and in (**f**) it is 201×201. The symbol $\square = a^2$ denotes unit interfacial area, where $a = 2.52$ Å is the lattice constant of a common 2D hexagonal unit cell of Co/Cu bilayer (with a lattice mismatch of about 0.65%)

This is a nonequilibrium generalization of the equilibrium torque expression found in ncDFT (Capelle et al. 2001) where $\mathbf{m}_{\text{eq}}(\mathbf{r}) = \langle \mathbf{r} | \boldsymbol{\rho}_{\text{eq}} \boldsymbol{\sigma} | \mathbf{r} \rangle$ in ncDFT is replaced by $\mathbf{m}_{\text{CD}}(\mathbf{r}) = \langle \mathbf{r} | \boldsymbol{\rho}_{\text{CD}} \boldsymbol{\sigma} | \mathbf{r} \rangle$. Note that in thermodynamic equilibrium the integral in Eq. (27) must be zero when integration is performed over all space, which is denoted as "zero-torque theorem" (Capelle et al. 2001), but $\mathbf{m}_{\text{eq}} \times \mathbf{B}_{\text{XC}}(\mathbf{r})$ can be nonzero locally which gives rise to equilibrium torque on the free FM layer that has to be removed by subtracting $\boldsymbol{\rho}_{\text{eq}}$ to obtain $\boldsymbol{\rho}_{\text{CD}}$ in Eq. (9) and plug it into Eq. (27).

We employ ATK package to compute STT in Co/Cu(9 ML)/Co spin valve illustrated in Fig. 2a using ncDFT Hamiltonian combined with Eq. (26). Prior to DFT calculations, the interface builder in the VNL package (Virtual Nanolab 2017) is employed to construct a common unit cell for Co/Cu bilayer. In order to determine the interlayer distance and relaxed atomic coordinates, DFT calculations using VASP (Vienna; Kresse and Hafner 1993; Kresse and Furthmüller
Fig. 7 The DL component of STT vector in symmetric Co/Cu(9 ML)/Co spin valve in Fig. 2a driven by current at small bias voltage V_b as a function of angle θ between the magnetizations $\mathbf{M}_{\text{fixed}}$ of the left Co layer and $\mathbf{M}_{\text{free}}$ of the right Co layer. Its value at $\theta = 90°$ is the sum of layer-resolved STT shown in Fig. 6f. The non-scf curve is computed from Eq. (26) using the rigid approximation (Haney et al. 2007; Wang et al. 2008; Heiliger and Stiles 2008; Jia et al. 2011), where the spin valve is described by collinear DFT Hamiltonian and magnetic moments of the fixed Co layer are rotated by an angle θ with respect to magnetic moments in the free Co layer. Conversely, in the computation of scf curve, the DFT Hamiltonian from the rigid approximation serves as the first iteration leading toward converged self-consistent ncDFT Hamiltonian of the spin valve

1996) with Perdew-Burke-Ernzerhof (PBE) parametrization (Perdew et al. 1996) of the generalized gradient approximation for the XC functional and projected augmented wave (Blöchl 1994; Kresse and Joubert 1999) description of electron-core interactions are performed. The cutoff energy for the plane wave basis set is chosen as 600 eV, while k-points were sampled on a 11×11 surface mesh. In ATK calculations, PBE XC functional, norm-conserving pseudopotentials for describing electron-core interactions and SG15 (medium) LCAO basis set (Schlipf and Gygi 2015) are employed. The energy mesh cutoff for the real-space grid is chosen as 100 Hartree.

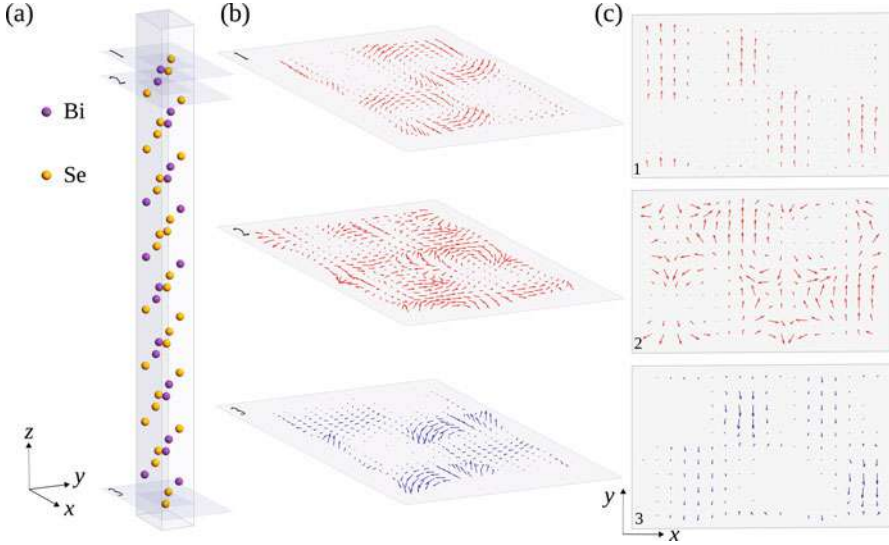
The layer-resolved Cartesian components of STT vector within the free Co layer are shown in Fig. 6d–f. The contribution from a propagating state oscillates as a function of position without decaying in Fig. 6e with a spatial period $2\pi/(k_\zeta^\downarrow - k_\eta^\uparrow)$ where ζ (η) denotes different sheets (Wang et al. 2008) of the Fermi surface for minority (majority) spin. This is due to the fact that noncollinear spin in Fig. 2a entering the right Co layer is not an eigenstate of the spin part of the Hamiltonian determined by $\mathbf{M}_{\text{free}}$, and it is, therefore, forced into precession. However, since the shapes of the Fermi surface for majority and minority spin in Co are quite different from each other (Wang et al. 2008), the spatial periods of precession can vary rapidly for different $\mathbf{k}_\parallel$ within the 2D Brillouin zone (BZ). Thus, summation of their contributions leads to cancelation and, therefore, fast decay of STT away


Fig. 8 (**a**) The arrangement of Bi and Se atoms within a supercell of Bi$_2$Se$_3$ thin film (infinite in the x- and the y-directions) consisting of five quintuple layers (one such layer contains three Se layers strongly bonded to two Bi layers in between) and total thickness ≈ 5 nm along the z-axis. (**b**) The vector field of current-driven nonequilibrium spin density $\mathbf{S}_{CD}(\mathbf{r})$ within selected planes shown in (**a**), generated by injection of unpolarized charge current along the x-axis. The planes 1 and 3 correspond to the top and bottom metallic surfaces of Bi$_2$Se$_3$ thin film, while plane 2 resides in the bulk at a distance $d \approx 0.164$ nm away from plane 1. (**c**) The vector fields in (**b**) projected onto each of the selected planes in (**a**). The real-space grid of points in panels (**b**) and (**c**) has spacing $\simeq 0.4$ Å. (Adapted from Chang et al. 2015)

from the interface (Stiles and Zangwill 2002; Wang et al. 2008), as demonstrated by plotting such sum to obtain the total STT per ML of Co in Fig. 6f.

The propagating vs. evanescent states are identified by finite (Fig. 6b) vs. vanishing (Fig. 6a), respectively, $\mathbf{k}_\parallel$-resolved transmission function obtained from the Landauer formula in terms of NEGFs (Stefanucci and van Leeuwen 2013)

$$T(E, \mathbf{k}_\parallel) = \text{Tr}\,[\boldsymbol{\Gamma}_R(E, \mathbf{k}_\parallel)\mathbf{G}_0(E, \mathbf{k}_\parallel)\boldsymbol{\Gamma}_L(E, \mathbf{k}_\parallel)\mathbf{G}_0^\dagger(E, \mathbf{k}_\parallel)], \qquad (28)$$

where the transverse wave vector $\mathbf{k}_\parallel$ is conserved in the absence of disorder. The total transmission function per unit interfacial area is then evaluated using (Ω_{BZ} is the area of sampled 2D BZ)

$$T(E) = \frac{1}{\Omega_{BZ}} \int\limits_{2D\ BZ} T(E, \mathbf{k}_\parallel), \qquad (29)$$

as shown in Fig. 6c. The transmission function in Fig. 6a at $\mathbf{k}_\parallel = (0, 0)$ vanishes at the Fermi energy, signifying evanescent state which *cannot* carry any current across

the junction. Nonetheless, such states can contribute (Ralph and Stiles 2008; Stiles and Zangwill 2002; Wang et al. 2008) to STT vector, as shown in Fig. 6d. Thus, the decay of STT away from Cu/Co interface in Fig. 6f arises both from the cancelation among contributions from propagating states with different $\mathbf{k}_\parallel$ and the decay of contributions from each evanescent state, where the latter are estimated (Wang et al. 2008) to generate $\simeq 10\%$ of the total torque on the ML of free Co layer that is closest to the Cu/Co interface in Fig. 2a.

Since the considered Co/Cu(9 ML)/Co spin valve is left-right symmetric, the FL component of the STT vector is zero. The DL component, as the sum of all layer-resolved torques in Fig. 6f, is plotted as a function of the relative angle θ between $\mathbf{M}_{\text{fixed}}$ and $\mathbf{M}_{\text{free}}$ in Fig. 7. The angular dependence of STT in spin valves does not follow $\propto \sin\theta$ dependence found in the case of MTJs in Figs. 4 and 5.

Although similar analyses have been performed before using collinear DFT Hamiltonian and rigid rotation of magnetic moments in fixed Co layer (Haney et al. 2007; Wang et al. 2008), in Fig. 7 an error made in this approximation was additionally quantified by computing torque using ncDFT Hamiltonian. The rigid approximation is then just the first iteration of the full self-consistent field (scf) calculations leading to the converged ncDFT Hamiltonian. The difference between scf and non-scf calculations in Fig. 7 is rather small due to large number of spacer MLs of Cu, but it could become sizable for small number of spacer MLs enabling coupling between two FM layers.

4 Example: Spin-Orbit Torque in FM/Monolayer-TMD Heterostructures

The calculation of SOT driven by injection of unpolarized charge current into bilayers of the type FM/HM shown in Fig. 2b, FM/monolayer-TMD shown in Fig. 2c, FM/TI, or FM/WSM can be performed using the same NEGF+ncDFT framework combining the torque operator $\mathbf{T}$, $\boldsymbol{\rho}_{\text{CD}}$ expressed in terms of NEGFs and ncDFT Hamiltonian that was delineated in Sect. 2 and applied in Sect. 3 to compute the STT vector in spin valves. Such first-principles quantum transport approach can also easily accommodate possible third capping insulating layer (such as MgO or AlO_x) employed experimentally to increase (Kim et al. 2013) the perpendicular magnetic anisotropy which tilts the magnetization out of the plane of the interface. However, the results of such calculations are not as easy to interpret as in the case of a transparent picture (Stiles and Zangwill 2002; Wang et al. 2008) in Fig. 6d–f explaining how spin angular momentum gets absorbed close to the interface in junctions which exhibit conventional STT. This is due to the fact that several microscopic mechanisms can contribute to SOT, such as the spin Hall effect (SHE) (Vignale 2010; Sinova et al. 2015) within the HM layer (Freimuth et al. 2014; Mahfouzi and Kioussis 2018) with strong bulk SOC and around FM/HM interface (Wang et al. 2016); current-driven nonequilibrium spin density – the so-called Edelstein effect (Edelstein 1990; Aronov and Lyanda-Geller 1989) – due to strong interfacial SOC; spin currents generated in transmission and reflection from

SO-coupled interfaces within 3D transport geometry (Zhang et al. 2015; Kim et al. 2017); and spin-dependent scattering of impurities (Pesin and MacDonald 2012a; Ado et al. 2017) or boundaries (Mahfouzi et al. 2016) in the presence of SOC within FM monolayers. This makes it difficult to understand how to optimize SOT by tailoring materials combination or device geometry to enhance one or more of these mechanisms.

An example of first-principles quantum transport modeling of the Edelstein effect is shown in Fig. 8 for the case of the metallic surface of Bi_2Se_3 as the prototypical 3D TI (Bansil et al. 2016). Such materials possess a usual bandgap in the bulk, akin to conventional topologically trivial insulators, but they also host metallic surfaces whose low-energy quasiparticles behave as massless Dirac fermions. The spins of such fermions are perfectly locked to their momenta by strong SOC, thereby forming spin textures in the reciprocal space (Bansil et al. 2016). In general, when charge current flows through a surface or interface with SOC, the presence of SOC-generated spin texture in the reciprocal space, such as those shown in Figs. 3e, g, and h, will generate nonequilibrium spin density which can be computed using

$$\mathbf{S}_{\text{CD}} = \frac{\hbar}{2}\text{Tr}\,[\boldsymbol{\rho}_{\text{CD}}\boldsymbol{\sigma}]. \tag{30}$$

In the case of simplistic Hamiltonians – such as the Rashba one for 2D electron gas (Winkler 2003), $\hat{H}_{\text{Rashba}} = (\hat{p}_x^2 + \hat{p}_y^2)/2m^* + \frac{\alpha_{\text{SO}}}{\hbar}(\hat{\sigma}_x\hat{p}_y - \hat{\sigma}_y\hat{p}_x)$, or the Dirac one for the metallic surface of 3D TI, $\hat{H}_{\text{Dirac}} = v_F(\hat{\sigma}_x\hat{p}_y - \hat{\sigma}_y\hat{p}_x)$ – the direction and the magnitude of $\mathbf{S}_{\text{CD}}$ are easily determined by back-of-the-envelope calculations (Pesin and MacDonald 2012b). For example, spin texture (i.e., expectation value of the spin operator in the eigenstates of a Hamiltonian) associated with $\hat{H}_{\text{Rashba}}$ consists of spin vectors locked to momentum vector along the two Fermi circles formed in the reciprocal space at the intersection of the Rashba energy-momentum dispersion (Winkler 2003) and the Fermi energy plane. Thus, current flow will disturb balance of momenta to produce $\mathbf{S}_{\text{CD}}$ in the direction transverse to current flow. The same effect is substantially enhanced (Pesin and MacDonald 2012b), by a factor $\hbar v_F/\alpha_{\text{SO}} \gg 1$ where v_F is the Fermi velocity in TI and α_{SO} is the strength of the Rashba SOC, because spin texture associated with $\hat{H}_{\text{Dirac}}$ consists of spin vectors locked to momentum vector along a *single* Fermi circle formed in the reciprocal space at the intersection of the Dirac cone energy-momentum dispersion (Bansil et al. 2016) and the Fermi energy plane. This eliminates the compensating effect of the spins along the second circle in the case of $\hat{H}_{\text{Rashba}}$. Note that nonzero total $\mathbf{S}_{\text{CD}} \propto V_b$ generated by the Edelstein effect is allowed only in nonequilibrium since in equilibrium $\mathbf{S}$ changes sign under time reversal and, therefore, has to vanish (assuming the absence of external magnetic field or magnetization).

In the case of a thin film of Bi_2Se_3 described by ncDFT Hamiltonian, unpolarized charge current injected along the x-axis generates $\mathbf{S}_{\text{CD}} = (0, S_{\text{CD}}^y, S_{\text{CD}}^z)$ on the top surface of the TI, marked as plane 1 in Fig. 8. The in-plane component S_{CD}^y, expected from back-of-the-envelope calculations sketched in the preceding paragraph, is an

order of magnitude larger than the out-of-plane component S_{CD}^z arising due to hexagonal warping (Bansil et al. 2016) of the Dirac cone on the TI surface. The spin texture on the bottom surface of the TI, marked as plane 3 in Fig. 8, has opposite sign to that shown on the top surface because of opposite direction of spins wounding along single Fermi circle on the bottom surface. In addition, a more complicated spin texture in real space (on a grid of points with $\simeq 0.4$ Å spacing), akin to noncollinear intra-atomic magnetism (Nordström and Singh 1996) but driven here by current flow, emerges within $\simeq 2$ nm thick layer below the TI surfaces. This is due to the penetration of evanescent wave functions from the metallic surfaces into the bulk of the TI, as shown in Fig. 8 by plotting $\mathbf{S}_{\mathrm{CD}}(\mathbf{r})$ within plane 2.

The conventional unpolarized charge current injected into the HM layer in Fig. 2b along the x-axis generates transverse spin Hall currents (Vignale 2010; Sinova et al. 2015; Wang et al. 2016) due to strong SOC in such layers. In 3D geometry, spin Hall current along the y-axis carries spins polarized along the z-axis, while the spin Hall current along the z-axis carries spins polarized along the y-axis (Wang et al. 2016). Thus, the effect of the spin Hall current flowing along the z-axis and entering FM layer resembles STT that would be generated by a fictitious polarizing FM layer with fixed magnetization along the y-axis and with charge current injected along the z-axis. While this mechanism is considered to play a major role in the generation of the DL component of SOT (Liu et al. 2012), as apparently confirmed by the Kubo-formula+ncDFT modeling (Freimuth et al. 2014; Mahfouzi and Kioussis 2018), the product of signs of the FL and DL torque components is negative in virtually all experiments (Yoon et al. 2017) (except for specific thicknesses of HM = Ta (Kim et al. 2013) layer). Although HM layer in Fig. 2b certainly generates spin Hall current in its bulk, such spin current can be largely suppressed by the spin memory loss (Dolui and Nikolić 2017; Belashchenko et al. 2016) as electron traverses HM/FM interface with strong SOC. Thus, in contrast to positive sign product in widely accepted picture where SHE is most responsible for the DL component of SOT and Edelstein effect is most responsible for the FL component of SOT, negative sign product indicates that a single dominant mechanism could be responsible for *both* DL and FL torque.

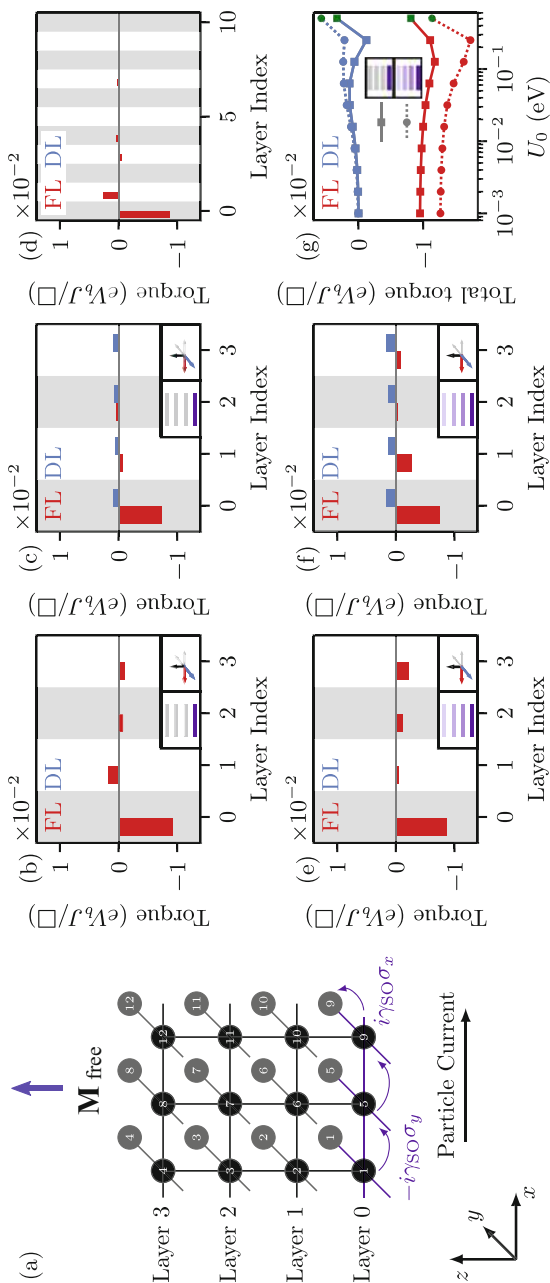
In order to explore how such single mechanism could arise in the absence of spin Hall current, one can calculate torque in a number of specially crafted setups, such as the one chosen in Fig. 9a where a single ultrathin FM layer (consisting of 4 or 10 MLs) is considered with the Rashba SOC present either only in the bottom ML (marked as 0 in Fig. 9a) or in all MLs but with decreasing strength to mimic the spin-orbit proximity effect exemplified in Fig. 3g, h. The setup in Fig. 9a is motivated by SOT experiments (Sklenar et al. 2016; Shao et al. 2016; Guimarães et al. 2018; Lv et al. 2018) on FM/monolayer-TMD heterostructures where SHE is absent due to atomically thin spin-orbit-coupled material. In such bilayers, clean and atomically precise interfaces have been achieved, while back-gate voltage (Lv et al. 2018) has been employed to demonstrate control of the ratio between the FL and DL components of SOT. Note that when bulk TMD or its even-layer thin films are centrosymmetric, its monolayer will be noncentrosymmetric crystal which results in lifting of the spin degeneracy and possibly strong SOC effects (Zhu et al. 2011).


Fig. 9 (**a**) Schematic view of an ultrathin FM layer comprised of few MLs, modeled as infinite square tight-binding lattices (with lattice constant a) in the xy-plane. The bottom layer 0 is assumed to be in direct contact with a spin-orbit-coupled material like TMD. (**b**)–(**g**) The layer-resolved FL and DL components of SOT vector per unit area $\square = a^2$ for the device in (**a**) where FM film is 4 MLs thick in all panels except (**d**) where the thickness is 10 MLs. The bottom layer 0 is assumed to host the Rashba SOC of strength $\gamma_{SO} = 0.2$ eV, induced by the spin-orbit proximity effect from monolayer-TMD (which is assumed to be insulating and, therefore, not explicitly considered), as illustrated in Fig. 3h for Co/monolayer-MoS$_2$. This is twice as strong as the exchange field in the FM layer, $\gamma_{SO}/J = 2$ in Eq. (31). In panels (**e**) and (**f**) the Rashba SOC was also added in layers $l > 0$ with strength 50% smaller than in layer $l − 1$ (i.e., $\gamma_{SO} = 0.2$, 0.1, 0.05, and 0.025 eV in layers 0–3, respectively). Panel (**g**) plots FL and DL components of SOT summed over all layers as a function of the strength of a homogeneous on-site potential $U_\mathbf{n} = U_0$ in Eq. (33) added into the central region of the thickness of 5 sites along the x-axis. The green square and dot in panel (**g**) mark SOT components at $U_0 = 0.5$ eV whose layer-resolved values are shown in panels (**c**) and (**f**), respectively. The temperature is set at $T = 300$ K, Fermi energy is $E_F = 1$ eV, and a grid of $N_{k_y} = 2000$ equally spaced k_y-points was used to sample periodically repeated lattice in the y-direction. The red and blue arrows in the insets of panels (**b**), (**c**), (**e**), and (**f**) denote $\mathbf{M}_{free} \times \mathbf{e}_y$ and $\mathbf{M}_{free} \times (\mathbf{M}_{free} \times \mathbf{e}_y)$ unit vectors along the direction of FL and DL components of SOT, respectively. The quad-graphs in the insets of panels (**b**), (**c**), (**e**), (**f**), and (**g**) signify the presence or absence of the Rashba SOC within layers 0–3 using the shade of the corresponding line

In order to be able to controllably switch SOC on and off in different MLs or to add other types of single-particle interactions, a setup is described in Fig. 9a using TBH defined on an infinite cubic lattice of spacing a with a single orbital per site located at position $\mathbf{n} = (n_x a, n_z a)$

$$\hat{H} = \sum_{\mathbf{n}} \varepsilon_{\mathbf{n}} \hat{c}_{\mathbf{n}}^\dagger \hat{c}_{\mathbf{n}} + \sum_{\langle \mathbf{nn'} \rangle} \hat{c}_{\mathbf{n}}^\dagger \mathbf{t}_{\mathbf{nn'}} \hat{c}_{\mathbf{n'}} - J \sum_{\mathbf{n}} \hat{c}_{\mathbf{n}}^\dagger \mathbf{M}_{\text{free}} \cdot \boldsymbol{\sigma} \hat{c}_{\mathbf{n}}. \tag{31}$$

Here $\hat{c}_{\mathbf{n}}^\dagger = (\hat{c}_{\mathbf{n}\uparrow}^\dagger \ \ \hat{c}_{\mathbf{n}\downarrow}^\dagger)$ is the row vector of operators which create electron at site $\mathbf{n}$ in spin-$\uparrow$ or spin-$\downarrow$ state, and $\hat{c}_{\mathbf{n}} = (\hat{c}_{\mathbf{n}\uparrow} \ \ \hat{c}_{\mathbf{n}\downarrow})$ is the column vector of the corresponding annihilation operators. The spin-dependent nearest-neighbor hoppings in the xz-plane form a 2×2 matrix in the spin space

$$\mathbf{t}_{\mathbf{nn'}} = \begin{cases} -t\mathbf{I}_2, & \text{for } \mathbf{n} = \mathbf{n'} + a\mathbf{e}_z, \\ -t\mathbf{I}_2 - i\gamma_{\text{SO}}\sigma_y, & \text{for } \mathbf{n} = \mathbf{n'} + a\mathbf{e}_x, \end{cases} \tag{32}$$

where $\gamma_{\text{SO}} = \alpha_{\text{SO}}/2a$ measures the strength of the Rashba SOC on the lattice (Nikolić et al. 2006), $\mathbf{I}_2$ is the unit 2×2 matrix, and $\mathbf{e}_\alpha$ are the unit vectors along the axes of the Cartesian coordinate system. The on-site energy

$$\varepsilon_{\mathbf{n}} = \left[U_{\mathbf{n}} - 2t \cos\left(k_y a\right) \right] \mathbf{I}_2 - 2\gamma_{\text{SO}}\sigma_x \sin(k_y a), \tag{33}$$

includes the on-site potential energy $U_{\mathbf{n}}$ (due to impurities, insulating barrier, voltage drop, etc.), as well as kinetic energy effectively generated by the periodic boundary conditions along the y-axis which simulate infinite extension of the FM layer in this direction and require k_y-point sampling in all calculations. The infinite extension along the x-axis is taken into account by splitting the device in Fig. 9a into semi-infinite left lead, central region of arbitrary length along the x-axis, and semi-infinite right lead, all of which are described by the Hamiltonian in Eq. (31) with the same values for $t = 1\,\text{eV}$, $J = 0.1\,\text{eV}$, and the γ_{SO} chosen in all three regions. Thus, γ_{SO} is homogeneous within a given ML, and always present $\gamma_{\text{SO}} = 0.2\,\text{eV}$ on layer 0, but it can take different values in other MLs. The Fermi energy is set at $E_F = 1.0\,\text{eV}$ to take into account possible noncircular Fermi surface (Lee et al. 2015) effects in realistic materials.

The SOT is often studied (Manchon and Zhang 2008; Haney et al. 2013; Lee et al. 2015; Li et al. 2015; Pesin and MacDonald 2012a; Ado et al. 2017; Kalitsov et al. 2017) using the Rashba ferromagnetic model in 2D, which corresponds to just a single layer in Fig. 9a. In that case, only FL torque component is found (Manchon and Zhang 2008; Kalitsov et al. 2017) due to the Edelstein effect and in the absence of spin-dependent disorder (Pesin and MacDonald 2012a; Ado et al. 2017). This is also confirmed in the 3D transport geometry in Fig. 9b, d, e where SOT vector, $\frac{2J}{\hbar}\mathbf{S}_{\text{CD}} \times \mathbf{M}_{\text{free}}$, on layer 0 has only FL component pointing in the $\mathbf{M}_{\text{free}} \times \mathbf{e}_y$ direction, as long as the device is infinite, clean, and homogeneous. In addition, nonzero FL component of SOT in Fig. 9b, d was also found on layers above layer 0

despite the fact that only layer 0 hosts $\gamma_{SO} \neq 0$. This is due to vertical transport along the z-axis in 3D geometry of Fig. 9a, but in the absence of the Rashba SOC on other layers, such effect decays fast as we move toward the top layer, as shown in Fig. 9d for 10 MLs thick FM film. The presence of the Rashba SOC with decreasing γ_{SO} on MLs above layer 0 generates additional nonequilibrium spin density $\mathbf{S}_{CD} \propto \mathbf{e}_y$ on those layers and the corresponding enhancement of the FL component of SOT on those layers in Fig. 9e.

We note that the Kubo-Bastin formula (Bastin et al. 1971) adapted for SOT calculations (Freimuth et al. 2014) predicts actually nonzero DL component of SOT vector for the Rashba ferromagnetic model in 2D due to the change of electronic wave functions induced by an applied electric field termed the "Berry curvature mechanism" (Lee et al. 2015; Kurebayashi et al. 2014; Li et al. 2015). Despite being apparently intrinsic, i.e., insensitive to disorder, this mechanism can be completely canceled in specific models when the vertex corrections are taken into account (Ado et al. 2017). It also gives positive sign product (Lee et al. 2015; Li et al. 2015) of DL and FL components of SOT contrary to majority of experiments where such product is found to be negative (Yoon et al. 2017). It is emphasized here that no electric field can exist in the ballistic transport regime through clean devices analyzed in Fig. 9b, d, e, for which the Kubo-Bastin formula also predicts unphysical divergence (Freimuth et al. 2014; Mahfouzi and Kioussis 2018; Lee et al. 2015; Kurebayashi et al. 2014; Li et al. 2015) of the FL component of SOT. Adding finite voltage drop within the central region, which is actually unjustified in the case of infinite, clean, homogeneous device, results in nonzero DL component of SOT also in the NEGF calculations (Kalitsov et al. 2017). However, the same outcome can be obtained simply by introducing constant potential $U_{\mathbf{n}} = U_0$ on each site of the central region acting as a barrier which reflects incoming electrons, as demonstrated in Fig. 9c, f, g. In the presence of both SOC and such barrier, spin-dependent scattering (Pesin and MacDonald 2012a; Ado et al. 2017) is generated at the lead/central-region boundary which results in nonzero component of $\mathbf{S}_{CD}$ in the direction $\mathbf{M}_{\text{free}} \times \mathbf{e}_y$ and the corresponding DL component of SOT $\propto \mathbf{M}_{\text{free}} \times (\mathbf{M}_{\text{free}} \times \mathbf{e}_y)$ acting on edge magnetic moments (Mahfouzi et al. 2016). This will, therefore, induce inhomogeneous magnetization switching which starts from the edges and propagates into the bulk of FM layer, as observed in experiments (Baumgartner et al. 2017) and micromagnetic simulations (Baumgartner et al. 2017; Mikuszeit et al. 2015).

Interestingly, Fig. 9g also demonstrates that the signs of the DL and FL component are opposite to each other for almost all values of $U_{\mathbf{n}} = U_0$ (except when $U_0 \simeq J$), as observed in the majority of SOT experiments (Yoon et al. 2017). Importantly, the spin-orbit proximity effect within the MLs of FM layer close to FM/spin-orbit-coupled-material interface, as illustrated in Figs. 3g, h and mimicked by introducing the Rashba SOC of decaying strength within all MLs of FM thin film in Fig. 9a, enhances both FL and DL components of SOT. This is demonstrated by comparing solid ($\gamma_{SO} \neq 0$ only on layer 0) and dashed ($\gamma_{SO} \neq 0$ on all layers 0–3) lines in Fig. 9g. This points out at a knob that can be exploited to enhance SOT by searching for optimal combination of materials capable to generate

penetration of SOC over long distances within the FM layer (Marmolejo-Tejada et al. 2017). In fact, in the case of FM/TI and FM/monolayer-TMD heterostructures, proximity SOC coupling within the FM layer is crucial for SOT efficiency (Wang et al. 2017) where it has been considered (Mellnik et al. 2014) that applied current will be shunted through the metallic FM layer and, therefore, not contribute to nonequilibrium spin density generation at the interface where SOC and thereby induced in-plane spin textures are naively assumed to reside.

5   Conclusions

This chapter reviews a unified first-principles quantum transport approach, implemented by combining NEGF formalism with ncDFT calculations, to compute both STT in traditional magnetic multilayers with two FM layers (i.e., the polarizing and analyzing FM layers with fixed and free magnetizations, respectively) and SOT in magnetic bilayers where only one of the layers is ferromagnetic. In the latter case, the role of the fixed magnetization of the polarizing FM layer within spin valves or MTJs is taken over by the current-driven nonequilibrium spin density in the presence of strong SOC introduced by the second layer made of HM, 3D TI, WSM, or monolayer-TMD. This approach resolves recent confusion (Freimuth et al. 2014; Kalitsov et al. 2017) in the literature where apparently only the Kubo formula, operating with expressions that integrate over the Fermi sea in order to capture change of wave functions due to the applied electric field and the corresponding interband electronic transitions (Freimuth et al. 2014; Lee et al. 2015; Li et al. 2015), can properly obtain the DL component of SOT. In addition, although the Kubo formula approach can also be integrated with first-principles calculations (Freimuth et al. 2014; Mahfouzi and Kioussis 2018), it can only be applied to a single device geometry (where infinite FM layer covers infinite spin-orbit-coupled-material layer while current flows parallel to their interface) and in the linear-response transport regime. In contrast, NEGF+ncDFT approach reviewed in this chapter can handle arbitrary device geometry, such as spin valves and MTJs exhibiting STT or bilayers of the type FM/spin-orbit-coupled-material which are made inhomogeneous by attachment to NM leads, at vanishing or finite applied bias voltage. In contrast to often employed 2D transport geometry (Manchon and Zhang 2008; Haney et al. 2013; Lee et al. 2015; Li et al. 2015; Pesin and MacDonald 2012a; Ado et al. 2017; Kalitsov et al. 2017; Ndiaye et al. 2017) for SOT theoretical analyses, it is emphasized here the importance of 3D transport geometry (Kim et al. 2017; Ghosh and Manchon 2018) to capture both the effects at the FM/spin-orbit-coupled-material interface and those further into the bulk of the FM layer. Finally, ultrathin FM layers employed in SOT experiments can hybridize strongly with the adjacent spin-orbit-coupled material to acquire its SOC and the corresponding spin textures on all of the FM monolayers. Such "hybridized ferromagnetic metals" can have electronic and spin structure (Fig. 3) which is quite different from an isolated FM layer, thereby requiring usage of both 3D geometry and first-principles Hamiltonians [of either tight-binding (Freimuth et al. 2014; Mahfouzi and Kioussis

2018) or pseudopotential-LCAO-ncDFT (Theurich and Hill 2001) type] to predict the strength of SOT in realistic systems and optimal materials combinations for device applications of the SOT phenomenon.

Low-Dimensional Materials at the Nanoscale

Low-dimensional materials at the nanoscale: Overview

24

James R. Chelikowsky

Contents

Abstract

Chapters in this section center on applications of computational methods to current and emergent materials, especially physically confined systems at the nanoscale.

1   Emergence

In this section, computational applications to "current and emergent" materials are presented.

Of course, current materials are ones of contemporary interest such as nanostructures, topological materials, and restricted dimensional materials such as graphene. Active research project focuses on such materials for device applications and fundamental understanding.

The term "emergent materials" is a more problematic one. The concept of an unanticipated property emerging as the number of atoms increase is not new. A key

reference in the evolution of this concept is Anderson's highly cited paper on *More Is Different* (Anderson 1972), published almost a half century ago. In his seminal paper, Anderson noted: "The ability to reduce everything to simple fundamental laws does not imply the ability to start from those laws and reconstruct the universe."

Consider a simple example. Atoms carry charge, but not dipoles. The idea that an isolated atom in free space might carry a dipole would seem to violate the isotropy of free space. However, when atoms are brought together to form solids, it is possible for a resulting crystal to be a "ferroelectric," i.e., the crystal possesses spontaneous electric polarization or a permanent dipole moment. The manifestation of ferroelectricity is claimed to be an emergent property as one would not have anticipated such a property by a study of the constituent atoms. The property only occurs when large number of atoms interacts. Hence, the title of Anderson's article reflects this emergence as "more is different."

Some have disparaged the use "emergence" in physics as commonly used by claiming it is ill defined, vague, and utilized solely for the purpose of obtaining research funding (Kivelson and Kivelson 2016). One aspect of such criticism is the anthropic nature of the definition, specifically, defining emergence as involving an "unanticipated" property. An unanticipated property is clearly a subjective judgment. One might argue that a particular "emergent property" should have anticipated and therefore not "emergent." Most scientists would argue that definitions of properties should not be dependent on a subjective judgment.

In this case, one might argue that a property deemed unanticipated by one scientist might not be so characterized by another scientist. This is not an uncommon situation. As the author recalls, the Nobel Laureate Linus Pauling once said in response to a question: "It's not a difficult problem if you know what you are doing." This, it could be argued, is like saying a difficult problem is no longer difficult once you know the solution. As such one would not characterize a problem as difficult in a scientific sense.

This said, scientists plainly use anthropic avenues of thought as they are human, and such loosely defined characterizations are common and widely accepted. For example, scientists often characterize materials by words such as "complex" or "advanced," and these terms are equally problematic in terms of an objective definition as is the term: emergent. Today's advanced material may not be so a decade from now, and terming a material as complex is clearly a subjective characterization. The argument about terming a property as emergent to obtain funding may centered more on the judgment of the grant officer than on science per se. Whatever the arguments about the meaning of an "emergent" property, a material possessing such a property is likely to be of more general interest than one not.

With such issues in mind, a recently proposed definition of an "emergent" property has been proposed that attempts to more objectively quantify the term. An emergent property should be defined as "a qualitative property that can only occur in the limit where the number of microscopic constituents tends to infinity" (Kivelson and Kivelson 2016). This definition is more rigorous as it removes the issue of whether the property is "unanticipated." However, this definition does not capture

the imagination often associated with emergent behavior as implied by colloquial use and Anderson's "more is different" perspective.

2   Size, Symmetry, and Restricted Dimensionality in Materials

Emergent material properties are often associated with issues of size, symmetry, and restricted dimensionality. The authors of articles in this section for the most part focus on nanoscale systems which exhibit size-dependent properties, some of them emergent and some not.

Consider the following thought experiment about size properties. Suppose we start with a bulk crystal. We can characterize its properties as either "intensive" or "extensive." Intensive properties are not dependent on its size. Density is such a property. If we considered a $1\,cm^3$ sample or a $10\,cm^3$, sample, the density would be the same. A bandgap of a semiconductor is a similar property as it does not change in such circumstance. Extensive properties include the mass or volume of the system. Now suppose we make the size of the system smaller and smaller. As we do so, we would eventually find some "intensive" properties to be dependent on the size of the system.

The bandgap of an insulating material is an obvious example. As the material approaches the nanoscale, the bandgap changes. When an inherently intensive property becomes dependent on size, one can usually argue that the materials reside in a nanoscale regime. As a crude estimate for that size regime, consider the "size" of an excitation in a semiconductor. Typically the Bohr radius of a hydrogenic model for an electron-hole pair in a semiconductor is around 5–10 nm. For systems smaller than this size, we expect the bulk bandgap to be significantly modified.

Consider the properties of a silicon nanocrystal. Very small nanocrystals of silicon are optically active, i.e., they absorb and emit light in the visible spectrum. By "very small" we mean a few hundred atoms. As the size of such a nanocrystal increases, two interesting phenomena occur. First, the optical gap becomes independent of size and saturates to a given value. Second, the optically active material becomes optically inactive.

In Fig. 1, we illustrate computations for the ionization potential, IP, and electronic affinity, EA, along with the highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) levels. The IP and EA energies are defined by

$$I = E(N - 1) - E(N)$$
$$A = E(N) - E(N + 1)$$

(1)

where E is the total electronic energy of the nanocrystal.

The quasiparticle gap is the energy to create noninteracting electron-hole pairs given by $IP - EA$. This is not the gap we expect for the absorption of light as we

are the eigenvalue levels for
the highest occupied
molecular orbital (HOMO)
and the lowest unoccupied
molecular orbital (LUMO).
(Chelikowsky in MTM
Chapter 24)
have not included interactions between the electron and hole. Also, we used density
functional theory to compute these energies. They are ground-state energies, but the
functional we used to compute these energies is approximate. The gap decreases as
the size of the nanocrystal increases and eventually approaches the gap given by the
difference in the highest occupied energy level and the lowest unoccupied energy
level.

While the quasiparticle gap is not equal to the actual optical gap, the trends are the
same. The evolution of the gap from a nanocrystal to the bulk is not what we would
call emergent with our working definition. The trend is not qualitatively different
and it is not unanticipated. As the size of nanocrystal decreases, the excitation
is physically confined to a smaller domain. We can argue using the uncertainty
principle that the energy of such an excitation should increase. This can be shown
by a simple model based on a finite well (Chan et al. 2008).

Why does an optically active Si nanocrystal become inactive as the size of the
nanocrystal increases? This effect is illustrated in Fig. 2. The oscillator strength for
optical transitions is reduced by more than an order of magnitude as the diameter of
the nanocrystal increases from 6 to 18 Å. In this sense, the optical properties of bulk
silicon are qualitatively different than for nanocrystal silicon.

The evolution of this property might again have been anticipated. In crystalline
silicon, conservation of crystal momentum prevents the absorption of light at the
bandgap threshold. The conservation of crystal momentum is a direct result of
translational symmetry, which does not exist in the limit of a small nanocrystal of
silicon.

Other nanoscale systems often reflect restricted dimensionality anisotropically
such as nanofilms and nanowires where the systems are confined in one or two
dimensions. A limiting case of a nanofilm includes two-dimensional materials

Fig. 2 Oscillator strength of
dipole-allowed transitions
near the absorption edge vs
cluster diameter. (Vasiliev
2002)
such as graphene or a single layer of MoS_2. By appropriately capitalizing on the
role of quantum confinement in these systems, workers hope to change properties
by changing the physical size of the material and not by changing its chemical
composition.

3   Computational Challenges for Emerging Materials

The study of emergent properties is computationally difficult owing to spanning
length scales and the large number of atoms involved. While the physical size
of a nanocrystal might be small, the number of atoms involved is not. Often
thousands of atoms are involved in nanoscale phenomena. Only within the last
decade have computers and algorithms evolved to the point where it is possible to
consider computations for nanostructures that are comparable in size to those made
experimentally.

A key outstanding issue remains centers on the structural properties of nanostruc-
tures, which are in general not known even for nanocrystals. While it may be safe
to assume that nanocrystal structures are similar to the bulk material, the surface
structure can be problematic. In particular, one of the issues with a confined system
is exactly how to confine it. Often nanostructures are passivated by some agent
to remove chemically active bonds on the surface or the nanocrystals themselves
embedded in inert matrixes.

While one might be able to compute the energy of systems with many atoms,
the near degeneracy of competing states often precludes a definitive prediction of
the ground state. Moreover, the number of degrees of freedoms can be too large
to optimize the nanostructure by energy minimization. Still, we can often learn
about a material by considering energetically accessible structures or an ensemble
of materials that may closely resemble experimental situations. For example, we

might consider a nanostructure created by a bulk fragment. If this system is then passivated by "capping atoms" that eliminate dangling bonds, we can obtain interesting perspectives on the role of quantum confinement.

Computational methods as outlined in the companion set of this Handbook: (*Methods: Theory and Modeling*) address many of these issues in detail.

4   Contributions

This section contains contributions that are centered on limited dimensionality at the nanoscale. The authors use a variety of computational means to examine structural, electronic, optical, and magnetic properties.

A number of the contributions focus on two-dimensional materials such as graphene sheets or nanoribbons:

- ▶ Chapter 26, "Functionalizing Two-Dimensional Materials for Energy Applications" by Bing Huang and Su-Huai Wei. This contributions is focused on the physical properties of some reprehensive 2D materials. These 2D materials include graphene, transition metal disulfides and diselenides, black phosphorus, and other metastable two-dimensional materials.
- ▶ Chapter 25, "Interaction of Hydrogen with Graphitic Surfaces, Clean and Doped with Metal Clusters" by Julio A. Alonso and María J. López. These authors review the work on the interaction of molecular and atomic hydrogen with graphene and graphene nanoribbons and address the effects due to the presence of metal clusters on the surface because of the evidence of their role in enhancing hydrogen storage.
- ▶ Chapter 29, "Interlayer Interactions in Low-Dimensional Layered Hetero-structures: Modeling and Applications" by Oded Hod. This work provides an overview of recent developments for constructing reliable, efficient, and transferable anisotropic interlayer force-fields for homogeneous and heterogeneous low-dimensional hexagonal layered materials. Applications to the study of the structural and tribological properties of layered structures are presented.
- ▶ Chapter 31, "Electronic Structure of Atomically Precise Graphene Nanoribbons" by Leopold Talirz and Carlo A. Pignedoli. This chapter guides the reader through a theoretical toolbox available for modeling the electronic structure of graphene nanoribbons, including a range of approaches from simple empirical models to state-of-the-art *ab initio* methods.

The remaining chapters center on nanostructures confined in two dimensions (nanowires) or in three dimensions (molecules, clusters, and nanocrystals).

- ▶ Chapter 27, "Spins in Semiconductor Nanocrystals" by Gustavo Martini Dalpian. Semiconductor nanocrystals can be used as hosts to trap and manipulate single spins, which can have different properties than their bulk counterparts,

owing both to quantum confinement. This chapter discusses how spins can be generated in nanocrystals by the insertion of impurities, either magnetic or not, or by magnetic polarons present at dangling bonds at their surfaces.

- ▶ Chapter 28, "Excited-State Properties of Thin Silicon Nanowires" by Li Yang. Nanowires are special in terms of anisotropy as physical confinement occurs in two directions resulting in a one-dimensional periodic system. Many-electron interactions can be computed using many-body perturbation theory methods based on the GW approximation and the Bethe-Salpeter equation. This chapter illustrates the results found with these computational tools indicating enhanced electronic interactions owing to restricted dimensionality and depressed electronic screening.

- ▶ Chapter 30, "Emergence of Functionalized Properties in Semiconductor Nanostructures" by James R. Chelikowsky. In this chapter computational methods are discussed that can be used to predict the emergence of nanoscale electronic properties in semiconductors, both intrinsic and extrinsic, and how these properties change as the size of the system decreased.

Julio A. Alonso and María J. López

Contents

Abstract

Hydrogen is viewed as a possible alternative to the fossil fuels in transportation. The technology of fuel-cell engines is fully developed, and the outstanding remaining problem is the storage of hydrogen in the vehicle. Porous materials, in which hydrogen is adsorbed on the pore walls, and in particular nanoporous carbons, have been investigated as potential onboard containers. Furthermore, metallic nanoparticles embedded in porous carbons catalyze the dissociation of hydrogen in the anode of the fuel cells. For these reasons the interaction of hydrogen with the surfaces of carbon materials is a topic of high technological interest. Computational modeling and the density functional formalism (DFT) are helping in the task of discovering the basic mechanisms of the interaction of hydrogen with clean and doped carbon surfaces. Planar and curved graphene provide good models for the walls of porous carbons. We first review work on the interaction

of molecular and atomic hydrogen with graphene and graphene nanoribbons, and next we address the effects due to the presence of metal clusters on the surface because of the evidence of their role in enhancing hydrogen storage.

1   Introduction

The interaction of hydrogen with the surface of carbonaceous materials is a topic of high interest in materials science. Intense work has been motivated by the concern that oil reserves in our planet may be exhausted in five decades or a bit more. Then, hydrogen is viewed as a candidate to replace gasoline as a fuel in cars (Ogden 2002). The engine technology is ready: those cars use an electric motor, based on a fuel cell in which hydrogen coming from the storage tank reacts with atmospheric oxygen producing an electric current, and the only emission from the reaction is water. More specifically, molecular hydrogen is dissociated in the anode of the fuel cell, the protons go through a proton exchange membrane and the electrons through an external circuit creating an electric current, and recombination and reaction with oxygen occurs in the cathode. These novel cars are now fabricated by the major car companies.

A crucial ingredient in this process is the storage of the hydrogen needed to feed the cell (Jena 2011). Hydrogen is a gas, and the present challenge is to find efficient ways to store enough hydrogen in a tank to be able to run the car for 500 or 600 Km. The technology currently in use consists in storing hydrogen gas in steel tanks at high pressures of 350–700 bar. However, in the opinion of many engineers, that method is not the ultimate solution. Hydrogen storage in solid materials is viewed as a safer and convenient alternative. Storage of hydrogen in light solid porous materials is a promising method because the storage mechanisms are the physical or chemical adsorption of hydrogen on the pore walls, and those porous materials show large specific surface areas up to several thousand m^2/g. An interesting class of porous materials is the family of nanoporous carbons. That family includes activated carbons synthesized by physical or chemical activation of carbon-organic precursors or coals (Jordá-Beneito et al. 2008), carbide-derived carbons synthesized by reacting metal carbides with halogens (Yushin et al. 2006), graphitic nanofibers, and carbon nanotubes. Experiments have been performed to measure the storage capacities of those materials, with the result that the amount of hydrogen stored at low temperatures (around 100 K) approaches the onboard storage targets of 6% of hydrogen in weight (wt) and 40 g of hydrogen per liter, but the storage capacity is lower at room temperature, far below the storage targets (Ansón et al. 2004; Jordá-Beneito et al. 2007; Lueking et al. 2005; Panella et al. 2005).

Experimental work has shown that the storage capacity of porous carbons can be enhanced by doping these materials with metallic atoms and nanoclusters (Contescu et al. 2009, 2011). Theoretical calculations and computer simulations have been performed to shed light on the mechanisms of interaction between hydrogen and clean or doped porous carbons. In this way, the calculations can help to improve the materials in the quest of the difficult task of fulfilling the storage targets.

2   Theoretical Methods

In most theoretical simulations of the interaction of hydrogen with porous carbons, the inner walls of the pores are modeled as single-layer graphitic-like nanostructures: graphene when simulating pores with planar surfaces, and carbon nanotubes or open fullerenes in the case of curved pore surfaces, and this model is supported by extensive computer simulations of the structure of porous carbons (López et al. 2011; De Tomás et al. 2017). The method generally used to investigate the interaction between hydrogen and the carbon substrates (clean or doped) is the density functional formalism, or DFT (Fiolhais et al. 2003), a method which combines (1) reasonable accuracy in describing the electronic structure and calculating interaction energies, on one hand, and (2) acceptable computation times, which allow simulating systems with more than 100 atoms easily, on the other. A key ingredient in the density functional calculations is the exchange-correlation energy functional and the corresponding exchange-correlation potential. The description of electronic exchange and correlation effects has advanced to a mature state, and a number of practical approximations are available. After the successful use for many years of the local density approximation (Fiolhais et al. 2003), most works today use functionals belonging to the family of generalized gradient approximations, or GGA (Perdew et al. 1996; Becke 2014). Two of the most commonly used exchange-correlation energy functionals, known as PW (Perdew et al. 1992) and PBE (Perdew et al. 1996), have been developed by Perdew and coworkers.

   The interaction between molecular hydrogen and graphitized surfaces is weak, and a part of this interaction comes from the van der Waals forces. Consequently, it is desirable to include dispersion corrections in the DFT calculations, and this field has been reviewed recently (Klimes and Michaelides 2012; Hermann et al. 2017). One family of DFT-based methods uses nonlocal correlation functionals in which the dispersion interactions are obtained directly from the electron density. In a second class of DFT methods, dispersion interactions are included empirically or semiempirically at different levels of complexity. At present, no particular method to include dispersion interactions in DFT can be generally preferred over all the others, and the best option is to restrict attention to the family of materials of interest in each particular case and perform careful tests of the dispersion methods and functionals applied to that family of materials. One example is the recent study of the physisorption of molecular hydrogen on benzene and graphene (Cabria et al. 2017), in which the results of different density functionals have been compared to ab initio quantum chemistry methods.

3   Molecular Hydrogen on Graphene

When molecular hydrogen interacts with a graphitized carbon surface without defects, the molecule binds weakly to the surface by a physisorption mechanism. The measured physisorption energy of H_2 on graphene is 0.048 eV (Mattera

Fig. 1 Relevant configurations for a H_2 molecule on top of a graphene surface. Three sites: A, on a carbon atom; B, on a carbon-carbon bond; H, on the center of a hexagon. For each site, three different orientations of the molecule axis are shown. The first subscript on the site index informs if the molecule axis is parallel of perpendicular to the graphene plane. The second subscript indicates if the axis is parallel or perpendicular to two C–C bonds of the hexagon. (Reproduced from Cabria et al. 2017, with permission of AIP Publishing)
et al. 1980; Costanzo et al. 2012). DFT calculations indicate that the most stable adsorption sites are at the center of the carbon hexagons with the molecular axis parallel to the graphene plane (Cabria et al. 2017). The adsorption energy obtained by the PBE functional corrected by dispersion corrections in a form proposed by Grimme, PBE-D2 (Grimme 2006), is $E_{ads} = 0.051$ eV, in good agreement with experiment, and the equilibrium distance from the molecule to the carbon plane is $d_e = 2.85$ Å. The perpendicular orientation of the molecular axis leads to a similar adsorption energy, and adsorption energies on other sites shown in Fig. 1, bridge positions between two C atoms, or positions on top of C atoms, are 0.01 eV smaller. In summary, adsorption energies depend only weakly on the adsorption site and orientation of the molecular axis. The adsorption energy can be interpreted as a sum of several contributions, all of them small. One contribution is due to the dispersion interactions (interaction between induced fluctuating electrical dipoles). Another contribution arises from the small overlap of the electron densities of molecule and substrate. Even in the absence of any rearrangement of the overlapping densities, electronic exchange and correlation effects produce a small bonding

contribution (Arellano et al. 2000). In addition, there is a rearrangement of the electron density (or electronic relaxation) that, although small, also contributes to binding. Calculations for H_2 adsorbed on the outer wall of carbon nanotubes lead to the same conclusion (Cabria et al. 2006), and an experimental estimation (Brown et al. 2000) gave $E_{ads} = 0.062$ eV.

How much hydrogen can be adsorbed on graphene is determined by the interplay between the H_2-graphene and the H_2–H_2 interaction potentials. The H_2–H_2 potential is repulsive for distances $d < 3.4$ Å between the two molecules and has a weak attractive tail with a shallow minimum of depth 0.003–0.004 eV at $d = 3.5$ Å (Okamoto and Miyamoto 2001). But the distance between the centers of two neighbor hexagons in graphene is only 2.46 Å, and this means that full covering of graphene (or a carbon nanotube) with one H_2 molecule per hexagon is not possible. An estimate of the affordable low temperature coverage can be done by considering a model (Okamoto and Miyamoto 2001) of a two dimensional lattice of physisorbed molecules interacting through an H_2–H_2 potential $V_{HH}(r)$ and writing the energy of N molecules physisorbed on area S as

$$E = N\left(-t + \gamma V_{HH}\left(r_{nn}\right)/2\right). \tag{1}$$

E is given as a sum of two terms. The first one is the total physisorption energy of noninteracting molecules, $-Nt$, written in a way that assumes the same value, $-t$, for the physisorption of each molecule; this is supported by the observation made above that the physisorption energies depend only weakly on the adsorption site. The second term accounts for the intermolecular H_2–H_2 interactions. The H_2–H_2 interactions are restricted to the nearest-neighbor molecules, and this is accounted for by the coordination number γ in the lattice ($\gamma = 6$ for a triangular lattice). The number of physisorbed molecules per area S is 1.154 S/r_{nn}^2 for a triangular lattice. Taking t as a parameter with values between 0.04 and 0.05 eV, and minimizing E with respect to the nearest-neighbor separation r_{nn}, leads to a coverage of 4.5–4.6% (weight of adsorbed hydrogen divided by the total weight of hydrogen and substrate). Since the walls of the pores are essentially graphene nanoribbons, this estimation, which neglects the effect of temperature, already indicates the difficulties of reaching the hydrogen storage targets with clean porous carbons.More precise estimations of the amount of hydrogen stored in porous carbons have been obtained with methods which combine thermodynamics and quantum mechanics (Patchkovsky et al. 2005; Cabria et al. 2007, 2011). As a result of pumping in hydrogen by applying an external pressure P_{ext}, the amount of stored hydrogen at a temperature T is determined by the thermodynamic equilibrium between a condensed phase formed by the hydrogen adsorbed on the pore walls and a gas phase corresponding to the non-adsorbed hydrogen in the material. First, the pores are modeled as cavities formed by two parallel graphene layers separated by a distance d (other pore geometries, cylindrical and spherical, have also been studied), and the potential confining the molecules in the pore is calculated using DFT or other quantum chemical methods. When d is small, the hydrogen molecules interact with the two walls and the confinement energy is larger. The quantum states for

the motion of the H_2 molecules in the confining potential well of the pores are calculated by solving the time-independent Schrödinger's equation, and the energies ε_i of those states are used to evaluate the partition function of the adsorbed H_2 phase, $Z_{ads} = \sum_i e^{-\frac{\varepsilon_i}{kT}}$, where k is Boltzmann's constant. The ratio $Z_{ads}/Z_{free} = K_{eq}$, where Z_{free} is the partition function of the gas of compressed free molecules confined in the volume of the pores, gives the equilibrium constant K_{eq} between the adsorbed and the compressed phases. K_{eq} allows relating P_{ext} and the pressure of the adsorbed phase, or internal pressure P_{int}, through the van't Hoff equation

$$K_{eq} = e^{\frac{1}{RT}\int_{P_{ext}}^{P_{int}} V_{molar}(P,T)dP} \tag{2}$$

where R is the gas constant. A key ingredient in this equation is the molar volume $V_{molar}(P,T)$, which is known as a function of P and T from existing parameterizations of the equation of state of hydrogen. Then, P_{int} is obtained for given values of P_{ext} and T from Eq. (2). Finally, using again the equation of state, the molar volume of the adsorbed hydrogen phase is obtained in terms of T and P_{int} (or P_{ext}). The predictions at low temperature are promising (Cabria et al. 2011): at 77 K, the gravimetric and volumetric storage capacities reach values of 3 wt% and 60 g/L, respectively, and the last one fulfills the technological target. Although such temperatures are too low for automotive applications, the prediction could be useful for outer space vehicles. Figure 2 presents calculated storage capacities for three pore shapes, planar, cylindrical, and spherical, at $T = 300$ K and $P = 10$ MPa, as a
Fig. 2 Excess gravimetric hydrogen storage capacities of planar, cylindrical, and spherical pores as a function of pore size, for confining potentials obtained using the Möller-Plesset (MP2) method. The results correspond to a temperature of 300 K and an external pressure of 10 MPa. (Reproduced from Alonso et al. 2013, with permission of Cambridge Univ. Press)

function of the pore size. The gravimetric storage capacities are below 1 wt%, but this value has to be increased by a factor in between one and two, because computer simulations indicate that about 50% of the pore walls in the porous carbons expose their two sides to gas adsorption; that is, those walls are shared by two pores. Figure 2 shows a maximum in each of the curves; that is, there is an optimum pore size near 1 nm, although the precise optimal value depends on the pore shape. In summary, the calculations predict that clean porous carbons do not fulfill the targets at room temperature, and this is consistent with experiment (Yushin et al. 2006). The ultimate reason is that the adsorption energies of H_2 on pristine graphitic surfaces, planar or curved, are below 0.10 eV, too small for the purposes of storage.

4   Atomic Hydrogen on Graphene

Atomic hydrogen adsorbs on graphene on top of C atoms, and the C atoms bonded to H protrude out of the carbon plane by 0.35–0.48 Å in DFT-GGA calculations (Ferro et al. 2004; Borodin et al. 2011), changing their hybridization partially from sp^2 to sp^3. This is a chemisorption state. The chemisorption energies are 0.81–0.86 eV, although there is an adsorption barrier of 0.2 eV (Jeloaica and Sidis 1999), confirmed recently (Aréou et al. 2011). Chemisorbed single H atoms have been observed on graphene supported on SiC (0001) surfaces (Merino et al. 2015). A physisorption state has been detected in scattering experiments (Ghio et al. 1980), and the calculations indicate that the physisorbed H atoms sit on top of the hollow sites at the hexagon centers. The physisorption binding energy is 0.03 eV, a value close to the thermal energy at room temperature, $kT = 0.025$ eV, and the activation energy barrier between the physisorption and chemisorption states is only 0.13 eV (Psofogiannakis and Froudakis 2009).

Using standard techniques for depositing atomic hydrogen on graphene, the most probable clusters forming at low temperature for H coverages of 1–2 at.% are dimers. Two different configurations of dimers have been observed by STM (Hornekaer et al. 2006; Merino et al. 2015); see Fig. 3, and DFT calculations have allowed to interpret those two configurations (Hornekaer et al. 2006; Psofogiannakis and Froudakis 2009; Merino et al. 2015): a structure with the two H atoms chemisorbed on adjacent C atoms (ortho dimer) and a second structure with the two H atoms chemisorbed on opposite carbons of an hexagonal ring, that is, as third neighbors (para dimer). The two C atoms protrude out of the carbon plane. The para is slightly more stable than the ortho configuration, the chemisorption energies of the dimers (with respect to two isolated H atoms) being 2.87 and 2.60 eV, respectively. These values are larger than the sum of the chemisorption energies of two well-separated H atoms, 1.72 eV, and consequently the two chemisorbed atoms interact substantially both in the para and ortho configurations. However, the above values of the dimer chemisorption energies are smaller than the energy required to split the H_2 molecule in two H atoms (4.5 eV), and this means that chemisorption of H only occurs starting with atomic H. Recombination of the two H atoms and desorption of the molecule has been observed in temperature-programmed desorption experiments (TPD). Those experiments indicate that the ortho are more
Fig. 3 (**a**) STM images of hydrogen dimers chemisorbed on a graphene layer grown on a SiC (0001) surface. In (**b**) the graphene grid has been superimposed, and the suggested position for the H atoms is indicated. (**c**) Model hydrogen dimers: para dimer (third-nearest neighbors) and ortho dimer (first neighbors). (Reproduced from Merino et al.2015, with permission of ACS)

stable than the para dimers under annealing, and this has been interpreted as the para dimers having a lower recombination energy barrier (Hornekaer et al. 2006).

The barrier for the migration of an isolated H atom from its stable position on top of a C atom to a position on top of a nearest-neighbor C atom obtained in DFT calculations is 0.99 eV, slightly less than the desorption barrier of 1.1 eV (Borodin et al. 2011), and a direct leap to a second nearest-neighbor C atom is less likely than two nearest-neighbor jumps, because the barrier is higher in the former case. Consequently, transport of atomic hydrogen on graphene is subject to a strong competition between diffusion and desorption. Molecular dynamics (MD) simulations in which the semiempirical Brenner potential (Brenner 1990) was used to model the interaction between C and H atoms have been performed to study the competition between diffusion and desorption (Borodin et al. 2011). The temperatures, 1200–2000 K, were high to allow for the observation of desorption and diffusion events within the simulation times. The simulations reveal that hydrogen atoms move by diffusion jumps and that the average number of jumps made by a hydrogen atom during its lifetime (the residence time on the graphene before it desorbs) is very small, close to one at those temperatures, slightly increasing as the temperature decreases. This is because the average lifetime increases from about 8 ps at 2000 K to about 0.5 ns at 1200 K. However, a small fraction of atoms performs more jumps, up to ten jumps for long lifetime events. Apart from jumps to first neighbor positions, correlated jump chains over two to five C–C bonds were observed. Interestingly, extrapolation to room temperature reveals that a hydrogen atom can travel two or three nanometers before detachment. This affects the nucleation and growth of hydrogen clusters on graphene: a dimer can grow by capturing H atoms deposited at distances of several Å or less from the dimer. Diffusion of H from one side of a graphene layer to the other side through a carbon hexagon is very unlikely because the calculations predict the existence of a high diffusion barrier between 3 and 4 eV (Miao et al. 2011).

Carbon atoms with coordination 2 surrounding vacancies or holes (groups of vacancies) in graphene and at the edges of graphene nanoribbons have unsaturated dangling bonds and are highly reactive, acting as catalysts for the dissociation of H_2. This molecule easily dissociates at those regions, because the dissociation barriers are small: 0.3 eV or less, depending on the particular exchange-correlation functionals used in the DFT calculations and the inclusion of dispersion interactions (Bores et al. 2012). The values of the chemisorption energies, measured with respect to the free molecule, depend on the system: 5.65 eV and 2.53 eV on zigzag and armchair edges of nanoribbons, respectively (Bores et al. 2012), and 3.06 eV on graphene vacancies (Granja-DelRío et al. 2017). The reason for the large difference between the two ribbon edges is that the separation between the two hydrogen atoms in armchair edges, 1.9 Å, is lower than in zigzag edges, 2.4 Å, and the closer proximity between the H atoms in the armchair edge weakens the C-H bonds. This becomes reflected in the changes of the density of electronic states. Adsorption and dissociation of H_2 at zigzag edges do not close the electronic gap at the Fermi level of the nanoribbons. In contrast, dissociation of H_2 at armchair edges introduces occupied states at the Fermi level and closes the gap, which is a signature of weaker C–H bonds.

Nanoribbons with zigzag edges support electronic states near the Fermi level which are localized at one edge of the ribbon (Son et al. 2006). States localized at one ribbon edge have spin orientation opposite to that of the states localized at the other edge, and this antiferromagnetic-like arrangement gives a total spin $S = 0$ to the ribbon. However, the dissociative adsorption of a hydrogen molecule at a zigzag edge changes the magnetic character of the nanoribbon, producing a configuration of non-compensated spins (Bores et al. 2012): the spin orientation of the electrons supplied by the two hydrogen atoms is opposite to that of the electrons of the edge states at the adsorbing edge, and then the net spin at the adsorbing edge is reduced, whereas the localized states at the other edge suffer no changes. As a result, the nanoribbon gets a magnetic moment of 2 μ_B. This is reflected in Fig. 4, where the difference between the electronic densities with spins up and down has been plotted. The left panel corresponds to a clean nanoribbon with excess of spin up on the upper edge and excess of spin down on the lower edge, and the right panel shows that the dissociative adsorption of H_2 at the upper edge quenches part of the spin up excess. Hydrogenation of the nanoribbon edges then provides a way to control the magnetism of carbon nanoribbons (Kusakabe and Maruyama 2003).

Graphitized glassy carbon grains present in interstellar clouds are believed to catalyze the recombination of H atoms to produce H_2 gas. Molecular dynamics simulations reveal that graphitized low density glassy carbons (densities lower than that of graphite) can be viewed as a disordered assembly of planar and curved graphene-like fragments leaving substantial space (pores) in between (López et al. 2011) and that the number of pores and their size decrease as the density of the material approaches that of graphite (Alonso et al. 2017). Those planar and curved fragments bear a substantial amount of defects, and also many open edges, mostly of zigzag type. Defects play an important role in carbon chemistry, including the above process of H–H recombination. A common family of defects is formed by holes,
Fig. 4 Difference between spin up and spin down electron densities, $\rho_\uparrow\left(\overrightarrow{r}\right) - \rho_\downarrow\left(\overrightarrow{r}\right)$, of a clean graphene ribbon (left) and a ribbon with a dissociated hydrogen molecule at the upper edge (right). Blue and red colors represent positive and negative isosurfaces, respectively, of value 0.01 e/au^3

or multi-vacancies, having reactive unsaturated dangling bonds. Experiments have confirmed the presence of those defects in samples of chemically produced defective graphene and in samples obtained by ball milling of graphite powder (Cavallari et al. 2016). The evidence arises from neutron vibrational spectroscopy of the hydrogenated samples and, more specifically, from the comparison of the measured inelastic neutron scattering (INS) spectra with the modeled INS spectra obtained from DFT-based molecular dynamics simulations, which provide the vibrational spectrum for hydrogen on specific graphene sites. The experimental spectra are well reproduced by considering in the model a proper proportion of H atoms chemisorbed at the edges of the flakes and inside small holes. Interestingly, the INS spectra change significantly with temperature in the temperature range between 5 and 300 K, and this is due to some H atoms moving, that is, changing their local environment. Because the binding of the chemisorbed H atoms to dangling bonds on edges or void sites is strong, the only way to understand the local motion of the H atoms at those temperatures is by quantum tunneling.

Graphene can be saturated with chemisorbed atomic hydrogen and an interesting new phase results with formula CH, known as graphane. Its existence was predicted by calculations based on a cluster expansion method (Sluiter and Kawazoe 2003), and later using DFT (Sofo et al. 2007), and it has been produced by different experimental methods (Sahin et al. 2015). In graphane, every C atom of the layer is covalently bonded to an H atom, and as a consequence the hybridization in the carbon layer changes from sp^2 to sp^3. The H atoms are bonded to C atoms on both sides of the carbon plane in an alternating manner, as shown in Fig. 5; that is, every C–C bond connects C atoms with H attached at opposite sides of the layer. All the C–H bond lengths are close to 1.10 Å, which is the typical value for C–H bonds in organic chemistry, and the bond lengths of the C–C bonds are close to the single C–C bonds in diamond. Graphene is a zero-gap semiconductor; however, graphane shows an electronic gap, and the best theoretical calculations performed,

Fig. 5 Structure of graphene in chair configuration. Dark and light spheres represent C and H atoms, respectively. Notice that each C atom bonded to an H atom above the carbon layer is surrounded by three C atoms bonded to H atoms below the carbon layer. (Reproduced from Sofo et al. 2007, with permission of APS)
using the many-body GW approximation, predict a value of 5.2 eV (Lebègue et al. 2009). The binding energy in a GGA calculation is quite large, 6.6 eV per atom, which means that graphane is more stable than any other hydrocarbon with the 1/1 carbon/hydrogen atomic composition. The conformation described above is known as the *chair* conformation. There are other possible arrangements, but those alternative isomeric conformations have lower binding energies.

5   Adsorption of Hydrogen on Graphene Doped with Non-transition Elements

Although the technological hydrogen storage targets are not achieved with clean graphitized porous carbons, experimental evidence indicates that doping the material with metallic atoms, clusters, or nanoparticles enhances the amount of stored hydrogen (Yang 2000; Bath et al. 2010). On the other hand, when the stored hydrogen feeds the fuel cell, the H_2 molecules are dissociated in the anode, which is formed by metallic nanoparticles embedded in a porous carbon. For these reasons, the interest in understanding the details of the interaction of hydrogen with metallic atoms and clusters supported on graphene (a good model for the carbon pore walls) has become a priority.

A family of dopants enhancing hydrogen storage is formed by metals with *s* and *p* electrons, like Li or K (Chen et al. 1999; Yang 2000). In this case the beneficial effect of the dopant atoms consists in increasing the binding energy of the hydrogen molecule to the pore walls. The most stable adsorption positions for a Li atom on graphene are the hollow sites above the center of carbon hexagons, and Li rests at a distance 1.7–1.8 Å above the carbon plane. The bonding, with strength close to 1 eV, is an admixture of covalent and ionic contributions, and the Li atom is partially ionized, transferring about half an electron to graphene (Khantha et al. 2004). The adsorption energies of H_2 increase substantially on Li-doped graphene compared to

Fig. 6 Polarization of the charge of an adsorbed H_2 molecule due to the presence of a Li atom nearby. Black and white regions indicate enhancement and depletion of electronic charge, respectively, compared to a free molecule. The position of the Li atom is indicated by the small red sphere. Upper panel, the molecule is placed above a C–C bond with the molecular axis perpendicular to the C layer. Lower panel, the molecule is placed above the center of a hexagon with the molecular axis parallel to the layer plane
clean graphene, reaching values of 0.17–0.20 eV per molecule (Cabria et al. 2005), and the same occurs for K-doping (Froudakis 2001). The increase of the adsorption energies is due to the polarization of the charge of H_2 by the electric field of the neighbor charged alkali atoms. The polarization of the charge of the H_2 molecule is shown in Fig. 6. Due to the increased adsorption energy of H_2 in the case of Li doping, the storage capacity of Li-doped porous carbons becomes enhanced. A rough estimate along the lines of the method presented in Sect. 3 indicates that the gravimetric hydrogen storage capacity grows to about 1.5 wt% in the case of slit pores, twice the value in Fig. 2 (Alonso et al. 2013). A proposed advantage of Li is that Li atoms do not cluster on a graphitized surface (Sun et al. 2006), because the experimental (Bréchignac et al. 1994) and calculated (Brito et al. 2014) binding energies of small Li clusters are smaller than the binding energy of a Li atom to graphene.

The alkaline-earth dopants Ca and Sr show some similarities with the simpler alkali dopants. The most stable positions on graphene obtained in DFT calculations are the hollow sites also, and the adsorption binding energy of Ca atoms amounts to 0.63 eV using the PBE approximation (Chan et al. 2008) and 0.99 eV using LDA (Ataca et al. 2009). DFT-PW calculations for Ca adsorbed on C_{60} predict a larger binding energy, 1.3 eV, due to the curvature of the fullerene (Yoon et al. 2008). Those values are higher than the binding energies per atom (E_b) of small free Ca clusters (Dai and Blaisten-Barojas 2008): $E_b = 0.07$ eV (Ca_2), 0.22 eV (Ca_3), 0.44 eV (Ca_4), 0.48 eV (Ca_5), 0.51 eV (Ca_6), and 0.62 eV (Ca_7). Consequently, dispersion of Ca on graphene, instead of three-dimensional clustering, is expected. In contrast, the binding strength of Be and Mg to graphene is too weak. The stronger bonding of Ca (and Sr) to graphene arises from the transfer of electronic charge from

the valence s electrons of these atoms to the π^* bands of graphene and back donation to the previously unoccupied d orbitals of the alkaline-earth atoms through their hybridization with the π^* states. The electrostatic repulsion between the charged dopant atoms prevents clustering, and the most favorable coverage of Ca is 12.5%, that is, one Ca atom for every four C hexagons, for single-side adsorption (or 25% for double-side adsorption). The charged dopants generate an electric field favoring the adsorption of molecular hydrogen around those atoms. DFT calculations predict that a single Ca or Sr atom attached to C_{60} can adsorb up to five H_2 molecules with quite constant binding energies, 0.2 eV per molecule in GGA calculations and 0.4 eV in LDA calculations (Yoon et al. 2008). C_{60} coated with 32 Ca atoms (one on each face of the fullerene) was explored, and it was found that the system can adsorb 92 H_2 molecules, nearly three per Ca atom, with the same binding energies given above. In the case of graphene, each Ca atom binds up to four or five H_2 molecules, depending on the Ca coverage (Ataca et al. 2009).

Interesting features appear when Ca is adsorbed on narrow graphene nanoribbons because of the influence of the ribbon edges and for graphene with holes (multivacancy defects). The Ca atoms prefer to occupy the hollow sites on carbon hexagons on the ribbon edge, instead of hexagons in the central part of the ribbon (Lee et al. 2010). The charge transferred to the carbon ribbon is more localized in the first case and leads to a stronger electrostatic interaction between Ca and the substrate and to larger binding energies. On the other hand, the binding energies on those sites are sensitive to the type of edges. For nanoribbons terminated in zigzag edges, the binding energies obtained from DFT-PW calculations are 2.0 eV on the edges and 1.1 eV on the central part of the ribbon. The electron transfer leaves the Ca atoms charged, and the electrostatic repulsion prevents the charged atoms from coming too close together. The calculated optimal separation on zigzag edges is 10 Å. The binding is weaker in the case of nanoribbons with armchair edges: 0.73 and 0.68 eV on the edges and ribbon center, respectively, close to the binding energy on extended graphene. Consistent with the above results, the binding energy of Ca on C hexagons surrounding multi-vacancy holes in which the arrangement of the C atoms is of zigzag type is relatively large, 1.3 eV. The average adsorption energies of molecular hydrogen around a Ca atom doping the edge of a zigzag nanoribbon are 0.18, 0.21, 0.20, 0.17, 0.16, and 0.13 eV per molecule for 1, 2, 3, 4, 5, and 6 H_2 molecules, respectively.

A few atoms such as nitrogen or boron, which have nearly the same size as carbon and can easily form three chemical bonds, can replace C atoms in graphene forming genuine substitutional impurities. Most other atoms are larger than carbon and do not fit in a graphene vacancy, protruding outward from the carbon plane. The presence of substitutional boron affects the adsorption of hydrogen on graphene. Interestingly, the B atoms do not provide stable adsorption sites for atomic hydrogen (Ferro et al. 2003). However, the presence of B enhances the binding strength of H on C atoms neighbors to B atoms. Substituted graphene models with compositions C_7B (12.5% B) and C_3B (25% B) have been studied (Ferro et al. 2004) using DFT. The calculated chemisorption energies of atomic H on C_7B and C_3B are 2.37 and 1.70 eV, respectively, and the protrusion out of the carbon plane of the

C atom involved in the C-H bond is smaller than in pure graphene. At a first sight, it may appear that the binding energy of H does not increase with rising B concentration. However, in those two models the substitutional B atoms are distributed in such a way that there are no B-B first neighbors. Allowing for the occurrence of B-B first neighbors in modified models with C_3B composition, the adsorption energy of atomic H is 3.49 eV, indicating that the location of the B atoms has a strong influence on the layer reactivity. Obviously, the probability of finding B-B nearest-neighbors in materials prepared in the laboratory increases with B concentration, so it will be easier to find those pairs in C_3B as compared to C_7B composition. Taking this into account, a correlation arises between the B concentration and the strength of the H bonding which is consistent with the experimental observation that retention of H in graphitic materials exposed to hydrogen plasma increases with B concentration (Schenk et al. 1995). Graphitic materials are exposed to hydrogen plasma, for instance, in experiments of nuclear fusion in tokamaks because carbon materials coat the walls in contact with the plasma. B also influences the diffusion of H atoms through a doped graphene layer, from one side to the other: the activation energy barrier drops from about 4 eV in pure graphene to 0.91 eV in C_7B (through a hexagon having two B atoms) and to 0.54 eV in C_3B (through a hexagon with a B atom). The lowering of the barrier is also consistent with the increased retention of hydrogen in doped carbon materials exposed to hydrogen plasma, because the H atoms find the walls more permeable and penetrate deeply into the solid. For H diffusion on the layer plane, the activation energy, near 1 eV on pure graphene, drops to 0.5 eV for B-doped graphene with composition C_3B. In the latter case, one possible diffusion path for H is from a C atom to a first neighbor C. An alternative path is from C to a second neighbor C atom through an intermediate B atom; in this case the maximum of the activation barrier occurs when H is on top of the B atom. As discussed above, substitutional B induces a better H retention capability in graphite. At the same time, experiments indicate that recombination into molecular hydrogen and desorption of H_2 under heating becomes easier in the B-doped carbons (Schenk et al. 1995). This result is not in conflict with the larger H chemisorption energies in the doped material (Ferro et al. 2004): recombination of two H atoms and desorption of H_2 on clean and doped graphene are complex processes involving several steps with activation barriers associated, and the presence of substitutional B lowers those barriers.

6 Adsorption of Hydrogen on Graphene Doped with Transition Metal Clusters

Experimental work provides evidence for an enhancement of the storage capacity of porous carbons doped with transition metal nanoparticles: vanadium (Zacharia et al. 2005), nickel (Wang and Yang 2008), ruthenium (Wang and Yang 2008), palladium (Contescu et al. 2009; Contescu et al. 2011), and platinum (Kim et al. 2008), among others. Since the adsorption of hydrogen is a surface process, clustering of the metal

Table 1 Calculated adsorption energies of metal atoms (M) on graphene, E_{ads}, binding energy per atom of free trimers, $E_b(M_3)/at$, and hexamers, $E_b(M_6)/at$, and experimental cohesive energy or the metal, E_c. All energies are given in eV

M	E_{ads} [1]	$E_b(M_3)/at$	$E_b(M_6)/at$	E_c
Ti	1.869	2.701 [2]	3.678 [2]	4.85
Fe	0.748	2.1 [3]	3.0 [3]	4.28
Pd	1.081	1.25 [4]	1.96 [4]	3.89
Au	0.096	1.66 [5]	2.56 [5]	3.81

[1] Chan et al. (2008), [2] Kumar et al. (2007), [3] Kima et al. (2014), [4] Cabria et al. (2012), and [5] Fernández et al. (2004)

atoms to form nanoparticles is usually viewed as a disadvantage. Actually, clustering of transition metal atoms on graphene or other carbon nanostructures is common; examples can be found in work on Ti (Sun et al. 2005) and Pd (Cabria et al. 2010). The reason for clustering is that the binding strength between the dopant atoms is larger than the adsorption energy of the dopant atom on graphene. This point is illustrated in Table 1 for a few selected examples: Ti, Fe, Pd, and Au. For all of them, the adsorption energy of the atom on graphene is not only smaller than the cohesive energy of the metal but also smaller than the binding energies per atom of small clusters (the Table reports results for trimers and hexamers). The fact that the adsorption energies of metal atoms on graphene are lower than the cohesive energies of the corresponding bulk metals is a general feature, but for a few non-transition metals, the adsorption energies are larger than the binding energies per atom of small clusters, as discussed above in the specific case of Ca. The enhancement of the hydrogen storage in the doped carbons has been generally ascribed to the mechanism of spillover from the nanoparticle to the substrate (Conner and Falconer 2006; Prins 2012), which is discussed below.

Theoretical work on the interaction of hydrogen with transition metal (TM) clusters supported on graphene is abundant, and the case of palladium, a dopant of interest in experimental studies (Contescu et al. 2009, 2011; Zacharia et al. 2005), is selected here to illustrate the main features of the interaction. DFT-GGA calculations predict that the lowest energy structure of free Pd_3 is an equilateral triangle, Pd_4 is a tetrahedron, Pd_5 is a trigonal bipyramid (a second structure, a square pyramid, is very close in energy, only 0.05 eV above), and Pd_6 is an octahedron (Cabria et al. 2012). The magnetic state of all these clusters is a spin triplet (magnetic moment $M = 2 \mu_B$). In general, the most stable structure of the free Pd cluster is also the most stable structure of the cluster adsorbed on pristine graphene. Supported Pd_3 has a triangular structure vertically oriented, Pd_4 is a tetrahedron lying on a triangular face, and Pd_6 is an octahedron lying on one of its faces. The rule also works for selected larger clusters studied, like Pd_{13} (Blanco-Rey et al. 2016). The only exception in the small-size range covered above occurs for Pd_5: in this case, the lowest energy structure of the adsorbed cluster is the square pyramid lying on its base.

Table 2 Calculated binding energies of Pd_n clusters to graphene. Adsorption energies for molecular adsorption of H_2 and dissociated chemisorption (H + H) on Pd_n clusters supported on graphene and dissociation barriers. Energies are given in eV. Adsorption energies are measured with respect to separated Pd_n@graphene and free H_2. Dissociation barriers near zero are lower than 0.03 eV

	Pd_2	Pd_3	Pd_4	Pd_5	Pd_6	Pd_{13}
$E_b(Pd_n@graph)$	1.26	0.76	0.84	0.49[a]; 0.68[b]	1.14	1.41

Barrier	Near 0	Near 0	0.70	0.26	0.30	Near 0

[a]Trigonal bipyramid
[b]Square pyramid

Pd_n clusters supported on graphitized surfaces easily adsorb hydrogen. Molecular H_2 binds to the cluster usually on top of carbon atoms, and the adsorption energies vary between 0.5 and 1 eV depending on the cluster size (Cabria et al. 2012). Those binding energies are substantially higher compared to those for H_2 adsorbed on clean graphene, but it should be noticed that the molecule is bound to the cluster. The binding can be interpreted as a mixture of a covalent contribution (electron density accumulates in the region between the molecule and the Pd atom) and polarization of the charge of the molecule. The H–H bond length of the adsorbed molecules becomes slightly elongated compared to free H_2, but the molecule is only activated and the H–H bond is not broken. On the other hand, a dissociated state also exists with the two atoms separately chemisorbed on the surface of the Pd cluster, and it is, in fact, more stable than the molecular state, at least for low covering. Table 2 shows the adsorption energies for molecular and dissociative adsorption. In a cluster there are usually different adsorption sites with slightly different adsorption energies, and the adsorption energies of this Table correspond to the highest in each case. The path to dissociation starting with the adsorbed molecule needs to surmount an activation barrier whose height depends sensitively on the cluster size, being very small in some cases.

Table 2 shows that the binding strength between small Pd_n clusters and graphene is not large. Furthermore, the binding becomes weakened after the adsorption of a hydrogen molecule, and adsorption of additional molecules enhances that effect (López et al. 2014). For instance, the energies required to desorb H_2-Pd_n metal-hydrogen complexes (0.97 eV for H_2-Pd_2, 0.77 eV for H_2-Pd_3, 0.63 eV for H_2-Pd_4, 0.60 eV for H_2-Pd_5, and 1.0 eV for H_2-Pd_6) are competitive with the energies required for desorbing the H_2 molecule (the values of $E_{ads}(H_2)$ in the Table 2). This will produce an undesirable contamination effect on the fuel cell in the step of releasing the adsorbed gas from the container. The problem disappears when the clusters are anchored to defects on the graphitized pore walls. This is because graphene defects are very reactive and the binding of the clusters to the defects is strong: between 5 and 6 eV for Pd_n clusters ($n = 1$–6) anchored to graphene vacancies (López et al. 2014). In spite of the strong binding, the deformation of the

structure of the anchored Pd clusters is minor compared with free clusters or with the clusters adsorbed on perfect graphene. Fortunately, the pore walls of graphitized porous carbons contain abundant defects which play a double role. First, by tightly anchoring small clusters, the formation of large clusters is hindered. Second, the contaminating effect disappears because metal-hydrogen complexes are not freed.

H$_2$ shows two adsorption modes on Pd clusters anchored to graphene vacancies: molecular adsorption (H$_2$) and dissociative adsorption (H+H), and there is competition between those two modes. Adsorption of H$_2$ on anchored Pd$_6$ has been studied in detail (Granja et al. 2015). The most stable structure of Pd$_6$ anchored to a vacancy is the octahedron resting on one of its triangular faces. That structure shows only tiny distortions with respect to free Pd$_6$, and the adsorption energy is 5.62 eV. The graphene layer becomes distorted around the anchored cluster: the C atoms underneath the Pd cluster protrude out of the carbon layer by 0.5–0.7 Å toward the Pd cluster, and C atoms of the next shell protrude out by about 0.3–0.4 Å. Up to seven H$_2$ molecules can be adsorbed on the Pd cluster with sizable adsorption energies: the adsorption energy of the first adsorbed molecule is 0.74 eV, and the individual adsorption energies of new added molecules steadily decrease by increasing coverage, reaching the value of 0.26 eV for the seventh added molecule. Beyond the seventh, new added molecules have very low adsorption energies.

For a single molecule, however, the dissociative (H+H) adsorption configuration is more stable than molecular adsorption, although dissociation requires surmounting an activation barrier. Dissociation drives a change of the structure of the anchored Pd$_6$ cluster: the distance between two neighboring Pd atoms increases, and the cluster structure changes from the octahedron to an incomplete pentagonal bipyramid. The dissociative chemisorption energy, measured with respect to the free H$_2$ molecule and the anchored octahedron, is 1.25 eV. This energy can be viewed as the difference of two terms: the dissociative chemisorption energy on the pentagonal bipyramid, 1.36 eV, minus the energy of 0.11 eV required to transform the anchored octahedron into an incomplete pentagonal bipyramid. The anchored incomplete bipyramid supports up to three dissociated molecules, plus other six non-dissociated.

Even if the isolated Pd atom and the Pd metal are nonmagnetic, small Pd clusters show nonzero magnetic moments (Moseler et al. 2001); see Table 3 for Pd$_n$, $n = 3$–6, and Pd$_{13}$ (Cabria et al. 2012). The magnetic moments can be manipulated by depositing the clusters on graphitized substrates and by adsorption of hydrogen (López et al. 2017). The spin magnetic moment of Pd$_{13}$, $\mu = 6 \ \mu_B$, is partially quenched to $\mu = 4 \ \mu_B$ upon depositing the cluster on pristine graphene, but the magnetic moments of the smaller clusters in the table remain unchanged. Adsorption of hydrogen on the supported Pd clusters leads to further quenching of the spin magnetic moment in all cases, although with subtle differences between clusters. The magnetic moments of supported Pd$_3$ and Pd$_{13}$ decrease due to the adsorption of molecular hydrogen (from $\mu = 2 \ \mu_B$ to 0 in Pd$_3$ and from $\mu = 4$ to $2 \ \mu_B$ in Pd$_{13}$). The subsequent dissociation of H$_2$ does not change the magnetic moment anymore.

Table 3 Calculated magnetic moments (in units of μ_B) of Pd_n clusters in different situations: free Pd clusters; Pd clusters deposited on pristine graphene; with molecular hydrogen adsorbed; with dissociated hydrogen

	Pd_3	Pd_4	Pd_5	Pd_6	Pd_{13}
Free	2	2	2	2	6
Pd_n on graphene	2	2	2	2	4
With H_2	0	2	2	2	2
With H+H	0	0	0	0	2

On the other hand, the magnetic moments of Pd_4, Pd_5, and Pd_6 do no change upon adsorption of molecular H_2, and the quenching occurs when the molecule dissociates.

The mechanism responsible for the enhancement of hydrogen storage on metal-doped porous carbons is under study. Evidently, the hydrogen adsorbed on the metal nanoparticles adds up to the hydrogen directly adsorbed on the carbon pore walls. A mechanism usually assumed in experimental works is spillover (Lueking and Yang 2004). In this mechanism the incoming H_2 molecule first interacts with the adsorbed nanoparticle, dissociates there, and the two H atoms independently diffuse through the nanoparticle. After reaching the nanoparticle border, the atoms spill to the substrate, diffuse further through the substrate surface until coming at rest, and end up adsorbed on the substrate. This mechanism has been investigated by performing DFT molecular dynamics simulations for the case of Pd clusters on a graphene substrate (Blanco-Rey et al. 2016). For incoming translational energies of 0.125 eV, a fraction of the incident H_2 molecules rebound on the cluster and return to the gas, a second group of molecules end up adsorbed on the cluster, and a third group dissociates after adsorption on the cluster. However, a sufficiently large number of simulations were performed, and not a single case of hydrogen spilling toward the carbon substrate was observed. The ultimate reason is that the activation barriers for spillover are large (larger than 2 eV in the two clusters studied, Pd_6 and Pd_{13}). This result suggests taking the spillover hypothesis with some care, at least in the case of Pd nanoparticles.

7   Conclusions

Computational modeling and the density functional formalism (DFT) are useful tools helping to discover the mechanisms of the interaction of hydrogen with clean and doped carbon surfaces, modeled as a graphene layer. Understanding those mechanisms is crucial in the improvement of hydrogen fuel cells, in the development of efficient hydrogen containers for transportation and in many catalytic processes.

Functionalizing Two-Dimensional Materials for Energy Applications

26

Bing Huang and Su-Huai Wei

Contents

Abstract

In this chapter, the authors have systemically reviewed the electronic properties of chemically functionalized two-dimensional (2D) materials for various applications. Hydrogenation and oxidization of graphene and silicene have been predicted to be efficient approaches to open sizable band gaps in these 2D materials, and the values of the band gaps can be tuned by varying the concentration of chemical absorbers. In this way these materials become very promising for both low-gap and large-gap energy-related applications. Modulation doping of

Materials and Energy Division, Beijing Computational Science Research Center, Beijing, China
e-mail: suhuaiwei@csrc.ac.cn

epitaxial 2D materials via substrates provides an alternative way to enhance the dopant and carrier densities in 2D materials. Meanwhile, the carrier mobility of the host 2D materials can be largely maintained after doping. The electronic and magnetic properties of transition-metal (TM)-doped graphene and single-layer boron nitride (BN) can be effectively controlled by the choice of the TM atoms and/or the intrinsic surface defects, which make TM-doped 2D materials holding great potential for spintronic applications. Finally, the authors show that alloying could be an important way to extend the employment of 2D materials in specific energy applications.

1   Introduction

2D materials are regarded as a new generation of nanomaterials that can exhibit unique electronic and optical properties compared to the traditional semiconductors. As in the case of traditional semiconductors, the use of two-dimensional (2D) materials for various energy-related applications is strongly dependent on the possibility of effectively controlling their electronic and optoelectronic properties via various "external" approaches. In the past years, various concepts and ideas have been proposed, including chemical functionalization, doping, and alloying, to tune the electronic properties of 2D materials and especially of graphene-based materials.

In the following, the authors will describe these ideas in several parts: in Sect. 2, the authors focus on the computational methods and models mentioned in this review chapter; in Sect. 3 the authors focus on hydrogenation and oxidization of graphene and single-layer silicon (silicene); in Sect. 4, the authors focus on the substrate-enhanced *n*- and *p*-type doping in graphene and magnetic doping properties in graphene and boron nitride; in Sect. 5, the authors focus on the discussion of structural and electronic properties of 2D C-N, Si-P, and Si-S alloys; and in Sect. 6, the authors will give a conclusion of this chapter.

2   Methods and Models

All the density functional theory (DFT) calculations the authors discuss were performed with the VASP code (Kresse and Furthmüller 1996). Projector-augmented-wave (PAW) potentials are used to describe the core electrons, and the generalized gradient approximation (GGA) for the exchange-correlation functional with the Perdew-Burke-Ernzerhof (PBE) functional (Perdew et al. 1996) is selected in our structural relaxation calculations. The Γ-centered *k*-point mesh with sufficient *k*-point density is used for the Brillouin-zone integration for all the structures. All the structures are fully relaxed until the force on each atom is less than 0.01 eV/Å. It is well known that DFT calculations both in the local-density approximations (LDA) and in the general gradient approximations (GGA) for the exchange-correlation functional underestimate the band gaps of semiconductors. Because calculations of the band gaps using hybrid exchange-correlation functionals

improve the agreement with experiment for both conventional semiconductors and low-dimensional materials (Garza and Scuseria 2016), the authors adopt the Heyd-Scuseria-Ernzerhof (HSE06) hybrid functional (Heyd et al. 2003) to calculate the electronic structures of all the systems the authors study. In particular, it has been shown that the HSE06 functional can describe the band gaps of new silicon phases very well, close to GW results (Xiang et al. 2013; Botti et al. 2012). To simulate the 2D material, a 15-Å vacuum layer is adopted to simulate isolated graphene, BN, silicene, etc.

To search for the ground-state structures at different alloy concentrations, the authors treat some of chemical functionalized 2D materials as alloy systems, and the authors use the cluster expansion (CE) method established in the alloy theory to describe the system. In the CE approach, the alloy Hamiltonian is mapped onto a generalized Ising Hamiltonian (Ferreira et al. 1989; Huang et al. 2013a). Generally, CE is able to represent any alloy energy by an appropriate selection of effective cluster interactions (J), and then it can predict the absolute lowest-energy structures within certain supercells. The J values can be determined by fitting them to the energies of selected configurations computed from first principles (van de Walle et al. 2002). The cross-validation (CV) score, obtained by a least-square fit, is used to measure the CE quality, and the authors have made sure that all the CE fittings in our study can reach a reasonably low CV score. The phase diagram of alloys is calculated by the Monte Carlo methods (van de Walle et al. 2002).

Some of the alloy structures discussed in this chapter were determined by the genetic algorithm (GA) in combination with DFT calculations to search for the global minimum structures with different alloy concentrations (Liu et al. 2007). For a given supercell with the fixed alloy concentration, the authors first generate tens of initial structures, and then the authors fully optimize both the cell parameters and the internal coordinates. To generate a new population, the authors perform the cut-and-splice crossover operator on parent structures chosen through the tournament selection. The next generation is chosen from the lowest-energy clusters among the parents and offspring. The process is repeated until the ground-state structure is located.

3 Chemical Functionalization of 2D Materials

Graphene, a single layer of carbon atoms arranged in a honeycomb lattice, has been a focus of recent research efforts (Novoselov et al. 2005, 2006; Zhang et al. 2005) due to its unique semimetallic zero-gap electronic structure and the massless Dirac fermion behavior. The unusual electronic and structural properties make graphene a promising material for the next generation of faster and smaller electronic devices. However, graphene lacks an essential feature for controlled and reliable transistor operation and energy applications, namely, a band gap. Several schemes have been proposed to open a band gap in graphene. Among them, chemical functionalization, via hydrogen- and oxygen-related chemical groups (-O, -OH, -COOH, etc.), is found to be a promising way to manipulate the electronic properties of graphene. Similar

to the studies in graphene system, chemical functionalization of other 2D systems by hydrogen and oxygen groups has also been extensively studied in the past years.

3.1   Hydrogenation of Graphene

The hydrogenation of graphene, as a prototype of covalent chemical functionalization, has been studied extensively (Stojkovic et al. 2003; Tsetseris and Pantelides 2012; Boukhvalov et al. 2008; Slijivancanin et al. 2011; Sofo et al. 2007). However, the fully hydrogenated graphene, known as graphane C_1H_1, is an insulator with a very large band gap (>5 eV) (Sofo et al. 2007), which is unsuitable for most energy-related applications. Therefore, some ideas were proposed to tune the band gap of 2D graphene by varying the hydrogen concentration.

Firstly, the hydrogenation of infinite 2D graphene is examined. Full hydrogenation of graphene has been extensively studied (Sofo et al. 2007), but the mechanism of hydrogenation is not well understood. It is well known that hydrogen atoms tend to absorb on the top of carbon atoms. To find the lowest-energy structure of graphene with different coverages of hydrogen atoms, Xiang et al. (2009) used the "cluster expansion" (CE) method (van de Walle et al. 2002). First, they consider the C_2T_4 alloy (see Fig. 1a) with the top sites T occupied by H atoms or vacancies. It is found that there are four important pair interactions as shown in Fig. 1a. The interaction between two H atoms adsorbed on the same C atom is repulsive (the J value for this configuration is 0.34 eV). However, the interaction parameter between two H atoms adsorbed on different sides of the two adjacent C atoms is attractive. Using the cluster expansion Hamiltonian, they can obtain the energy of a given alloy configuration and thus the ground-state structure of the partially hydrogenated graphene. As shown in Fig. 1b–e, the strong H clustering or phase separations always occur at different H concentrations on graphene surface; therefore, the global ground state of a partially hydrogenated graphene will divide into graphene and graphane parts (Xiang et al. 2009).

The strong phase separation in graphene-graphane system can be applied to modulate the electronic properties of finite graphene, e.g., with 1D edges (Xiang et al. 2009). First, one can consider the adsorption of a single H atom on a zigzag-edge-terminated graphene nanoribbon, as shown in Fig. 2a. The calculated adsorption energies are shown in Fig. 2b, and the positive adsorption energy is a consequence of the formation of C-H bond. Therefore, the added H atom prefers to locate at the edge carbon atom (site 1) than other sites by at least 1.1 eV, because the number of carbon-carbon p_z-p_z π bonds is the largest in this configuration. Experimentally, it was found that the atomic layer deposition of metal oxide on graphene grows actively on edges, indicating that the chemical reactivity at the edges of graphene is high (Wang et al. 2008, 2009). Interestingly, the dependence of the adsorption energy on the distance between the adsorbed site and the edge is not monotonic. It displays an odd-even oscillation with a smaller adsorption energy at even sites, and the adsorption energy of even (odd) sites increases (decreases) with the distance; eventually the energy difference between even and odd site adsorptions becomes

very small. The smallest adsorption energy at site 2 might be due to the presence of
two rather unstable edge carbon atoms near site 2 that participate in the formation
of only one π-π bond.

A second H atom will adsorb on the opposite site of the carbon atom (site 2)
adjacent to the edge carbon atom (site 1) to which the first H atom is bound, so as
to saturate the broken bond. This configuration is more stable than that with two
H atoms adsorbed on two outermost edge carbon atoms, for which the adsorption
energy is about twice the adsorption energy of a single H atom on an edge carbon
atom. The third H atom is expected to adsorb on the edge carbon atom adjacent to
the carbon atom to which the second H atom is bound. If the number of H atoms is
equal to the total number of edge carbon atoms (on both edges), all the H atoms will
adsorb on the outermost carbon atoms of one edge of graphene, as shown in Fig. 2c.
When the number of H atoms is twice the total number of edge carbon atoms, the
excess H atoms will bind with the outermost carbon atoms of another edge, resulting
Fig. 2 (**a**) The structure of zigzag-edge graphene with numbers indicating different nonequivalent carbon sites. The supercell adopted in the DFT calculations is denoted by solid horizontal lines. (**b**) The adsorption energy of one H atom on different carbon sites as labeled in (**a**). in a symmetric configuration (see Fig. 2d). The H atoms adsorb on the outermost zigzag bare carbon chain of one edge and then on the outermost zigzag bare carbon chain of the other edge. The process of alternating hydrogenation continues until no more free H atom is available. It should be noticed that this conclusion is very general and independent on the specific edge configurations.

To understand the electronic properties of partially hydrogen-functionalized graphene, Xiang et al. compare partially hydrogenated zigzag-edge graphene nanoribbon (ZGNR) with four bare zigzag carbon rows and hereafter referred to as 8-ZGNR-4, with 4-ZGNR without adsorbed H atoms as a representative example (Xiang et al. 2009). In both cases, they find that the electronic ground

state is the antiferromagnetic (AFM) state in which each of the two electronic edge states is ferromagnetically ordered but the two edge states are antiferromagnetically coupled to each other (Son et al. 2006). Moreover, they have nearly the same local magnetic moment ($\sim$0.10 μ_B). Because the density functional theory (DFT) calculations based on local-density approximations (LDA) or generalized gradient approximations (GGA) are well known to seriously underestimate the band gap of semiconductors, they calculate the band structure of partially hydrogenated graphene by employing the HSE06 functional (Heyd et al. 2003), which was shown to give a good band gap for many semiconductors including ZGNRs (Hod et al. 2008). The HSE06 band structures calculated for 4-ZGNR and 8-ZGNR-4 in the AFM state are shown in Fig. 3a, b, respectively. In the energy region of the band gap, the band structure of 8-ZGNR-4 is similar to that of 4-ZGNR, and the band gap (1.44 eV) of 8-ZGNR-4 is close to that (1.53 eV) of 4-ZGNR. Therefore, the electronic properties of partially hydrogenated graphene are determined by those of its graphene part, i.e., the bare zigzag carbon rows. Moreover, Xiang et al. also predict that ZGNRs with a small number of bare zigzag carbon rows, e.g., N = 4, are promising solar cell absorption materials; 8-ZGNR-4 (and N-ZGNR-4 with N > 4) has a direct band gap that is close to the optimal value ($\sim$1.5 eV) (Thompson and Frechet 2008) for the solar energy harvesting and high carrier mobility.

Besides double-sided functionalized graphene, which can be realized in a chemical functionalized freestanding graphene, Xiang et al. have studied the single-sided hydrogen-functionalized graphene (Xiang et al. 2010a), which might be realized in a functionalized epitaxial graphene. The thermodynamically stable single-side hydrogenated graphene structures are nontrivial and unexpected, as shown in Fig. 4 for several different H concentrations. This is significantly different from the case of

Fig. 3 Electronic band structures of (**a**) 4-ZGNR and (**b**) partially hydrogenated 8-ZGNR with four bare zigzag carbon rows (i.e., 8-ZGNR-4) in the AFM state from HSE06 calculations. Fig. 4 (**a** and **b**): The low-energy structures of two single-side hydrogenated graphene at a H concentration of 1/8. (**c**) and (**d**) are two proposed functionalized structures in Boukhvalov et al. (2008) and Slijivancanin et al. (2011), respectively. The numbers (in eV/H) in rectangles denote the average adsorption energies. The unit cells are marked. The hydrogen coverages (Hc) are shown. (Adopted from Xiang et al. 2010a)
double-sided functionalization of graphene. The peculiar adsorption configuration is a consequence of the competition between electronic kinetic energy and elastic bending strain energy: the hydrogen atoms tend to be close to each other to lower the kinetic energy of carbon π electrons, while the phase separation between sp^3 carbon part and sp^2 graphene is prohibited by the large strain caused by the single-sided hydrogen adsorption. Previous studies based on the same computational methods as those of Xiang et al. (2010a) suggested two possible single-side hydrogenated graphene structures (Boukhvalov and Katsnelson 2008a; Zhou et al. 2009), as shown in Fig. 4c, d. However, the formation energies are much higher (by at least 0.3 eV) than the one proposed by Xiang et al. (2010a), as shown in Fig. 4. This suggests that the macroscopic single-sided hydrogen adsorption on graphene is a cooperative phenomenon, which can hardly be described by the adsorption preference of a small number of hydrogen atoms. It should be noted that even with the same H coverage (0.25 or 0.5), the single-side hydrogenated graphene structure based on the new bent models has a much lower energy although the single-side hydrogenated graphene is thermodynamically unstable at this H coverage.

3.2   Oxidization of Graphene

Graphene oxide (GO) is of particular interest since chemical reduction in GO has been demonstrated as a promising route for mass production of graphene (Eda et al. 2008; Tung et al. 2009; Li et al. 2008; Gilje et al. 2007; Stankovich et al. 2006; Brodie 1859). In addition, GO shows promise for use in several technological applications such as polymer composite (Li et al. 2008), dielectric layers in nanoscale electronic devices, and the active region of chemical sensors.

GO, which was first prepared by Brodie in 1859 (Stankovich et al. 2006), consists of oxidized graphene layers with the hexagonal graphene topology (Wilson et al. 2009). Although it is now widely accepted that GO bears hydroxyl and epoxide functional groups on its basal plane (Gao et al. 2009), as confirmed by a recent high-resolution solid-state 13C-NMR measurement (Cai et al. 2008), the complete structure of GO has remained elusive because of the pseudorandom chemical functionalization of each layer.

Several first-principles studies (Kudin et al. 2008; Boukhvalov and Katsnelson 2008b; Yan et al. 2009) have been performed to investigate the structure and energetics of epoxide and hydroxyl groups on single-layer graphene. And some possible structures were manually selected and examined to obtain a good structural model for GO. However, the selection of these structures may not be the real ground-state structure of GO, which may give incorrect conclusions on the electronic properties of GO in the real samples. Xiang et al. adopted the global structural search method in combination with density functional theory (DFT) to search the global minimum structures of oxidized graphene with different oxidation levels (Xiang et al. 2010b). As a first step, they considered only the arrangement of epoxide groups on single-layer graphene to simplify the model.

The GA simulations (Xiang et al. 2010b) reveal two low-energy structures of C_1O, as shown in Fig. 5. In both structures, each of the carbon atoms is bonded to two neighbor carbon atoms and two O atoms; thus there is no sp^2 carbon. The structure shown in Fig. 5b is rather simple. There are epoxy pair chains along the zigzag direction which are parallel to each other. The authors will refer to this model as the epoxy pair model (D_{2h} symmetry) hereafter. The formation of an isolated epoxy pair was suggested in a theoretical study on the graphene oxidative process (Li et al. 2009; Zhang et al. 2009a). It was also shown that an isolated epoxy pair is less stable than a carbonyl pair (Li et al. 2009). However, in the fully oxidized graphene case, it is found in Xiang et al. (2010b) that that the epoxy pair chain is more stable than the carbonyl pair chain. The lowest-energy structure (C_{2v} symmetry) (Fig. 5a) of C_1O has a lower energy than the epoxy pair model. The small energy difference suggests that both phases might coexist at certain finite temperature. In the lowest-energy structure, there are isolated six-membered carbon rings, which are connected to the neighboring six-membered carbon rings through two epoxy pairs and four unzipped epoxy groups. For each six-membered carbon ring, there are two normal epoxy groups. Therefore, the complex structure is termed as the mix model. One can obtain the epoxy pair model from the mix model by moving the unzipped epoxy groups on top of the normal epoxy groups.

When the oxygen concentration is reduced, i.e., the O/C ratio is less than 1, it is found that the strong phase separation occurs, which will separate the CO_x ($x < 1$) structure into CO_1 part and graphene part (Huang et al. 2013a; Xiang et al. 2010b). The origin of this phase separation can be understood by the additional cluster expansion (CE) calculations (Huang et al. 2013a).

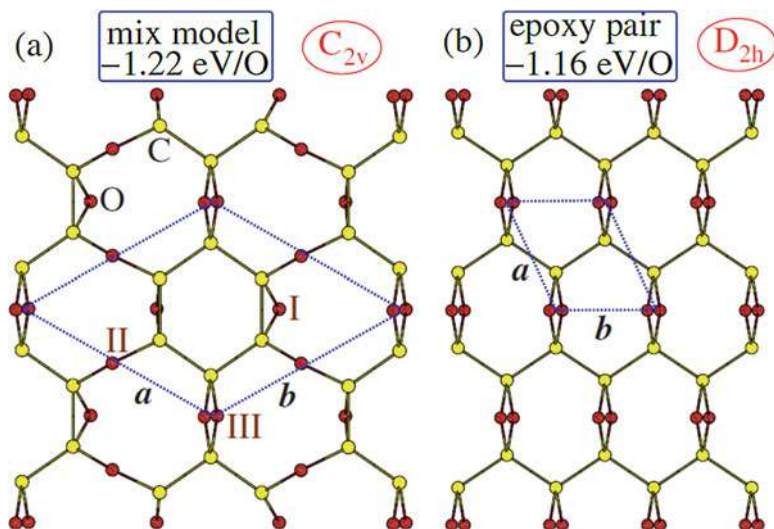
The formation energy (E_f) of selected 120 CO_x different structures is calculated using ab initio methods with the maximum O/C ratio of 1, as shown in Fig. 6a. The J values defining the CE are obtained by fitting to the DFT-GGA energy


Fig. 5 (**a**) The structure of the mix model (C_{2v} symmetry) which is predicted to be the lowest-energy C_1O phase. (**b**) The low-energy C_1O phase with the epoxy pair model (D_{2h} symmetry), which has a higher energy by only 0.06 eV/O than the mix model. "I," "II," and "III" in (**a**) indicate normal epoxy, unzipped epoxy, and epoxy pair, respectively. The unit cells are enclosed by dashed lines. The numbers give the formation energy of the oxidized graphene structures. (Adopted from Xiang et al. 2010b)

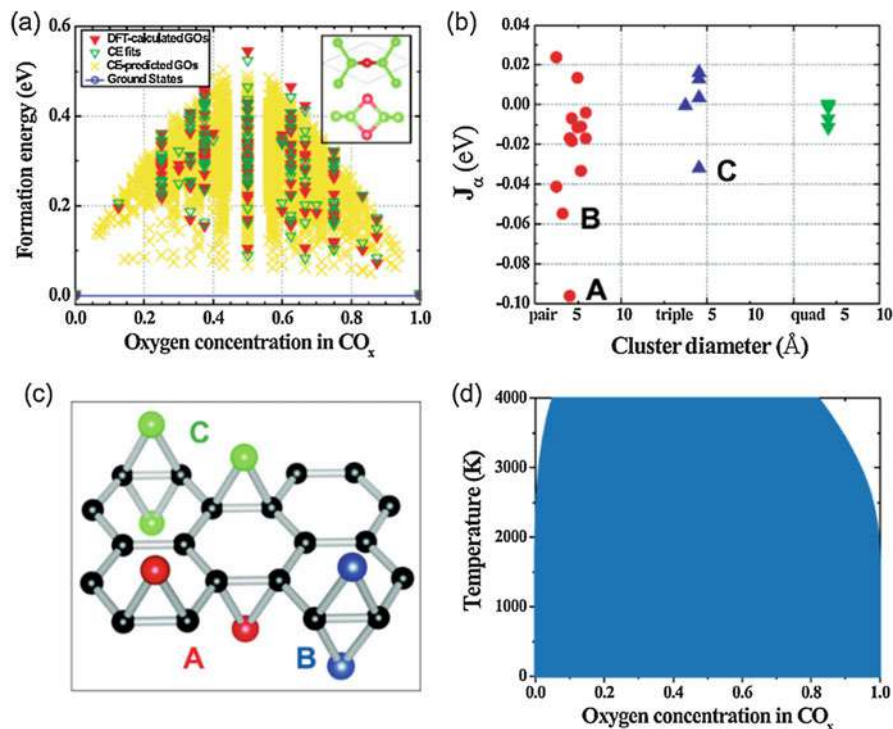
values of selected GO structures, and the CE contains 26 J up to four-point clusters which are shown in Fig. 6b. Apparently, J are dominated by negative values (attractive interactions for oxygen atoms), and the strengths of negative J are significantly larger than those of positive ones (repulsive interactions for oxygen atoms). Interestingly, the authors find that these negative J are largely (>60%) contributed by the interactions of oxygen atoms at the different graphene sides. For example, the two largest negative J values for pairs (marked as A and B in Fig. 6b) are contributed by the interactions between the nearest and third-nearest oxygen atom pairs at different sides, while the largest negative J for triple cluster oxygen interaction (marked as C in Fig. 6b) is a combination of A and B, as shown in Fig. 6c. The constructed CE are then used to calculate the E_f of all enumerated symmetry-inequivalent structures ($\sim$25,000), and the results are shown in Fig. 6a. Overall, the authors find that there are no intermediate ground states for $0 < x < 1$, which is consistent with the dominant negative values of J for short-range pairs and strongly indicates that the ground states of CO_x ($x < 1$) will separate into a graphene phase and a CO_1 phase. As the typical values of x in CO_x in the current experiments are usually smaller than 0.5, the authors can understand that inhomogeneous phase generally exists in almost all the GO samples. Our calculations explain quite well the experimental discovery that thermally reduced GO is separated into unoxidized


Fig. 6 (**a**) The calculated formation energies of CO_x (with respect to graphene and CO_1 shown in Fig. 5b) along with the corresponding CE fits as a function of oxygen concentration x in the GO system. graphene regions and high-oxidized GO regions that have a quasi-hexagonal unit cell with an unusually high 1:1 O:C ratio (Mattson et al. 2011).

One may expect to enhance the solubility of GO alloys at high growth temperature, which is proved to be a very successful idea in the growth of many conventional alloys like III nitrides (Ho and Stringfellow 1996; Bergman and McHale 2011) and Cu(In, Ga) Se_2 solar cell materials (Wei et al. 1990, 1999). In order to investigate this possibility, the phase diagram for graphene CO_x (0 < x < 1) is calculated by Monte Carlo simulations, as shown in Fig. 6d. The authors find that the miscibility temperature of GO even at quite low oxygen concentration (x < 0.05) is around 4000 K, which is rather high and close to the melting point of graphite (Bundy 1989). The calculated phase diagram clearly demonstrates that it is impossible to get homogeneous GOs by the conventional Hummers methods under the typical

temperature for preparing thermally reduced GOs (Brodie 1859; Wilson et al. 2009; Gao et al. 2009; Cai et al. 2008).

3.3   Chemical Functionalization of Silicene

Silicon is the leading material in semiconductor industries because of its wide usage in transistors, solar cells, and other electronic devices. Silicene, the silicon equivalent of graphene, has recently attracted significant attention because it is predicted to be stable and has graphene-like electronic structures including the presence of the Dirac cone at the Fermi level (Takeda and Shiraishi 1994; Fagan et al. 2000; Guzman-Verri and Lew Yan Voon 2007; Cahangirov et al. 2009; Zhang et al. 2017) and because of its compatibility with mature Si-based electronics. Recent experimental data show that epitaxial silicene can be successfully grown on some metal substrates, such as Ag (Lalmi et al. 2010; Vogt et al. 2012; Feng et al. 2012; Chen et al. 2012), Ir (Meng et al. 2013), and ZrB_2 (Fleurence et al. 2012). Similar to graphene, the feasibility of employing silicene for various electronic applications depends largely on the possibility of controlling its electronic properties by chemical functionalization. In contrast to graphene, it is well known that Si favors sp^3 hybridization, whereas sp^2 hybridization is dominated in silicene. This special feature is expected to give rise to very unique properties during chemical functionalization of silicene. For example, the external adsorbate or dopant may largely perturb the unfavorable sp^2 Si bonds and induce some unexpected structural transitions.

For silicene, F, O, and H are selected as typical adsorbates for chemical functionalization because they are successful for modifying the electronic properties of graphene (Huang et al. 2013b). Our calculations in Vogt et al. (2014) show that F (H) prefers to stay on the top of the Si atom, while O prefers to stay at the bridge site of a Si-Si bond, as in graphene. However, because silicene is less stable than bulk Si, currently, it can only be epitaxially grown on some special substrates to maintain the 2D structure and avoid the formation of bulk Si. For epitaxial silicene, the adsorbates are expected to attach only on the top basal plane of silicene. Therefore, the authors first focus on (single-sided) F- or O- functionalized silicene.

For pristine silicene (inset of Fig. 7a), the calculations in Huang et al. (2013b) show that the Si-Si bond length is 2.25 Å (shorter than 2.36 Å in bulk Si) and the buckling height is 0.44 Å, in agreement with previous calculations (Chen et al. 2012). For fluorinated silicene (SiF_x), the highest F concentration is $x = 1$. In the structure of SiF_1 (inset of Fig. 7a), the Si-Si bond length is stretched to 2.41 Å, and then silicene becomes flat. Although the Si atoms in SiF_1 are fully fourfold coordinated, the bond lengths and bond angles are far from those pertinent to sp^3 hybridization in bulk Si. The E_f values of selected 115 SiF_x structures are calculated using first-principles methods, and they are in the range of -0.4 eV$\sim$0.4 eV, as shown in Fig. 7a. The CE Hamiltonian of SiF_x is obtained by fitting to the 115 first-principles energies, and then all the energies of SiF_x alloys are calculated using the CE approach, and the results are shown in Fig. 7a. Interestingly, three intermediate ground states are discovered, as plotted in Fig. 7c–e for $Si_{12}F_4$, Si_6F_3,

and $Si_{12}F_{11}$, respectively. The intermediate ground states are determined by the fact that all the E_f of SiF_x with the concentrations between two neighboring intermediate ground states are above the ground-state line. For $Si_{12}F_4$ and Si_6F_3 (Cs symmetry), spontaneous structural warping appears after F adsorption; i.e., the arrangement of the nearly planar honeycomb lattices in silicene is now transformed to some ordered rippled structures. In the structure of $Si_{12}F_4$ (Si_6F_3), 8 (5) out of 12 (6) Si atoms are fourfold coordinated with the neighboring Si and F atoms to maximize the sp^3 hybridization and lower the total energies, and the average bond length between fourfold-coordinated Si is the same as that in bulk Si. For the structure of $Si_{12}F_{11}$, the basic honeycomb structure is maintained after fluorination, as shown in Fig. 7e. The only Si atom without F adsorption in $Si_{12}F_{11}$ is pushed down and forms a bond length of 2.35 Å with the neighboring Si atoms to maximize the ideal sp^3-like hybridization.

For the epitaxial SiOx, the highest O concentration is x = 0.5 and its structure is shown in Fig. 7b. The E_f with a total of 97 alloy structures are calculated using first-principles methods and fitted by the CE Hamiltonian. Using the CE Hamiltonian, our search identified a single intermediate ground-state $Si_{14}O_4$, as shown in Fig. 7b. In the structure of $Si_{14}O_4$ (C_{2V} symmetry), the original hexagonal sublattice shrinks to a rippled rectangular sublattice, as shown in Fig. 7f. Interestingly, in this structure all the Si atoms form four bonds with the neighboring Si or O atoms to realize the sp^3 hybridization, while each O atom forms two bonds with the neighboring Si atoms. This kind of spontaneous structural transition results in a new ground state. Furthermore, the authors find that chemical functionalization of epitaxial silicene is irreversible because of the induced structural transitions. This scenario is significantly different from that of graphene.

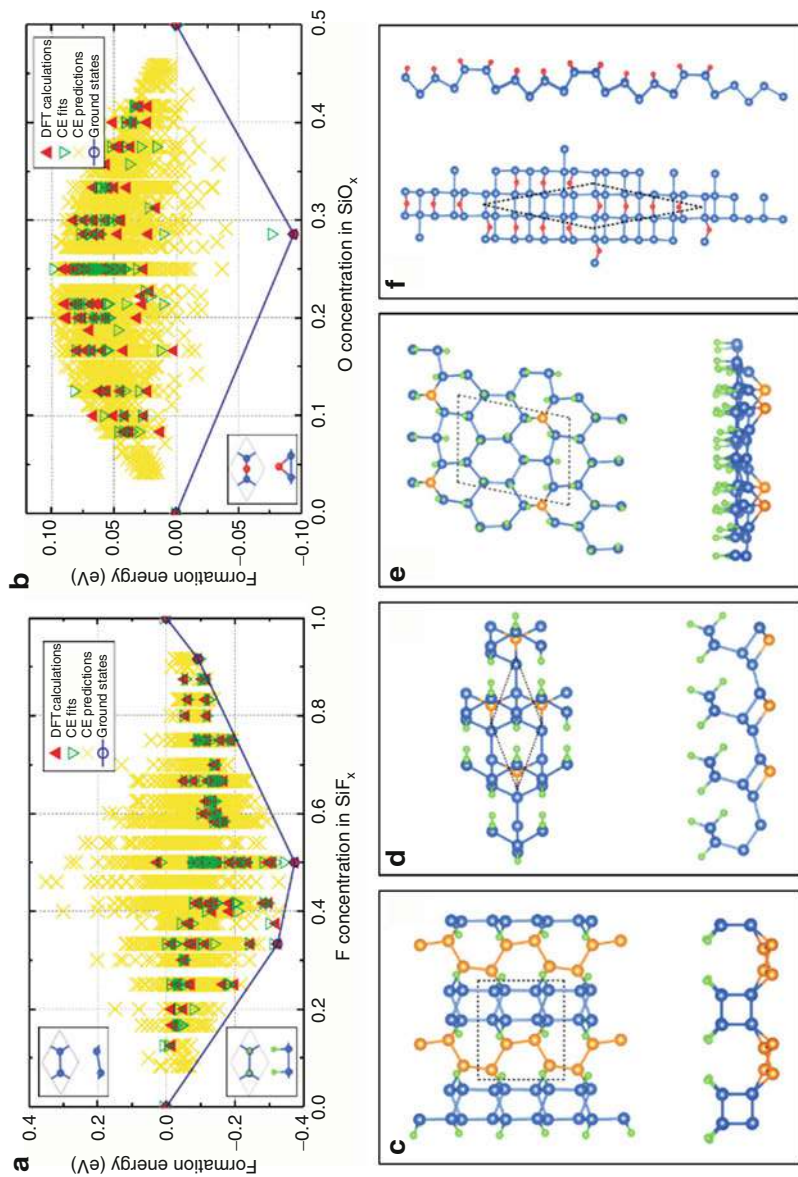
It is interesting to understand the chemical functionalization effects on the electronic properties of silicene. The electronic band structures for these discovered intermediate ground states of SiF_x and SiO_x are shown in Fig. 8. The authors find that $Si_{12}F_4$ is an intrinsic semiconductor with a slightly indirect band gap of 1.11 eV, similar to bulk Si. However, the energy difference between the direct and indirect band gaps (0.07 eV) in $Si_{12}F_4$ is extremely small based on the HSE06 calculations, compared to that of bulk Si (2.3 eV in experiments or HSE06 calculations), indicating that it may replace bulk Si for optoelectronic applications. The CBM and VBM of $Si_{12}F_4$ are mainly contributed by the electrons of the threefold-coordinated Si atoms. Interestingly, Si_6F_3 behaves as an *n*-type semiconductor with an indirect band gap of 0.51 eV. In Si_6F_3, there is only one Si atom that is threefold coordinated, and the structure could be considered a silicon fluoride system with an F (anion) vacancy. The anion vacancy state has one unpaired electron close to the conduction band and is strongly hybridized with the conduction band. Similar to Si_6F_3, $Si_{12}F_{11}$ can also be considered a silicon fluoride with an F vacancy, but the defect state in this 2D structure is quite localized and is resonant inside the valence band. As a result, $Si_{12}F_{11}$ behaves as a *p*-type semiconductor with a direct band gap of 2.17 eV. $Si_{14}O_4$ shows unexpected metallic behavior (negative band gap), partially because of the large sublattice distortion. The band crossing the Fermi level is mostly contributed by the hybridized *3s* and $3P_z$ states from the Si atoms (those that are not bonded with oxygen atoms).


Fig. 7 (continued)

Besides single-layer silicene, bilayer silicene has also been synthesized in the experiments (Vogt et al. 2014). Especially, bilayer silicene is more stable than single-layer one. Therefore, the authors have also studied the chemical functionalized bilayer silicene. By using a similar process for the study of chemical functionalized monolayer silicene, the authors have studied hydrogenated bilayer silicene. Interestingly, for single-sided hydrogenation, six intermediate ground states are discovered, as plotted in Fig. 9 for $Si_{16}H_2$ (C_{2v} symmetry), $Si_{28}H_6$ (C_1 symmetry), $Si_{24}H_6$ (C_2 symmetry), $Si_{28}H_8$ (C_2 symmetry), $Si_{12}H_4$ (C_{2v} symmetry), and $Si_{16}H_6$ (C_{2v} symmetry). One common characteristic of these ground states is that the adsorbed H atoms on the top of some specific Si atoms break the underneath Si-Si bonds and induce some local structural distortions. The average Si-Si bond length (2.34 Å) and bond angle (106°) at the structural distortion sites are close to those in bulk Si, which indicates that the induced distortion is to generate the sp^3 hybridization and lower the total energies. Generally, the hexagonal sublattice of silicene is kept during hydrogenation, which is significantly different from that of hydrogenated single-layer silicene (Huang et al. 2013b) and consistent with the fact that bilayer silicene is more stable than single-layer silicene.

For double-sided SiH_x, six intermediate ground states are discovered at specific H concentrations, which are quite different from chemically functionalized double-sided graphene (Huang et al. 2013a). Usually, there are no intermediate ground states in chemically functionalized freestanding 2D materials with single-atom thickness because the existence of strong double-sided adsorbate-adsorbate interactions can give rise to the clustering of adsorbates (Huang et al. 2013a). For double-sided hydrogenated bilayer silicene, the formation of the sp^3 bond on one side and the subsequent increase in the layer-layer distance significantly reduce the strength of the attraction of H on opposite sides. This explains why some intermediate ground states can form in double-sided hydrogenated bilayer silicene. As shown in Fig. 4, those structures are $Si_{16}H_4$ (D_{6h} symmetry), $Si_{12}H_4$ (D_{2h} symmetry), Si_8H_4 (D_{2h} symmetry), $Si_{12}H_8$ (D_{2h} symmetry), $Si_{16}H_{12}$ (D_{2h} symmetry), and $Si_{12}H_{10}$ (D_{3h} symmetry). In these six ground states, it is found that H atoms prefer to symmetrically adsorb on the top and bottom sides of silicene, giving rise to relatively higher structural symmetry compared to single-sided hydrogenation. Similar to single-sided SiH_x, H adsorption breaks the underneath Si-Si bonds, and the local structural distortion around Si atoms can generate the ideal sp^3 hybridization. The calculated average binding energy between H atoms and bilayer silicene in these ground states is around 820 meV/H. Generally, the ground

Fig. 7 (**a**) The calculated formation energies (E_f) of epitaxial SiF_x along with the corresponding CE fits as a function of x. The E_f of 6000 symmetry-inequivalent structures calculated from CE are also plotted here. Inset: the top and side views of the structures of silicene and SiF_1. (**b**) is the same as (**a**), but for epitaxial SiO_x, the 10,000 symmetry-inequivalent structures calculated from CE are shown. The top and side views of the structure of $SiO_{0.5}$ are shown as an inset in (**b**). The top and side views of the four discovered intermediate ground-state structures for (**c**) $Si_{12}F_4$, (**d**) Si_6F_3, (**e**) $Si_{12}F_{11}$, and (**f**) $Si_{14}O_4$. In these structures, the blue, green, and red atoms represent the Si, F, and O, respectively. The three-bonded Si atoms are highlighted by orange color, and the unit cells are marked by a dashed line. (Adopted from Huang et al. 2013b)
Fig. 8 The electronic band structures for these discovered ground states of epitaxial SiF_x and SiO_x: (**a**) $Si_{12}F_4$, (**b**) Si_6F_3, (**c**) $Si_{12}F_{11}$, and (**d**) $Si_{14}O_4$. state of a single- or double-sided SiH_x structure with an arbitrary concentration could be phase separated into its neighboring ground states. For example, the ground state of any double-sided $SiH_{0.4}$ structure can be the combination of $Si_{12}H_4$ (x = 1/3, Fig. 10b) and Si_8H_4 (x = 1/2, Fig. 10c) structures. This kind of phase separation is also experimentally observed in chemically functionalized graphene.

In Fig. 11, the authors have plotted the calculated band gaps of these single-sided and double-sided SiH_x ground states as a function of H concentration. For some special indirect band-gap semiconductors, if the gap differences between the indirect band gap and minimum direct band gap are less than 0.1 eV, the authors call them quasi-direct gap semiconductors. Quasi-direct band-gap systems may behave as direct band-gap systems in most optoelectronic applications (Watanabe et al. 2004). As shown in Fig. 11, the authors find that there are large oscillations for the band gaps of single-sided SiH_x as a function of H concentration, which is significantly different from that of double-sided SiH_x. Single-sided $Si_{28}H_6$ and $Si_{24}H_6$ have direct (or quasi-direct) band gaps of 1.01 and 1.30 eV, respectively, and double-sided $Si_{16}H_4$ and $Si_{12}H_4$ structures have direct (or quasi-direct) band gaps of 1.52 and 1.46 eV, respectively. Clearly, these four SiH_x compounds have suitable band gaps for solar-absorbing applications. Interestingly, it is also found that double-sided Si_8H_4, $Si_{12}H_8$, $Si_{16}H_{12}$, and $Si_{12}H_{10}$ have direct (quasi-direct) band gaps of 1.85, 1.99, 2.43, and 2.85 eV, respectively, which lie within red, orange, green, and blue colors, as shown in Fig. 11b. Because Si_8H_4, $Si_{16}H_{12}$, and $Si_{12}H_{10}$ can realize the red, green, and blue colors, in a LED application, it may be possible to mix them in order to realize white color. Today, III-nitride materials, e.g., InGaN alloys, have become the front-runner for achieving phosphor-free white LEDs via the combination of RGB emitters because the alloys with different compositions can, in principle, produce blue, green, and red LEDs. However, it is known that it is exceedingly difficult to obtain red InGaN LEDs, and the efficiency of green

LEDs using InGaN is also relatively low. This is partially because there is a large lattice mismatch (>10%) between GaN and InN, which can induce significant phase separations and dislocations during the formation of InGaN alloys. Obviously, the well-ordered SiH_x-layered structures the authors discovered here could overcome the large lattice-mismatch issue in InGaN alloys for high-efficiency white lighting. Moreover, it is found that layered materials have unique advantages over the conventional bulk materials for lighting because of the very strong optical transition rates at their band edges (Watanabe et al. 2004; Huang et al. 2012a).

4 Doping of 2D Materials

4.1 Enhanced Dopant and Carrier Densities in Graphene via Substrate

Controlling the type and density of charge carriers by doping is at the heart of graphene-like 2D electronics. However, the development of reliable chemical

doping methods in graphene is still a real challenge. Direct doping of graphene with substitutional dopants is rather difficult, because the strong covalent C-C bonds make graphene one of the strongest materials in the world (Geim and Novoselov 2007). Until recently, doping of graphene has mainly been achieved through reactive molecular or atomic adsorbates in experiments, which is difficult to implement under current device technology. Moreover, direct doping usually suppresses the high carrier mobility of graphene evidently (Peres 2010). Comparing to mechanical exfoliation of graphene from graphite, large area epitaxial growth of graphene layers on a silicon carbide (SiC) surface shows huge application potentials and has apparent technological advantages over the mechanical exfoliation method. Interestingly, the authors find that substitutional doping could be strongly enhanced in epitaxial graphene grown on SiC substrate compared to that of freestanding graphene (Huang et al. 2011a). The formation energies of dopants can reduce by as much as ∼8 eV. The type and density of carriers in epitaxial graphene layer could be effectively manipulated by suitable dopants and surface passivation. Contrasting to direct doping of freestanding graphene, the carriers of epitaxial graphene are weakly scattered by dopants due to the spatial separation between scattering centers (dopants) and the conducting channel (epitaxial graphene).

The carriers in graphene could be manipulated by p-/n-type dopants, like in conventional semiconductors. Al, B, P, and N are considered as substitutional dopants, as they are widely used in C- and Si-based materials. The calculated formation energy differences for graphene-SiC system are shown in Fig. 12. Interestingly, Al prefers to substitute the Si atom of the SiC substrate or substitute the C atom of the interface buffer layer, and the formation energy of Al decreases dramatically by ∼8.26 eV compared to freestanding graphene case. B and P atoms prefer to substitute C atoms of the buffer layer, and the formation energies of dopants decrease largely by 2.36 and 5.27 eV, respectively, compared to freestanding graphene cases. Besides doping in the buffer layer, the formation energies of B and P at SiC surface are also reduced by 1.46 and 4.87 eV, respectively, compared to freestanding graphene cases. Contrary to the cases of Al, B, and P doping, N atom prefers to substitute the C atom of top SiC substrate with a reduction of formation energy by 3.52 eV, as shown in Fig. 12d. The similar phenomenon of substrate-enhanced doping is also found on the SiC (0001) surface, with the E_f of dopants decreased by as much as 10.8 eV.

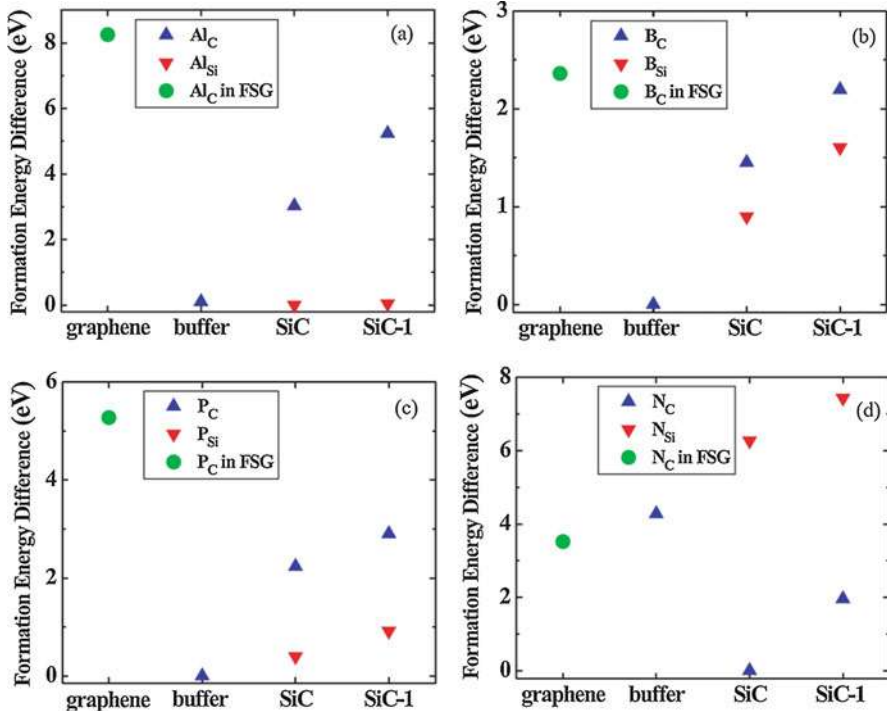
These quite different doping behaviors between different dopants and different layers in the graphene-SiC system could be understood by considering the structural strain in the various epitaxial graphene-SiC layers, the different atomic covalent radiuses, and the electronegativity of dopants. Since the interface buffer layer is under large tensile strain, Al, B, and P atoms could be easier to substitute C atoms in this layer due to the larger covalent radiuses of Al, B, and P than sp^2 C. The rippled (deformed) structure reduces the doping difficulty in the buffer layer to some extent. Furthermore, because the electronegativity of C is larger than that of Si in SiC, Si behaves as positively charged cation, and C acts as negatively charged anion. Al atom has lower electronegativity and a little larger covalent radius than Si, so it would prefer to substitute Si atom in the SiC matrix to increase the negative


Fig. 12 The calculated formation energy differences of dopants (**a**) Al, (**b**) B, (**c**) P, and (**d**) N in a graphene-SiC system as a function of different layers. The formation energies of dopants in freestanding graphene (FSG) are also plotted in these figures for comparison. (Adopted from Huang et al. 2011a)

Coulomb interaction between Al and C. Differing from Al, B, and P, the structural tensile strain increases the difficulty of N doping in the graphene layer because N has a smaller covalent radius than C. The N atom has even higher electronegativity than C, so it would prefer to substitute the C atom in the SiC matrix to increase the negative Coulomb interaction between Si and N, which is in agreement with the calculated trend of formation energy in Fig. 12d. The above results and analysis show that overcoming the doping difficulty with significant enhanced dopant and carrier densities in graphene could be generally achieved through substrates, and it can also be applied to other layered or thin-film systems.

4.2   Magnetic Properties of Transition-Metal Doping in Graphene

Control of magnetism is the key issue of spintronics. 2D materials could have some advantages relative to conventional 3D materials used for controllable magnetism. In this section the authors demonstrate that strain and electric field can be applied to

control the magnetic moments of 2D materials effectively, which might open a new door for spintronics.

Transition-metal (TM) doping in graphene can induce magnetism, and strain can be further applied to modulate the magnetic properties of TM-graphene system (Huang et al. 2011b). The authors take the case of a single Mn atom adsorption on graphene as a primary example to demonstrate the strain effect on the TM-graphene system. The calculated strain-dependent magnetic moments are shown in Fig. 13a. A biaxial strain η is applied to the graphene system. A positive (negative) η means the TM-graphene system is under tension (compression). For pristine graphene (PG) without vacancies, the Mn atom prefers to stay at the hollow site (above the carbon hexagon center) of PG, and the total magnetic moment of the Mn atom is 5.7 μ_B, indicating that the Mn atom is in a high-spin state. The height and average bond length between Mn and its nearest C atoms are 2.09 Å and 2.54 Å, respectively, as shown in Fig. 13b, c. The binding energy of Mn on PG is about 0.45 eV, as shown in Fig. 13d. When a biaxial tensile strain η is applied for Mn-PG, interestingly, the magnetic ground state changes from high spin to low spin ($\sim$3.1 μ_B) abruptly at the critical strain of $\eta = 0.05$, as shown in Fig. 13a. Accompanying the magnetic transition, the height and average bond length between the Mn atom and its nearest C atoms decrease sharply to 1.50 and 2.16 Å, respectively, as shown in Fig. 13b, c. The binding energy of the Mn atom increases to 1.15 eV when $\eta = 0.05$. In contrast to the sharp transitions of spin states and local adsorption structures, the binding energy increases continuously as a function of η, as shown in Fig. 13d.

TM atoms on PG have low migration barriers based on DFT-GGA calculations so that it may be mobile at room temperature (Krasheninnikov et al. 2009). However, our climbing-image nudged-elastic band calculations (Cai et al. 2008) based on DFT-GGA calculations show that the migration barrier for the Mn atom on PG increases from 0.36 eV to 0.89 eV under a tension of $\eta = 0.10$, giving rise to a decrease of more than eight orders of magnitude in the diffusion coefficient at room temperature, which implies that the migration can be suppressed significantly. It also indicates that an adequate variation of strain can be used to control the patterning of TM atoms on graphene. Furthermore, it is known that the mobility of the TM atom becomes markedly reduced in the presence of vacancies (Cretu et al. 2010). For instance, the migration barriers for TM atoms on vacancies are larger than 3 eV (Krasheninnikov et al. 2009).

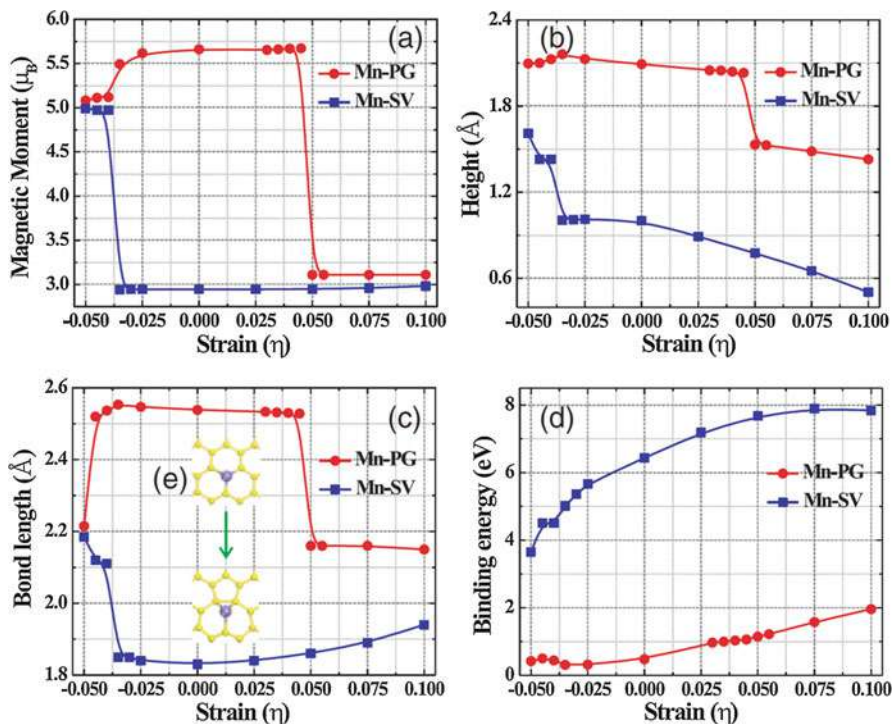
Similar to the case of Mn on PG, a similar magnetic transition between high-spin and low-spin states is found for Mn atoms adsorbed near the single-vacancy (SV) sites in graphene (Mn-SV). Unlike the Mn-PG case, the unstrained Mn-SV is in a low-spin state with the magnetic moment of $\sim$3 μ_B, as shown in Fig. 13a. The local adsorption structures of the Mn atoms are shown in Fig. 13e. The binding energy of the Mn atom is 6.4 eV, which is much larger than the Mn-PG case, indicating that the Mn-SV system is quite stable. Interestingly, a compression of $\eta = -0.04$ can convert the magnetic ground state from low spin ($\sim$3 μ_B) to high spin ($\sim$5 μ_B) for Mn-SV. Under compression, the graphene layer produces a spontaneous rippling with the formation of a C-C dimer bond near SV, as shown in Fig. 13e. As results, the height and the average bond length between Mn and its nearest C atoms increase signifi-


Fig. 13 (**a**) Magnetic moments of Mn atom adsorption on pristine graphene (PG) and defective graphene with a single vacancy (SV) as a function of strain. (**b**) Heights between Mn atoms and the nearest C atoms as a function of strain for Mn-PG and Mn-SV systems. (**c**) Average bond lengths between Mn atoms and the nearest C atoms as a function of strain for Mn-PG and Mn-SV systems. (**d**) Binding energies of Mn atoms on graphene as a function of strain for Mn-PG and Mn-SV systems. (**e**) Local structural transition for Mn-SV system from $\eta = 0$ (up structure) to $\eta = -0.04$ (down structure). (Adopted from Huang et al. 2011b)

cantly under compression, which weakens the binding. In general, the authors find that tensile (compressive) strain can enhance (reduce) the binding strength between TM atom and graphene, which is consistent with experimental observation (Geim and Novoselov 2007). It is interesting to observe that the electronic and magnetic structures of the Mn atom depend strongly on the strain of graphene layer, thereby leading to the strain-induced sudden change of the magnetic ground state. The strain affects the local geometry of carbon atoms around the Mn atom in two ways. It changes the height of Mn atom above the graphene layer and generates a ripple structure under the compressive strain. The change of the local environment, which determines the distance and symmetry of C p orbitals with respect to that of Mn d orbitals, can lead to a dramatic change in the magnetic d orbitals due to the strong spin-dependent hybridization between Mn d and C π orbital states.

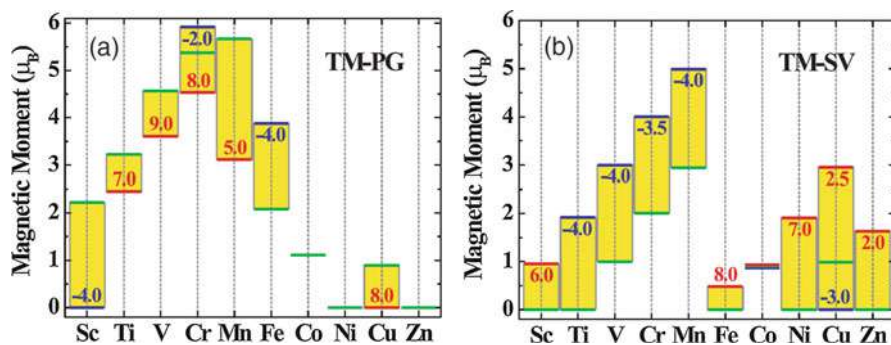
The strain control of the magnetism generally exists for almost all the TM atoms from Sc to Zn on graphene. The range of magnetic moments of TM-graphene


Fig. 14 The range of magnetic moments of TM atoms adsorption on graphene (**a**) without vacancy and (**b**) with SV under strain. The intrinsic magnetic moments of TM graphene without strain are shown as green lines, while the maximum and minimum magnetic moments of TM graphene caused by compressive (or tensile) strain (in unit of %) are shown by blue (or red) line. (Adopted from Huang et al. 2011b)

systems under realistic strain $-0.05 < \eta < 0.10$ is shown in Fig. 14. The transition of magnetic states for TM-PG systems under strain could be either continuous (e.g., V, Ti, and Cr) or abrupt (e.g., Sc, Mn, Fe, and Cu), as shown in Fig. 13a, which is mainly due to different strain-dependent ligand splitting and hybridization. Interestingly, strain can also control the adsorption sites of TM atom, for example, the adsorption site of Cu (Sc and Fe) on graphene converts from C-C bridge (hollow) site to hollow (C-C bridge) site at $\eta > 0.08$ ($\eta < -0.04$). The spin transition is even more remarkable in the TM-SV cases, as shown in Fig. 3b. For example, compressive strains of -0.04, -0.04, and -0.035 could transfer Ti-, V-, and Cr-SVs from low-spin to high-spin states, respectively, similar to Mn-SV. Tensile strains of 0.025, 0.06, and 0.07 could transfer Cu-, Sc-, and Ni-SVs from low-spin to high-spin states, respectively. It should be noticed that at least 66% (50%) of total magnetic moments of the Cu-SV (Ni-SV) system originates from the nearest C atoms around vacancy.

4.3 Magnetic Properties of Transition-Metal Doping in Boron Nitride

Because of the lack of band gap in graphene, as demonstrated in Fig. 13, the TM d orbitals strongly couple with the conduction or valence bands of graphene, and further control of the charge and magnetic states of TM/graphene system is quite difficult, but the reliable control of the charge and magnetic states of a magnetic material is a key step for spintronics and quantum information devices. Naturally, one may expect to solve this difficulty by replacing metallic graphene layer with some semiconducting layers, e.g., BN. Owing to the large chemical difference between cation B and anion N atoms, these ionic layer structures display large

heteropolar band gaps. Because the energies of TM *3d* orbitals can exist inside the band gap, i.e., not in the conduction or valence band as in the case of TM/graphene, the authors expect that these in-gap TM *3d* orbitals may be easier to be controlled by various approaches and the BN layer systems might be considered as preferential magnetic materials for low-dimensional spintronics. As for the case of graphene, the authors now focus on BN with intrinsic defects.

Depending on the position and symmetry of in-gap levels induced by vacancies, it is expected that they can interact with the adsorbed TM atom to achieve the controllable charge and magnetic states of TM/BN. For instance, since the energies of TM *3d* orbitals are roughly located at the middle of the gap of BN, they could behave as TM^{3+} ion after coupling to triple-acceptor V_B or TM^{2+} ion after interacting with double-acceptor V_{BN}. Since the in-gap levels induced by V_N are comparable to that of *3d* orbitals of TM in energy, instead of charge transfer, hybridization effect can play a critical role in determining the magnetic states of TM-VN.

When a TM atom is adsorbed at these vacancies (Fig. 15a), the binding energy of a TM atom on V_B is significantly larger than that of a TM atom on V_{BN} and V_N, which could be understood by the larger charge transfer effect in TM-V_B. Among these 3d TM atoms studied in Huang et al. (2012b), Sc is the one with the largest binding energy on V_B, as shown in Fig. 15b, consisting with the fact that the 3d orbitals of Sc are highest in energy than other 3d TM atoms and the large energy gain corresponds to charge transfer from Sc to BN. For TM atoms adsorption on V_{BN}, two electrons of TM atom transfer to V_{BN}, giving rise to TM^{2+} charge state. The alignment of the remaining *3d* levels exactly follows the Hund's rule, as shown in Fig. 15d. For TM atoms adsorption on V_B, TM atoms exactly exhibit TM^{3+} state after three electrons transfer to V_B. The trend of magnetic moment of TM-VN can be understood by the competing between crystal field splitting and exchange energy splitting (Huang et al. 2012b).

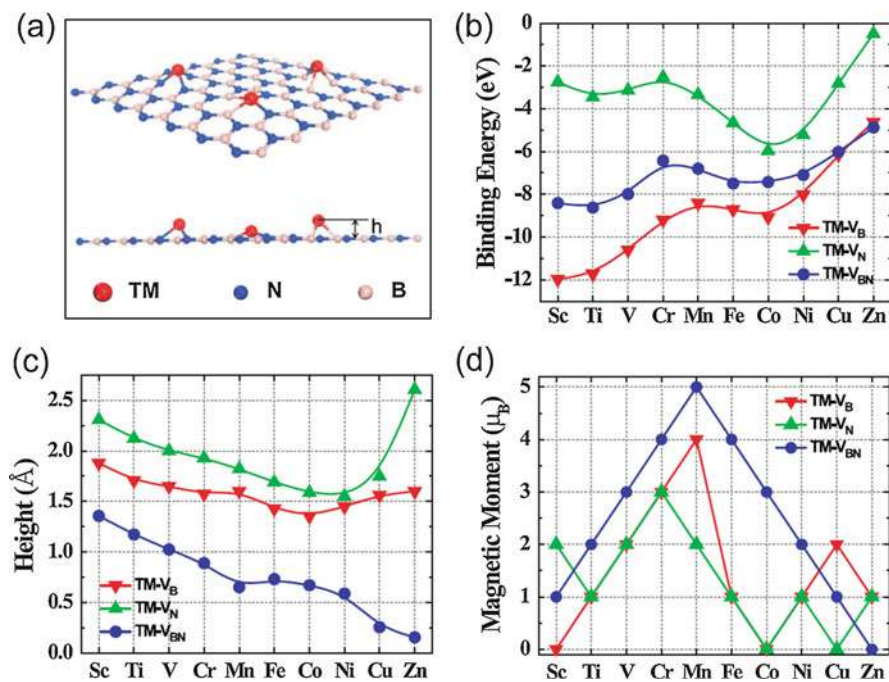
The understanding above suggests that the magnetic properties of TM/BN can be tuned if the authors can effectively adjust the relative energy positions of TM and/or defective BN. Especially, applying an external electric field E_{ext} can shift the relative energy-level positions because TM and BN are not in the same plane and because TM and BN can have opposite charge states when BN is defective. Taking Mn-V_B as an example (Fig. 16), Mn-V_B exhibits a high-spin configuration without an E_{ext} (Fig. 15d). A positive E_{ext} exerts a force on the system, pushing the Mn closer to the BN because Mn is positively charged and BN is negatively charged. This increases the crystal field splitting. Remarkably, when E_{ext} is increased to 1.0 V/nm, the height of Mn atom on V_B is decreased suddenly from 1.6 Å to 1.5 Å. The large increase of the crystal field splitting causes a spin crossover, i.e., charges are transferred from the spin-up channel to the spin-down channel (Fig. 16c), and the spin configuration converts from high spin to low spin, as shown in Fig. 4b. This low-spin state is found to be a metastable one with a total energy of 360 meV higher than that of the high-spin state in the absence of E_{ext}. Therefore, a negative critical E_{ext} is required to convert the low-spin state to high-spin one to achieve the spin crossover. The similar physical mechanism results in the spin configuration of Co-V_{BN} transfer


Fig. 15 (**a**) The schematic structure of TM atoms adsorbed on V_B, V_N, and V_{BN} in BN. (**b**) The binding energies of TM atoms adsorption on V_B, V_N, and V_{BN} in BN. (**c**) The height of the TM atoms above the BN surface when TM atoms adsorb on V_B, V_N, and V_{BN}. (**d**) The magnetic moments of BN with TM atoms adsorption on V_B, V_N, and V_{BN}. (Adopted from Huang et al. 2012b)

from high spin to low spin when E_{ext} is about 3.0 V/nm (Fig. 16b). The fact that larger E_{ext} is required for the Co-V_{BN} system than the Mn-V_B system is consistent with the fact that the Co-V_{BN} is less ionized, i.e., less charge transfer between TM and BN, than Mn-VB. It is worth to notice that the small critical E_{ext} in these systems indicates that it is possible to achieve this spin-crossover effect in experiments (Zhang et al. 2009b). The calculations show that this spin-crossover effect exists generally in TM/III–V and TM/II–VI layer structures, which strongly suggests that these TM/ionic layer systems could be used for electromagnetic applications such as E_{ext}-driven nonvolatile memory or energy devices.

5 Alloying of 2D Materials

Besides chemical functionalization and doping, alloying could be another choice to modulate the electronic properties of 2D materials for various energy applications (Xiang et al. 2012; Huang et al. 2015a, b; Zhu et al. 2015; Yang et al. 2017a, b; Luo et al. 2011).

(**b**) The magnetic moments of Co-V_{BN} and Mn-V_B as a function of E_{ext}. (**c**) The energy shift of d orbitals for Mn-V_B as a function of E_{ext}. The Fermi level is set to zero. (Adopted from Huang et al. 2012b)

5.1   2D C-N Alloy

First, the authors focus on the 2D C-N alloy systems. Based on the CE method, Xiang et al. identified two intermediate ground states, i.e., C_3N and $C_{12}N$, as shown in Fig. 17. To further confirm the CE results, a global minimum structural optimization method based on particle swarm optimization (PSO) is adopted to confirm the CE-proposed structures. In 2D PSO simulations (Yang et al. 2017a), the graphene lattice structure is not assumed, which is different from the CE method. Instead, random structures (both atomic positions and cell parameters) are generated to initialize the simulations. The initial structures are subsequently relaxed before the PSO operations are performed. The PSO simulations show that the most stable 2D nitrogen-carbon alloy structure with 25% N concentration is indeed the structure (a p6mm plane group of 2D systems) shown in Fig. 17a. The PSO simulations for the 2D nitrogen-carbon alloy structure with 7.7% nitrogen concentration do not give structures more stable than the $C_{12}N$ shown in Fig. 17b. This result supports the stability of the proposed $C_{12}N$ structure. The authors note that the formation energies of C_3N and $C_{12}N$ are positive if graphene and the N_2 molecule are taken as the references. However, many experiments have shown that N atoms can be
Fig. 17 (**a**) The ordered N-doped graphene superstructure for C_3N. (**b**) The ordered N-doped graphene superstructure for $C_{12}N$. Unit cells of the superstructures are enclosed by dashed lines. Each right panel displays the enlarged view of the structure that is enclosed by a red circle in the left panels. The numbers denote the bond lengths (in Å). The Clar formulas are specified by the circle, solid, and dashed lines. (Adopted from Xiang et al. 2012)

incorporated into graphene. What the authors have demonstrated is that C_3N and $C_{12}N$ are the most stable structures once N atoms are incorporated into graphene.

The band structures for the C_3N and $C_{12}N$ superstructures from the LDA calculations are shown in Fig. 18. Interestingly, both superstructures are found to be semiconductors: C_3N has an indirect band gap (about 0.26 eV from the LDA calculation). $C_{12}N$ has instead a direct band gap (about 0.62 eV from the LDA calculation) at the M point. Because the p_z orbital of a nitrogen atom will be almost fully occupied by the two π electrons, the mechanism for the band-gap opening in graphene induced by nitrogen doping can be understood by examining only the bonding situation of carbon π electrons.

The Clar's theory of the aromatic sextet (Wassmann et al. 2010) has been shown to be a simple and powerful tool to predict the stability and the electronic/magnetic structure of graphene-related systems. According to Clar's rule, for a given system, the representation with a maximum number of Clar sextets, called the Clar formula, is the most representative one. Here, the authors show the Clar formulas for C_3N and $C_{12}N$ in the right panels of Figs. 17a

Fig. 18 (**a**) The LDA band
structures for (**a**) C_3N and (**b**)
$C_{12}N$. The horizontal green

levels. The contributions from
N p_z orbitals to the wave
functions are indicated by the
radii of the solid spheres.
(Adopted from Xiang et al.
2012)
and 18b, respectively. In C_3N, each six-membered ring forms a Clar sextet.
C_3N has one unique Clar formula and thus belongs to the class 1CF of the
(pseudo)-all-benzenoid structure. In contrast, $C_{12}N$ has no Clar sextets and thus
is non-benzenoid. Because each nitrogen atom forms three single bonds with the
neighboring carbon atoms, the nitrogen atoms are excluded when the authors
construct the Clar formula. The Clar formulas shown in Fig. 17 are in good
agreement with the C-C bond lengths of relaxed structures from the DFT cal-
culation. All the C-C bond lengths in C_3N are the same: 1.393 Å. For $C_{12}N$,
some C-C bonds (marked by an additional solid line) have shorter bond lengths,
1.388 Å, which can be considered a normal C-C double bond; and there are weak
C-C double bonds (marked by an additional dashed line) with bond lengths of
1.406 Å; all the other C-C bonds are single bonds. Therefore, the authors can
understand that there is a large band gap between the occupied carbon π states
and the unoccupied carbon π states in both C_3N and $C_{12}N$. Our analysis for the
wave-function characters indicates that the highest occupied band near π is mainly
contributed by nitrogen p_z orbitals, and there are some contributions from carbon p_z
orbitals when the Brillouin-zone boundary is approached. The lowest unoccupied
band is mostly contributed by the carbon p_z orbitals. The gap between the highest
occupied carbon π state and the CBM is larger than 1.5 eV (in LDA) in both C_3N
and $C_{12}N$, which is in accord with Clar's theory. Therefore, the authors predict that
collective nitrogen doping can induce exotic semiconducting behavior in graphene
instead of *n*-type doping behavior. The real band gap should be larger because the
LDA functional underestimates the band gap. It is well known that LDA seriously

underestimates the band gap of semiconductors; thus, the authors calculate the electronic structures of C_3N and $C_{12}N$ by employing the screened HSE06 hybrid functional, which has been shown to give a good band gap for many semiconductors. Our HSE06 calculations show that C_3N and $C_{12}N$ have the band gaps of 0.96 eV and 0.98 eV, respectively. The authors note that the band gaps of the nitrogen-doped graphene are close to the band gap (about 1.12 eV) in silicon.

5.2   2D Si-P Alloy

As 2D Si and P have been achieved in the recent experiments, an interesting question is whether stable 2D silicon phosphide (Si_xP_y) monolayers with different stoichiometries can exist in the Si-P phase diagram. If so, what kinds of stable stoichiometries can they have, and do they have more attractive electronic properties than that of 2D Si or P? The answers to these questions are not only scientifically important to extend our current knowledge of 2D materials, but also can provide an approach for the discovery of new 2D functional materials beyond the existing materials. By combining global structural search (PSO) and first-principles calculations, the authors have found several stable or metastable semiconducting Si_xP_y monolayers, which can only be formed at the stoichiometries of $y/x \geq 1$, as shown in Fig. 19.

When $y/x \geq 1$, a large number of Si_xP_y monolayers with negative ΔH emerge, and most of these satisfy the classical electron counting rule, i.e., Si atoms are fourfold coordinated, while P atoms are threefold coordinated to realize full sp^3 hybridization. For Si_1P_1, the lowest-ΔH phase has a GaSe-type (P-6m2) structure with $\Delta H = -0.159$ eV/atom, as shown in Fig. 20a. The P-3ml and P21/m phases (Fig. 20b, c) have a slightly higher ΔH value than that of the P-6m2 phase. When the P composition is further increased to the stoichiometry of Si_1P_2, seven Si_1P_2 with negative H values appear in the phase diagram. The lowest-ΔH phase has Pm symmetry. As shown in Fig. 20d, the Pm Si_1P_2 structure can be considered as the stacking of one zigzag P chain on the h-BN-like SiP monolayer in each unit cell. The second lowest-ΔH phase is P-42$_1$m Si_1P_2, which has a slightly higher ΔH than that of the Pm phase. Interestingly, the Si_2P_3 pentagon is the basic building block to form the P-42$_1$m Si_1P_2 structure, as shown in Fig. 20e. For the stoichiometry of Si_1P_3, the authors find two structures with negative ΔH, and the lowest-ΔH one has C2/m symmetry, as shown in Fig. 20f.

In terms of the calculated ΔH values of all the 2D Si_xP_y, the authors can obtain the ground-state convex hull of 2D Si_xP_y, as shown in Fig. 19. Obviously, P-6m2 Si_1P_1 and Pm Si_1P_2 are located on the convex hull, indicating that they are stable against disproportioning into other neighboring compounds. It is important to compare the thermal stabilities of the predicted monolayer Si_xP_y to the existing bulk Si_xP_y phases. For the stoichiometry of Si_1P_1, the bulk Cmc21 phase has a negligibly lower ΔH value than the predicted monolayer P-6m2 phase, while the bulk F-43m phase has a significantly positive ΔH value. For the stoichiometry of Si_1P_2, the predicted monolayer Pm phase also has a quite similar ΔH value as the bulk Pbam and Pa-3 phases.
Fig. 19 Thermodynamic stability of 2D Si_xP_y indicated by the calculated formation enthalpies (ΔH) of various 2D Si_xP_y compounds with respect to elemental decomposition into diamond silicon and black phosphorus. The solid blue circles represent the predicted lowest-ΔH Si_xP_y at each P composition. The half-solid green circles represent other predicted Si_xP_y compounds with negative ΔH values. The ground-state convex hull of 2D Si-P compounds is denoted by the solid lines. For comparison, the calculated ΔH values of four previously known bulk Si_xP_y compounds, i.e., F-43m Si_1P_1, Cmc2$_1$ Si_1P_1, Pbam Si_1P_2, and Pa-3 Si_1P_2, are also plotted as red triangles. (Adopted from Huang et al. 2015a)

5.3   2D Si-S Alloy

One promising approach for the discovery of new materials is "atomic transmute" in which one type of elements is transmutated into its neighboring elements in the periodic table but the total number of valence electrons is kept unchanged. In 2D materials, it is well known that by transmutating two C atoms in group IV graphene into one B atom and one N atom, monolayer groups III–V material h-BN can be obtained with wide band gap and new functionalities. Similarly, it is possible to replace two P atoms in phosphorene or in monolayer blue phosphorus by one Si atom and one S atom and predicted new 2D materials α-SiS and β-SiS with interesting properties (Zhu et al. 2015). However, it is not clear whether these are the ground-state structures for these materials.

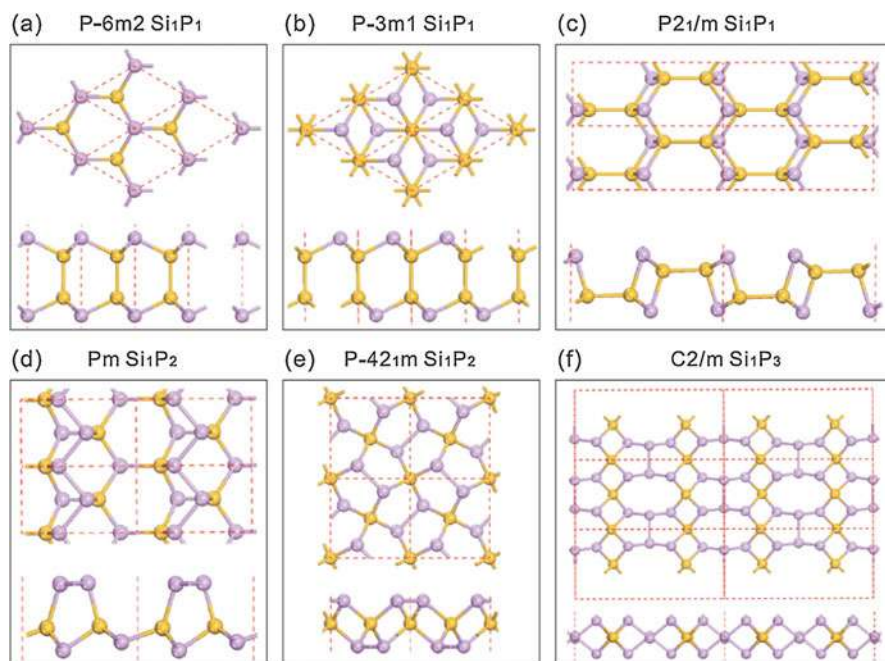
To identify the ground-state structures of SiS, Yang et al. have performed the global structural search method, which can effectively catch the global ground-state structure of a compound (Yang et al. 2017a). The lowest-energy structure of Si_2S_2 (Pmma symmetry) obtained from this search is shown in Fig. 21a. In Pmma-SiS, Si atoms form zigzag chains along b directions (see bc-plane projections in Fig. 21a),


Fig. 20 Structures of 2D Si_xP_y. The top view (upper) and side view (lower) of (**a**) P-6m2 Si_1P_1, (**b**) P-3m1 Si_1P_1, (**c**) P2$_1$/m Si_1P_1, (**d**) Pm Si_1P_2, (**e**) P-42$_1$m Si_1P_2, and (**f**) C2/m Si_1P_3. Violet and yellow spheres are P and Si atoms, respectively. The unit cells are marked by the red dashed lines. (Adopted from Huang et al. 2015a)

which are sandwiched and also connected by two S layers. Each Si atom is bonded to two other Si atoms and two S atoms, while each S atom is bonded to two Si atoms. As a result, the system obeys the "octet rule," which means that both S and Si atoms have eight valence electrons to fully occupy the outmost *sp* shells and each bond (including S dangling bonds) contains two electrons; thus this structure should be chemically stable. However, the calculated phonon spectrum for this Si_2S_2 cell shows that there is one small imaginary frequency around X point, which implies that periodicity of atomic arrangements along a direction should be doubled. Indeed, the authors found by structural search that Si_4S_4 (Pma2 symmetry) is dynamically more stable, as shown in Fig. 21c. In Pma2-SiS, both top and bottom S atom layers are alternatively slightly rotated around the a axis or titled toward positive and negative b direction. This long-range periodicity in S layers lowers the total energy slightly and removes the imaginary frequency from the phonon spectrum. Consequently, the structure in Fig. 21c is both chemically and dynamically stable. Besides Pmma-SiS and Pma2-SiS, it is also found that another interesting structure in Si_2S_2 unit cell, as shown in Fig. 21b, can exist. In this structure, all the Si atoms are in ab plane and form stretched honeycomb lattices with top and bottom S layers inserted into Si-Si bonds. Because of the similarity between this structure and unbuckled silicene and graphene oxide, the authors name it as silicene sulfide,
Fig. 21 Top and side views of structures for (**a**) Pmma-SiS, (**b**) silicene sulfide of Cmmm symmetry, and (**c**) Pma2-SiS. Blue is for Si and yellow is for S atoms. (Adopted from Yang et al. 2017a)

which has Cmmm symmetry. In this structure, both Si and S atoms also obey "octet rule," and thus it should be chemically stable.

The band structures and density of states of Pma2-SiS and silicene sulfide are shown in Fig. 22. Clearly, both of them are direct band-gap semiconductors with band gaps of 1.22 and 1.01 eV for Pma2-SiS and silicene sulfide, respectively, from the HSE06 calculations. The authors also performed G_0W_0 calculations for our structures and then obtained the optical band gaps of Pma2-SiS and silicene sulfide are 1.35 and 1.14 eV, respectively. Because their optical band gaps are close to the optimal values required for solar cell absorbers, they can be good candidate semiconductors for photovoltaic applications.

6   Conclusions

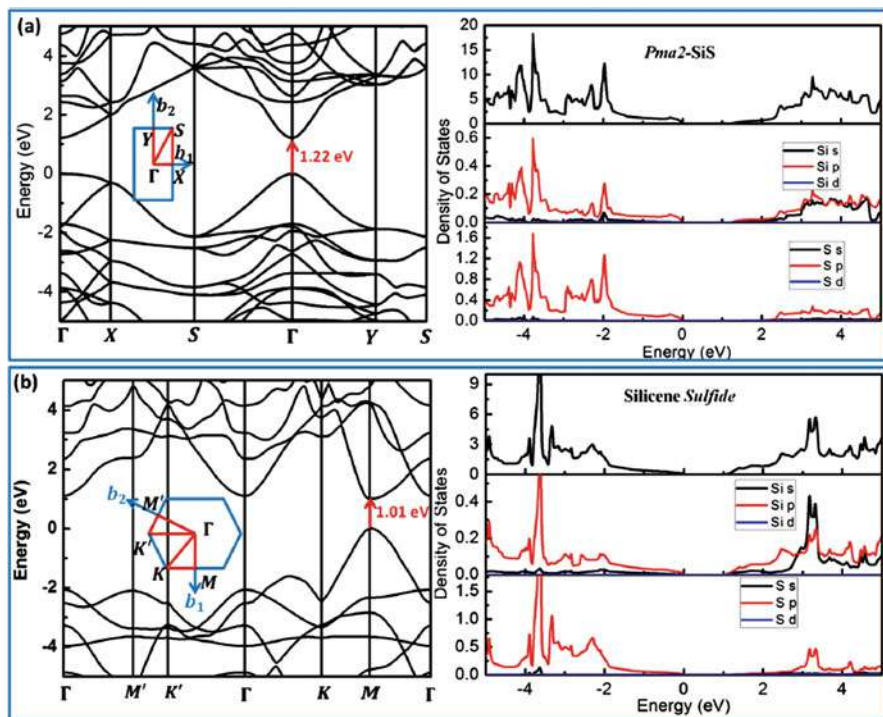
In conclusion, the authors have described the electronic properties of functionalized 2D materials that are useful for various applications, including solar applications, spintronic applications, and solid-state lighting. Our review clearly shows


Fig. 22 Band structures and (partial) density of states for (**a**) Pma2-SiS and (**b**) silicene sulfide. (Adopted from Yang et al. 2017a)

that first-principles (density functional theory based) calculations are powerful approaches to understand the fundamental physical properties of 2D materials. For examples, our calculations and analysis have allowed us to propose new approaches to modify the optoelectronic properties of several 2D materials via chemical functionalization, to suggest a new way to enhance the doping efficiency in graphene via substrate doping and carrier injection, to show the possibility of using 2D materials in spintronic applications via magnetic atom doping, as well as to reveal that alloying can dramatically expand the exploitation of 2D materials in energy applications. Our review is intended not only to present current research activities on chemical functionalized 2D materials but also to generate new ideas in the field. In the future study of 2D materials, the authors expect that more attention will be paid to design new functionalized 2D materials by heterojunction engineering and discover novel 2D topological materials, such as quantum spin hall insulators. The authors believe that investigation with more advanced computational methods will further extend the applications of 2D systems in energy and spintronic domains.

Spins in Semiconductor Nanocrystals

27

Gustavo Martini Dalpian

Contents

Abstract

Semiconductor nanocrystals are being used as hosts to trap and manipulate
single spins. Spins in nanocrystals can have different properties than their bulk
counterparts, owing both to quantum confinement and surface effects. We will
show that spins can be generated in nanocrystals by the insertion of impurities,
either magnetic or not, or by magnetic polarons present at dangling bonds at their
surfaces. This chapter reports theoretical contributions to this field, where the
density functional theory is used to simulate these functionalized nanocrystals.

1 Introduction

During the last 30 years, the development of nanoscience has led to the possibility
of manipulating nanostructures at the atomic level. Nanocrystals can be grown in

G. M. Dalpian (✉)
Center for Natural and Human Sciences, Federal University of ABC, Santo André, SP, Brazil
e-mail: gustavo.dalpian@ufabc.edu.br

a wide variety of geometries and shapes, and for many of the known compounds, leading to the possibility of fine-tuning their properties. When the *relatively-new* field of nanoscience met with the mature area of magnetism, new phenomena arose. Having magnetic spins in nanocrystals leads to the possibility of controlling and manipulating single spins in an atomic level. Besides the exciting fundamental challenges related to single-spin manipulation, there is also a wide variety of possible applications of this type of technology, going from spin filters (Efros et al. 2001) to single electron transistors (Qu and Vasilopoulos 2006). The ability to manipulate quantum processes at the level of single impurities forms the basis of an area of research called solotronics (Kobak et al. 2014).

Understanding the nature of spins in semiconductor nanocrystals is, consequently, an important task in order to successfully manipulate them. Theoretical and computational tools based on the density functional theory (DFT) and on pseudopotentials methods are a suitable choice for modeling these materials since they combine precision with the possibility of simulating the nanostructures in similar ways as they occur in the laboratory. Modern methodologies can simulate nanostructures with thousands of atoms, both with and without periodic boundary conditions.

In this text, we will qualify two different types of spins in semiconductor nanocrystals and report theoretical, DFT-based results on them. The first type of spin involves the insertion of extrinsic elements into the semiconductor host, in a procedure very similar to what is done for semiconductors (Dietl 2010). The most popular impurities are transition metal atoms, which usually have large exchange splittings, leading to large local magnetic moments. Besides these magnetic elements, it is also possible to observe spins and a magnetic response by inserting nonmagnetic impurities into the nanocrystal, such as carbon or nitrogen in ZnO. This might have advantages since standard elements used for magnetic semiconductors are often toxic and very expensive.

The second way of obtaining spins in nanocrystals is through the intrinsic existence of surfaces in these materials. Dangling bonds present at these surfaces might act as localized spins of magnetic ions, producing a similar effect as the insertion of transition metals into the host nanocrystal.

2   Doped Nanocrystals

Most bulk semiconductors can also be grown as low dimensional nanostructures. Even materials that have only been studied more deeply in the last few years, as the Halide Perovskites, have already been synthesized in the form of nanocrystals (Castañeda et al. 2016). The same is true for other, more traditional, semiconductors such as Si, ZnO, CdTe, CdSe, and so on. In order to broaden the possibility of applications of these nanostructures, it is important to functionalize them. Doping is one of the most conventional ways of functionalizing semiconductors and should also be a suitable path for semiconductor nanocrystals. However,

this can be a formidable task owing to kinetic limitations and self purification mechanisms.

Turnbull, in 1950, was the first one to argue that small droplets would have a smaller concentration of defects when compared to bulk (Turnbull 1950). He was interested in understanding the formation of crystal nuclei in liquid metals. This crystallization is usually induced by the presence of impurities or interfaces. His arguments were basically statistical: the probability of having impurities inside very small droplets should be much smaller than in larger crystals. In 2005, Erwin et al. (2005) argued that the limiting factor for doping a semiconductor nanocrystal was the binding energy of the impurity to the surface of the nanocrystal. In 2006, Dalpian and Chelikowsky (2006) showed that the formation energy of the impurity increases as the size of the nanocrystal decreases. This is a direct consequence of the fact that the impurity levels get deeper as the size of the nanocrystal decreases. This *pinning* of the impurity levels has also been observed experimentally (Norberg et al. 2006). Using DFT calculations, effective mass models, and magnetic circular dichroism spectroscopy, it has been shown that the donor binding energies of Co^{2+} impurities in ZnSe quantum dots are pinned irrespective of the size of the nanocrystal. This occurs owing to the smaller effect of quantum confinement in the localized Co_d levels when compared to the HOMO (highest occupied molecular orbital) and the LUMO (lowest unoccupied molecular orbital) of the nanocrystal.

A lot of advances in the area of doped nanocrystals happened in the last decade, leading to the successful control of doped nanocrystals from an experimental perspective (Mocatta et al. 2011).

From a theoretical perspective, in order to simulate semiconductor nanocrystals, one has to build molecular models that resemble what happens in these nanostructures. In this chapter, nanocrystals are generated by cutting spherical regions from a bulk crystal, as schematically shown in Fig. 1a. This nanocrystal will be defined by its center (that can be a bond, interstitial position or an atom) and its radius. Depending on the definition of the center of the nanocrystal, its symmetry might be changed (Dalpian et al. 2006). The generated structure, shown in Fig. 1b, will present a high density of surface dangling bonds, which will certainly interfere in the final results. Later on this chapter, the importance of these surface dangling bonds will be discussed. However, at this point, we are mostly interested in quantum confinement effects, and we would like to avoid surface states. To do that, the nanocrystal's surface atoms are saturated with pseudo-hydrogen atoms, carefully generated with fractional charges in order to maintain electron counting. Details about this theoretical procedure were thoroughly described by Huang et al. (2005a).

Within the methodology described above, one can easily obtain information about the quantum confinement effects in nanocrystals, such as the increase of the bandgap as the size of the nanocrystals decreases. Quantum confinement effects on doped nanocrystals can also be explored through these methods by inserting impurities into them. This procedure will be described in the next section.
Fig. 1 Procedure used to generate spherical ZnO nanocrystals: (**a**) and (**b**) a spherical region is cut from the bulk crystal; (**c**) the surface dangling bonds are saturated with pseudo-hydrogen atoms. Red and grey circles represent oxygen and Zn atoms, respectively. The small, white circles represent the pseudo-hydrogen saturation

2.1 Magnetic Impurities

To simulate magnetic impurities inside nanocrystals, we substitute one of the internal atoms of the nanocrystal by a transition metal impurity. This process has been successfully done experimentally for a variety of materials and dopants, providing a large quantity of experimental results for comparison. These results include Mn in ZnS (Donegá et al. 2002), Mn in CdS (Nag et al. 2010), Co and Ni in ZnO (Schwartz et al. 2003), Co in ZnSe (Norberg and Gamelin 2005), and many others.

From a computational point of view, one of the first works dedicated to understand the spintronic properties of nanocrystals was performed by Huang, Makmal, Chelikowsky, and Kronik in 2005 (Huang et al. 2005b). They studied the magnetic properties of Mn-doped Ge, GaAs, and ZnSe nanocrystals using real space ab initio pseudopotential methodologies (Chelikowsky et al. 1994), based on the density functional theory. These calculations were performed with the PARSEC code (Kronik et al. 2006). In this chapter, we will not detail the methodology used for performing these calculations, since this has already been discussed in other chapters. However, it is important to mention that real space methods have the advantage of avoiding the need to use large supercells, with large vacuum layers, that are usually needed in plane wave codes. The important parameter in this case is the grid spacing, which might influence in the final calculated properties (Chelikowsky et al. 2011).

When Mn is inserted into these semiconductor nanocrystals, the half-metallicity trends observed in the bulk are preserved. Substituting a Ge atom by Mn will introduce Mn_d orbitals into the band gap of the nanocrystal. Owing to the crystal field, these d levels will split into a tri-degenerated t_2 and a two-degenerated e level. The picture is very similar for GaAs and ZnSe. For Ge, there will be two holes in the t_2 level, whereas substituting Ga by Mn in GaAs will insert one hole. No holes are inserted when Mn substitutes Zn in ZnSe. This effect has been studied for four different sizes of nanocrystals: X_9MnY_{10}, $X_{18}MnY_{19}$, $X_{40}MnY_{41}$, and $X_{64}MnY_{65}$, where X = Ge, As or Zn and Y = Ge, As or Se, respectively, and the index indicates the number of atoms of that type in the nanocrystal. It was observed

that, as the impurity states are highly localized, they are less affected by quantum confinement than the delocalized host states, such as the HOMO and the LUMO. As the size of the nanocrystals decreases, the Mn-related levels become deeper inside the band gap. This causes the ferromagnetic stabilization to be dominated by double exchange mechanisms via localized holes.

The insertion of Mn atoms into II-VI semiconductor does not insert carriers (holes) into the system, since Mn is isovalent to the type-II atom. Consequently, Mn substitution into ZnO nanocrystals does not induce a ferromagnetic response. However, May et al. (2012) have shown that a ferromagnetic response can be obtained by the insertion of external p-type dopants. This can be done by photoexcitation of electrons or by atomic substitution. May suggested that doping ZnO quantum dots with N (at the oxygen site) would lead to a ferromagnetic response in Mn-doped ZnO.

Owing to the localized nature of transition metal impurities, a frequent concern relies on the appropriateness of density functionals to simulate such materials. Whereas the generalized gradient approximation (GGA) or local density approximation (LDA) are very popular amongst chemists and physicists, they should not be applied in a straightforward manner for all systems. In order to elucidate this issue, Badaeva et al. (2008) tested several density functionals to better understand the properties of Co-doped ZnO nanocrystals. They have compared experimental data for the dopant-carrier magnetic exchange interactions with LSDA, GGA, and hybrid PBE1 functionals (Perdew et al. 1997). Hybrid functionals include a fraction of Hartree-Fock exchange, leading to a better description of localized states and of bandgaps. The overall conclusion was that hybrid functionals are usually better suited to study this type of system, although qualitative responses are already obtained with other functionals.

2.2 Nonmagnetic Impurities

In the previous section, we discussed spins in semiconductor nanocrystals that were created by the insertion of transition metal atoms. However, it is also possible to get spins in semiconductor nanocrystals by inserting nonmagnetic atoms into the nanocrystals or by the presence of other types of defects.

One of the first theoretical reports on ferromagnetism in nondoped semiconductors was made by Pemmaraju and Sanvito (2005), in a study about intrinsic point defects in HfO_2. They have observed that oxygen vacancies are spin-polarized in this kind of system and that there are exchange interactions between neighboring vacancies, leading to the possibility of a macroscopic magnetization of the whole crystal. This result was important to help understand experimental observations of magnetism in nondoped samples of HfO_2.

As intrinsic defects, which happen spontaneously in the crystal, can lead to a macroscopic magnetization, one could use similar principles to engineer magnetism into nanocrystals without the need of transition metal atoms. This task can also be obtained by inserting nonmagnetic impurities, such as Carbon or Nitrogen, into quantum dots. To test this idea, Kwak and Cheliwkoswky (2009) studied Carbon-

doped ZnO nanocrystals. In this case, Carbon atoms enter in substitution to oxygen, inserting two holes into the system. The ground state of C-doped ZnO is spin-polarized, with a magnetic moment of $2\mu_B$, originated from its *2p* states. As these are mainly localized states, it has been shown that quantum confinement has limited effect on the defect states, making ferromagnetism robust through different sizes of nanocrystals.

3   Surface Magnetization in Semiconductor Nanocrystals

The surface saturation described previously in Fig. 1c is a theoretical artifact to remove the nanocrystals' surface states from the energy gap. This is only performed to isolate the effects of quantum confinement. Although the effects of quantum confinement are modeled correctly within this model, the surface does not represent what happens in experiment. This type of saturation models a perfect saturation, where the density of dangling bonds at the surface tends to zero. Although this methodology is precise to study quantum confinement effects, we lose the rich nature of the surface of the nanocrystals. In order to analyze the surface effects on nanoparticles and their implications on properties, we have removed all surface saturation and then optimize these structures, allowing all atoms to move to their minimum energy positions. The surface of a nanocrystal can reconstruct in several new arrangements. Owing to these structural changes, and the presence of dangling bonds, the electronic structure of the nanocrystal is also altered, and a magnetic signal, or spin polarization, can also be observed. This magnetization is usually termed as d_0 ferromagnetism, similar to the case of nonmagnetic doping described previously.

From an experimental perspective, there are several observations of ferromagnetic responses in materials that should be nonmagnetic. This *phantom ferromagnetism* (Coey et al. 2008) was first reported in 2008. For nanocrystals, Garcia (Garcia et al. 2007) showed that nondoped ZnO nanoparticles could have a small ferromagnetic response, depending on the way the nanocrystals are saturated. When the nanocrystal is covered with Thiol molecules, a larger magnetization is observed than when the nanocrystals are covered with TOPO. These different signals are explained by different surface saturations, leading consequently to a different density of surface dangling bonds.

The nanocrystals observed in these experiments represent a saturation that is in between the two saturation limits mentioned above: (i) full pseudo-hydrogen saturation and (ii) no saturation. By studying nonsaturated nanocrystals, we will be able to learn about the properties of these dangling bonds and infer about what happens in experiment.

Spins on dangling bonds at the surface of CdSe colloidal nanocrystals have been recently reported and studied (Biadala et al. 2017). These spins have been called "magnetic polarons."

3.1   Surface Reconstructions

To simulate the surface of nanocrystals, after carving a spherical nanocrystal in a bulk region, as shown in Fig. 1a, we minimize the forces on all atoms letting the surfaces reconstruct. We have analyzed ZnO nanocrystals in the zinc blende (ZB) and the wurtzite (WZ) structures and were able to observe several different types of reconstructions and several different structural motifs for ZnO nanocrystals. We have studied different sizes of nanocrystals, with diameters ranging from 0.9 nm to 1.5 nm. The surface of each nanocrystal was reconstructed in a different way, giving us a broad range of different defects, including planar faces, steps, kinks, adislands, adatoms, dimers, and others. We have considered the majority of possible motifs present at any nanocrystal surface.

The most frequent motifs are the formation of planar faces and of dimers. Figure 2 shows a structural model of a saturated ZnO nanocrystal with 147 atoms and of the nonsaturated, optimized counterpart. This planar reconstruction on ZnO has also been reported for thin films (Tushe et al. 2007). Most of these reconstructions occur to reduce the dangling bond density at the surface. The formation of dimers, as also observed in Fig. 2, is very common to several surfaces, including Si(001).

Besides surface reconstructions, removal of bond saturation leads to the striking observation of surface magnetization in these structures. The magnetization is strongly localized at the surfaces of the nanocrystals, with almost no signal at their interior. Figure 3 is an illustration of this phenomenon. The figure shows the radial distribution function of the spin density for different sizes of ZnO nanocrystals. The insets show the spin charge density, i.e., the total charge density for spin up minus total charge density for spin down. This radial distribution clearly shows that the magnetization in these nanostructures is mostly localized at the surface.

Although many motifs that present magnetization were observed, the surface magnetization was not observed in all of our simulated nanocrystals. Our conclusion is that some kind of atomic order inside the nanocrystal is needed for
Fig. 2 Illustration of planar faces that occur in some nanocrystals after the passivation is removed. In this figure, the ZnO nanocrystal has 147 Atoms
Fig. 3 Radial distribution of the spin density for three sizes of ZnO nanocrystals: (**a**) 4 Å; (**b**) 6 Å; (**c**) 7 Å. The inset shows a real space representation of the spin density distribution within the nanocrystal

the magnetization to be observed. For nanocrystals which structure was strongly reorganized, almost resembling an amorphous structure, no magnetization was observed (Schoenhalz et al. 2009 and 2010). Besides testing different sizes of nanocrystals (with up to 238 atoms), we have also tested different crystal structures. The ground state crystal structure of bulk ZnO is the wurtzite structure, although the energy difference to the zinc blende structure is not large. On Table 1 we report the total magnetization of the studied nanostructures.

Other nanostructured ZnO materials have also been shown to present a ferromagnetic ordering without the need of magnetic impurities. This is the case of ZnO nanowires (Podila et al. 2010), where the surface magnetization can also be used to explain the observed results.

As surfaces are delocalized and spread over the whole material, this effect should suffice to explain the observed magnetization in nondoped ZnO nanostructures (Garcia et al. 2007). Other extended defects such as grain boundaries and dislocations should also be able to hold a macroscopic magnetization.

Table 1 Total magnetization for nonsaturated ZnO nanocrystals (in Bohr magnetons). The number of atoms in the nanocrystal and the structure (ZB = zinc blende and WZ = wurtzite) is also shown (Schoenhalz et al. 2009)

Number of atoms	Structure	Total magnetization
35	ZB	$2\mu_B$
87	ZB	$4\mu_B$
147	ZB	$2\mu_B$
38	ZB	0
86	ZB	$2\mu_B$
238	ZB	0
39	WZ	0
92	WZ	$2\mu_B$
34	WZ	0
88	WZ	0

3.2   Interaction Between Surfaces and Magnetic Impurities

As demonstrated so far, spins in semiconductor nanostructures can be observed when impurities are inserted into the nanocrystal or by the simple fact that they exhibit large surface:volume ratios and that the surface is not perfectly saturated, presenting dangling bonds. A larger degree of complexity appears when both impurity spins and surface magnetizations are considered. This leads to the possibility of an exchange interaction between the delocalized spins at the surface and the localized impurity states.

A prototype case for studying this system is Co-doped ZnO nanocrystals (Schoenhalz and Dalpian 2013). There are plenty of theoretical and experimental results for the bulk system, with strong controversies about its ground state. Co has seven d electrons, and when inserted into ZnO, these d levels will be placed at the band gap. The total magnetic moment per Co atom is $3\mu_B$, because the e levels are lower in energy than the t_2 levels. Figure 4 shows the most important eigenvalues of three different nanocrystals and a comparison to the nondoped nanocrystals. For bulk ZnO, as the band gap is reduced in ab initio calculations, the Co d levels might be incorrectly placed away from the bandgap. Nanocrystals, with larger bandgaps, do not suffer from these problems.

When two impurities are present inside the nanocrystal, the most stable magnetic coupling is antiferromagnetic, since no carriers are present. This leads to a controversy because experimental results report a ferromagnetic configuration for this kind of system. Our results indicate that this ferromagnetism can be understood by the existence of the surfaces, as reported before for pure ZnO nanocrystals.

To simulate the effect of the surfaces on doped nanocrystals, we have used a procedure similar to the one used for nondoped nanocrystals: we remove the surface saturation, insert an impurity inside the nanocrystal, and optimize its structure. A very rich variety of spin configurations has been observed, depending on the size, structure, surfaces, and number of dopants inside the nanocrystal. Besides the usual hybridization and crystals field splittings observed in bulk ZnO and on saturated ZnO nanocrystals, in nonsaturated nanocrystals we also observe a strong interaction

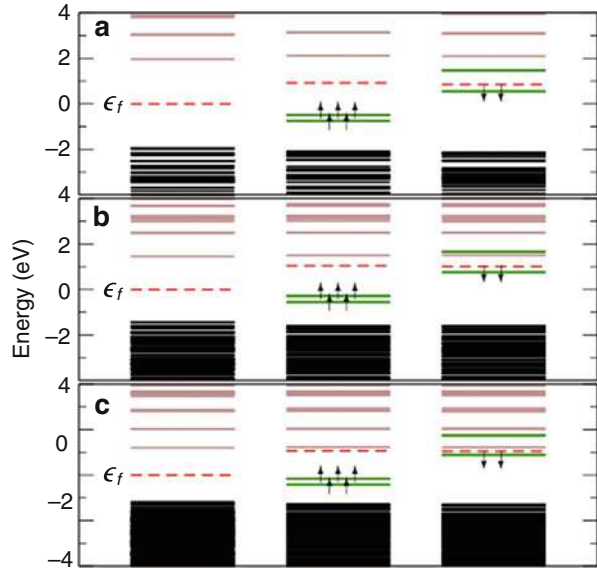
Fig. 4 Comparison of energy levels of a doped and undoped zinc blende NC. The set of eigenvalues in the left are for the pure, undoped nanocrystal, and the second and third sets represent the majority and minority spin channels, respectively. The undoped NC has (**a**) 35, (**b**) 87, and (**c**) 147 atoms of Zn and O. The doped NC had one of the Zn atoms (the most central) substituted by a Co atom for each nanocrystal


Fig. 5 Radial distribution of the spin density for ZnO nanocrystals. The green line indicates the case of the Co-doped nanocrystal, and the yellow line indicates the case for the bare nanocrystal. The insets show the real space representation of the spin density
between the Co atom and the surface states, lowering the symmetry and tuning the occupation of the impurity atoms.

Figure 5 presents the radial spin density distribution for a Co-doped ZnO nanocrystal. In this case, there is only one impurity inside the nanocrystal. The curve in green is for the doped nanocrystal, with one Co atom near the center of the nanocrystal. For this case, we observe a magnetization both at the center (Co atom) and at the surface of the nanocrystal. For the sake of comparison, we also show the magnetization for the non-doped nanocrystal. In this case, only the surface magnetization is observed.

For the doped nanocrystal case, the removal of the surface saturation had two main effects. The first one was to induce a surface magnetization, as shown in Fig. 5. The second effect is related to the magnetic coupling between two Co impurities inside the nanocrystal. For the saturated case, as there are no carriers in Co-doped ZnO, the most stable configuration between the spins of the Co atoms is antiparallel, i.e., antiferromagnetic. For unsaturated, reconstructed nanocrystals, the lowest energy configuration is when the spins of the Co atoms are parallel to each other, i.e., a ferromagnetic configuration. This occurs owing to the strong hybridization of the Co atoms with the surfaces, which might act as donors or acceptors changing the magnetic ground state. (Schoenhalz and Dalpian, 2013)

4   Conclusions and Perspectives

The results presented in this chapter show the complex nature of spins in semi-conductor nanocrystals. Owing to quantum confinement and surface effects, the behavior of these spins might be very different from their bulk counterparts. New phenomena are observed. Also, due to the reduced size of the nanocrystals, one has the possibility of inserting single impurities into them, leading to the possibility of single spin manipulation. This has potential applications ranging from quantum computing to spintronic devices.

The results presented in this chapter clearly show the importance of considering both quantum confinement and the surface structure for understanding the ground state properties of doped nanocrystals. As there are limited experimental methods that can precisely track the properties of these surfaces, theoretical methods become indispensable tools to understand their properties.

Excited-State Properties of Thin Silicon Nanowires

28

Li Yang

Contents

Abstract

Calculating many-electron interactions is crucial in determining excited-state properties of low-dimensional structures and is often beyond the capability of density functional theory, which is a ground-state theory. First-principles many-body perturbation theory can better describe many-electron effects and has been successfully employed to study excited-state properties of a wide range of solids. Such properties include quasiparticle energies, excitonic effects, and optical absorption spectra. In one-dimensional ultrathin silicon nanowires, which have been regarded as building blocks of nanoscale devices, many-electron interactions are substantially enhanced because of reduced dimensionality and weak electronic screening. If we employ many-body perturbation theory based on GW calculations for a silicon nanowire with a diameter of 1.2 nm, the quasiparticle band gap is 3.2 eV. This value is twice of that calculated from

density functional theory. Excitonic effects and optical absorption spectra, which cannot be obtained solely from GW calculations, are obtained by solving the Bethe-Salpeter equation. The calculated electron-hole binding energy is 1.2 eV for the same sized silicon nanowire. This binding energy is about two orders of magnitude larger than those found in bulk semiconductors. Our results agree well with recent measurements.

1   Introduction

Many-electron interactions are crucial in understanding excited states and are of fundamental importance in the exploration of new physics and device applications. Bare electrons interacting with other electrons and nuclei form single-particle excitations known as electron "quasiparticles." Excited electrons and holes can attract each other by Coulombic interactions to form two-particle excitations, which are called excitons. Interacting excitons may form four-particle excitations called "biexcitons." An exciton can also interact with an extra electron or hole to form a three-particle excitation called a "trion." These many-body excitations serve as the foundation for a diverse assortment of electric, transport, magnetic, and optical properties of solids.

To date, numerous low-dimensional structures have been successfully fabricated and intensively studied, which include zero-dimensional (0D) quantum dots and nanocrystals; one-dimensional (1D) nanowires (NWs), nanotubes (NTs), and nanoribbons (NRs); and two-dimensional (2D) structures such as graphene, transition metal dichalcogenides, and black phosphorous. Among these structures, single crystalline silicon nanowires (SiNWs) have attracted significant attention as they are potential building blocks for nanoscale devices, such as field-effect transistors, logic circuits, sensors, lasers, and light-emitting diodes (Cui and Lieber 2001; Sirbuly et al. 2005). Consequentially, understanding and predicting excited-state properties in SiNWs are of fundamental interest.

Many-electron interactions are substantially enhanced in nanostructures owing to quantum confinement and weak electronic screening. As a result, excited-state properties, such as quasiparticle band gaps and optical spectra, are significantly different from those of bulk structures. For example, photoluminescence (PL) data reveal a substantial blueshift in semiconducting NWs with decreasing size (Katz et al. 2002). Scanning tunneling spectroscopy (STS) data show a significant increase of the electronic band gap of thin semiconducting SiNWs (Ma et al. 2003).

First-principles approaches based on density functional theory (DFT) (Hohenberg and Kohn 1964; Kohn and Sham 1965) are an extremely successful tool to study atomic and electronic structures of solids (Cohen and Louie 2016). However, DFT is a ground-state theory and cannot accurately capture many-electron effects and excited-state properties. In contrast, many-body perturbation theory (MBPT) (Louie and Rubio 2005) has been proven reliable for calculating and predicting excited-state properties of a broad range of systems. These systems include many molecules, quantum dots, 1D structures, 2D structures, and bulk crystals (Hybertsen

and Louie [1986](#); Rubio et al. [1993](#); Blasé et al. [1995](#); Onida et al. [1995](#); Oğüt et al. [1997](#); Albrecht et al. [1998](#); Rohlfing and Louie [1998](#), [2000](#); Spataru et al. [2004a](#); Park et al. [2006](#); Neaton et al. [2006](#); Yang et al. [2007c](#), [2009](#); Qiu et al. [2013](#); Tran et al. [2014](#)).

The computational framework of MBPT consists of three steps. DFT is employed to calculate the ground-state properties, e.g., to obtain minimum-energy atomic structures and Kohn-Sham eigenvalues and wavefunctions. Then quasiparticle energies are evaluated within the GW approximation to provide band gaps and band-edge energies. Finally, the Bethe-Salpeter equation (BSE) is solved to obtain the two-particle excitation (exciton) energies, exciton wavefunctions, and optical absorption spectra. Thin SiNWs will be used as an example to present details of MBPT simulations and excited-state properties of 1D nanostructures. Our DFT calculations were performed using the Quantum Espresso package (Giannozzi et al. [2009](#)). Our MBPT calculations were performed using the BerkeleyGW package (Deslippe et al. [2012](#)).

2 Excited-State Properties of SiNWs

2.1 DFT Results of SiNWs

Substantial advances have been achieved in fabricating single-crystal SiNWs with diameters as small as 1 nm and lengths of a few tens of μm (Ma et al. [2003](#)). Numerous experiments, such as PL and STS, have shown unique transport and optical properties of SiNWs, which dramatically deviate from those of bulk silicon (Katz et al. [2002](#); Ma et al. [2003](#)). Given the vital role played by silicon in the semiconductor industry and the characteristic size of future microelectronic devices (sub-10 nm), understanding quantum-confinement effects and predicting their impacts on excited-state properties of ultrathin SiNWs are of broad interests for both fundamental science and device applications.

SiNWs synthesized in experiment often grow along specific crystallographic directions. The wires have a roughly cylindrical shape along with a chemically passivated surface (Morales and Lieber [1998](#); Homles et al. [2000](#)). Self-purification processes can also occur in SiNWs. In such processes, impurities or defects spontaneously migrate from the interior of the wire to the surface (Dalpian and Chelikowsky [2009](#)) and improve the single-crystalline purity.

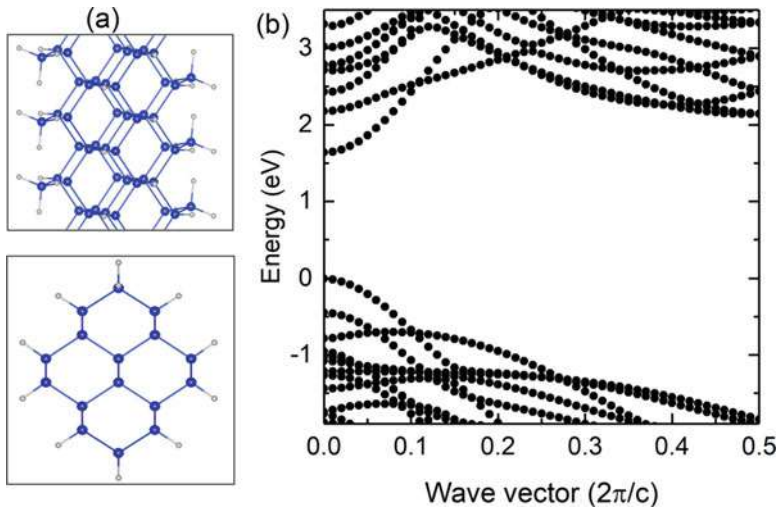
In computational approaches, the cylindrical wire model is constructed with a bulk-like structure in the interior. Dangling bonds on the surface are passivated by hydrogen atoms so that no complex of SiH_3 occurs (Zhao et al. [2004](#)). Shown in Fig. [1a](#) is a ball-and-stick model for a SiNW growing along the [110] direction with a diameter of 1.2 nm. Surface reconstruction can happen in SiNWs and affect its electronic and optical properties. For example, as shown in Fig. [1a](#), a full structural relaxation calculated within DFT in the local density functional approximation (LDA) shows that the direction of $Si-H_2$ bonds on the SiNW surface must be tilted to avoid soft phonon modes (Yang and Chou [2011](#)).


Fig. 1 (**a**) Side and top views of the ball-and-stick model of a H-passivated SiNW along the [110] direction. The diameter is around 1.2 nm. (**b**) DFT/LDA-calculated band structure of the 1.2-nm SiNW. The energy of the top of the valence band is set to be zero

Many new, important features of the electronic structures of SiNWs are found even at the DFT/LDA level. The DFT/LDA band structure of the 1.2-nm SiNW is presented in Fig. 1b. First, quantum confinement significantly increases the band gap: the DFT/LDA value is about 1.6 eV, which is much larger than that of the indirect DFT/LDA band gap of bulk silicon ($\sim$0.5 eV). Second, the band gap is direct in this thin SiNW. This feature may be of great help to broaden the range of silicon applications because the indirect band gap limits the use of bulk silicon in relevant optical applications. Further analysis (Zhao et al. 2004) has shown that this direct band gap is a band-folding effect; the conduction band minimum along the $\Gamma - X$ direction of bulk silicon is folded into the zone center of SiNWs. Interestingly, not all thin SiNWs exhibit the direct-gap feature. Other first-principles calculations predict that the direct/indirect band gap feature is sensitive to the orientation of SiNWs. For instance, the band gap can be indirect for thin SiNWs along the [111] direction (Yan et al. 2007). Finally, the degeneracy of light and heavy holes of the valence band maximum (VBM) of bulk silicon is eliminated. This is a quantum confinement effect because the energy levels of a free particle in a quantum well are inversely proportional to the particle mass. As a result, light holes and heavy holes experience different quantum conferment effects, and the degeneracy of energy levels is eliminated. Similar features have been predicted for the electronic structure of other types of ultrathin NWs, such as germanium NWs (Beckman et al. 2007).

In addition, studies based on DFT calculations have suggested various approaches for tuning the band gap and the absolute band-edge energies (referred to the vacuum level) of SiNWs. For example, applying axial strain can modulate the band gap, direct/indirect band-gap transitions, and band offsets of SiNWs

(Wu et al. 2009). Surface passivation and shape engineering can be utilized to control the band structure of SiNWs. For instance, OH passivation can enhance the band gap by a few hundred meV (Nolan et al. 2007). Tapered structures have been proposed to engineer quantum confinement and tune the absolute band-edge energies to realize charge separation within a single SiNW (Wu et al. 2008), which is useful for photovoltaic applications. Finally, motivated by studies of gated graphene nanoribbons (Son et al. 2006), an electrostatic gate field has been reported to be able to efficiently control the band structure of SiNWs (Nduwimana and Wang 2014).

2.2   Quasiparticle Band Structure and Band Gap of SiNWs

The GW approximation within MBPT (see Chap. 15, "Modeling Excited States of Confined Systems" of MTM by Hung and Öğüt) has proven successful in providing reliable quasiparticle band gaps of solids. Hedin suggested using MBPT to expand the self-energy into a product of the screened Coulomb interaction, W, and the single-particle Green's function, G, namely $\Sigma \approx iGW$, which is called the GW approximation (Hedin 1965). In the 1980s, first-principles GW calculations were established by Hybertsen and Louie (Hybertsen and Louie 1986). Since this pioneering work, GW theory has been successfully applied for obtaining reliable quasiparticle energy gaps of a wide range of solids (Hybertsen and Louie 1986; Shirley and Louie 1993; Blasé et al. 1994, 1995; Onida et al. 1995; Öğüt et al. 1997; Delerue et al. 2000; Zhao et al. 2004; Neaton et al. 2006; Yang et al. 2007c; Qiu et al. 2013)

We employ a non-self-consistent G_0W_0 calculation to calculate quasiparticle band gaps of a free-standing 1.2-nm SiNW. The computation setups of such GW calculations are critical to obtain converged quasiparticle energies (Shih et al. 2010; Peelaers et al. 2011; Ping et al. 2012 Qiu et al. 2013). The k-point sampling grid in the reciprocal space is set to be $1 \times 1 \times 32$. The static polarizability is calculated within the random-phase approximation (RPA), and the dynamic screening is obtained by the general plasmon pole (GPP) model (Hybertsen and Louie 1986). Usually the calculations of static polarizability and the Coulomb-hole part of self-energy require a sum of all unoccupied (conduction) states. Here a modified static-remainder approximation is applied to achieve the converged summation with a finite number of conduction states (Deslippe et al. 2013). Finally, a slab Coulomb truncation scheme is utilized to remove artificial interactions between neighboring periodic cells to mimic a free-standing SiNW (Ismail-Beig 2006; Rozzi et al. 2006). It is worth noting that the drawback of G_0W_0 is its dependence on the starting point.

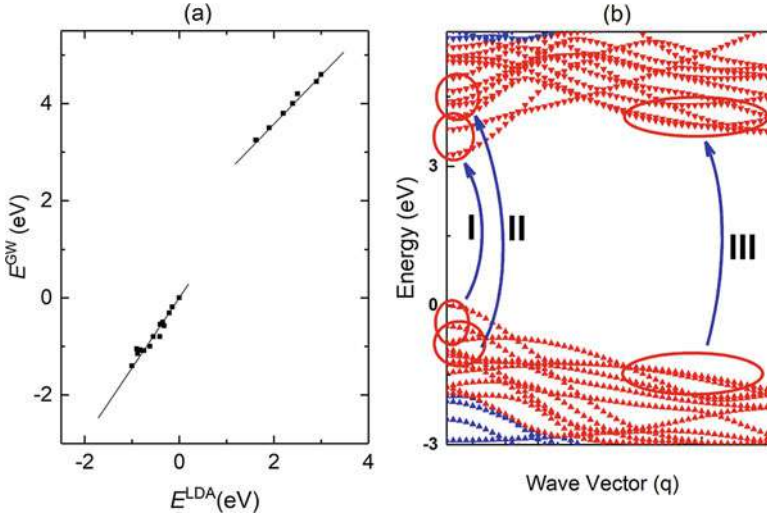
In Fig. 2a, GW-calculated quasiparticle energies are presented according to their DFT/LDA energies. The most important feature is that many-electron interactions induce a significant self-energy correction: a 1.62 eV correction to the 1.6-eV DFT/LDA band gap, nearly a 100% enhancement. This self-energy correction is significantly larger than that of bulk silicon, which is about 0.7 eV. Such an enhanced GW correction agrees with other studies of 1D CNTs (Spataru et al. 2004a) and h-BN nanotubes (Park et al. 2006), in which the self-energy correction is also


Fig. 2 (**a**) The quasiparticle energy vs the DFT/LDA energy. The linear fits are applied to those of valence states and conduction states, respectively. (**b**) The quasiparticle band structure of the 1.2-nm SiNW along the [110] direction. Those interband transitions, which are prominent in the optical absorption spectrum, are marked by "I," "II," and "III"

1∼3 eV. The reduced dimensionality and weak electronic screening of free-standing SiNWs are reasons for the enhancement of self-energy corrections. In fact, the dielectric function of free-standing SiNW is very different from that of bulk silicon. The diagonal components of the dielectric function of free-standing SiNWs are substantially smaller than those of bulk silicon (Yang et al. 2007a). Particularly within the long-wave limit, the dielectric function of free-standing thin SiNWs approaches the vacuum value (1). This is substantially smaller than the known static permittivity of bulk silicon, which is about 12.

The self-energy correction is an approximately linear function of the DFT/LDA energy in Fig. 2a. This behavior is similar to the one calculated in bulk semiconductors and 1D CNTs (Hybertsen and Louie 1986; Spataru et al. 2004a). As a result, linear functions can be used to fit GW corrections to the DFT/LDA band energies. With these fitted results, the whole quasiparticle band structure of a 1.2-nm SiNW can be plotted in Fig. 2b. Compared with the DFT/LDA band structure (Fig. 1b), the GW correction mainly increases of the band gap, and the important direct band-gap feature is kept.

Computing the quasiparticle band gap as a function of the diameter of SiNWs is of broad interest. Unfortunately, the simulation cost of GW calculations is proportional to N^4, where N is the number of electrons per unit cell. This is substantially more expensive than that of DFT computations, which scales as N^3 in principle, although slightly less than that in practice. With contemporary computation facilities, GW calculations of SiNWs with significantly larger diameters are formidable. An interpolation approach can be applied to approximate a solution to this problem. For instance, the quasiparticle band gap can be fit by

$$E_g = E_g^{bulk} + {A}\Big/{d^\alpha} \; , \tag{1}$$

where d is the diameter of SiNWs, and A and α are fitting parameters. The exponent α is usually about 1.4~1.8 (Zhao et al. 2004; Yan et al. 2007), which depends on the orientation of SiNWs, and smaller than 2, indicating that many-electron energy does not follow the simple scaling law of kinetic energy of a single particle within an infinite quantum well.

Additionally, the quasiparticle band gaps of SiNWs growing along different orientations have been calculated (Yan et al. 2007). Enhanced quasiparticle band gaps were identified. Interestingly, despite different orientations, GW corrections of SiNWs with similar diameters are found to be nearly identical.

The absolute quasiparticle band-edge energies referred to the vacuum level are important for broad applications. For example, SiNWs can be potentially useful for renewable energy applications such as water splitting (Zhang et al. 2011a), in which the absolute band edge energies are crucial for electron transfers and redox reactions. GW calculations for SiNWs with a diameter less than 2 nm result in absolute energy of the valence band maximum (VBM) lower than -5.5 eV, making such wires useful for water splitting (Yan et al. 2007).

GW quasiparticle band gaps also agree well with measurements. The STS measurements (Ma et al. 2003) showed that the band gap of ultrathin SiNWs with a diameter around 1 nm can reach 3.4 eV, which is very close to the GW-calculated value of 3.2 eV of 1.2-nm [110] SiNW (Zhao et al. 2004).

2.3   Optical Absorption Spectra and Excitonic Effects

In semiconductors, an electron can be promoted from a valence band to a conduction band by an incident photon, resulting in optical absorption. The excitation creates a positively charged "hole" in the valence band, which interacts with the excited electron owing to the screened Coulombic interaction. The interacting e-h pair forms an exciton. Excitonic effects are important for understanding optical properties of semiconductors and insulators. For example, as illustrated in Fig. 3a, without considering excitonic effect, the E_1 peak around 3.5 eV is notably absent in the calculated single-particle spectrum. When excitonic effects are included, the E_1 peak is resolved, and the overall optical absorption spectrum agrees well with experiment (Albrecht et al. 1998; Rohlfing and Louie 2000). Excitonic effects are also crucial for applications. The photovoltaic performance of solar cells is strongly influenced by exciton generation, diffusion, and dissociation (Gregg 2003). Previous work has demonstrated the importance of excitons in carbon and h-BN nanotubes (Spataru et al. 2004a; Park et al. 2006), semiconductor quantum dots, and nanocrystals (Oğüt et al. 1997). In the following, optical absorption spectra, excitonic effects, and fine structures of e-h pairs of thin SiNWs will be presented.

Single-particle results:

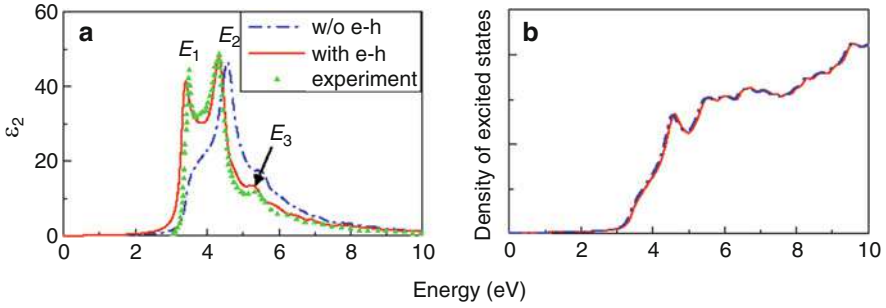
The single-particle optical absorption spectrum can be obtained within the RPA:


Fig. 3 (**a**) Optical absorption spectra and (**b**) density of excited states of bulk silicon with and without excitonic effects included. Experiment data (Philipp 1972; Aspnes and Theeten 1980; Lautenschlager et al. 1987) are included in (**a**). A Lorentzian broadening with a width of 0.10 eV is applied

$$\varepsilon_2 \left(\omega \right) = \frac{16\pi e^2}{\omega^2} \sum_{v,c} \left| \vec{\lambda} \cdot \left\langle v \middle| \vec{v} \middle| c \right\rangle \right|^2 \delta \left(\omega - (E_c - E_v) \right), \tag{2}$$

where $\vec{\lambda}$ is the polarization vector of incident light, v and c are valence and conduction states, respectively, and $\vec{v}$ is the velocity operator. E_c and E_v are the quasiparticle energies of conduction states and valence states, respectively. Only the interband transitions between conduction and valence states with the same crystal momentum are considered because the momentum of incident photon is usually much smaller than the size of the first Brillouin zone.

The single-particle optical absorption spectrum of the 1.2-nm SiNW along the [110] direction is illustrated in Fig. 4a. Twelve valence bands and 12 conduction bands are included in interband transitions for the converged absorption spectrum up to 8 eV. Although the direct band gap is around 3.2 eV, the single-particle optical absorption is not significant until 4.5 eV. This feature indicates that the optical interband transition between the VBM and CBM is very weak, and the direct band gap of SiNWs remains optically inactive. In fact, the interband transitions between band edges are forbidden by the face-centered cubic symmetry of silicon lattices, and the band-folding-induced direct band gap does not change the corresponding optical selection rule. As a result, in addition to the fundamental band gap, a symmetry gap exists in the optical absorption of SiNWs.

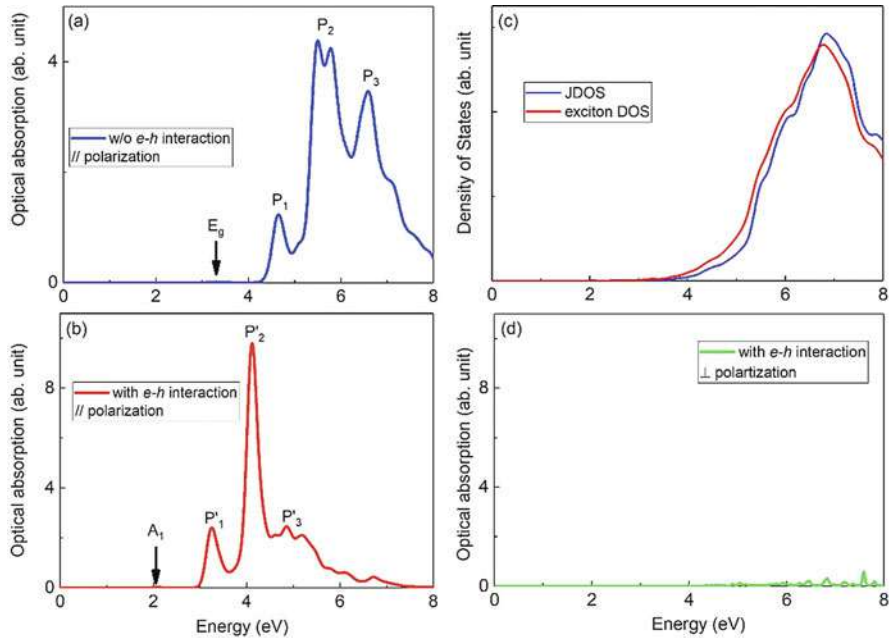
When compared with bulk silicon, new features emerge in the single-particle optical absorption spectrum of SiNWs. As marked in Fig. 4a, there are three dominant peaks (P_1, P_2, and P_3), which are different from the known double-peak (E_1 and E_2) feature of bulk silicon (Fig. 3a). These significant absorption peaks in SiNWs have complex origins associated with interband transitions. For example, the P_1 peak arises mainly from those transitions marked by "I" in Fig. 2b and the P_2 peak comes mainly from those transitions marked by "II" and "III."


Fig. 4 (**a**) The single-particle optical absorption spectrum of the 1.2-nm SiNW along the [110] direction. (**b**) That with e-h interaction included. Both spectra are for incident photo polarized along the axial direction. The band gap (E_g) and the lowest-energy singlet exciton (A_1) are marked by arrows, respectively. (**c**) The joint density of single-particle states and the density of excitonic states. (**d**) The optical absorption spectrum of photon polarized vertically to the axial direction of the SiNW. Excitonic effects are included. A Lorentzian broadening with a width of 0.10 eV is applied to all these figures

A more detailed analysis (Yang et al. 2007a) shows that the transitions of II and III correspond to the E_1 peak in bulk silicon at 3.5 eV, which is blueshifted, enhanced, and split in thin SiNWs. The bulk E_1 peak is owing to transitions in the neighborhood of the L point in the bulk Brillouin zone between the top valence band and the nearly parallel lowest conduction band along the [111] direction. In the [110] SiNWs, the bulk L points map to either the Γ point or the zone boundary. Therefore, the corresponding transitions appear around $k = 0$ transitions labeled by II and between parallel bands in the 1D Brillouin zone (transitions labeled by III). The peak marked by P_3 relates to the bulk absorption peak E_2. It consists of many complicated interband transitions in the SiNW, which are not labeled in Fig. 2. Similar results of shifted and split absorption peaks have been observed in other semiconducting nanostructures, e.g., InP nanowires (Yu et al. 2003) and nanocrystals (Vasiliev et al. 2002).

Two-particle results:

Excitons are crucial for understanding the optical properties of semiconductors and insulators. Exciton eigenvalues and wavefunctions can be obtained by solving

the corresponding Dyson's equation. Under the Tamm-Dancoff approximation (Fetter and Walecka 1971), the wavefunction of exciton S in a crystal can be written as

$$\chi_S\left(\overrightarrow{x}_e, \overrightarrow{x}_h\right) = \sum_k \overset{\text{hole elec}}{\sum_v \sum_c} A^S_{vck} \psi_{ck}\left(\overrightarrow{x}_e\right) \psi^*_{vk}\left(\overrightarrow{x}_h\right), \tag{3}$$

where A^S_{vck} is the exciton amplitude, and $\psi_{ck}\left(\overrightarrow{x}_e\right)$ and $\psi_{vk}\left(\overrightarrow{x}_h\right)$ are the electron and hole wavefunctions, respectively. These single-particle wavefunctions are usually obtained by DFT (LDA or GGA) calculations. k is the wave vector of periodic systems. The Dyson's equation for the two-body Green's function can be written as

$$\left(E_{ck} - E_{vk}\right) A^S_{vck} + \sum_{k'v'c'} \langle vck| K^{eh} \left|v'c'k'\right\rangle A^S_{v'c'k'} = \Omega^S A^S_{vck}, \tag{4}$$

which is called the BSE. Many-body effects of *e-h* interactions are included into the interaction kernel K^{eh} that is a four-point energy-dependent function (Rohlfing and Louie 2000) and contains two types of *e-h* interactions, the bare *e-h* exchange interaction and the direct (screened) attractive interaction. The GW-calculated dielectric screening will be used in constructing the *e-h* interaction kernel K^{eh}. For most intrinsic semiconducting materials, since the plasmon energy is much larger than the *e-h* interaction energy, the static approximation is employed to eliminate the energy dependence of the interaction kernel (Rohlfing and Louie 2000), which substantially simplifies the simulation to solve BSE.

Once the BSE (Eq. 4) is solved, the two-body optical absorption spectrum can be obtained by

$$\varepsilon_2\left(\omega\right) = \frac{16\pi e^2}{\omega^2} \sum_S \left|\overrightarrow{\lambda} \cdot \sum_{vck} A^S_{vck} \langle vk| \overrightarrow{v} |ck\rangle\right|^2 \delta\left(\omega - \Omega_S\right), \tag{5}$$

The BSE approach has been used to compute excitonic states and corresponding optical absorption spectra for a wide range of nanostructures and bulk crystals (Onida et al. 1995; Albrecht et al. 1998; Rohlfing and Louie 1998, 1999, 2000; Spataru et al. 2004a; Capaz et al. 2006; Neaton et al. 2006; Park et al. 2006; Yang et al. 2007b, 2009; Qiu et al. 2013; Tran et al. 2014). The calculation of *e-h* interaction kernel is very time-consuming, so an interpolation scheme is usually adopted (Rohlfing and Louie 2000; Spataru et al. 2004b). The *e-h* interaction kernel is first calculated on a coarse k-grid in the reciprocal space and interpolated onto a finer k-grid, to improve the convergence of exciton eigenvalues and eigenfunctions. For the 1.2-nm SiNW a $1 \times 1 \times 32$ coarse k-grid is used to obtain the *e-h* interaction kernel, and an interpolated $1 \times 1 \times 128$ fine k-grid is used for the convergence of exciton energies (to within 0.1 eV). Truncation of the Coulomb interaction is also necessary to mimic a free-standing nanostructure (Ismail-Beig 2006; Rozzi et al. 2006).

Enhanced excitonic effects have been calculated in ultrathin SiNWs (Yang et al. 2007a; Bruno et al. 2007) and Si/Ge NWs (Palummo et al. 2010a) using the described BSE approach. The two-particle optical absorption spectrum of a 1.2-nm SiNW is presented in Fig. 4b, in which the polarization of incident light is along the axial direction. *e-h* interactions drastically change the single-particle absorption spectrum. All three main peaks are generally redshifted by about 1∼1.5 eV after inclusion of e-h interactions. This excitonic effect is substantially different from that observed in the spectrum of the bulk. There the *e-h* interaction mainly enhances the E_1 peak while the whole optical absorption spectrum does not significantly shift. In contrast, *e-h* interactions dramatically shift and reshape optical spectra in semiconducting nanostructures. If excitonic effects are neglected, the calculated optical spectra of nanostructures are not qualitatively correct in either energies or profiles.

Electron-hole binding energy is a direct measure of excitonic effects. As marked in Fig. 4b, the lowest-energy exciton (A_1) is located at 2 eV. Given that the quasiparticle band gap is ∼3.2 eV, the *e-h* binding energy is about 1.2 eV, which is about two orders of magnitude larger than that of bulk silicon (∼14 meV). Two reasons contribute to this enhanced *e-h* interaction: (1) The result in Fig. 4b is for a suspended thin SiNW. In such a free-standing 1D structure, most electric field lines are outside. Consequently, the overall dielectric screening is much weaker than that of bulk structures. (2) The thin SiNW effectively confines electrons and holes within a 1D geometry that physically enhances their proximity. For example, 1D hydrogen model with a bare Coulomb interaction will give a bound state with infinite binding energy. This has been noticed in understanding enhanced excitonic effects of free-standing CNTs (Spataru et al. 2004a).

When both the joint density of states (JDOS) of single particles and the DOS of excitons are plotted in Fig. 4c, the excitonic effect shifts the DOS by about 0.3 eV, which is different from the DOS in bulk silicon (Fig. 3b). Compared with the enhanced *e-h* binding energy of the exciton between the VBM and CBM, the small shift of DOS indicates that, despite enhanced *e-h* interactions, most excitonic states do not have a large *e-h* binding energy. From the substantial change of optical absorption spectrum shown in Fig. 4a, b, one can infer that the optical absorptions spectrum is dictated by a small number of excitons having both large *e-h* binding energies and significant optical oscillator strength.

SiNWs have lower symmetries than bulk Si. In contrast to the isotropic optical absorption spectrum of bulk silicon, anisotropic optical spectra of SiNWs have been reported at the level of single-particle absorption (Zhao et al. 2004). A notable excitonic effect is that the *e-h* interactions can enhance the anisotropic response. As shown in Fig. 4d, the optical absorption spectra of the incident light with different polarization directions vary dramatically. The absorption spectrum for the incident light polarized vertically to the axial direction is strongly suppressed (Bruneval et al. 2005; Yang et al. 2007a). This feature is known as a "local field effect." A strong depolarization field is developed vertically to the axial direction because the wavelength of the incident photon is much larger than the diameter of nanostructures (Spataru et al. 2004b). The *e-h* exchange interaction is essential to capture this local field effect, as shown in Fig. 4d. On the other hand, such a highly polarized optical

response enhances the use of SiNWs and many other 1D semiconductors for optical and radio applications (Gudiksen et al. 2002; Dresselhaus 2004).

Because of the **strong** *e-h* interaction, the quasiparticle band gap and the energy of the optical absorption edge (the so-called optical band gap) are significantly different. In bulk semiconductors with direct band gaps, the optical band gap is nearly the same as the quasiparticle (transport) band gap owing to the weak *e-h* binding energy. However, in this 1.2-nm SiNW, the quasiparticle band gap is about 3.2 eV while the "optical band gap" is about 2.0 eV (the energy of the lowest-energy exciton). Therefore, it is necessary to differentiate these two concepts before studying **the** electronic structure of nanomaterials.

The electronic self-energy correction increases the quasiparticle band gap while enhanced *e-h* interactions contribute to large exciton binding energies, which substantially redshift the optical absorption spectrum. Both effects are significant, but they affect the final optical spectrum in opposite directions, which results in some cancellation. Significant absorption peaks remain around the 3∼5-eV range for a SiNW with a diameter of as small as 1.2 nm (Yang et al. 2007a). This energy range of the significant optical absorption spectrum calculated by the GW-BSE approach is similar to the DFT/LDA result, although the profiles of optical spectra and the physics behind are very different.

2.4 Exciton Spectrum and Fine Structure

An analysis of the sequence of *e-h* binding energies forms the foundation for constructing simple models that are widely employed to understand excitonic effects in nanostructures. For example, the *e-h* binding energy of monolayer WS_2 can be extrapolated from the measured sequence of exciton peaks according to a non-hydrogenic energy series (Chernikov et al. 2014). The role of quantum confinement on exciton spectra and corresponding *e-h* models of 1D SiNWs (Zhang et al. 2011b) are of fundamental interest.

The most interesting excitons are those associated with transitions between the CBM and VBM around the Γ point in the SiNW. Since the CBM and VBM have quadratic dispersions, a hydrogenic model based on the effective mass approximation should accurately describe the sequence of band-edge excitons. First-principles BSE calculations have identified four bound excitons which are labeled as A_1, A_2, A_3, and A_4. They are associated with transitions around the band edges at the zone center. The binding energies of these excitons are plotted in Fig. 5a and also a fitting using a hydrogenic-like model (dashed line), namely **scaling** as $1/n^x$, where *n* is the main quantum number. The fitting exponent x turns out to be 1.8 (Yang et al. 2007a), which is surprisingly close to the value **2** of the hydrogenic model. This hydrogen-like exciton spectrum is helpful for the modeling of e-h pairs in other 1D semiconducting structures thus avoiding expensive first-principles simulations.

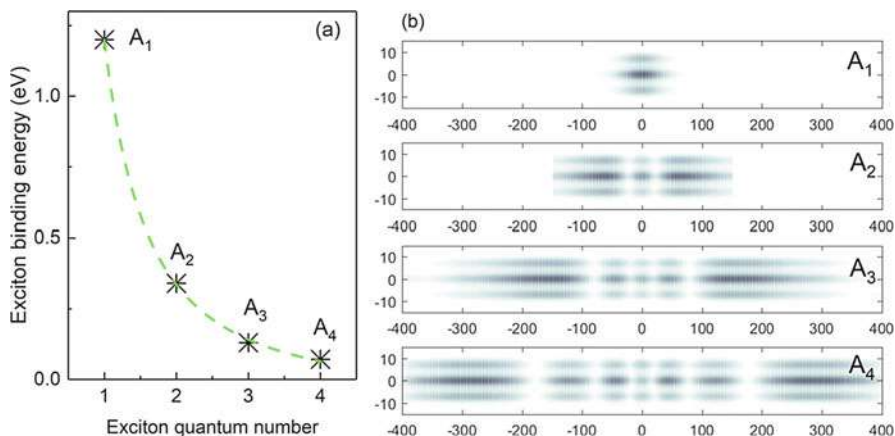
In Fig. 5b, excitonic wavefunctions of these four states are plotted in real space. According to Eq. (3), an exciton is a two-body excitation with six spatial degrees


Fig. 5 (**a**) The *e-h* binding energy of excitons relative to the band edge around the Γ point. The green dash line is the fitting curve. (**b**) The real-space excitonic wavefunctions. The hole is fixed at the center of each plot. The length unit is the Bohr radius

of freedom. In Fig. 5b, the hole position is fixed at the center of the figures, and the corresponding electron wavefunction is plotted. As the quantum number increases, more nodal structures develop along the wire direction, in a way similar to the 1 s, 2 s, 3 s, and 4 s of hydrogenic states. This similarity confirms that the sequence of excitonic levels can be described by hydrogen-like models, despite the role of quantum confinement.

Enhanced singlet-triplet splitting: When an exciton **forms**, the spins of the electron and the hole may have various configurations. If the total spin is zero, the exciton is in the spin-singlet state; if the total spin is one, the exciton is in the spin-triplet state. The energy difference between singlet and triplet excitons is determined by the bare-exchange interaction between the electron and hole wavefunctions. The singlet-triplet (exchange) splitting dictates many important optical properties of nanomaterials (An et al. 2007; Srivastava et al. 2008). For instance, the spin-singlet exciton can be optically bright and exhibits a shorter radiative lifetime whereas the spin-triplet exciton is optically dark and exhibits a longer radiative lifetime. In SiNWs with strong quantum confinement, the *e-h* exchange interaction is increased by the enhanced overlap between electron and hole wavefunctions. Using a first-principles BSE approach, the enhancement of the singlet-triplet energy splitting is calculated to be as large as 90 meV (Palummo et al. 2010b) in thin SiNWs, while that of bulk silicon is less than 5 meV.

2.5   Extrinsic Factors and "Cancellation" Effect

Substrates and encapsulations used in fabricating nanostructures may change the role of excitonic effects in nanostructures. Studies have shown that these supporting

Interlayer Interactions in Low-Dimensional Layered Hetero-structures: Modeling and Applications

29

Oded Hod

Contents

Abstract

The field of nanoscale material science has experienced a true revolution over the past 30 years with the discovery of the quasi-zero- and one-dimensional cage-like structures of fullerenes and nanotubes. The successful isolation of graphene about a century ago has further triggered an avalanche of studies unraveling its unique physical and chemical properties. This, in turn, has led to numerous breakthroughs of basic science nature as well as diverse potential technological applications in the fields of nanoscale electronics, flexible displays, solar cells, DNA sequencing, chemical sensing, composite materials, solid lubrication, and many others.

Following extensive studies of the properties of graphene, much attention was recently paid to other members of the two-dimensional (2D) hexagonal layered materials family including hexagonal boron nitride (*h*-BN) and several transition metal dichalcogenides. Interestingly, stacking individual layers of these materials to form homogeneous and heterogeneous structures results in unique

physical characteristics that depend on the specific chemical composition of the system and can be tuned via the application of external perturbations. This opens numerous opportunities for combinatorial materials design with versatile structure-function relations. Understanding what determines the properties of such complex structures and how to control them remains a challenge yet to be met in order for these materials to fulfill their full potential.

Theory and computation may offer a valuable microscopic perspective toward achieving this goal. The reduced-dimensions of materials at the nanoscale allow for a unique interplay between theory, computation, and experiment. Here, accurate fully atomistic simulations can complement experiments both in analyzing and rationalizing experimental results and in providing reliable predictions that can minimize the need for demanding trial and error experimental efforts.

Such theoretical treatments of 2D materials require special attention to their anisotropic nature characterized by a strong in-plane covalent bonding network and weaker interlayer interactions. While state-of-the-art quantum mechanical approaches can simultaneously describe these interactions with high accuracy, their computational demand often limits their applicability to relatively small systems. An efficient alternative can be provided by carefully tailored classical force-fields. When appropriately parameterized against experimental results or high accuracy calculations of small model systems, these can provide a reliable description of the structural, mechanical, tribological, and heat transport properties of realistic nanoscale systems with atomic scale resolution. Such force-fields that provide a proper description of intralayer interactions in a variety of 2D materials have been developed over the years and are accessible via standard molecular dynamics simulation codes. Surprisingly, despite the great scientific interest in 2D layered materials, complementary interlayer force-fields that can accurately capture both their binding and sliding energy landscapes are currently available for a very limited set of systems.

In the present chapter, I provide a brief review of recent developments of reliable, efficient, and transferable anisotropic interlayer force-fields for homogeneous and heterogeneous low-dimensional hexagonal layered materials. To demonstrate the performance of these methods, a few applications to the study of the structural and tribological properties of quasi-one- and quasi-two dimensional layered structures will be presented.

1   Introduction

The successful isolation of graphene, a one atom thick hexagonal carbon layer, by Novoselov and Geim in 2004 marked the opening of a new era in materials science (Novoselov et al. 2004; Geim and Novoselov 2007; Li and Kaner 2008; Geim 2009; Rao et al. 2009). The study of its unique physical properties including exceptional mechanical strength (Lee et al. 2008), superlubric tribological characteristics (Dienwiebel et al. 2004; Koren et al. 2015), remarkable room temperature electron mobilities (Novoselov et al. 2005a; Morozov et al. 2008), high thermal

conductivity (Balandin et al. 2008; Cai et al. 2010; Xu et al. 2014), quasi-relativistic electronic structure (Geim and Novoselov 2007), and controllable optical properties is flourishing even more than a decade later. Nevertheless, despite this wealth of outstanding material characteristics, the semi-metallic nature of graphene limits its applicability in switchable nanoscale electronic devices. This has triggered the scientific community to search for graphene alternatives within the diverse family of layered inorganic materials (Novoselov et al. 2005b, 2016; Deng et al. 2016).

Currently, two-dimensional (2D) inorganic materials are at the forefront of scientific research with an ever-growing number of chemical compositions including hexagonal boron nitride (*h*-BN), germanene, silicene, phosphorene, transition metal dichalcogenides, such as molybdenum and tungsten disulfide (*2H*-MoS_2 and *2H*-WS_2) and diselenide (*2H*-$MoSe_2$ and *2H*-WSe_2), among others (Heine 2015; Li and Zhu 2015). Similar to graphene, these materials exhibit diverse physical properties and appear in many structural forms ranging from planar configurations to nanotubes, scrolls, onions, and cones.

The recently demonstrated ability to stack such 2D materials in homogeneous as well as heterogeneous few-layered structures (Novoselov et al. 2016; Deng et al. 2016; Dean et al. 2010; Geim and Grigorieva 2013; Wang et al. 2014; Das et al. 2015) opens a vast combinatorial material space enabling the design of novel structures exhibiting desired physical properties. Furthermore, electromechanical manipulation of such structures can be used to gain control over their physical properties – a basic requirement for their future technological application (Koren et al. 2015, 2016; Leven et al. 2013).

Here, theory and computation play a prominent role in efficiently scanning the vast material space, identifying potential candidates that are expected to exhibit the desired physical properties, and studying their sensitivity towards external perturbations. This can focus the demanding experimental efforts on a selected group of predesigned structures and increase the probability of obtaining the required 2D material functionality. Moreover, a synergic cooperation between theory, computation, and experiment, where experimental data are used to refine theoretical models and computational algorithms that, in turn, provide more accurate predictions, can formulate a feedback cycle that will considerably enhance the efficiency of 2D materials design.

An accurate theoretical account of the physical and chemical properties of layered (and other) materials requires a full quantum mechanical treatment of their electronic structure. Computational methodologies that may provide such ultimate accuracy include wave function-based configuration interaction or coupled clusters methods as well as quantum Monte-Carlo procedures (Nightingale and Umrigar 1999; Pang 2016). These methods, however, are quite unfavorable in terms of the scalability of their computational burden with system size and are hence limited to very small molecular structures. Green's function-based methods that can efficiently sum high-order terms in a perturbative expansion scale better with system size and hence can treat somewhat larger systems (Sakai et al. 2015). Density functional theory (DFT) (Hohenberg and Kohn 1964; Kohn and Sham 1965) is currently probably the most popular method to study the physical properties of large systems

(Sakai et al. 2015). While being exact in principle, its practical approximations provide a good balance between computational efficiency and accuracy. Nowadays, DFT calculations of material properties involving hundreds of atoms are being routinely performed in many research groups (Barone et al. 2011). If one desires to treat even larger systems on a fully atomistic and quantum mechanical basis, accuracy is often further compromised to gain computational efficiency. Here, methods like the variational Hartree-Fock formalism (Szabo and Ostlund 1989), semi-empirical approaches (Pople 1970), density functional based tight-binding approximations (Porezag et al. 1995; Kwon and Tománek 2000; Miró et al. 2013; Zahid et al. 2013), or empirical tight-binding (Szabados et al. 2006; Carlson and Dumitrică 2007) can be used to provide approximate descriptions of 2D material properties.

Often, however, a fully quantum mechanical treatment is not required and a much simplified classical picture is sufficient to efficiently and accurately describe many material properties. Specifically, when considering static structural and mechanical properties of various materials (Chen et al. 2013; Butz et al. 2014; van Wijk et al. 2015) as well as their dynamic tribological (Guo et al. 2007; Guerra et al. 2010; Reguzzoni et al. 2012a; Vanossi et al. 2013; van Wijk et al. 2013; Xu et al. 2013; Ze 2014; Kang and Lee 2014) and heat transport characteristics (Jiang 2014a), Newtonian dynamics with carefully designed force-fields (FF) can provide valuable insights (Frenkel and Smit 2002; Allen and Tildesley 2009; Rapaport 2009). Obviously, this results in considerable computational gain enabling the treatment of extremely large atomistic models including tens of thousands of atoms for relatively long timescales. Furthermore, it allows for devising multiscale approaches, where the information gained from fully atomistic calculations serves to design coarse-grained and continuum models. Nevertheless, this comes at the expense of neglecting explicit quantum mechanical effects and even more importantly the need to design system specific interatomic potentials with limited transferability.

With this respect, the formulation of dedicated force-fields for 2D materials and their layered constructs has to account for their inherent structural anisotropy. The individual layers can be viewed as a network of covalently bonded atoms organized in a periodic hexagonal lattice structure. Upon stacking, each layer interacts with its neighboring counterparts via long-range dispersion and electrostatic interactions. Hence, a strategy involving a separate treatment of intralayer and interlayer interactions is often invoked.

2   Intralayer Interactions

The intralayer force-field term usually involves six main ingredients including (see Fig. 1): (http://cbio.bmt.tue.nl/pumma/index.php/Theory/Potentials; Rappe et al. 1992) (i) bonded two-body interactions describing the bond stretching and compression energy; (ii) bonded three-body interactions accounting for angle bending penalties; bonded four-body interactions depicting (iii) improper and (iv) dihedral
Fig. 1 Illustration of several intralayer force-field term contributions: (**a**) Bond stretching and compression; (**b**) angle bending; (**c**) improper angle deformation; (**d**) torsional angle deformation; (**e**) van der Waals interactions; (**f**) electrostatic interactions

torsional deformations; (v) nonbonded van der Waals (vdW) interactions; and (vi) nonbonded electrostatic interactions.

The first two components are often represented by simple harmonic springs of the form $V_{ij}^{(i)}\left(r_{ij}\right) = k_{ij}\left(r_{ij} - r_{ij}^0\right)^2$ and $V_{ijk}^{(ii)}\left(\theta_{ijk}\right) = k_{ijk}\left[\cos\left(\theta_{ijk}\right) - \cos\left(\theta_{ijk}^0\right)\right]^2$. Here, r_{ij} is the distance between atomic center i and j, θ_{ijk} is the angle defined by atomic centers i, j and k (see Fig. 1a, b), r_{ij}^0 and θ_{ijk}^0 are the equilibrium ij pair interatomic distance and ijk triad angle, respectively, and k_{ij} and k_{ijk} are the corresponding force constants. Improper torsion is often also described by a harmonic potential of the form $V_{ijkl}^{(iii)}\left(\delta_{ijkl}\right) = k_{ijkl}^{(iii)}\left(\delta_{ijkl} - \delta_{ijkl}^0\right)^2$, δ_{ijkl} being the improper angle (see Fig. 1c) and $k_{ijkl}^{(iii)}$ and δ_{ijkl}^0 being the corresponding force constant and equilibrium improper angle, respectively. Dihedral angle torsion can be depicted by a periodic potential of the form $V_{ijkl}^{(iv)}\left(\phi_{ijkl}\right) = k_{ijkl}^{(iv)}\left[1 + \cos\left(\eta_{ijkl}\phi_{ijkl} - \phi_{ijkl}^0\right)\right]$, where ϕ_{ijkl} is the dihedral angle (see Fig. 1d), $k_{ijkl}^{(iv)}$ is the corresponding force constant, ϕ_{ijkl}^0 sets the equilibrium dihedral angle, and η_{ijkl} is the multiplicity factor signifying the number of minima that this potential term possesses. The nonbonded vdW term is often described by the two-body Lennard-Jones (LJ) potential of the form $V_{ij}^{(v)}\left(r_{ij}\right) = 4\epsilon_{ij}\left[\left(\sigma_{ij}/r_{ij}\right)^{12} - \left(\sigma_{ij}/r_{ij}\right)^6\right]$ where ϵ_{ij} and $\sqrt[6]{2}\sigma_{ij}$ are the binding energy and equilibrium distance of the ij atomic pair, respectively (see Fig. 1e). Note that this expression accounts not only for the long-range attractive vdW interactions but also for short-range repulsions. Finally, interatomic monopolar electrostatic interactions are calculated using Coulombs law $V_{ij}^{(vi)}\left(r_{ij}\right) = q_i q_j/\left(4\pi\epsilon_0 r_{ij}\right)$, where ϵ_0 is the vacuum permittivity and q_k is the effective partial charge of atom k (see Fig. 1f).

It should be noted that while the expressions described above are commonly used to describe the intralayer interactions in layered materials they are, by no means, the only ones available. For example, if a reactive force-field is required, the harmonic bonded two-body terms can be replaced by an anharmonic potential that allows for bond breaking and formation. Furthermore, the force-field parameters can be varied according to the local chemical environment, thus providing flexibility to describe different bond-orders and accounting for various chemical binding schemes.

The various force-field parameters have to be determined separately for each material. The fitting procedure can be performed against experimentally measured material properties, such as the Young modulus, the shear modulus, lattice constants, phonon spectra, and heats of formation. Alternatively, they can be calibrated to fit results of higher accuracy methods such as state-of-the-art DFT calculations. Dedicated intralayer force-field parameterizations are available for a variety of layered materials including graphene and its derivatives (Al-Jishi and Dresselhaus 1982; Tersoff 1988; Brenner 1988, 1990; Stuart et al. 2000; Brenner et al. 2002; Los and Fasolino 2003; Ghiringhelli et al. 2005a, 2008; Los et al. 2005; Perebeinos and Tersoff 2009; Lindsay and Broido 2010; Jiang 2015; O'Connor et al. 2015), h-BN (Sevik et al. 2011), and $2H$-MoS$_2$ (Jiang 2015; Wakabayashi et al. 1975; Jiménez Sandoval et al. 1991; Brunier et al. 1992; Morita et al. 2008; Liang et al. 2009; Varshney et al. 2010; Jiang et al. 2013; Nicolini and Polcar 2016), many of which are implemented in open source or commercial software packages. These have been successfully used to describe a variety of material properties including the structural and mechanical behavior (Tersoff 1992; Lu 1997; Hertel et al. 1998; Fasolino et al. 2007; Bets and Yakobson 2009; Costamagna et al. 2012; Singh et al. 2013, 2015; Bucholz and Sinnott 2013; Jin-Wu et al. 2013; Jiang 2014b; Jiang and Park 2014), thermal transport characteristics (Varshney et al. 2010; Che et al. 2000; Mohamed and Deepak 2001; González Noya et al. 2004; Yao et al. 2005; Lindsay and Broido 2011), crack propagation (Xiaonan et al. 2015), and melting dynamics of 2D monolayers (Singh et al. 2015).

3   Interlayer Interactions

The interlayer force-field term usually involves three main contributions: long-range attractive vdW interactions, short-range Pauli repulsions, and electrostatic interactions. The latter, which is required when atoms in different layers have a sizable partial charge, can often be described by a simple Coulombic term similar to the $V_{ij}^{(vi)}$ intralayer expression given above (see Fig. 1f). To describe the attractive vdW and repulsive Pauli interactions, the LJ (or Morse (Los and Fasolino 2003; Los et al. 2005; Ghiringhelli et al. 2005b; Karssemeijer and Fasolino 2011)) potential is often chosen similar to the intralayer $V_{ij}^{(v)}$ expression (see Fig. 1e) (Nicolini and Polcar 2016; Lebedeva et al. 2011a; Shibuta and Elliott 2011; Ye et al. 2012, 2015; Jayasena et al. 2013; Liu et al. 2015; Kushima et al. 2015). With appropriate parameterization, this expression can provide a good description of the interlayer
Fig. 2 Anisotropic Pauli repulsion term: (**a**) illustration of the anisotropic p_z orbital overlap variations during interlayer sliding; (**b**) definition of the lateral interatomic distance; (**c**) definition of the local surface normal. binding energy curve (Szabados et al. 2006; Jiang 2015; Brunier et al. 1992; Varshney et al. 2010; Jiang et al. 2013; Lu 1997; Bucholz and Sinnott 2013; Jiang and Park 2014; Singh et al. 2015; Girifalco and Lad 1956; Green et al. 1974; Weiss and Phillips 1976; Kuzuba et al. 1985; Lu et al. 1992; Tersoff and Ruoff 1994; Kwon and Tománek 1998; Buldum and Lu 1999; Girifalco et al. 2000; Girifalco and Hodak 2002; Qian et al. 2003; Michel and Verberck 2011; Tolga et al. 2016). However, using the same parameters to study relative interlayer sliding fails to reproduce the corrugated sliding energy landscape and results in too shallow energy barriers (Carlson and Dumitrică 2007; Stuart et al. 2000; Palser 1999; Kolmogorov and Crespi 2000, 2005; Shtogun and Woods 2010; Lebedeva et al. 2011b; Reguzzoni et al. 2012b; Neek-Amal and Peeters 2014; Strutyński et al. 2014; Korhonen and Koskinen 2015; Jiang and Park 2015). Hence, the ability of LJ type potentials to reliably describe many structural, mechanical, and tribological properties of layered materials may be considerably hindered.

The origin of this deficiency in the LJ potential was identified by Kolmogorov and Crespi (KC) to be the use of isotropic expressions that depend only on interatomic distances to describe an anisotropic material property (Kolmogorov and Crespi 2000, 2005; Lebedeva et al. 2011b). Focusing on graphene, KC realized that when two layers slide upon each other, electron clouds associated with the p_z orbitals around carbon atoms residing on adjacent layers overlap as the atoms pass each other (see Fig. 2a). This, in turn, induces Pauli repulsion variations resulting in a corrugated sliding energy landscape. Since the electron density overlap depends on the lateral distance between the crossing atoms, an interlayer pair-potential of the following form was suggested (Kolmogorov and Crespi 2005):

$$V^{KC}(r_{in}, \rho_{in}) = e^{-\lambda(r_{in}-z_0)}\left[C + f(\rho_{in}) + f(\rho_{ni})\right] - A(r_{in}/z_0)^{-6}. \qquad (1)$$

This expression includes a LJ type long-range attractive term scaled by $A = 10.238$; an isotropic Morse-like short-range exponential repulsive term with the equilibrium interlayer distance $z_0 = 3.34$ Å, exponent $\lambda = 3.629$ Å^{-1}, and scaling factor $C = 3.030$; and an anisotropic short-range Gaussian repulsive term of the form $f(\rho) = e^{-(\rho/\delta)^2} \Sigma_n c_{2n}(\rho/\delta)^{2n}$ that depends on the lateral distance, ρ,

between each pair of atoms on adjacent layers scaled by $\delta = 0.578$ Å. The nonzero coefficients of the polynomial multiplying the Gaussian are given by $c_0 = 15.71$, $c_2 = 12.29$, and $c_4 = 4.933$. The lateral distance, ρ_{in}, is defined as the shortest distance between atom n on one layer and the surface normal at atom i residing on an adjacent layer (see Fig. 2b). For a hexagonal lattice, the simplest definition of the local surface normal at a given atomic position is the unit vector perpendicular to the triangle formed by its three nearest neighbors (see Fig. 2c). Since for curved systems generally $\rho_{in} \neq \rho_{ni}$ the pair potential is symmetrized to fulfill Newton's third law. With the inclusion of the anisotropic repulsive term, the KC potential was shown to simultaneously provide a good description of both interlayer binding and sliding energy landscapes (see Fig. 3) (Kolmogorov and Crespi 2000, 2005; Reguzzoni et al. 2012b).

Despite this notable success and the ever growing interest in 2D materials, the KC approach (and related methods (Lebedeva et al. 2011b, 2012; Popov et al. 2011)) has not been extended to describe other layered materials for more than a decade since its inception. Recently, however, the transferability of the method was demonstrated where a KC type potential was applied to the graphene/h-BN hetero-structure (van Wijk et al. 2014; Woods et al. 2016). In this study, the FF parameters have been set to reproduce experimentally observed moiré superstructures arising from the 1.8% intralayer lattice constant mismatch between graphene and h-BN. This indicated the ability of the KC force-field to describe the structural properties of homogeneous and heterogeneous junctions of 2D materials.

To harness the full predictive capabilities of KC-type FFs to describe the interlayer interactions in a variety homogeneous and heterogeneous layered materials structures, a slightly modified functional form, termed interlayer potential (ILP), was recently suggested. The ILP accounts for monopolar electrostatic interactions and allows for simple parameterization against state-of-the-art first-principles calculations based on pair-wise (Tkatchenko and Scheffler 2009; Marom et al. 2011) and many-body dispersion corrected (Tkatchenko et al. 2012; Ambrosetti et al. 2014) screened-hybrid (Heyd et al. 2003; Heyd and Scuseria 2004a, b) density functional theory calculations (Leven et al. 2014, 2016a; Maaravi et al. 2017; https://pubs.acs.org/doi/10.1021/acs.nanolett.8b02848).

The ILP consists of a modified KC **short-range anisotropic repulsive term** of the form:

$$V_{Rep}(r_{in}, \rho_{in}) = \text{Tap}(r_{in}) \times e^{\alpha_{in}\left(1 - \frac{r_{in}}{\beta_{in}}\right)} \left[\varepsilon_{in} + C_{in} \left(e^{-\left(\frac{\rho_{in}}{\gamma_{in}}\right)^2} + e^{-\left(\frac{\rho_{ni}}{\gamma_{in}}\right)^2} \right) \right], \qquad (2)$$

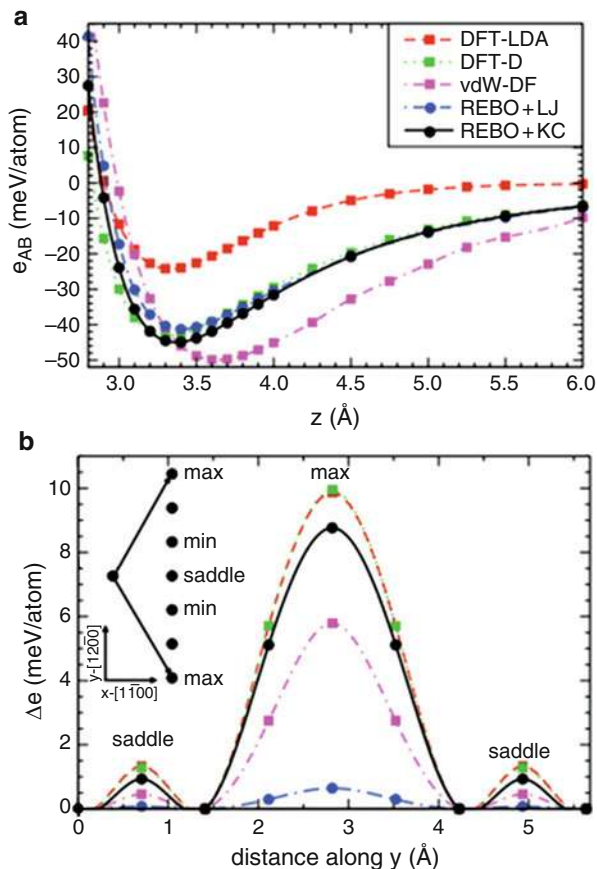
where ε_{in} and C_{in} are constants setting the energy scales associated with the isotropic and anisotropic repulsion, respectively, β_{in} and γ_{in} set the corresponding interaction ranges, and α_{in} is a parameter defined to set the steepness of the isotropic repulsion term. Note that for computational efficiency, the 4th degree polynomial multiplying the anisotropic Gaussian repulsion term appearing in the original KC expression (see Eq. (1) above)


Fig. 3 Interlayer (**a**) binding and (**b**) sliding energy curves of bilayer graphene calculated using the LJ (full blue circles) and KC (full black circles) interlayer potentials compared to a reference dispersion corrected DFT calculation (full green squares). is replaced by a constant factor. Furthermore, a taper function of the form $\text{Tap}(r_{in}) = 20(r_{in}/R_{cut})^7 - 70(r_{in}/R_{cut})^6 + 84(r_{in}/R_{cut})^5 - 35(r_{in}/R_{cut})^4 + 1$, which provides a continuous (up to third derivative) cutoff for interatomic separations exceeding R_{cut}, is used to damp the long-range contribution of the repulsive term. These modifications simplify the FF expressions and reduce the computational cost while providing a satisfactory description of the interlayer interactions (Leven et al. 2014, 2016a; Maaravi et al. 2017).

To treat the **long-range attractive interactions,** the Tkatchenko and Scheffler (TS) dispersion correction scheme to DFT is considered (Tkatchenko and Scheffler 2009). Within this approach, widely used semi-local or hybrid exchange-correlation density functional approximations that are known to provide an inadequate

description of long-range van der Waals (vdW) interactions are augmented by a term that decays asymptotically with the interatomic distance as r^{-6}. This term is damped at short distances to avoid double-counting of short-range correlation effects. In the ILP, the following pair-wise long-range attractive term is adopted:

$$V_{Att}\left(r_{in}\right) = \text{Tap}\left(r_{in}\right)\left\{-\left[1 + e^{-d\left[\left(r_{in}/\left(S_R \cdot r_{in}^{eff}\right)\right)-1\right]}\right]^{-1} \cdot \frac{C_{6,in}}{r_{in}^6}\right\}. \tag{3}$$

Here, r_{in}^{eff} is the sum of effective equilibrium vdW atomic radii of atom i and atom n residing on different layers, $C_{6,in}$ is the pair-wise dispersion coefficient of the two atoms in the solid-state environment, and d and S_R are unit-less parameters defining the steepness and onset of the short-range Fermi-Dirac type damping function. Similar to the repulsive term, long-range taper damping is implemented to reduce computational burden. This specific form is chosen as it allows the extraction of the various parameters directly from first-principles calculations avoiding the need for experimental data that is macroscopic by nature, very difficult to obtain, and mostly unavailable for many 2D layered materials and hetero-structures thereof.

In cases where atoms residing on the interacting layers bear sizable effective charges, electrostatic contributions should be taken into account. To this end, the formalism implemented in the ReaxFF scheme can be utilized (van Duin et al. 2001). Within this approach, a shielded Coulomb potential term of the form:

$$V_{Coul}\left(r_{in}\right) = \text{Tap}\left(r_{in}\right) \times \left[kq_iq_n/\sqrt[3]{r_{in}^3 + (1/\lambda_{in})^3}\right] \tag{4}$$

is used. Here, k is Coulomb's constant and λ_{in} is a shielding parameter introduced to eliminate the short-range singularity of the classical monopolar electrostatic interaction expression. This shielding takes effect in regions where Pauli repulsions between overlapping electron clouds dominate the interlayer potential and hence has minor influence on the results. When considering periodic systems, the long-range taper cutoff can be replaced by Ewald summation techniques (Ewald 1921; Toukmaji and Board 1996) in order to avoid conditionally convergent sums (Hod 2012a).

In many cases, the effective ionic charges, q_i and q_n, can be treated as constant values throughout the simulation. Nevertheless, in order to provide a general description, they can be dynamically evaluated using the electronegativity equalization method (EEM) (van Duin et al. 2001; Mortier et al. 1986; Njo et al. 1998; Bultinck et al. 2002). This method relies on a principle formulated by Sanderson stating that when a molecule or a solid is formed, the electronegativities of the constituent atoms equalize to give a global electronegativity of the entire system (Sanderson 1951, 1983). Hence, the electronegativity of a given atom within the molecular or solid environment (χ_i) is written in terms of the corresponding isolated atom electronegativity (Parr et al. 1978) $\left(\chi_i^0\right)$ and hardness (Parr and Pearson 1983; Sanderson 1976) $\left(\eta_i^0\right)$ as $\chi_i = \left(\chi_i^0 + \Delta\chi_i\right) + 2\left(\eta_i^0 + \Delta\eta_i\right)q_i +$

$\sum_{j\neq i} kq_j / \sqrt[3]{r_{ij}^3 + (1/\lambda_{ij})^3}$. Here, $\Delta\chi_i$ and $\Delta\eta_i$ represent the electronegativity and hardness variations due to the embedding molecular or solid environment and the last term represents the electrostatic potential induced by all other atoms in the system (Weismiller et al. 2010). The effective atomic charges can then be obtained by enforcing the guiding principle that within the molecular or solid environment all atomic electronegativities should equal the equilibrated molecular electronegativity $\chi_{i=1...N} = \chi_{eq}$. To this end, the following matrix equation is solved:

$$
\begin{pmatrix}
2\left(\eta_1^0 + \Delta\eta_1\right) & k/\sqrt[3]{r_{12}^3 + (1/\lambda_{12})^3} & \cdots & k/\sqrt[3]{r_{1N}^3 + (1/\lambda_{1N})^3} & -1 \\

where the isolated atomic electronegativities and hardnesses, χ_i^0 and η_i^0, their corresponding molecular or solid environment variations $\Delta\chi_i$ and $\Delta\eta_i$, and the total charge, Q, are provided as input. The latter is dictated by the modeled system, whereas the former are used as fitting parameters.

While originally parameterized for homogeneous h-BN and graphene junctions (Leven et al. 2014; Maaravi et al. 2017), as well as for heterogeneous junctions thereof (Leven et al. 2016a), with appropriate parameterization the ILP should be transferable to a variety of layered materials such as different graphene allotropes including pentaheptite, haeckelite, dimerite, and octite (David et al. 2010); graphane; graphyne; germanene; silicene; stanene; phosphorene; and members of the transition metal dichalcogenides family such as molybdenum and tungsten disulfide and diselenide. As demonstrated in the next section, such an extension will make the ILP a versatile and powerful simulation tool for the study of the structural, mechanical, dynamic, and heat transport properties of homogeneous and heterogeneous layered material structures.

4   Applications

An illustrative demonstration of the performance of classical ILPs for studying interlayer interactions in layered materials is the case of the graphene/h-BN heterojunction. This heterojunction has gained great attention from the scientific community in recent years (Geim and Grigorieva 2013; Wang et al. 2014; Das et al. 2015; Leven et al. 2016a) due to its rich physical properties that include a controllable electronic band-gap (Chen et al. 2014; Fan et al. 2011; Jung et al. 2015; Yankowitz et al. 2012), ultrahigh electron mobility (Dean et al. 2010; Levendorf et al. 2012; Tang et al. 2013), the demonstration of Hofstadter's butterfly

phenomenon (Ponomarenko et al. 2013; Dean et al. 2013), and the manifestation of controllable hyperbolic meta-material characteristics (Dai et al. 2015).

Owing to the intrinsic lattice-constant mismatch between graphene and *h*-BN, the former tends to deform when placed on a multilayer *h*-BN substrate in order to adapt to the underlying crystal lattice (van Wijk et al. 2014; Yankowitz et al. 2012; Dean et al. 2013; Yang et al. 2013; Woods et al. 2014). The resulting moiré superstructures alter graphene's electronic and optical properties thus opening new opportunities for technological applications (Jung et al. 2015; Kumar et al. 2015). Naturally, modeling such superstructures from first-principles is a prohibitively demanding task. This, in turn, calls for the utilization of classical ILPs.

Figure 4 presents the fully relaxed structure of a free-standing graphene/*h*-BN bilayer supercell calculated using the graphene/*h*-BN ILP (Leven et al. 2016a). A clear moiré superstructure is obtained (see panel (d)), where regions of optimal interlayer registry (blue regions in panel (a)) and distance (blue regions in panel (b)) and intralayer bond lengths (red regions in panel (c)) are separated by sharp domain walls characterized by increased interlayer distance and compressed intralayer bond lengths in accordance with experimental findings (Yankowitz et al. 2012; Woods et al. 2014). Furthermore, due to the lack of rigid support, the calculation predicts that the entire structure should become highly corrugated. This latter observation was recently verified experimentally (Argentero et al. 2017).

Such moiré superstructures are expected to have considerable effect on the tribological properties of the heterojunctions. To investigate this, the graphene/*h*-BN ILP (Leven et al. 2016a) has been recently used to simulate the frictional
Fig. 4 Fully relaxed graphene/*h*-BN free-standing bilayer. (**a**) Local registry index map, where blue and red colors represent optimal and worst interlayer stacking, respectively. The calculation is performed using the registry index method that defines a purely geometric quantitative measure of interlattice commensurability (Leven et al. 2013, 2016a; Koren et al. 2016; Marom et al. 2010; Hod 2010, 2012b, 2013; Blumberg et al. 2012; Garel et al. 2012; Oz et al. 2016; Leven et al. 2016b); (**b**) interlayer distance map; (**c**) graphene intralayer bond-length map; and (**d**) overall structure of a fully relaxed, free-standing, graphene/*h*-BN bilayer. behavior of the heterojunction (Mandelli et al. 2017). It was found that for the aligned interface (where the lattice vectors of the two layers are parallel), with contact size below the characteristic lateral dimension of the elevated superstructure ridges, the junction behaves like its homogeneous counterparts with friction forces that grow linearly with the contact area. Superlubricity sets in due to the progressive appearance of moiré patterns resulting in a transition to collective stick-slip motion of the ridges that eventually turns into smooth soliton-like sliding with increasing contact size (see Fig. 5). For angularly misaligned contacts (where the lattice vectors of the two layers are rotated with respect to each other), incommensurability effects, also appearing in homogeneous junctions, are enhanced and the friction coefficients further drop by orders of magnitude and remain extremely low, even under external loads. These simulations indicated the potential of achieving robust superlubricity, independent of the relative interfacial orientation, and sustainable under external loads, in practical applications utilizing two-dimensional layered materials heterojunctions.

A similar phenomenon is found to occur in homogeneous multiwalled nanotubes, where the lattice mismatch results from the curvature difference between adjacent nanotube walls. Due to the frustrated geometry of the tube's circumference, this may result in a pronounced faceted superstructure, where the circular cross-section is deformed into a more stable polygonal one (Garel et al. 2012, 2014; Liu and Cowley 1994; Gogotsi et al. 2000; Zhang et al. 2003, 2005; Celik-Aktas et al. 2005a; Golberg et al. 2007a, b; Nigues et al. 2014). For narrow nanotubes, the excessive stain involved in the formation of sharp vertices is not compensated by the energy gain of forming the planar facets; hence, faceting is suppressed. However, above a certain nanotube diameter, typically of 12 nm (Garel et al. 2012), the standard circular cross section can be strongly distorted and faceting may appear (see Fig. 6).

Here, as well, modeling such systems from first-principles is impractical and classical ILPs serve as a viable alternative for studying their structural and mechanical properties. Hence, to decipher the mechanism that underlies facet formation and dictates their character, elaborate geometry relaxations of a wide set of double-walled carbon and boron nitride nanotubes were performed (Leven et al. 2016b). It was found that regardless of the nanotube identity (namely, diameter, and chemical composition), chiral angle matching between adjacent layers is a necessary
Fig. 5 Snapshots of the soliton-like smooth sliding motion of the moiré superstructure ridges occurring upon shearing of a graphene/*h*-BN junction. (Reprinted with permission from Mandelli et al. (2017). Copyright (2017) American Chemical Society)
Fig. 6 Schematic representation of achiral double-walled carbon (top two rows) and boron-nitride (bottom two rows) nanotubes, showing their structure and local registry patterns prior to and after geometry relaxation. Each frame shows seven double-walled nanotubes with diameters in the range of 5–20 nm. Five groups of double-walled nanotubes are presented (from left to right): ZZ@ZZ $(n,0)@(n + 8,0)$; AC@AC $(n,n)@(n + 4,n + 4)$, $(n,n)@(n + 5,n + 5)$ and $(n,n)@(n + 6,n + 6)$; and ZZ@AC. For the ZZ@ZZ systems the $n = 55, 80, 105, 130, 155, 180$, and 243 nanotubes are chosen. For the AC@AC systems the $n = 31, 46, 60, 75, 89, 104$, and 140 are chosen. For the ZZ@AC systems, the following set is considered: $(54,0)@(36,36)$, $(80,0)@(51,51)$, $(104,0)@(65,65)$, $(130,0)@(80,80)$, $(154,0)@(94,94)$, $(179,0)@(108,108)$, and $(241,0)@(144,144)$. The local registry index color bar (right) ranges from blue to red, representing the optimal and worst stacking modes of graphene and h-BN, respectively. Grey, pink, and blue spheres on the right-hand-side represent carbon, boron, and nitrogen atoms, respectively. (Reprinted with permission from Leven et al. (2016b). condition for the formation of faceting. Considering first achiral nanotubes, where both nanotube walls are of the same type (either zigzag (ZZ) or armchair (AC)), it was found that above a critical diameter that corresponds well with experimental observations (Garel et al. 2012), evenly spaced extended axial facets form (see Fig. 6). Notably, the number of facets equals the interlayer difference in number of circumferential unit-cells. Interestingly, similar axial facets are formed also for mono-chiral double-walled nanotubes, where both nanotube walls are chiral but share the same chiral angle (see left column in Fig. 7). Elongated helical facets, similar to those commonly observed in experiment, appear in nanotubes that exhibit small interlayer chiral angle mismatch (see middle columns in Fig. 7). These are gradually suppressed with increasing interwall chiral angle difference resulting in outer layer corrugation, which is induced by the moiré superlattice, in agreement with experiments (Schouteden et al. 2013). Since multiwalled boron-nitride nanotubes exhibit better interwall chiral angle matching (Celik-Aktas et al.
Fig. 7 Schematic representation of (120,100)@(126,105) (leftmost column), (60,60)@(66,65) (second column), (70,70)@(77,74) (third column), (68,68)@(75,70) (fourth column), and (71,71)@(80,72) (rightmost column) double-walled boron-nitride nanotubes showing their local interlayer registry patterns before (top row) and after (middle row) geometry relaxation. The color bar on the right refers to the interlayer spacing of the different systems presented in the bottom row. The colors used in the local registry index patterns are the same as in Fig. 6 above. The chiral angle difference between the inner and outer shells is indicated at the top of each column. (Reprinted with permission from Leven et al. (2016b). Copyright (2016) American Chemical Society)

2005a; Golberg et al. 1999, 2000; Celik-Aktas et al. 2005b) than their carbon counterparts (Schouteden et al. 2013; Zuo et al. 2003; Li et al. 2003; Koziol et al. 2005; Hashimoto et al. 2005; Xu et al. 2006; Ducati et al. 2006; Hirahara et al. 2006; Gao et al. 2006; Guo and Guo 2007; Guan et al. 2008), these findings rationalize the experimental observation of relative abundance of faceting in the former (Celik-Aktas et al. 2005a, b; Golberg et al. 1999, 2000).

In resemblance to the effect of moiré structures on the interlayer sliding friction of planar interfaces, nanotube circumferential faceting is expected to have a notable impact on the interwall sliding friction. When the relative axial or angular alignment of adjacent nanotube walls is varied, the corresponding interwall lattice registry changes. If the nanotube is faceted, then this modification results in rearrangement of the faceted superstructure (Guerra et al. 2017). In the case of achiral or mono-chiral double-walled nanotubes, where the facets are axially aligned, a series of unfaceting and refaceting events occurs during the interwall motion accompanied by facet rotation and reconfiguration (see Fig. 8a, b). For bi-chiral systems, where helical facets appear, interwall telescoping results in rotation of the entire faceted superstructure akin to a rotating Archimedean screw (see Fig. 8c). These global structural variations introduce new dissipative channels that enhance interwall friction (Guerra et al. 2017). This, along with the above-mentioned fact that faceting is more abundant in multiwalled boron-nitride nanotubes than in their carbon counterparts, may rationalize recent experimental measurements showing that the former exhibit enhanced interwall friction (Nigues et al. 2014).
Fig. 8 Facet reconfiguration during interwall pull-out and rotation in (**a**) armchair (104,104)@(109,109); (**b**) zigzag (180,0)@(188,0); and (**c**) bichiral (70,70)@(77,74) double-walled boron-nitride nanotubes. θ, z, and Ψ values appearing in panels (**a**) and (**b**) indicate the relative angular and axial positions of the outer and inner walls and the corresponding facet rotation angle, respectively. The two configurations appearing in panel (**c**) have relative interwall angular and axial orientations of 0.2°/2.4 Å (left) and 0.2°/3.2 Å (right). These correspond to configurations close to the maximum and minimum of the interwall sliding-rotation potential energy surface, respectively. Red, white, and blue atom false coloring indicate low, average, and high atomic interlayer energy, respectively. (Reprinted with permission from Guerra et al. (2017). 5   Summary

Two-dimensional hexagonal layered materials are of the most promising systems in the field of material science to deliver new technological breakthroughs. The large variety of members in this family and their diverse chemical and physical properties form a vast playground for the design of homogeneous and heterogeneous systems presenting novel structure-function relations. The small dimensions characterizing this field of research call for a synergic interplay between experiment, theory, and computation. With this respect, carefully tailored classical force-field may provide valuable insights on the atomistic nature of different structural, mechanical,

dynamical, and tribological phenomena found in these systems. In the present chapter, a review of recent advances in the field of anisotropic force-fields for describing the interlayer interactions in hexagonal layered materials has been provided. The performance of such force-fields was demonstrated via several applications that address the structural and frictional properties of planar hetero-junctions of graphene and *h*-BN as well as faceted double-walled nanotubes. The good agreement obtained with several experimental observations indicates the predictive power of the developed interlayer force-fields and their ability to rationalize experimental results. The extension of such dedicated force-fields to treat other layered materials is an ongoing effort that, when fulfilled, is expected to enable the discovery of novel low-dimensional structures. Furthermore, the utilization of such force-fields within the framework of multiscale modeling as a source of reliable atomistic information for coarse grained and continuum treatments (Leven et al. 2013; Koren et al. 2016; Leven et al. 2016a; Jung et al. 2015; Kumar et al. 2015; Marom et al. 2010; Hod 2010; Hod 2012b; Blumberg et al. 2012; Garel et al. 2012; Hod 2013; Oz et al. 2016; Leven et al. 2016b; Girifalco 1992; Last et al. 1999; Shenoy et al. 2008; Lu et al. 2009; Yang et al. 2011; Chenxi et al. 2014; Ruiz et al. 2015; Ward 2016; Lebedev et al. 2016) may lead to the development of new nano- and microelectromechanical systems with diverse functionalities based on the promising concepts of 2D layered materials.

Emergence of Functionalized Properties in Semiconductor Nanostructures

30

James R. Chelikowsky

Contents

Abstract

The role of functionalizing properties of semiconductor materials in the bulk by doping is reasonably well understood. However, as the length scale of merit approaches the nano-regime, the interplay of restricted dimensionality and quantum confinement can complicate the role dopants play in altering electronic properties. In particular, well-known rules for describing defects in the bulk may become inoperative at the nanoscale. We illustrate how computational methods can be used to predict the emergence of nanoscale electronic properties in semiconductors and how these properties change as the size of the system is decreased.

1   Introduction

"Functionalization" of material properties is accomplished by changing the chemical makeup of a material so that it possesses a desirable property. In organic materials this can be accomplished by adding functional groups. A similar process occurs in semiconductor materials by the controlled addition of impurities, i.e., doping. Indeed, without precise control of the electronic properties using dopants, solid-state devices would not exist.

A classic example of functionalized electronic materials is the construction of a *pn* junction diode (Kittel 2005). A *pn* junction relies on the existence of an interface between *p*-doped and *n*-doped materials. The *p*-doped material can be created by adding boron atoms to bulk silicon, and the *n*-doped material can be created by adding phosphorous atoms to bulk silicon. The addition of these doping atoms results in profound differences in the silicon host material. For example, one boron atom for every hundred thousand silicon atoms increases the conductivity of pure silicon by a thousandfold at room temperature (Kittel 2005). In a *pn* junction, the electronic states of the host are modified so that an internal field occurs. When an external field is applied, the internal field can be increased or decreased to control the flow of electrons (or holes) so that the resulting current is rectified.

The process and control of such impurity atoms like boron and phosphorous account for the phenomenal progress in the electronics industry with the creation of devices ranging from a simple transistor some 50 years ago to contemporary nanoscale integrated circuits containing billions of transistors. As a consequence, the computational power present in a typical cell phone or handheld personal data device vastly exceeds that of the first electronic computers.

However, as we place more transistors on a chip, the physical dimensions of a transistor become smaller. At a certain point, the size of a transistor will start to affect its physical property. Specifically, size-dependent quantum mechanical phenomena will occur. This was recognized some time ago. In 1959, Richard Feynman presented a seminar (Feynman 1992) in which he stated: "When we get to the very, very small world—say circuits of seven atoms—we have a lot of new things that would happen that represent completely new opportunities for design. Atoms on a small scale behave like nothing on a large scale, for they satisfy the laws of quantum mechanics. So, as we go down and fiddle around with the atoms down there, we are working with different laws, and we can expect to do different things. We can manufacture in different ways. We can use, not just circuits, but some system involving the quantized energy levels, or the interactions of quantized spins, etc." Feynman's comments had little impact in directing new work (Toumey 2005) as the technological framework for nanoscale control took time to implement. Today his comments appear prescient.

The design rules that work successfully at macroscopic dimensions may not be operative at nanoscale dimensions as the physical properties of nanoscale materials can be significantly different than the bulk material. For example, an optically inactive material such as silicon can become optically active at the nanoscale (Canham 2000; Shirley et al. 2000).

The use of "size" to modify the physical properties of materials, without changing their chemical composition technological implications in a number of areas: sensors for bioimaging (Michalet et al. 2005), energy devices such as solar cells (Gur et al. 2005; Ellingson et al. 2005), and wavelength tunable lasers (Klimov et al. 2007).

In general, functionalization at the nanoscale whether by exploiting quantum confinement or by doping is of great importance, but the nanoscale presents new and challenging issues. The inclusion of just one dopant atom in a thousand-atom nanocrystal might exceed the solubility expected for a bulk crystal; in the case of P-doped Si, a doping concentration of one part in a hundred thousand atoms would be considered extremely heavy doping.

Physically, it seems plausible that dopants would interact differently with nanocrystal hosts as a function of size (Beaulac et al. 2010). As the nanocrystal decreases in size, the ratio of surface to bulk atoms grows. The interaction of the dopant with the surface can allow a decrease in any strain energies as the surface atoms are more readily displaced than the bulk atoms, owing to their lower coordination number. Moreover, as the nanocrystal becomes smaller, quantum confinement increases the bandgap and can effectively turn a small bandgap semiconductor into a large gap semiconductor, which is known to be difficult to dope (Chadi 1994; Neumark 1997; Troparevsky and Chelikowsky 2001).

Understanding the doping process at the nanoscale requires a better picture of both thermodynamics and kinetics. Computational methods can be used to solve the electronic structure problem and address some of these issues. In the case of Si, computational work has accurately predicted many properties, and there is no reason to believe that these studies would not describe the nanoscale with similar accuracy. In the early 1980s, it was conclusively demonstrated that one could determine accurate structural energies of silicon. For example, the energetics of a number of different phases of silicon were examined (Yin and Cohen 1980) with the equations of states for dense phases carefully mapped out and found to be in agreement with high-pressure experiments. Moreover, these studies predicted the existence of superconductivity in a high-pressure form of Si. This prediction was confirmed by the experiment within a few years (Chang et al. 1985). Shortly after the realization that accurate structural energies could be computed, methods for ab initio molecular dynamics were introduced (Car and Parrinello 1985).

While these computational methods have greatly enhanced our understanding of bulk materials, their application to the nanoscale is often problematic. Nanostructures are still "large," in a quantum sense. The number of atoms contained within a "smallish" 10 nm nanocrystal of Si is roughly 50,000. Current methods for electronic structure descriptions are ill-suited for such systems as one would have to solve for over 100,000 energy levels. The memory required and the computationally intensive nature of such a problem are often beyond the state of the art, although such systems are becoming within our computational grasp. Here we illustrate how computational approaches and advances can be used to illuminate the quantum behavior and the physical properties of dopants at the nanoscale

for systems approaches containing thousands of atoms using electronic structure methods discussed in Volume 1 of this handbook (Chap. 24 "Extending the Scale with Real-Space Methods for the Electronic Structure Problem" of the MTM set by Chelikowsky).

2   Defect Levels in Doped Nanocrystals

Phosphorus atoms added to bulk silicon represent the leading example of an *n*-type semiconductor. Phosphorous induces defect energy states very close in energy to the conduction band. For such *shallow* donor states, i.e., states within a few kT of the conduction band, electrons can be easily thermally excited. These carriers greatly enhance the conductivity of the original pure semiconductor.

As one considers making device materials at smaller length scales, a central question is whether this picture will continue to be valid (Pavesi and Turan 2010). Quantum confinement in this size regime is expected to alter the electronic properties of doped Si nano-crystals (Yoffe 2001; Melnikov and Chelikowsky 2004; Chan et al. 2008; Chelikowsky et al. 2011). Important questions arise. For example, will the defect energy levels continue to shallow or not. Also, is there a length scale where device construction based on macroscopic guidelines fails? These are the questions that Feynman intuited in the late 1950s.

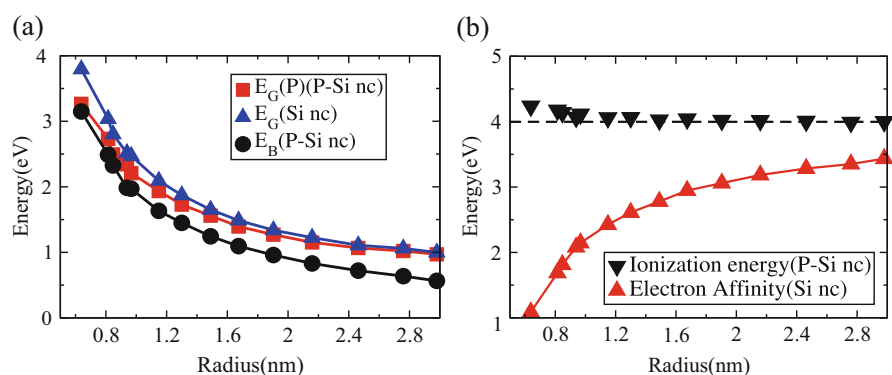
In Si nanocrystals, the bandgap, E_G, increases as the crystal size decreases owing to quantum confinement as depicted in Fig. 1a. After doping with P, a defect energy level is created within the bandgap. Since P atom has one more electron than a Si atom, the extra electron creates a donor state. The binding energy of the donor within a bulk crystal can be defined as the energy difference between the defect energy level and the conduction band minimum. Within a confined system, this definition is problematic because the electron in the lowest unoccupied state remains


Fig. 1 (**a**) The dependence on the nanocrystal radius of the energy gap E_G in Si nanocrystal(▲), the binding energy E_B(●), the energy difference between the defect level and the highest doubly occupied level $E_G(P)$ in P-doped Si nanocrystal(■). (**b**) Ionization energy of P-doped Si nanocrystal(▼) and electron affinity of pure Si nanocrystal(▲) plotted as a function of nanocrystal radius

physically localized near the P atom. The corresponding definition of the binding energy at the nanoscale is the energy required to ionize a P-doped Si nanocrystal by removing an electron minus the energy gained by adding the electron to a pure Si nanocrystal.

One can calculate the ionization energy I_d for P-doped Si nanocrystals as

$$I_d = E_P(n-1) - E_P(n), \tag{1}$$

where n is the number of electrons in a neutral P-doped Si nanocrystals. $E_P(n)$ and $E_P(n-1)$ are the ground-state total energy of a neutral and positively charged P-doped Si nanocrystals, respectively. The electron affinity of pure Si nanocrystals can be determined by

$$A_p = E_{Si}(n-1) - E_{Si}(n), \tag{2}$$

where $E_{Si}(n-1)$ and $E_{Si}(n)$ are the ground-state total energy of a neutral and negatively charged Si nanocrystals, respectively. The binding energy E_B for the donor electron is the difference between these two quantities:

$$E_B = I_d - A_p. \tag{3}$$

The calculated ionization energy and electron affinity as a function of nanocrystal size are illustrated in Fig. 1b. The electron affinity of pure Si nanocrystal decreases with size owing to the increase of kinetic energy of the added electron by quantum confinement, which can be considered a consequence of the uncertainty principle. We note that the ionization energy of P-doped Si nanocrystal depends weakly on nanocrystal size, i.e., it is effectively pinned to the vacuum level, and remains close to the bulk value of ~ 4 eV.

In Fig. 1a, the size dependence of the energy difference ($E_G(P)$) between the singly occupied defect energy level and the highest doubly occupied level for the doped Si nanocrystal is plotted. The binding energy E_B of P-doped Si nanocrystal as a function of size is also shown. As the size of the nanocrystal increases, the sum $E_G(P)$ for the doped nanocrystal and the binding energy E_B should converge to the bulk Si bandgap.

In nanocrystals, the defect electron is found to be more tightly bound as nanocrystal size decreases. This is largely due to the weak screening (Öğüt et al. 1997, 2003) in quantum dots. For nanocrystal up to 6 nm in diameter, the binding energy is significantly larger than kT at room temperature. A fit to the calculated binding energy E_B scales as $R^{-1.1}$. By extrapolating to a large radius, E_B tends to a limiting "bulk" value of 0.06 eV, which is somewhat higher than the experimental value of 0.044 eV; however, the difference is within the fitting error and likely fortuitously close since density functional theory was used to perform the computations.

2.1   Characterization of the Defect Wave Function

In Fig. 2a, the defect-state charge density is plotted along the [100] direction. As
the nanocrystal size increases, the defect wave function becomes more delocalized.
The maxima of the charge density at around 0.2 nm correspond to the bond length
between the P at the origin and its first Si neighbors. We can remove these atomic
details by spherically averaging the defect wave function as shown in Fig. 2b.
The defect wave function exponentially decays from the origin in Fig. 2c, and
the decay corresponds very well to the conventional understanding of defects in
semiconductors: the defect ion and the defect electron form a hydrogen-like system
with the wave function described as $\psi \sim \exp\left(-r/a_B^{\text{eff}}\right)$.

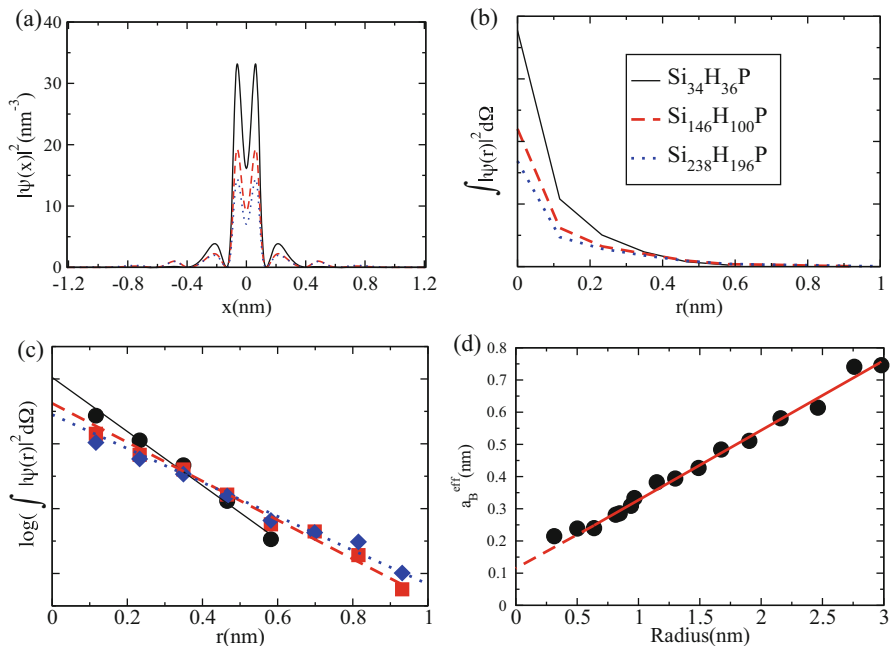
From the decay of the defect wave function, we can obtain an effective Bohr
radius a_B^{eff} and its dependence on nanocrystal size as plotted in Fig. 2d. The effective
Bohr radius varies nearly linearly with nanocrystal radius, R, up to 3 nm where R
is approximately five times a_B^{eff}. Nonlinearity can be observed for very small Si
nanocrystals, and a_B^{eff} appears to converge to ~ 0.2 nm as $R \to 0$. The limit tends
to the size of a phosphorus atom while retaining an sp^3 configuration. The effective
Bohr radius a_B^{eff} is not expected to remain linear with the radius R for large Si


Fig. 2 (**a**) Charge density for the dopant electron along the [100] direction for three P-doped Si
nanocrystals with different radii. x is the coordinate along that direction. Their spherically averaged
charge densities are plotted in (**b**). A log-linear plot of (**b**) is illustrated in (**c**). Effective Bohr radius
a_B^{eff} corresponding to the dopant electron is plotted in (**d**) as a function of nanocrystal radius

nanocrystals. In the bulk limit, a_B^{eff} is ~2.3 nm assuming a dielectric constant of 11.4 and effective electron mass of 0.26 times the free electron mass. The dependence on R should achieve this bulk limit for large Si nanocrystals, which are removed from the size regime as shown in our figure.

2.2 Hyperfine Splitting of Defects

If the defect wave functions are known, one can compare to the experiment by computing the hyperfine splitting (HFS), which arises from an interaction of an electron spin with a nuclear spin (Feher 1959). The isotropic HFS constant a can be calculated from

$$a = \frac{2}{3}\mu_0 g \mu_B g_N \mu_N |\psi(0)|^2, \tag{4}$$

where μ_0 is the permeability of free space; g and g_N are the electron and the P nucleus g-factor, respectively; μ_B and μ_N are the Bohr and nuclear magneton; and $|\psi(0)|^2$ is the defect charge density evaluated at the P position (Weil and Bolton 2007). Pseudopotential calculations do not yield the true core charge density, which can differ strongly from the all-electron potentials within the core region. This deficiency can be overcome using a scheme from Van de Walle and Blöchl that utilizes the pseudopotential wave functions as input (Van de Walle and Blochl 1993). The correct amplitude of the wave function at the P core (positioned at the origin) can be obtained from

$$|\psi(0)|^2 = |\psi_{ps}(0)|^2 \frac{|\phi_{AE}^s(0)|^2}{|\phi_{ps}^s(0)|^2}, \tag{5}$$

where $\psi_{ps}(0)$ is the defect wave function evaluated at the P position using pseudopotential and $\phi_{AE}^s(0)$ and $\phi_{ps}^s(0)$ are the all-electron and pseudo-s-wave for an isolated P atom in free space. This formalism assumes that the impurity state is localized on the impurity atom, which need not be the case as discussed later in this review.

The calculated HFS is plotted in Fig. 3 for P atom located at the center of Si nanocrystal. Very good agreement between experimental data (Fujii et al. 2002) and the theoretical calculations is observed (Chan et al. 2008). For nanocrystals with radius between 2 to 3 nm, the HFS is around 100 G, which considerably exceeds the bulk value of 42 G. Moreover, the HFS continues to increase as the nanocrystal size decreases. This is a consequence of quantum confinement as illustrated in Fig. 2. The defect wave function becomes more localized at the P site as the radius decreases, leading to a higher amplitude of the wave function at the P nucleus. For small nanocrystals, the HFS can be significantly changed by atomic relaxation owing to the influence of a relatively large surface area.

Fig. 3 Calculated hyperfine splitting for P-doped Si nanocrystals as a function of nanocrystal radius is plotted together with experimental data(▲) from Fujii et al. (2002). Calculated results corresponding to structures arising from an unrelaxed exact bulk-like geometry(●) and to structures relaxed to a local energy minimum(♦) are shown in the figure
Effective mass theory has yielded similar results (Debernardi and Fanciulli 2009), although such methods cannot readily determine structural energies of the P substitutional sites. The most favorable structural position of the P impurity in a Si nanocrystal is problematic. Studies have verified that the symmetry of the P away from the surface is substitutional with the tetrahedral symmetry unbroken. After substituting the center Si atom by P, one can intentionally perturb the position of the P atom randomly such that the symmetry of the system was broken. However, on relaxation to a local energy minimum, the four P-Si bond lengths are preserved, and a tetrahedral geometry has been observed (Chan et al. 2008). Depending on the size of the nanocrystal, the P-Si bond varies from 0.236 to 0.238 nm (the calculated bulk Si-Si bond length is 0.236 nm) (Chan et al. 2008). Hence, the introduction of P atom does not break the symmetry of the system, and the relaxation is small, The P-Si bond length between different nanocrystals varies at most by 0.002 nm. The resulting HFS is illustrated in Fig. 3. For Si nanocrystals with radius larger than 1.5 nm, the effect of relaxation diminishes, and the difference between unrelaxed and relaxed results is within ∼10%.

We can consider the structural energetics of the doping site by varying the P position along the general [100] direction as illustrated in Fig. 4. Since the details of the nanocrystal surface are unknown, the P atom is not allowed to replace a Si on the surface of the nanocrystal that is passivated by a H atom. For the remaining sites, it is possible to relax the nanocrystals to an energy minimum. Results for five small nanocrystals are shown in Fig. 5. We see that for Si nanocrystals with a diameter smaller than ∼2 nm (the number of Si atoms is less than a hundred), P tends to substitute Si near the surface. Otherwise, the center of the nanocrystal is the energetically most favorable position. This suggests that a "critical size" exists for nanocrystals; below this size, P atoms will be energetically expelled toward the surface.

The presence of the P defect creates stress to the Si nanocrystal, and the doped nanocrystal can relieve this stress by expelling the P atom toward the surface, where surface relaxation or reconstruction may accommodate the stress. In contrast, if the P atom is not at the center of the nanocrystal, the defect wave function is distorted

Fig. 4 A perspective view of a Si nanocrystal. The lightly shaded atoms correspond to Si atoms, and the small atoms on the surface of the nanocrystal are H atoms. The heavily shaded atoms correspond to the Si atoms that will be substituted by P. The numbers measure the distance away from the origin in the unit of Si bond length
and less localized around P, leading to a loss in Coulomb energy between the P ion and the defect electron. Hence, for the slightly larger nanocrystals (the number of Si atoms more than around 150), a basin of attraction extending several Si bond lengths can be observed that favors a site for P atom near or at the center of the nanocrystal.

The HFS evaluated for different P positions inside the Si nanocrystal is shown in Fig. 5. There is a general trend for the HFS to drop notably as the P atom gets close to the surface of the nanocrystal. For a P site away from the surface, smaller variations in the HFS can be observed. However, for large Si nanocrystal, we can see that the HFS varies within ∼10% of the value with P at the center position. In comparing with the experimental results in Fig. 3, we find it unlikely that the synthesized Si nanocrystals have P located near the surface, as this will result in much smaller HFS than those calculated. P-doped Si nanocrystals are made experimentally by sputtering followed by annealing at high temperature (Fujii et al. 2003). The P atom resides in energetically favorable locations, which in general are close to the center of the Si nanocrystal, during the annealing process.

3   Self-Purification of Defects in Semiconductors

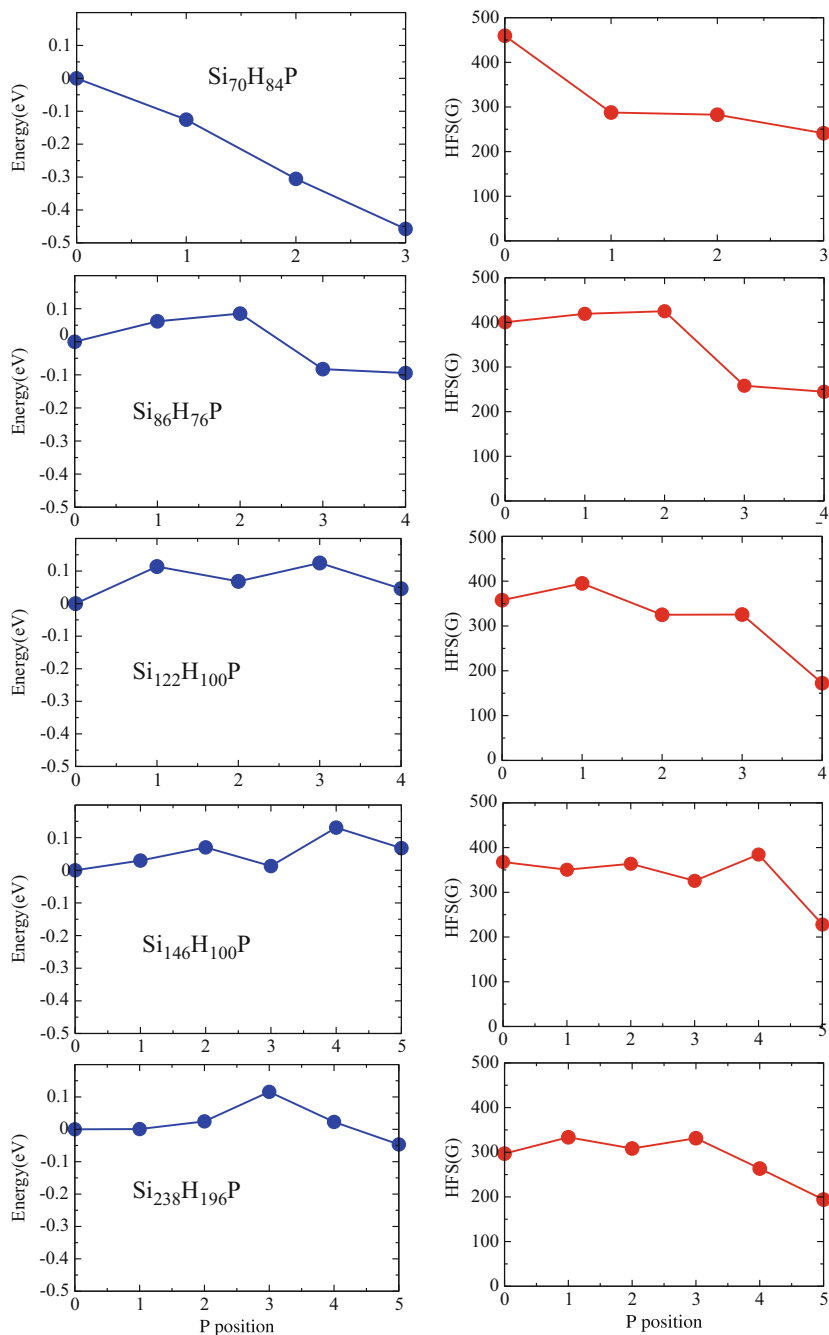
Doping of nanocrystals is often a difficult task (Stowell et al. 2003; Mikulec et al. 2000; Beaulac et al. 2010). "Self-purification" mechanisms are claimed to make this task even more difficult, i.e., a defect or impurity atom can be expelled from the nanocrystal to the surface leaving the interior of the nanocrystal defect-free (Dalpian and Chelikowsky 2006). Several reports in the literature support this thesis as there


Fig. 5 Difference in energy (left) and HFS (right) as the P atom moves away from the center of the Si nanocrystal. The energies are with respect to the energy of the Si nanocrystal with P at the center. The x-axis measures the distance of P atom away from the origin as illustrated in Fig. 4

is a tendency for impurities to cluster at the surface of the nanocrystals. To avoid this situation, specialized synthesis procedures have been developed to inhibit the diffusion of a dopant to the surface (Pradhan et al. 2005; Yang et al. 2008; Nag et al. 2008).

Computational work regarding theoretical mechanisms for doping at the nanoscale remains somewhat limited owing to the many degrees of freedom involved in any simulations. One proposal suggests that the incorporation of impurities is predominantly limited by the kinetics of the adsorption on the surface of the nanocrystals (Erwin et al. 2005). Another proposal focuses on thermodynamic effects in order to understand difficulty in doping in nanocrystals (Dalpian and Chelikowsky 2006; Chelikowsky et al. 2011).

Under thermodynamical equilibrium, the population of impurities or defects in a given host material is given by

$$N = N_s \exp\{(G_f/k_bT)\} \tag{6}$$

where N_s is the total number of impurity sites in the lattice, G_f is the Gibbs free formation energy of the impurity, k_b is the Boltzmann constant, and T is the temperature. Assuming that the entropic contribution will be similar for several configurations of a similar defect, one can substitute G_f by the formation energy of the defect: ΔH_f.

Consider the case of a Mn atom replacing a Cd atom in CdSe as an example appropriate for synthesizing a dilute magnetic semiconductor. The formation energy of a substitutional Mn impurity in a host CdSe material is a function of the elemental chemical potentials of the impurity and the host constituents and also a function of the Fermi energy of the system (Zhang and Northrup 1991; Wei 2004).

When using ab initio total energy methods, this formation energy can be calculated as follows:

$$\Delta H_f = E_T^{Mn} - E_T + (E_{Cd} + \mu_{Cd}) - (E_{Mn} + \mu_{Mn}), \tag{7}$$

where E_T^{Mn} is the total energy of the host with the impurity, E_T is the total energy of the host without the impurity, E_{Cd} and E_{Mn} are the elemental energies of Cd and Mn, and μ_i is related to the range of the chemical potentials in different thermodynamic limits.

For nanoscale materials, such as nanocrystals, the number of available sites where the impurities can be localized (N_s) can be as much as 20 orders of magnitude smaller than in standard bulk materials. Consequently, as the number of available sites for the impurities to be localized is much smaller than bulk, we would expect that nanostructures should have a smaller number of impurities than bulk materials. This can be understood by considering that N_s in Eq. 6 is small. For example, if the probability of defect in a bulk crystal is 1 in 10,000, the probability of a hundred-atom nanocrystal having such a defect would be small. This was first proposed by Turnbull in 1950, many decades before the advent of nanoscience and nanotechnology. Although this is a simplistic approach, e.g., it ignores the role of

a surface altogether, it represents one of the first attempts to explain why "small" systems might have a negligible probability of containing defects.

Besides the number of available sites, the formation energy (H_f) can also play a role in the population of defects in a nanocrystal. The formation energy of a certain impurity depends on the position of the impurity inside the nanostructure, i.e., it varies from the surface of the nanostructure or at its core (as indicated for P in Si in Fig. 5). The formation energy also depends on the size of the nanostructure. Quantum confinement effects, which are larger in smaller nanocrystals, can lead to an increased formation energy, leading to smaller impurity concentrations. For example, quantum confinement effects are observed in DX$^-$ centers in GaAs quantum dots (Li et al. 2005; Besteiro et al. 2010); B- and P-doping in Si nanoclusters (Cantele et al. 2005) and nanowires (Peelaers et al. 2006); donors, acceptors, and isovalent impurities in ZnSe (Li et al. 2008); Mn impurities in InAs nanocrystals (Arantes et al. 2008); and Mn in CdSe nanocrystalsChan et al. (2009). Similar effects have also been reported for B and N impurities in SiC nanowires (Santos de Oliveira and Miwa 2009) and Mn impurities in InP nanowires (Schmidt 2008).

For the specific case of Mn impurities in CdSe nanocrystals, calculations have indicated a small tendency for impurities to be localized at the surface of the nanocrystals (Chan et al. 2009). For example, an energy gain of 0.02 eV was found for a Mn atom moving from the center of the nanocrystal toward its surface. This trend is observed in small nanocrystals ($Cd_{30}Se_{28}$) and for larger nanocrystals ($Cd_{79}Se_{68}$). For the larger nanocrystals, an structural anisotropy for the stability of the impurities was observed. The energy gain is larger when the impurity moves along the $\langle 100 \rangle$ direction than when it moves along the $\langle 111 \rangle$ direction. This anisotropy occurs owing to a more effective strain relief in the $\langle 111 \rangle$ direction. By construction, the nanocrystals used in these calculations (Chan et al. 2009) present a dipole moment in the $\langle 111 \rangle$ direction, whereas this does not happen in the $\langle 100 \rangle$ direction. This dipole moment can affect the energetics of the Mn defect inside the nanocrystal. In Fig. 6a, we show the calculated self-consistent potentials along two different directions inside the nanocrystal. As can be observed, this potential is anisotropic along the $\langle 111 \rangle$ direction, which is the cause for the difference in the energetics of the impurities along these two directions. It is possible that impurities could be manipulated by subjecting these systems to a directed electric field (Chan et al. 2009).

In Fig. 6 the energy difference for some of the studied positions for the Mn atom inside the nanocrystal is illustrated in different directions. The insets (a) and (b) show the direction in which the positions are tested. In (c) we show the variation of the total energy for these positions (Chan et al. 2009).

Although the fact that the Mn atom prefers to be localized at the surface of the nanocrystal clearly indicates that at equilibrium the impurities would all tend to be localized at these positions, i.e., would be expelled from the nanocrystal, this diffusion of the impurity into the surface might be kinetically inhibited. This might happen because the diffusion barrier for the Mn atom to move toward the surface might be large, and it would take a long time for a single jump to occur. Diffusion
Fig. 6 (**a**) and (**b**) An atomic model of a $Cd_{79}Se_{68}$ nanocrystal in two different perspectives. The Cd atoms are colored gray, Se in yellow, and the small blue atoms at the surface correspond to the capping atoms. The number labels the Cd atom to be substituted by Mn. (**c**) The change in total energy of the $Cd_{78}Se_{68}Mn$ nanocrystal as Mn moves toward the surface. (**d**) A plot of the self-consistent potential V_{SCF} (averaged in the plane perpendicular to the plotting direction). The troughs in the potential correspond to Se atoms, while the peaks correspond to the Cd atoms for the (100) direction and the shoulders close to the peaks are the positions of the Cd atoms for the (111) direction. The dotted lines indicate the boundary of the nanocrystal

barriers for the bulk material are usually of the order of a few eV, leading to diffusion hopping times as large as 1 h (Norris et al. 2008). To assess this problem for nanoscale materials, the diffusion barrier for a Mn atom for a bulk CdSe crystal and inside a CdSe nanocrystal have been calculated (Chan et al. 2009). The mechanism involving the diffusion of a Mn can be quite complex, including *kickout* mechanisms and exchange of atoms. However, previous work suggests that the diffusion of Mn in bulk GaAs and CdSe involves interstitial defects (Edmonds et al. 2004). In Fig. 7, we illustrate the calculated barrier for interstitial diffusion in bulk CdSe and for the $(Cd_{30}Se_{28})$ nanocrystal. This diffusion barrier is related to the trajectory of a Mn atom from a tetrahedral interstitial position, where the Mn atom is surrounded by four Cd atoms (T_{Cd}) to an interstitial position where there are four Se (T_{Se}) atoms around the Mn atom. Each intermediate structure was obtained by fixing one atom in the nanocrystal and the x coordinate of the Mn atom: all other coordinates were optimized. A total of 11 geometries were used in order to obtain the diffusion barrier and the saddle point in each path. The diffusion barrier for the nanocrystals was calculated to be 0.35 eV, and for bulk we obtain a value of 0.84 eV. As the diffusion

Fig. 7 Diffusion barriers of
the Mn atom for the $Cd_{30}Se_{28}$
nanocrystal and for bulk
CdSe. The ball and stick
models at the bottom indicate
the diffusion pathway
barrier in nanocrystals is dramatically smaller than in bulk, the expulsion of the
defect to the surface might easily take place in nanocrystals. Another interesting
observation from Fig. 7 is that the Mn atom prefers to be localized at the T_{Se} position
as opposed to the T_{Cd} site for the bulk limit. This preference disappears in the
nanocrystals owing to the larger localization of the Mn_d levels in quantum confined
systems.

Studies have also revealed that there might be a significant change in the stability
of an impurity inside a nanocrystal as the size of the nanocrystal changes (Dalpian
and Chelikowsky 2006). We have observed that, for smaller nanocrystals, where
quantum confinement effects are stronger, the formation energy of an impurity
is usually larger than in bulk or in larger nanocrystals. In Fig. 8, we illustrate the
variation of the formation energy, compared to bulk value, for several different types
of impurities in different host materials taken from several different sources. As can
be observed in these examples, the formation energy usually increases (becomes
less favorable) when the size of the nanocrystal decreases. For some impurities
this effect is larger than for others, such as when large valence differences exist,
although this trend is present in all defects shown. As this effect is observed in
several different kinds of impurities, its origin might be related to several different
effects. One of the most important effects is related to the increased localization of
the impurity levels in smaller nanocrystals. This would increase the energetic cost
to form these defects as the size of the nanocrystal decreases.

4   Raman Spectroscopy of Nanocrystals

Raman spectroscopy is a particularly useful technique for characterizing the prop-
erties of nanostructured Si materials (Li et al. 2000; Volodin et al. 1998; Nesheva
Fig. 8 Variation of the formation energy of several impurities as the size of a nanocrystal is changed. (**a**) Cantele et al. (2005), (**b**) Li et al. (2008), (**c**) Dalpian and Chelikowsky (2006)

et al. 2002) as it is a well-established experimental technique for characterizing a wide range of materials. It is highly sensitive to both the atomic and electronic structure of the substrate. Consequently, materials have unique Raman signatures, which can be used in identifying different species.

Inelastic scattering of light, or Raman scattering, is conceptually simple. When light interacts with matter, such as a molecule, most of the light is scattered elastically. This is called Rayleigh scattering. A small fraction, (10^{-6}), either gains or loses energy during the collision by moving the molecule into a different vibrational mode. The shift in wavelength corresponds to the energetic difference between the vibrational modes. Generally, at ambient temperatures, the majority of molecules are in the lowest energy mode and are excited to a higher mode by the photons. As a result, the exiting radiation is lower energy than the incident radiation. This is called Stokes Raman and is typically more prevalent than the opposite effect, anti-Stokes Raman.

Not every vibrational mode is Raman active. A mode is only Raman active if the derivative of the polarizability with respect to the normal coordinate is nonzero at the equilibrium point. As a rule of thumb, stretching modes that lengthen bond lengths and change the size of the molecule are generally Raman active. Symmetric bending modes that do not change bond length are usually not Raman active (Li et al. 2000; Volodin et al. 1998; Nesheva et al. 2002).

Raman spectroscopy has many advantages as an experimental technique. Raman analysis can be performed on samples in gas, liquid, or solid phase. It is useful for biological materials and can be performed on aqueous solutions without interference from the water solvent. One of the foremost disadvantages of Raman spectroscopy is that the signal strength is very weak.

Si nanostructures can be optically active by demonstrating a strong visible photoluminescence (Zhang et al. 1995, 1994; Wolkin et al. 1999; Furukawa and Miyasato 1988) in striking contrast to the bulk phase, making them suitable for use as optoelectronic devices (Pavesi et al. 2000). Also, their compatibility with existing Si-based technologies enhances their utility in nanoscale electronics applications (Tiwari et al. 1996; Choi et al. 1998). In addition to changes in the optical properties of bulk materials at the nanoscale, changes in the vibrational modes of a nanocrystal also exist owing to a physically constrained nanostructure. An analysis of Raman spectroscopy centers on understanding a combination of changes in the optical and vibrational properties of Si nanostructures. A striking feature of the Raman spectra of Si nanocrystals is that the main optical Raman peak red-shifts and broadens as the nanocrystal size is decreased.

To explain such observations, Richter, Wang, and Ley (RWL) proposed a phenomenological model attributing these confinement effects to a relaxation of the wave-vector selection rule (Richter et al. 1981). This model is widely accepted and used extensively in the calculation of Raman spectra and interpretation of experimental data (Wei et al. 2007; Faraci et al. 2005, 2006; Valentin et al. 2008). More sophisticated techniques such as the partial density method and bond polarizability approximation have also been used to study the Raman spectra of Si nanocrystals (Zi et al. 1996, 1997, 1998; Cheng and Ren 2002). These techniques give better results than the RWL theory; however, they still rely on parameters derived from bulk calculations, and their transferability is not guaranteed.

The two primary pieces of information needed to calculate a Raman spectrum are the vibrational modes and the dielectric susceptibility, both of which can be calculated from first principles using pseudopotentials and density functional theory. The computational methods used for the Raman work outlined here are discussed elsewhere in this handbook (Chap. 24 "Extending the Scale with Real-Space Methods for the Electronic Structure Problem" of the MTM set by Chelikowsky) and in the literature (Steele 1971; Wilson et al. 1980; Khoo et al. 2010; Bobbitt and Chelikowsky 2016a, b). The vibrational properties of nanocrystals can be computed by the force constant method (Parlinski et al. 1997), and Raman spectra were evaluated using the Placzek approximation (Porezag and Pederson 1996; Umari and Pasquarello 2005; Parlinski et al. 1997; Bobbitt and Chelikowsky 2016a, b).

We can illustrate the vibrational modes of Si nanocrystals by computing the dynamical matrix. As an example, we consider Si nanocrystals $Si_{87}H_{76}$, $Si_{147}H_{100}$, and $Si_{281}H_{163}$ having diameters 1.4, 1.7, and 2.2 nm, respectively, that were selected for our study. These nanocrystals were generated by cutting atom-centered spheres out of bulk Si and passivating dangling bonds on their surfaces with H atoms. The nanocrystals are illustrated in Fig. 9.

We plot the calculated Si vibrational density of states (VDOS) for each nanocrystal in Fig. 10. VDOS contributions from passivating H atoms have been excluded

Si$_{87}$H$_{76}$ (1.4 nm)   Si$_{147}$H$_{100}$ (1.7 nm)   Si$_{281}$H$_{172}$ (2.2 nm)
Fig. 9   Ball and stick model for relaxed structures of H-passivated Si nanocrystal

Fig. 10   Si VDOS per atom for Si nanocrystals and bulk Si
as they are irrelevant to the problem. We also computed the VDOS of bulk Si to represent the limit of infinite nanocrystal size.

There are two prominent peaks in the Si VDOS, a low-frequency acoustic peak centered in the range of 100–150 cm^{-1} and a high-frequency optical peak in the vicinity of 480 cm^{-1}. As the nanocrystal size gets smaller, the acoustic peak is red-shifted, and the amplitude of the high-frequency optical peak is decreased. Both these observations point toward a shift of VDOS to lower frequencies with decreasing nanocrystal size. The total shift in VDOS frequencies is due to the competing influences of surface atom under-coordination and bond length contraction (Khoo et al. 2010). Under-coordinated Si surface atoms have a greater impact on nanocrystal vibrational frequency than bond length contractions. It can be argued that the red shift of Si VDOS for nanocrystals with decreasing nanocrystal size (as seen in Fig. 10) is due to their larger surface-to-volume ratios, as this leads to a larger proportion of under-coordinated surface atoms that lower vibrational frequencies.

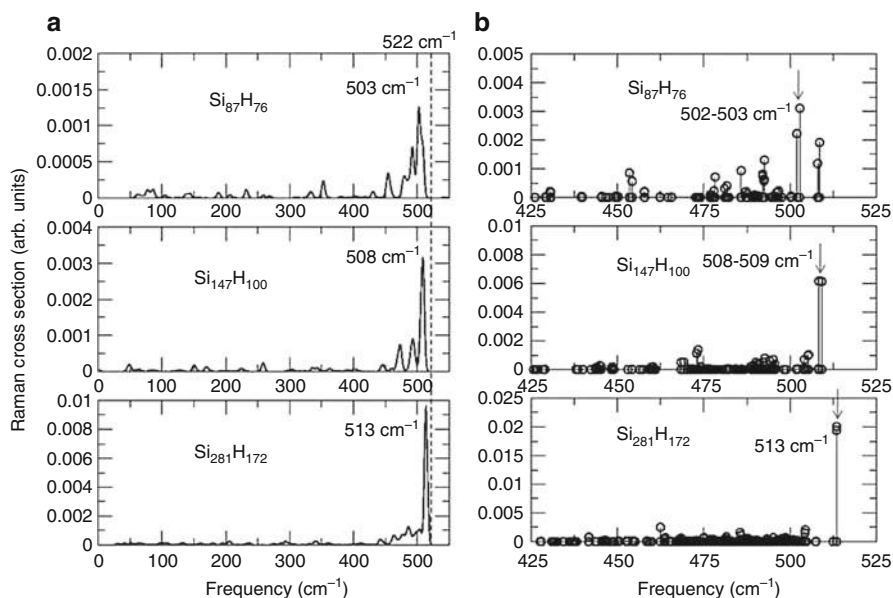
In Fig. 11, we plot the calculated Raman cross sections as a function of frequency for the Si$_{87}$H$_{76}$, Si$_{147}$H$_{100}$, and Si$_{281}$H$_{172}$ nanocrystals with a broadening of 2.5 cm^{-1}. The main Raman peak in the range of 500–520 cm^{-1} is asymmetrically broadened and red-shifted with decreasing nanocrystal diameters, consistent with experimental observations. Our calculated optical mode frequency for bulk Si is 522 cm^{-1}, as indicated by the dashed line, and it is in good agreement with experimental values (Iqbal and Veprek 1982). Among the nanocrystals we have


Fig. 11 Calculated Raman cross sections for Si nanocrystals with (**a**) broadening of 2.5 cm^{-1} and (**b**) no broadening. Dotted line in (**a**) represents frequency of Raman peak position for bulk Si, and arrows in (**b**) denote nanocrystal eigenmodes corresponding to the Γ-point bulk optical mode

studied, only $Si_{281}H_{172}$ (diameter 2.2 nm) is large enough to be compared directly with the experiment, and our calculated peak frequency of 513 cm^{-1} agrees well with the experimentally measured value of 514 cm^{-1} for nanocrystalline Si of diameter 2.3 nm (Ossadnik et al. 1999).

Also in Fig. 11, we plotted the Raman cross-sectional contribution from each nanocrystal mode as a function of mode frequency without broadening. It can be seen that the number of vibrational modes that contribute to the Raman spectra increases as the nanocrystal diameter is decreased and this leads to an asymmetric broadening and partial red shift of the Raman peak. These observations are consistent with the RWL theory, which predicts an increasing number of vibrational modes contributing to the Raman spectra for decreasing nanocrystal diameters. However, it is also clear from the figure that most of the Raman red shift does not originate from the activation of lower-frequency modes. Peak frequencies in the broadened Raman spectra of Fig. 11 follow closely the frequencies of three nearly degenerate vibrational modes with the largest Raman cross-sectional contributions (marked by arrows). By projecting these eigenmodes onto bulk phonon eigenvectors, we have identified them as originating from the optical modes in bulk, and it is the lowering of these mode frequencies with decreasing nanocrystal size that leads to the Raman red shift. The softening of these eigenmodes results from the presence of under-coordinated Si atoms on the nanocrystal surface, as noted before. Our explanation represents a qualitative departure from the RWL theory, which attributes

Fig. 12 The vibrational density of states for $Si_{87}H_{76}$ and $Si_{86}H_{76}P$ nanocrystals with P-dopant near the surface and center positions
Table 1 Force constants and atomic masses of the Si and P atoms at the center of the $Si_{87}H_{76}$ and $Si_{86}H_{76}P$ nanocrystals

Si	14.3	28.1
P	12.9	31.0

the Raman red shift to a relaxation of the wave-vector selection rule. Instead, the size dependence of nanocrystal vibrational frequencies has a much stronger effect on the Raman peak frequencies in Si nanocrystals.

Suppose we replace a Si atom by a P in a Si nanocrystal. We can also compute the Raman spectra for different sites and assess whether the Raman spectra change. In Fig. 12, we illustrate the vibrational density of states results for P at different sites within the $Si_{87}H_{76}$ nanocrystal. The results may seem odd as nothing of note happens, i.e., most of the vibrational modes remain unchanged. We can compute the force constants for P and Si atoms in equivalent sites, and to verify this is the case. For the center atom of the nanocrystal, the force constants associated with an infinitesimal displacement of a Si atom and a P atom are listed in Table 1, along with the corresponding atomic masses.

The force constants are very similar for both atoms. The P constant is smaller and we expect that. First, the mass of the atom is slightly higher than Si. Second, P has an extra electron. There is no bonding orbital for the extra P electron; all the bonds are saturated. This weakens the bonds between the P atom and neighboring Si atoms. This can indeed be verified on close inspection of the peaks at 100 and 480 cm^{-1} in Fig. 12. If one moves the P atom from the center of the nanocrystal to the surface; we do not find significant differences. As a consequence, the vibrational modes do not offer a means to either detect or locate the P atom. This is not the situation for the Raman spectra (Khoo and Chelikowsky 2014). In Fig. 13, the Raman spectra are illustrated with and without a P-dopant. Two dopant cases are presented with the P atom at the center of the nanocrystal and near the surface.

The Raman spectra for the undoped case are dominated by a single prominent peak at 503 cm^{-1} originating from the so-called Γ-point optical mode. This

Fig. 13 Raman cross section
for $Si_{87}H_{76}$ and $Si_{86}H_{76}P$
nanoclusters with P-dopant at
the center and near the
surface
frequency is slightly red-shifted relative to the bulk-Si value of $522\,cm^{-1}$ owing
to vibration softening and selection rule effects in a finite system.

The introduction of a P-dopant leads to qualitative changes in the calculated
Raman spectra. The number and positions of the peaks are changed depending on
the position of the dopant in the nanocrystal. For the center-doped nanocrystal, the
main feature in the spectrum is a peak at about $400\,cm^{-1}$. For the surface-doped
case, there are multiple peaks appearing at the frequencies 70, 320, 380, 450, and
$480\,cm^{-1}$.

The electric susceptibility and its derivative with respect to nuclear displacements
play an important role in understanding Raman spectra. This assumption is consis-
tent with the increase in magnitude of the Raman spectra, as we expect P-doping to
increase the responsiveness of Si to external electric fields. Raman can be used as a
tool to predict where dopants may reside, whereas the vibrational modes cannot.

5   Summary

As the physical size of electronic materials decreases, quantum-related properties
emerge. One goal of simulation and computation is to consider systems of increasing
size and complexity to address how properties emerge. Advances in physical

concepts, algorithms, and computational hardware allow us to consider larger and larger systems. Conversely, experimentalists can synthesize and characterize smaller and smaller nanostructures. These trends have "crossed" for many electronic materials allowing theorists to simulate systems that are larger than the smallest ones made by experimentalists. This cross-point will have significant long-term consequences for understanding quantum mechanical phenomena that results from the physical confinement of the system. As Feynman noted such an understanding is important as the design rules that work successfully at macroscopic dimensions may not be operative at nanoscale dimensions.

Electronic Structure of Atomically Precise Graphene Nanoribbons

31

Leopold Talirz and Carlo A. Pignedoli

Contents

Abstract

Atomically precise graphene nanoribbons promise to combine the outstanding electronic properties of graphene with an electronic bandgap that is sufficiently large for digital-logic applications at room temperature. After a brief introduction

to nanoribbon nomenclature, experimental synthesis, and characterization, this chapter guides through the theoretical toolbox available for modeling their electronic structure, starting from simple empirical models and ending with state-of-the-art ab initio methods.

1   Introduction

1.1   Terminology

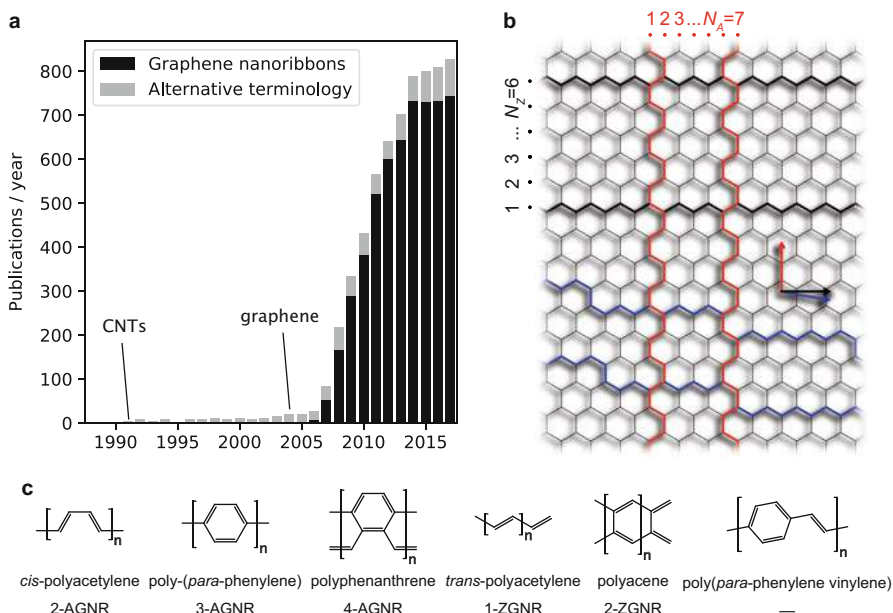
Graphene nanoribbons (GNRs) are strips of graphene with nanoscale widths, meaning widths below 100 nm. While the term is firmly established today, Fig. 1a illustrates that, historically, authors have been using alternative terms, such as *carbon nanoribbons*, *nanographite ribbons*, or *one-dimensional graphite*. Besides the width limit, the term GNR imposes no hard geometrical constraints in terms of length, aspect ratio, or edge shape and thus applies to a diverse set of graphene-derived nanostructures.


Fig. 1 Graphene nanoribbon (GNR) nomenclature. (**a**) Scientific articles related to GNRs from 1997 to 2017, indicating the discovery of carbon nanotubes (CNTs) and graphene. Counted are publications with *graphene nanoribbon(s)* in their title, abstract, or keywords (black). Alternative terms (gray) include, in descending order of frequency, *graphene ribbon(s)*, *carbon nanoribbon(s)*, *nanographite ribbon(s)*, *graphite ribbon(s)*, *graphitic ribbon(s)*, *one-dimensional graphite*, *graphene nanostrip(s)*, *nanographene ribbon(s)*, and *graphene nanowiggle(s)*. Source: Web of Science. (**b**) GNRs with armchair (red), zigzag (black), and chiral (blue) edges, shown on a graphene sheet. (**c**) GNR-type polymers with their chemical and GNR nomenclature

One defining characteristic of a GNR is the direction, along which a graphene sheet would need to be cut in order to produce it. Graphene has two high-symmetry directions, termed *armchair* and *zigzag* after the shape of the edges they produce. Fig. 1b shows examples of ribbons cut along the armchair direction (red) and the zigzag direction (black). Ribbons cut along any intermediate direction (blue) are termed *chiral*.

By convention, the width of armchair GNRs (AGNRs) is given as the number N_A of carbon dimer lines across the ribbon and the width of zigzag GNRs (ZGNRs) as the number N_Z of carbon zigzag lines. While dedicated notations exist for GNRs with specific edge shapes, there is no generally accepted notation covering GNRs with arbitrary edge shape.

The freedom in the edge shape also differentiates GNRs from the closely related single-walled carbon nanotubes (CNTs): only a subset of GNRs can be rolled up to form a defect-free CNT, and a CNT can be unzipped in multiple ways, producing different GNRs. As a consequence, the notation used to classify CNTs based on the chiral vector (n, m) cannot simply be transferred to GNRs.

The GNRs produced from the bottom-up through linking of molecular building blocks belong to the family of polymers, and some of the most narrow GNRs listed in Fig. 1c are well-known in polymer science. As polyacetylene still lacks benzenoid rings, it is debatable whether its *trans* and *cis* configurations should be considered the narrowest zigzag and armchair GNR, respectively. The wider poly-acene (2-ZGNR) and poly(*para*-phenylene) (3-AGNR), however, already satisfy this criterion.

Finally, GNR terminology often stops at defining the carbon backbone, although the decoration of the GNR edge by other chemical species can significantly impact the properties of a GNR. If no other information is provided, GNR edges are often implicitly assumed to be decorated by hydrogen such as to passivate any dangling bonds. Nevertheless, there are other relevant possibilities, and a complete specification of a GNR needs to include information on the edge passivation.

1.2   Why Graphene Nanoribbons?

Theoretical investigations of the electronic structure of GNR-type polymers can be traced back to the 1980s, when extending the carbon backbone of *trans*- and *cis*-polyacetylene was considered a promising avenue for improving the environmental stability of these π-conjugated conductive polymers (Yamabe et al. 1982; Tanaka and Yamabe 1985; Tanaka et al. 1987; Lowe et al. 1986).

In the 1990s, GNRs were reintroduced as a convenient theoretical model to study the effect of edge shape on the electronic and magnetic properties of nanoscale graphene, in view of their relevance for porous carbon and defective carbon nanotubes (Volpilhac and Hoarau 1978; Klein 1994; Fujita et al. 1996; Nakada et al. 1996).

In the 2000s, the seminal experiments on the electric field effect in graphene (Novoselov et al. 2004) renewed interest in GNRs – this time not as organic

conductors but as "semiconducting graphene." Graphene field-effect transistors have been shown to operate at frequencies beyond 400 GHz (Cheng et al. 2012) by leveraging the high mobility of charge carriers in graphene. The lack of a bandgap, however, limits the on/off ratio of graphene transistors to ≈10 at room temperature, which is far too low for many applications, both in high-frequency signal amplification and in digital electronics (Schwierz 2010, 2013). Cutting graphene into nanoribbons offers a natural way of opening a bandgap via quantum confinement.

The first key question is how narrow these ribbons need to be in order to exhibit significant electronic bandgaps. A rudimentary estimate of how quantum confinement affects the bandgap can be derived directly from the linear dispersion relation of graphene near the Fermi level:

$$E(q) \approx \pm \hbar v_F q \tag{1}$$

where the plus sign corresponds to the π^* conduction band, the minus sign corresponds to the π valence band, $v_F \approx 10^6 \frac{m}{s}$ is the Fermi velocity (Grüneis et al. 2008), and $\mathbf{q} = \mathbf{k} - \mathbf{K}$ the crystal wave vector measured relative to the Dirac point $\mathbf{K}$.

In a GNR of width w, the transverse component of $\mathbf{k} = (k^\perp, k^\parallel)$ is quantized to discrete values $k_n^\perp = n\frac{\pi}{w} = n\,\Delta k$, $n \in \mathbb{N}$. This limits how closely $\mathbf{k}$ can approach the Dirac point in reciprocal space. If the Dirac point falls midway between $k_n^\perp$ and $k_{n+1}^\perp$, the closest distance to the Dirac points is $\Delta k/2$, thus yielding a bandgap

$$\Delta = 2|E(\Delta k/2)| = \hbar v_F \Delta k \approx 2 \text{ eV nm}/w \tag{2}$$

Room-temperature digital-logic applications require on/off ratios in the $10^4 - 10^6$, which can be translated into a minimum bandgap of 0.4 eV (Kim et al. 2011). Equation (2) indicates that in order to open a bandgap of this magnitude in graphene, the graphene ribbons indeed cannot be more than a few nanometers wide.

While Eq. (2) is useful as a rule of thumb (Berger et al. 2006), it has numerous shortcomings, which are pointed out and addressed over the course of this chapter, working toward a computational model of the electronic structure of GNRs that is suitably accurate for comparison to experiments on atomically precise GNRs.

1.3   The Race for Atomic Precision

Opening a bandgap by quantum confinement offers the exciting prospect of tuning the value of the bandgap to just the right value for the intended application, simply by controlling the width of the GNRs. However, this path is not quite as straightforward as one might anticipate.

At a width of 5 nm, a GNR is just about 50 carbon atoms across. Patterning structures of such small dimensions is a major challenge for state-of-the-art

lithography (Hwang et al. 2015). On top of this, the electronic structure of these one-dimensional systems is also sensitive to the atomic structure of their edges, and even weakly irregular edges are predicted to give rise to scattering and localization of electrons (Gunlycke et al. 2007; Stampfer et al. 2009). If the high charge carrier mobilities of the parent material graphene are to be maintained, the GNR edges – meaning both the carbon skeleton and its passivation – should be made atomically precise.

Cutting graphene into atomically precise nanoribbons clearly is a daunting task, and so bottom-up approaches have been explored that aim at synthesizing a GNR from molecular precursors. Unfortunately, traditional polymerization chemistry faces a solubility problem with conjugated macromolecules containing some hundreds to thousands of atoms: as the width and length of the GNR increases, so does the strength of intermolecular π-π interactions, promoting aggregation (Yang et al. 2008; Narita et al. 2015).

One way to overcome this problem is to combine solution-based synthesis of specifically designed molecular precursors with on-surface synthesis of the GNRs, as sketched in Fig. 2a: the precursor molecules are evaporated onto a crystalline noble metal surface, which activates their docking sites. The activated molecules diffuse on the surface and undergo polymerization. At elevated temperature, additional carbon-carbon bonds form via cyclodehydrogenation, yielding the target GNR (Cai et al. 2010). By design, the precursor defines the GNR width, edge structure, and edge passivation down to the single atom, i.e., it defines its electronic structure. This ability to produce GNRs with uniform electronic properties is a crucial prerequisite for GNR-based technology (ITRS 2013).

The on-surface approach has not only been successful in providing a growing range of atomically precise GNRs (Fig. 2b) (Talirz et al. 2016a) but also has the advantage of producing the GNRs on a clean surface, where they can be studied by high-resolution surface-probe techniques, such as atomic force microscopy (AFM) and scanning tunneling microscopy (STM). As these techniques make it possible to determine both the atomic structure and the electronic structure of individual GNRs experimentally, they provide important benchmarks for the accuracy of computational modeling efforts.

1.4 Computational Challenges

Synthetic routes to a number of GNRs have been found, but their exploration is technically challenging, time-consuming, and expensive. This provides opportunities for computational modeling in the form of the following challenges:

1. Predicting which GNR targets are worth pursuing for a given application
2. Evaluating possible synthetic routes to a target GNR
3. Guiding the interpretation of complex measurements

In the context of atomically precise GNRs, the focus has only recently shifted from their synthesis to their incorporation into field-effect transistors (Bennett et al.
Fig. 2 On-surface synthesis of atomically precise GNRs. (**a**) Molecular Lego: deposition of the molecular building block (1) onto a crystalline noble metal surface at temperature $T = T_1$ activates their docking sites (2) by removing the halogen atoms. The activated radicals diffuse across the surface and polymerize (3). At elevated temperature $T_2 > T_1$, additional chemical bonds form (4), yielding the planar GNRs. (**b**) Selection of successful synthetic routes toward a B-doped 7-AGNR (Kawai et al. 2015), 9-AGNR (Talirz et al. 2017), 6-ZGNR (Ruffieux et al. 2016), and chevron-type GNR (Kawai 2013). Shown are sketches of precursor molecules and the GNR structure, together with atomically resolved images of the GNRs, obtained using non-contact atomic force microscopy (AFM) with CO tips. Scale bar 1 nm. AFM images are reproduced from corresponding references with permission

2013; Chen et al. 2016; Llinas et al. 2017). While electronic structure calculations do inform the decisions on which GNR targets to pursue, those calculations tend not to consider the GNRs' environment in a device, since the atomistic details of this environment in current prototype devices are still unknown. As the production of field-effect transistors using atomically precise GNRs matures, however, this first challenge will become increasingly important.

The second challenge has been recognized for some time, and efforts have been directed toward it (Talirz et al. 2016b). In practice, however, computational insight does not yet play a major role in the selection of synthetic strategies. Predicting the reaction path of a complex molecule on a noble metal surface still is a difficult problem, and it is outside the scope of this chapter.

It is the third challenge, where computational modeling has made the greatest contribution so far, in terms of rationalizing nontrivial observations in microscopy and spectroscopy. In view of this fact, it is instructive to briefly go through the experimental tools available for studying the electronic structure of atomically precise graphene nanoribbons and the observables they provide access to (Fig. 3).

On the one hand, there are "ionizing" spectroscopies, which excite the sample through the removal or the addition of electrons, thus leaving the sample in a charged excited state. This family includes scanning tunneling spectroscopy (STS, electron removal or addition), photoelectron spectroscopy (PES, electron removal), and inverse photoelectron spectroscopy (IPES, electron addition). The minimum energy required to remove an electron from the neutral GNR is termed *ionization energy I*, and the maximum energy that can be gained by adding an electron to the
Fig. 3 Characterizing the electronic structure of GNRs from on-surface synthesis: (**a**) photoelectron spectroscopy (PES). Electrons are ejected from the sample using X-ray or ultraviolet lasers. The distribution of kinetic energies of ejected electrons provides access to the density of states of the sample. In angle-resolved PES (ARPES), detection is recorded as a function of the polar angle ϑ (and azimuthal angle φ), which allows to resolve the energy-momentum relation of the initial states. (**b**) Scanning tunneling spectroscopy (STS): electrons tunnel from the sample to a sharp tip or vice versa, depending on the applied bias voltage. By scanning the tip across the sample surface, the derivative of the tunneling current with respect to the bias voltage provides a map of the local density of states. (**c**) Reflectance difference spectroscopy (RDS): electron-hole pairs are created by excitations via a tunable laser, and reflectance is recorded as a function of photon energy. The optical absorption by the GNR is isolated by measuring the difference in reflectance between incoming light polarized along the GNRs (which must be uniformly aligned) and light polarized perpendicular to the GNRs

neutral GNR is the *electron affinity A*. Their difference defines the *electronic* (band) gap $\Delta_{el} = I - A$, also known as *transport* gap or *fundamental* gap.

On the other hand, there are "optical" spectroscopies, in which the sample is excited through absorption of a photon of energy $h\nu < I$ and thus remains charge-neutral. This family includes reflectance difference spectroscopy, a technique adapted particularly to the study of surface-adsorbed GNRs. After an optical excitation, the sample contains both an excited electron and the hole it left behind. It can therefore be viewed as a combination of two independent charged excitations: one that adds the hole and one that adds the electron. The simultaneous presence of electron and hole, however, leads to a Coulomb attraction between the two oppositely charged particles which reduces the energy required to create the charge-neutral excitation. If the electronic gap is a *direct* one (i.e. the corresponding optical transition is not forbidden by momentum-based selection rules), then the *optical* gap $\Delta_{opt} = \Delta_{el} - E_b$ is reduced by the *exciton binding energy* Eb.

The better a material can screen the Coulomb interaction between the electron and hole, the lower is the exciton binding energy. While exciton binding energies in bulk inorganic semiconductors are often negligibly small (<25 meV for Si, GaAs and GaN Dvorak et al. 2013), the weaker electronic screening in nanomaterials can give rise to substantial exciton binding energies in excess of 1 eV.

This has two important consequences for the quantitative modeling of GNRs: First, there is no *single* band structure that describes all electronic excitations in a GNR, and any viable theoretical approach needs to consider the type of excitation (in the following, we use Δ for the gap of non-interacting theories and add the appropriate subscripts only where the method takes the type of excitation into account). And second, in any real-world scenario, the material *surrounding* the GNR (which every atom of the GNR is in direct contact with) plays a crucial role in determining how charges are screened *inside* the GNR. While the study of GNRs in isolation provides important insights into their intrinsic electronic structure, for challenges 1 and 3 it is indispensable to take the influence of their surrounding into account.

2   Empirical Models

2.1   Clar's Theory: π-Electrons with Pen and Paper

Clar's theory of the aromatic sextet provides a simple formalism to predict the distribution of π-electrons in polycyclic aromatic hydrocarbons (PAHs) (Clar 1972). It is based on the insight that π-electrons in PAHs tend to *delocalize*. The π-electron distribution in PAHs is therefore not properly represented by one particular Kekulé structure consisting of single and double bonds. A more appropriate representation is provided by the superposition or *resonance* of *all* possible Kekulé structures.

The Clar sextet shown in Fig. 4 provides an intuitive visual representation of the delocalized nature of the six π-electrons in an aromatic cycle – two possible configurations of single and double bonds are replaced by one ring. This notation

Fig. 4 The Clar sextet, representing the superposition of two complementary Kekulé structures
Fig. 5 Clar formulas for (**a**) triphenylene, (**b**) anthracene, and (**c**) graphene. The unit cell of graphene is shown in gray
allows to cover the different possible Kekulé structures of a given molecule with significantly less effort, simply because a structure containing n Clar sextets represents 2^n Kekulé structures. It also introduces a natural hierarchy: the more Clar sextets a structure contains, the more Kekulé structures it represents and thus the higher its weight in the superposition.

The Clar structure (or Clar *cover*) with the maximum number of sextets is termed the *Clar formula*. It is shown in Fig. 5 for three different cases. Triphenylene has a unique Clar formula containing three Clar sextets. Anthracene can host only one Clar sextet at a time but has three Clar formulas that again should be considered *resonating* between each other. Note that the superposition of Clar structures can lead to certain Kekulé structures being counted multiple times. In the case of anthracene, for example, the Kekulé structures represented by the central Clar formula in Fig. 5b are already contained in the two other Clar formulas on the left and right.

Since the bonds sticking out of a Clar sextet are single bonds, a Clar structure can never contain two Clar sextets directly adjacent to each other. The maximally dense network of Clar sextets is found in graphene, where it forms a $(\sqrt{3} \times \sqrt{3})$R30° superstructure with respect to the graphene unit cell. In infinite graphene, this network of Clar sextets can be shifted between three equivalent positions, as shown in Fig. 5c.

Up to this point, the introduction of Clar sextets has merely improved the *visualization* of the π-electron distribution. The understanding gained in this process, however, allows to make qualitative predictions about actual physical observables. By distinguishing between single bonds, aromatic bonds, and double bonds with corresponding bond orders of 1, 1.5, and 2, bond lengths can be predicted on a qualitative level (Pauling et al. 1935). The relative thermodynamic stability of different molecules can be judged by analyzing the degree of π-electron delocalization via counting of Clar sextets. And finally, the π-electron distribution *itself* is an observable that is accessible, for example, in scanning tunneling microscopy.

While Clar formulas are the Clar structures that, individually, represent the largest number of Kekulé structures, they do not necessarily cover *all* possible Kekulé structures. In general, a full analysis thus needs to go beyond the Clar formula and consider Clar structures with lower number of aromatic sextets. For finite benzenoid nanostructures, Clar structures can be computed straightforwardly by a computer program (Chou and Witek 2012, 2014).

Clar's theory has been applied extensively to nanographenes (Fujii and Enoki 2012). In the case of graphene nanoribbons, Clar's theory provides insight into how the boundary conditions imposed by different edge types impact delocalization. Armchair graphene nanoribbons with monohydrogenated edges are found to group into three families, depending on their width N_A (Wassmann et al. 2010):

- $N_A = 3p$: one unique Clar formula
- $N_A = 3p + 1$: two Clar formulas
- $N_A = 3p + 2$: $3p$ Clar formulas

with $p \in \mathbb{N}$. As illustrated by the examples shown in Fig. 6a–c, the Clar formulas for $N_A = 3p$ and $N_A = 3p + 1$ exclude certain hexagons from hosting sextets, giving rise to significant variations in bond order. The Clar formulas for $N_A = 3p + 2$ on the other hand allow the sextets to propagate throughout the GNR, just like in graphene, and the simple tight-binding model discussed in Sect. 2.2 predicts these GNRs to be gapless.

This classification based on the number of Clar formulas can be extended to edges with varying hydrogenation states, and it has been demonstrated that the corresponding predictions concerning bond lengths and π-electron distribution as a function of edge geometry and passivation are in agreement with density functional theory calculations (Wassmann et al. 2010).

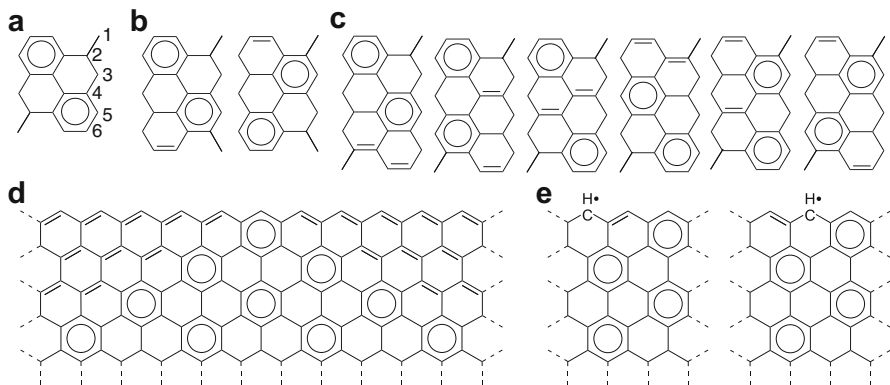
Clar's theory furthermore provides a simple explanation for the localized states found at monohydrogenated graphene zigzag edges. As shown in Fig. 6d, based on the ordinary Kekulé structures, only a single Clar sextet can be placed directly at a monohydrogenated zigzag edge. In comparison to infinite graphene, the π-electrons thus have significantly less opportunity to delocalize, resulting in a low thermodynamic stability. If, however, a double bond is broken in order to introduce an unpaired electron at every third "zag," the dense network of Clar sextets of graphene can be recovered (see Fig. 6e).


Fig. 6 Clar formulas of graphene nanoribbons. (**a–c**) Clar formulas for armchair graphene nanoribbons of the $N_A = 3p$ (**a**), $N_A = 3p + 1$ (**b**), and $N_A = 3p + 2$ (**c**) families. (**d**) Aperiodic Clar formula for infinite zigzag edge. (**e**) Periodic Clar formulas for infinite zigzag edge, enabled by introducing one unpaired electron every three "zags." (Figures (a–c) adapted from Corso et al. 2018)

The breaking of double bonds constitutes a relaxation of the usual requirement that Kekulé structures form the basis for determining the π-electron distribution. The stabilization gained by the delocalization can, however, outweigh the cost of the bond breaking. When this is the case, Clar's theory predicts zigzag edges to be characterized by highly reactive electronic states that are localized near the edge and host one electron every three "zags" – which is confirmed by higher-level theories such as tight binding (Fujita et al. 1996) or density functional theory (Son et al. 2006).

2.2   Tight Binding: Hopping on the Honeycomb Lattice

In the tight-binding approach, the problem of determining the electronic wave function in all of space is reduced to finding its optimal representation in a basis of pre-determined orbitals that are localized at atomic *sites*. For the case of graphene, the tight-binding representation can be made particularly simple, and its formulation predated the seminal experiments on graphene by many decades (Wallace 1947; Saito et al. 1998).

A general Hamiltonian matrix element between orbital m at site i and orbital n at site j is given by

$$H_{im,jn} = \langle \phi_{im} | \hat{\mathscr{H}} | \phi_{jn} \rangle = \langle \phi_{im} | - \hbar^2 \nabla^2 / 2m + V(\mathbf{r}) | \phi_{jn} \rangle \tag{3}$$

In graphene, all carbon atoms are electronically equivalent and have three nearest neighbors separated by $a \approx 0.142$ nm (Pauling et al. 1935), while the next-nearest neighbor distance is larger by a factor of $\sqrt{3} \approx 1.7$. As a first approximation, the

interaction between carbon sites can therefore be restricted to nearest neighbors. Since the main focus is on the delocalized π-electrons, which are less strongly bound than the electrons in the σ-bonds, one can further represent each carbon atom by a single $2p_z$ orbital, i.e., the indexes m, n can be dropped. Finally, the on-site term $H_{i,i}$ is identical for all sites and can be set to zero, since it results merely in a constant shift of the energy scale. The only non-zero matrix element remaining is the hopping integral (or *transfer* integral) $H_{i,j} =: -t$ between two neighboring sites i and j. In practice, t is usually treated as a parameter that is adjusted to fit the resulting electronic band structure against experiment (Bostwick et al. 2006) or ab initio calculations (Saito et al. 1998), yielding values in the range between 2.5 and 3 eV (Reich et al. 2002).

In second quantization, the corresponding tight-binding Hamiltonian reads

$$\hat{\mathscr{H}} = -t \sum_{\langle ij \rangle} \hat{c}_j^\dagger \hat{c}_i + \hat{c}_i^\dagger \hat{c}_j \tag{4}$$

where the sum extends over pairs of nearest neighbors and $\hat{c}_i^\dagger, \hat{c}_j$ are the electron creation and annihilation operators at site i and j.

Solving the tight-binding model involves solving the generalized eigenvalue problem

$$H\mathbf{v} = \varepsilon S \mathbf{v} \tag{5}$$

$$S_{ij} = \langle \phi_i | \phi_j \rangle \tag{6}$$

for the eigenenergies ε_α with corresponding eigenvectors $\psi_\alpha(\mathbf{r}) = \sum_j v_{\alpha j} \phi_j(\mathbf{r})$. In graphene, however, the overlap S_{ij} between $2p_z$ orbitals on neighboring sites is found to be < 0.1 (Reich et al. 2002) and can be neglected, leaving t as the sole parameter of the model. Note that this makes the model equivalent to the Hückel molecular orbital theory (Hückel 1933) with resonance integral $\beta = t$ and the Coulomb integral α set to zero.

For the two-dimensional hexagonal lattice of graphene, Hamiltonian (4) yields the dispersion

$$E(\mathbf{k}) = \pm t \sqrt{3 + 2\cos\left(\sqrt{3}k_x\right) + 4\cos\left(\sqrt{3}k_x/2\right)\cos\left(3k_y/2\right)} \tag{7}$$

where $\mathbf{k} = (k_x, k_y)$ is given in units of $1/a$. As shown in Fig. 7c, this formula already predicts the semimetallic nature of graphene, including the linear dispersion at the K and K' points. One simple way of fixing the parameter t is to match the experimental Fermi velocity $v_F \approx 10^6 \frac{m}{s}$ via the relation $\hbar v_F = 3ta/2$, yielding $t \approx 3.1$ eV.

Furthermore, this model allows to study the local electronic structure near graphene edges (Fujita et al. 1996; Nakada et al. 1996). When the edge carbon atoms are assumed to be passivated by one hydrogen atom each, they are sp^2-hybridized,
Fig. 7 (**a**) Real-space representation of graphene's primitive cell with lattice vectors $\mathbf{a}_1 = (\sqrt{3}, 0)$, $\mathbf{a}_2 = \left(\frac{\sqrt{3}}{2}, \frac{3}{2} \right)$ in units of the nearest-neighbor distance a. (**b**) First Brillouin zone of graphene with reciprocal lattice vectors $\mathbf{b}_1 = \left(\frac{2\pi}{\sqrt{3}}, -\frac{2\pi}{3} \right)$, $\mathbf{b}_2 = \left(0, \frac{4\pi}{3} \right)$ and high-symmetry points $\Gamma = (0, 0)$, $M = \left(\frac{\pi}{\sqrt{3}}, \frac{\pi}{3} \right)$, $K = \left(\frac{4}{3} \frac{\pi}{\sqrt{3}}, 0 \right)$. (**c**) Band structure corresponding to (7), following the path indicated in (**b**)
Fig. 8 (**a**) Numbering scheme for widths of ribbons with armchair and zigzag edges. The lattice constants are related by $a_{ac} = \sqrt{3} a_{zz} = 3a$. (**b**) Lowest π-electronic state of 7-AGNR, repeated periodically. (**c**) Lowest π-electronic state of 6-ZGNR, repeated periodically. The wave function at site j is represented by a circle with area $\propto |\psi(\mathbf{r}_j)|$

and thus each contributes one π-electron, just like the carbon sites in the interior. In nearest-neighbor tight binding, the edge boundary condition simply requires the wave function to vanish on the nearest-neighbor sites *outside* the edge.

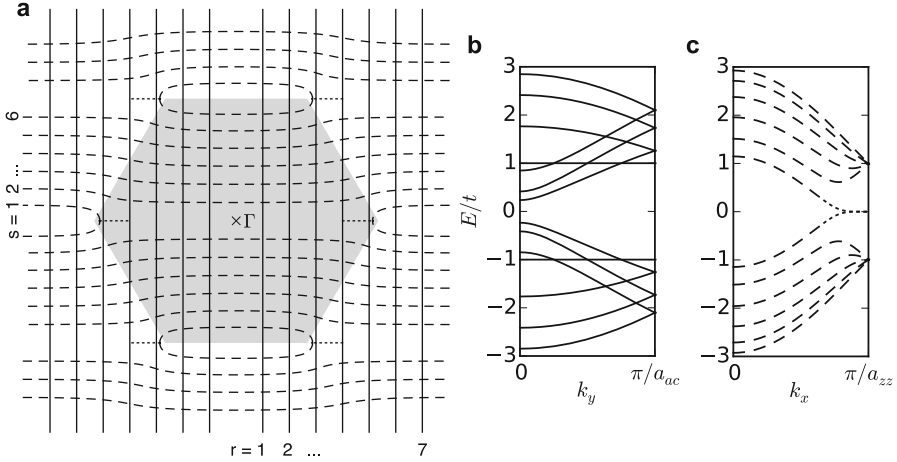
Figure 8b shows the lowest π-electronic state of an AGNR. Considering the AGNR embedded into a virtual graphene lattice, one realizes that its eigenstates can be obtained by restricting an appropriate linear combination of two eigenstates of graphene to the lattice sites of the AGNR. The allowed crystal wave vectors have the form $\mathbf{k}^{\pm} = (\pm r \frac{2\pi}{2w}, k_y)$, where $r \in \{1, \dots, N_A\}$ and $w = \frac{\sqrt{3}}{2}(N_A + 1)$ is the width of the AGNR. The electronic band structure of AGNRs can thus be obtained simply by inserting $\mathbf{k}^{\pm}$ into (7), which corresponds to cutting the dispersion of graphene along N_A straight lines of constant k_x (see Fig. 9).


Fig. 9 (**a**) Brillouin zone of graphene with cutting lines for $N_A = 7$-AGNR (continuous) and 6-ZGNR (dashed). Band structures of 7-AGNR (**b**) and 6-ZGNR (**c**), plotted in their respective first Brillouin zones

For ZGNRs this is not the case, as illustrated by Fig. 8c: the periodic repetition of the eigenstates of the GNR would not even lie on the virtual graphene lattice. Nevertheless, they can still be obtained analytically (Wakabayashi et al. 2010), and their dispersion can still be represented as N_Z *curved* cuts of the graphene dispersion, except for the localized edge states that are indicated as dotted lines in Fig. 9a, c.

The formula for the bandgap of AGNRs differs between the three families identified previously via Clar's theory and yields $\Delta(3p+1) > \Delta(3p) > \Delta(3p+2)$:

$$\Delta(N_A) = \begin{cases} -2t\left[1 + 2\cos\left(\frac{r}{N_A+1}\pi\right)\right], & N_A = 3p, \quad r = 2p+1 \\ +2t\left[1 + 2\cos\left(\frac{r}{N_A+1}\pi\right)\right], & N_A = 3p+1, \ r = 2p+1 \\ 0, & N_A = 3p+2, \ r = 2p+2 \end{cases} \tag{8}$$

where $p \in \mathbb{N}$, and r denotes the index of the band closest to the Fermi level.

In the limit of large widths ($N_A \to \infty$), this yields a first refinement of the rudimentary formula (2):

$$\Delta(N_A) = \begin{cases} ta\frac{\pi}{w} + \mathcal{O}\left(\frac{1}{w^2}\right) \approx 1.4\,\text{eV nm}/w, & N_A \in \{3p, 3p+1\} \\ 0, & N_A = 3p+2 \end{cases} \tag{9}$$

By taking the boundary conditions at the armchair edges properly into account, this model predicts a smaller bandgap for the $N_A = 3p$ and $N_A = 3p+1$ families than formula (2), while for $N_A = 3p+2$, the bandgap vanishes entirely, since the cutting lines cross the K point.

In agreement with Clar's theory, the model predicts the existence of nonbonding electronic states that are localized near the zigzag edge and host one electron every three "zags." The corresponding energy band, shown in Fig. 9 for the 6-ZGNR, is metallic for ZGNRs of all width. For general GNR shapes, where no analytic solutions are available, there are open source tools that simplify the task of constructing and solving the tight-binding model for both finite and periodic systems (Coh and Vanderbilt 2017).

The formal equivalence with the Hückel molecular orbital theory allows to transfer the graph theoretical results obtained in this field to the tight-binding description of graphene nanostructures. A graphene nanostructure can be regarded as a hexagonal (or *benzenoid*) graph, the carbon atoms being its *vertexes* $\{v_i\}$ and the bonds between carbon atoms its *edges*. The nearest-neighbor tight-binding Hamiltonian (4) is then given simply by $(-t)$ times the *adjacency matrix* (Günthard and Primas 1956; Li et al. 2012)

$$A_{ij} = \begin{cases} 1 & v_i, v_j \text{ adjacent} \\ 0 & \text{otherwise} \end{cases}$$

Since the trace of A vanishes, so does the sum of its eigenvalues, i.e., $\sum_i \varepsilon_i = 0$, where the sum goes over both occupied and empty states.

For hexagonal graphs, the number of negative and positive eigenvalues, corresponding to the number of bonding and antibonding orbitals, is equal (Fajtlowicz et al. 2005). Furthermore, their number can be found by counting the maximum number of pairwise nonadjacent edges β, i.e., the maximum number of double bonds in the corresponding Kekulé structure (Fajtlowicz et al. 2005). Since the total number of orbitals is given by the total number of vertexes N_v, the number of zero-energy *nonbonding* orbitals is obtained as $\eta = N_v - 2\beta$. These considerations can be used to classify the electronic structure of nanographenes based on topological arguments only (Wang et al. 2009). Note, however, that η is *not* equal to the number of edge-localized states, since their energies may differ from zero.

The nearest-neighbor single-orbital tight-binding model can be extended in numerous ways. Respecting the non-zero overlap integrals results in breaking particle-hole symmetry (Saito et al. 1998). Introducing site-dependent potentials in order to model symmetry breaking due to a supporting substrate or to capture the different chemical environment at the edge leaves the bandgaps unchanged to first order. Adapting hopping integrals to the different carbon-carbon bond lengths near the GNR edges, however, opens a bandgap for AGNRs of the $N_A = 3p + 2$ family (Son et al. 2006). The range of hopping may be extended. Allowing hopping between second-nearest neighbors affects the electronic structure near the Fermi level only by a rigid shift to first order in the hopping integrals (White et al. 2007). Hopping between third-nearest neighbors, on the other hand, plays a significant role (Gunlycke and White 2008). Increased flexibility may also be obtained by enlarging the basis set, e.g., to three orbitals per carbon site (Boykin et al. 2011). The additional complexity introduced by these extensions, however, comes at the cost of

additional parameters, which are typically fitted to band structures calculated by ab initio methods.

The extensions described above have in common that the electrons are still treated as noninteracting Fermions. In GNRs with widths in the low nm regime, dielectric screening is reduced significantly, giving rise to enhanced Coulomb interactions between quasiparticles. It is therefore unlikely that any of these models can be fitted to accurately describe the quasiparticle band structure of graphene nanoribbons over the whole range of widths from narrow GNRs up to graphene (Boykin et al. 2011).

2.3   The Hubbard Model: Many-Body Physics On-Site

One extension of the tight-binding model that *does* introduce explicit Coulomb interactions is the Hubbard model (Hubbard 1963):

$$\hat{\mathscr{H}} = -t \sum_{\langle ij \rangle, \sigma} \left(\hat{c}_{j\sigma}^{\dagger} \hat{c}_{i\sigma} + \hat{c}_{i\sigma}^{\dagger} \hat{c}_{j\sigma} \right) + U \sum_{i} \hat{n}_{i\uparrow} \hat{n}_{i\downarrow} \tag{10}$$

where the electron spin $\sigma \in \{\uparrow, \downarrow\}$ is now made explicit, $\hat{n}_{i\sigma} = \hat{c}_{i\sigma}^{\dagger} \hat{c}_{i\sigma}$ is the spin-resolved electron density at site i, and $U > 0$ describes the energy penalty associated with the on-site Coulomb repulsion between two electrons of different spins (in a single-orbital model, two electrons of the *same* spin can never occupy the same lattice site due to the Pauli exclusion principle).

The physics described by the Hubbard model is that of a competition between the kinetic energy of electrons, which is minimized by *delocalization*, and the Coulomb energy, which favors complete *localization* of each electron on one lattice site. The apparent simplicity of this lattice model for a short-range Coulomb interaction is deceptive. The Hubbard term is diagonal in real space but non-diagonal in momentum space, while exactly the opposite is true for the tight-binding term. Today, more than half a century after Hubbard's original description of the model, exact solutions for ground-state energy, excitation spectrum, etc. are available only for one-dimensional chains, where two electrons passing each other must actually hop directly "through" each other (Essler et al. 2005) (GNRs are *not* one-dimensional in this sense).

Some exact properties of the Hubbard model relevant to graphene nanostructures are known. Lieb proved for bipartite lattices at half-filling (and a repulsive value of U) that the ground state is nondegenerate and its total spin S is given by $S = \frac{1}{2}|N_A - N_B|$, where N_A and N_B are the number of atoms of the two sublattices (Lieb 1989). The theorem holds equally for periodic and finite structures (Lieb 1989). In particular, the total spin of nanographenes with equal numbers of atoms of both carbon sublattices, such as zigzag graphene nanoribbons, is therefore always equal to zero. Furthermore, Sorella and Tosatti performed quantum Monte Carlo calculations for the honeycomb lattice at zero temperature (Sorella and Tosatti

1992), showing that a transition from the semimetallic to an insulating state occurs, when the ratio U/t grows beyond a value of 4.5 ± 0.5.

For computing spectral properties and electron distributions of graphene nanoribbons, however, exact solutions of the Hubbard model are typically not feasible, and approximation is required. In this context it is helpful to know the relative magnitude of the two model parameters t and U. Like t, U is not a physical observable and is obtained by fitting models to experiment. Following (Yazyev 2010), the data concerning U seems to be rather scarce. From studying the localized spin distribution associated with solitons in thin films of polyacetylene (Ito et al. 1974), an effective $U \approx 3$ eV was extracted (Thomann et al. 1985). Assuming that the value of U in graphene is similar, one obtains $U/t \approx 1$. This places graphene neither in the extreme of $U \ll t$, where Gutzwiller's variational approach would yield a semimetal with a renormalized hopping integral (Gutzwiller 1965; Brinkman and Rice 1970), nor in the extreme $U \gg t$ of the Mott insulator, which can be described in terms of a Heisenberg model with antiferromagnetic coupling depending on t. For graphene, a different route for approximation is therefore required.

In the mean-field approximation, $\hat{n}_{i\sigma}$ is replaced by $\langle\hat{n}_{i\sigma}\rangle + \delta\hat{n}_{i\sigma}$, and terms of $\mathscr{O}(\delta\hat{n}_{i\sigma}^2)$ are neglected, resulting in

$$\hat{\mathscr{H}} = -t \sum_{\langle ij\rangle,\sigma} \left(\hat{c}_{j\sigma}^\dagger \hat{c}_{i\sigma} + \hat{c}_{i\sigma}^\dagger \hat{c}_{j\sigma} \right) + U \sum_i \langle\hat{n}_{i\uparrow}\rangle\hat{n}_{i\downarrow} + \langle\hat{n}_{i\downarrow}\rangle\hat{n}_{i\uparrow} - \langle\hat{n}_{i\uparrow}\rangle\langle\hat{n}_{i\downarrow}\rangle \quad (11)$$

The Hubbard term now involves only one-particle operators, and the model (11) can be solved by determining the optimal distribution of spins in a self-consistent manner. Another way to arrive at the same approximation is to make the Ansatz of a single Slater determinant of spin orbitals. In this sense, the mean-field approximation of the Hubbard model is nothing but the unrestricted Hartree-Fock method on a lattice.

For armchair GNRs, the mean-field Hubbard model predicts no breaking of spin symmetry and thus produces the same band structure as the tight-binding model. For zigzag GNRs, however, magnetic moments are predicted to form at the zigzag edges (Fujita et al. 1996), which give rise to a staggered sublattice potential for the electrons of each spin channel and opens a bandgap. As illustrated in Fig. 10a, the spins align in parallel along the edge and antiparallel between opposite edges.

While it is common practice to draw spins pointing out of the GNR plane, it is important to keep in mind that there is no preferred absolute alignment of spins at room temperature due to the low spin-orbit splitting in freestanding graphene nanostructures. Even the *relative* alignment of spins must be limited in range (see Section "Density Functional Theory: Exchange and Correlation in Real Space"), since the Mermin-Wagner theorem rules out long-range magnetic order at finite temperature in one and two dimensions (Mermin and Wagner 1966).

Mean-field approximations replace a many-body problem by a one-body problem with an averaged *effective* interaction. In general, this neglect of correlation may be justified, if many interactions are involved in the average – the accuracy of the mean-
Fig. 10 ZGNRs in the Hubbard model. (**a**) Spin-up (filled circles) and spin-down (empty circles) densities of the 8-ZGNR for $U/t = 1.2$. Circle area is proportional to local magnetic moment. field approximation of the Hubbard model should increase with the coordination number Z of each lattice site. A priori, the two-dimensional honeycomb lattice with $Z = 3$ would not seem like a particularly suitable candidate, and, indeed, the neglect of quantum fluctuations leads to a substantial shift of the Mott-Hubbard transition from $U/t \approx 4.5$ to $U/t \approx 2.23$ (Sorella and Tosatti 1992). Still, the ratio of $U/t \approx 1$ in graphene puts it safely below the transition, and case studies for finite nanographenes show that the mean-field description agrees reasonably well with exact diagonalization and Quantum Monte Carlo simulations (Feldner et al. 2010). This makes the mean-field Hubbard model a computationally inexpensive alternative to ab initio methods when studying the spin distribution in nanographenes and its effect on the π-electronic structure (Yazyev 2010).

3   Ab Initio Methods

3.1   From First Principles

All ab initio electronic structure methods are ultimately rooted in the quantum mechanical Schrödinger equation:

$$\hat{\mathscr{H}} \, \Psi(\mathbf{r}_1, \ldots, \mathbf{r}_N, \mathbf{R}_1, \ldots, \mathbf{R}_M, t) = i\hbar \frac{\partial}{\partial t} \Psi(\mathbf{r}_1, \ldots, \mathbf{r}_N, \mathbf{R}_1, \ldots, \mathbf{R}_M, t) \, .$$

(12)

The Schrödinger equation describes the time evolution of a system of N electrons and M nuclei in terms of the wave function Ψ, whose absolute square

$|\Psi(\{\mathbf{r}_j\}, \{\mathbf{R}_k\}, t)|^2$ equals the probability to find the system in the configuration specified by the electronic coordinates $\{\mathbf{r}_j\}$ and nuclear coordinates $\{\mathbf{R}_k\}$ at time t. Further coordinates, such as the spin of electrons or nuclei, are suppressed here for clarity and can be thought of as being included in $\mathbf{r}_j$ and $\mathbf{R}_k$.

The Hamiltonian operator $\hat{\mathscr{H}}$ contains the physical model appropriate for the particular system and the quantities of interest – here, graphene nanoribbons and their π-electronic structure. This information can be used to justify simplifications of the most general form of $\hat{\mathscr{H}}$, three of which are outlined in the following.

First, in the absence of time-dependent external potentials, $\hat{\mathscr{H}}$ does not explicitly depend on time. Without loss of generality, the search for solutions to Eq. (12) can thus be restricted to stationary states, whose trivial time-dependence $\Psi(t) = \exp(-iEt/\hbar)\Psi(0)$ can be factored out. This yields the time-independent Schrödinger equation

$$\hat{\mathscr{H}} \, \Psi(\mathbf{r}_1, \ldots, \mathbf{r}_N, \mathbf{R}_1, \ldots, \mathbf{R}_M) = E \, \Psi(\mathbf{r}_1, \ldots, \mathbf{r}_N, \mathbf{R}_1, \ldots, \mathbf{R}_M) \,. \qquad (13)$$

Second, graphene nanoribbons are made up of light elements, and the electrons in both π- and σ-bands move at velocities far below the speed of light. For a basic estimate, one connects the maximum binding energy $E_b \approx 20\,\mathrm{eV}$ of σ-electrons in graphene to the kinetic energy T via the virial theorem $T = \langle \hat{T} \rangle = -E = E_b$ (Engel and Dreizler 2011) and finds a Lorentz factor $\gamma = 1 + E_b/m_e c^2 \approx 1 + 4 \cdot 10^{-5}$, corresponding to a velocity $v = \sqrt{1 - \gamma^{-2}}c \approx 0.01c$.

The low atomic number of carbon also leads to weak spin-orbit coupling, which is estimated to be of the order of $1\,\mu\mathrm{eV}$ for flat graphene and $\approx 10\,\mu\mathrm{eV}$ in the presence of the slight corrugations that can occur in substrate-supported graphene (Huertas-Hernando et al. 2006). It is therefore safe to consider the nonrelativistic limit for the valence electronic structure of graphene nanoribbons.

And third, carbon nuclei are $M_n/m_e = 12u/m_e \approx 2.2 \cdot 10^4$ times heavier than electrons and thus generally move slower. Born and Oppenheimer showed that, when expanding the Hamiltonian $\hat{\mathscr{H}}$ up to fourth order in $\kappa = \sqrt[4]{m_e/M_n}$, the electrons follow the nuclear motion *adiabatically*, i.e., always remaining in their instantaneous ground state (Born and Oppenheimer 1927; Born and Huang 1954). In the adiabatic Born-Oppenheimer approximation, the wave function can be written as a product

$$\Psi(\{\mathbf{r}_j\}, \{\mathbf{R}_k\}) = \Psi_{\{\mathbf{R}_k\}}(\{\mathbf{r}_j\}) \, \chi(\{\mathbf{R}_k\})$$

of an electronic wave function $\Psi_{\{\mathbf{R}_k\}}$ and a nuclear wave function χ, where the equation for $\Psi_{\{\mathbf{R}_k\}}$ involves only the instantaneous *positions* of the nuclei, not their momenta. In the following, the subscript $\{\mathbf{R}_k\}$ is dropped for convenience.

The adiabatic approximation can break down, when electronic excitations can occur at the energy scales corresponding to nuclear vibrations. While the vanishing bandgap in graphene makes the adiabatic approximation problematic (Pisana et al. 2007), the narrow graphene nanoribbons discussed here have substantial electronic

gaps, and the adiabatic approximation should hold. Note, however, that this does not imply that nuclear vibrations can be disregarded altogether. When computing the electronic structure at finite temperatures, the effect of nuclear vibrations should be taken into account. Even at zero temperature, the quantum-mechanical zero-point motion of light nuclei can give rise to an appreciable renormalization of the electronic gap, such as $\approx 6\%$ for the optical bandgap of diamond (Cardona and Thewalt 2005). While these effects can be captured *within* the adiabatic approximation, they require the computation of the electron-phonon coupling matrix elements and have historically often been neglected. For recent ab initio work in this direction, see (Poncé et al. 2014; Cannuccia and Marini 2012).

Combining these three simplifications yields the time-independent Schödinger equation for nonrelativistic electrons in the Born-Oppenheimer approximation

$$\hat{\mathscr{H}}\,\Psi(\mathbf{r}_1,\ldots,\mathbf{r}_N) = E\,\Psi(\mathbf{r}_1,\ldots,\mathbf{r}_N) \tag{14}$$

where the Hamiltonian is now given explicitly by

$$\hat{\mathscr{H}} = -\sum_j \frac{\hbar^2}{2m_e}\nabla^2_{\mathbf{r}_j} + \frac{1}{2}\sum_{j\neq k}\frac{1}{4\pi\varepsilon_0}\frac{e^2}{|\mathbf{r}_j - \mathbf{r}_k|^2} \tag{15}$$

$$-\sum_{jJ}\frac{1}{4\pi\varepsilon_0}\frac{Z_J e}{|\mathbf{r}_j - \mathbf{R}_J|} + \frac{1}{2}\sum_{J\neq K}\frac{1}{4\pi\varepsilon_0}\frac{(Z_J e)(Z_K e)}{|\mathbf{R}_J - \mathbf{R}_K|} \quad . \tag{16}$$

It contains the kinetic energy of electrons, the Coulomb repulsion between electrons, the Coulomb attraction between electrons and nuclei, as well as the Coulomb repulsion between nuclei. Since the motion of electrons and nuclei has been decoupled, the only term involving more than one spatial coordinate of the wave function is the Coulomb interaction between electrons. The Hamiltonian can therefore be written as

$$\hat{\mathscr{H}} := \sum_j \hat{h}(\mathbf{r}_j) + \frac{1}{2}\sum_{j\neq k}\frac{1}{4\pi\varepsilon_0}\frac{e^2}{|\mathbf{r}_j - \mathbf{r}_k|^2} \tag{17}$$

where $\hat{h}(\mathbf{r}_j)$ is a one-particle operator.

Finding accurate and efficient approximations to Eq. (14) is a formidable task, and generations of theoretical chemists and physicists have developed a whole arsenal of ab initio methods to tackle it. The following sections mention three methods that have proven useful in the study of atomically precise graphene nanoribbons.

While tight binding and the mean-field Hubbard model are usually introduced as empirical models with parameters to be fitted either against experiment or accurate calculations, it is worth noting that, these models (and their parameters) can be derived rigorously as approximations of ab initio methods such as density functional

theory (Foulkes and Haydock 1989; Foulkes 2016). Their extension provides a smooth transition – via semiempirical methods – toward ab initio methods free of empirical parameters.

3.2 Density Functional Theory: Exchange and Correlation in Real Space

Density functional theory (DFT) has evolved to become the most frequently used electronic structure method to study condensed matter systems. Since great introductory texts (Martin 2004) as well as reference works (Engel and Dreizler 2011) are readily available, this section assumes the reader is familiar with the basic theory and focuses on aspects relevant to the practical application of DFT to GNRs.

The electronic structure of GNRs predicted by Kohn-Sham density functional theory with standard (semi-)local exchange-correlation functionals is in qualitative agreement with the mean-field Hubbard model, when the various extensions discussed in Sect. 2.2 are taken into account. As shown in Fig. 11, AGNRs are predicted to be semiconducting with no spin polarization. Within each family, the bandgap is again approximately inversely proportional to the GNR width w and can be parametrized for $w \to \infty$ as (Yang et al. 2007):

$$\Delta(N_A) \approx \begin{cases} 0.8\,\text{eV}\,\text{nm}/w, \ N_A = 3p \\ 1.6\,\text{eV}\,\text{nm}/w, \ N_A = 3p + 1 \\ 0.3\,\text{eV}\,\text{nm}/w, \ N_A = 3p + 2 \end{cases} \tag{18}$$

thus providing a further refinement of Eq. (2).

In ZGNRs, the local (spin-)density approximation (LDA) confirms the familiar breaking of spin and sublattice symmetry, which opens a bandgap that is roughly inversely proportional to the GNR width w (Son et al. 2006). DFT has also been used to map out the dispersion of rotational spin-wave excitations along the zigzag edge, yielding a spin-spin correlation $\langle \hat{\mathbf{s}}_i \, \hat{\mathbf{s}}_{i+l} \rangle \propto \exp(-l/\xi(T))$ with correlation length $\xi(T) \approx 300\,\text{K}\,\text{nm}/T$ for $T > 10\,\text{K}$ (Yazyev and Katsnelson 2008). At room temperature, spins along the zigzag edge are thus expected to align only over length scales of $\approx 1\,\text{nm}$. Possible avenues for increasing ξ to values suitable for room-temperature spintronics applications include enhancing the magnetic anisotropy through substrate-induced spin-orbit coupling. For example, the spin-orbit splitting in graphene can be increased more than hundredfold to $\approx 10\,\text{meV}$ via adsorption on transition metal dichalcogenides (Wang et al. 2016b).

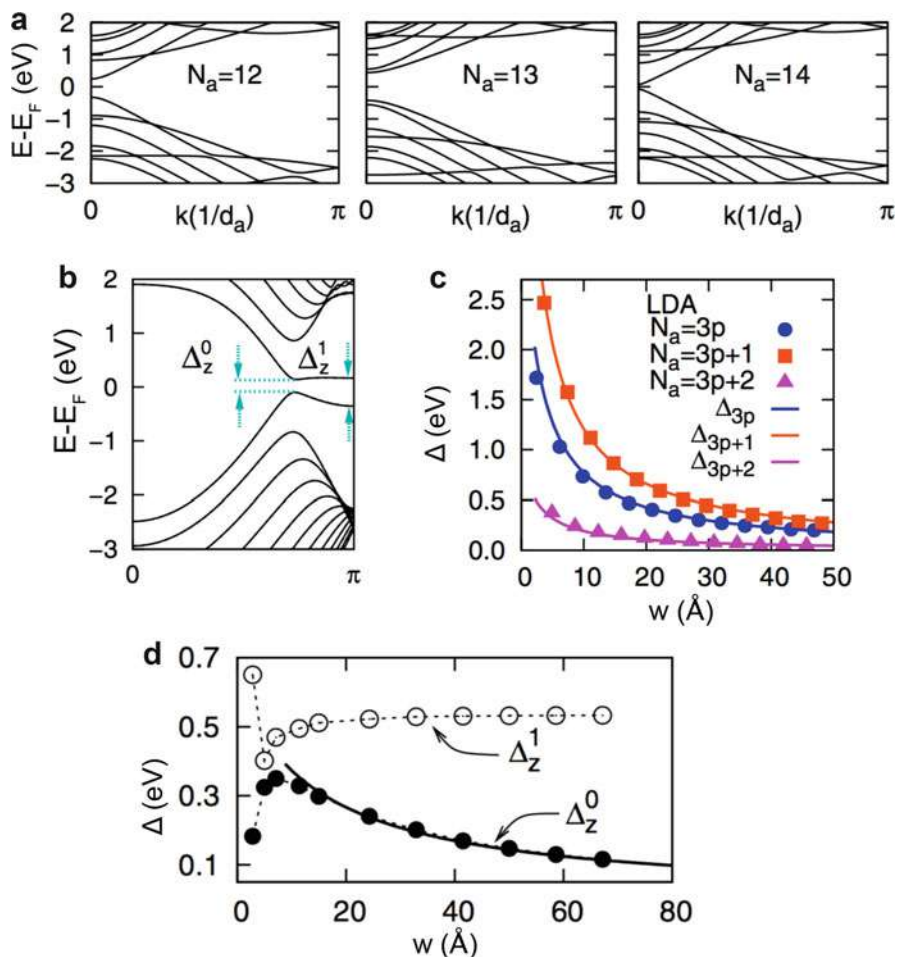
While the qualitative agreement with the (extended) mean-field Hubbard model also holds for the shape of the single-particle electronic states on the carbon lattice, DFT seamlessly incorporates changes in atomic geometry due to the presence of edges and their chemical passivation. This makes DFT well-suited for comparison against experimental methods that probe and resolve the local density of states, such as scanning tunneling microscopy/spectroscopy (Talirz et al. 2013; Kimouche et al.


Fig. 11 Electronic structure of GNRs in the local density approximation (LDA). (**a**) Band structure of armchair GNRs from groups $N_A = 3p, 3p + 1, 3p + 2$. (**b**) Band structure of 12-ZGNR. (**c**) Kohn-Sham gap Δ of AGNRs as a function of width w. (**d**) Kohn-Sham gap Δ_Z^0 of ZGNRs as a function of width w. (Adapted with permission from Son et al. (2006), copyright (2006) American Physical Society)

2015). One peculiarity of STM is that the tip scans over the atoms at a distance of several Å, i.e., it proves the exponential tail of the electronic states, and care needs to be taken in order to ensure an accurate representation of these tails in STM simulations (Tersoff 1989).

Gas-phase DFT calculations of GNRs involving hundreds of atoms can be routinely performed with a wide range of well-tested codes (Lejaeghere et al. 2016). Conformational changes due to adsorption on a substrate can be included by considering a combination of quantum mechanics and molecular mechanics (QM/MM),
Fig. 12 Example of slab geometry: (**a**) short 7-AGNR adsorbed on four-layer Au(111) slab, terminated by H to remove the lower surface state. 2×4 nm unit cell containing 674 atoms. The unit cell is repeated periodically in three dimensions and relaxed with PBE, plus DFT-D3 dispersion correction. (**b**) Close-up of relaxed geometry for terminations with Br (I), radical (II), H (III), and 2H (IV) at the central carbon atom of the terminus. Termination (II) interacts strongly with the Au(111) surface, causing the carbon atom to bend down toward the surface by $\approx$1Å. where the substrate is treated using cheap empirical force fields. If the GNR is expected to form chemical bonds with the substrate, as shown in panel II of Fig. 12b, the substrate needs to be treated at the level of DFT. In this case, the number of atoms can easily grow beyond a thousand, as both the number of layers of the substrate slab and the distance between surface-adsorbed GNRs need to be converged.

Another challenge associated with modeling interactions with a substrate is dispersion forces: by construction, the usual (semi-)local approximations to correlation lead to an exponential decay of the interaction between atomic fragments for large separations R (Rydberg et al. 2003) and are thus unable to accurately capture dispersion forces with their asymptotic form $\propto 1/R^6$. Yet, in the absence of chemical bonds, dispersion forces dominate the interaction of GNRs with a substrate and play a key role in determining the adsorption height. This deficiency can be corrected by adding interatomic potentials of appropriate asymptotic form, termed "DFT-D," or double integrals over the electron density and gradient, termed "vdW-DF," to the density functional (Grimme 2011; Berland et al. 2015). While these corrections improve the description of dispersion forces substantially and at negligible computational overhead, both face the problem of how to avoid double counting of correlation. In DFT-D, this is handled by damping the correction at short interatomic distances, and it has been pointed out that molecular binding energies in some cases are more sensitive to the empirical parametrization of this damping function than to the physically meaningful dispersion coefficients (Hanke 2011). In vdW-DF, the correction is undamped, thus handing the task back to the density functional. These issues become particularly relevant for systems that fall in between the extremes of dispersion-dominated physisorption and covalent bonding,

where the DF and the correction need to work together. One example from this chemisorption regime is ZGNRs adsorbed on Au(111), where DFT-D-corrected calculations predict the preservation of magnetic edge states (Li et al. 2013), but low-temperature STS experiments seem to suggest otherwise (Ruffieux et al. 2016; Wang et al. 2016a).

Finally, Kohn-Sham DFT is a theory of the electronic ground state, and while knowledge of the exact density functional would enable finding the exact electronic ground-state density, the energy spectrum of the fictitious noninteracting Kohn-Sham system does not correspond to excitation energies of the many-body system (except for the energy of the highest occupied level, which corresponds to the ionization energy) (Perdew and Levy 1983). In particular, the Kohn-Sham gap differs from both the electronic gap Δ_{el} and the optical gap Δ_{opt}, even in exact DFT.

3.3 The *GW* Approximation: Screening of Charged Excitations

The GW approximation of many-body perturbation theory replaces the electronic self-energy Σ by $i\hbar GW$ (the first-order expansion in W), where G denotes the single-particle Green function and W the screened Coulomb interaction (Hedin 1965). The GW approximation has a long history of successful application in predicting electronic bandgaps in solids (Hybertsen and Louie 1985; Godby et al. 1986; van Schilfgaarde et al. 2006) and is described in detail in the literature (Hedin and Lundqvist 1969; Martin et al. 2016) and in the Chap. 15, "Modeling Excited States of Confined Systems" by Hung and Öğüt in the MTM set of this handbook. More recently, it has been shown to provide reasonably accurate ionization potentials and electron affinities for small molecules (Knight et al. 2016). In GNRs, the accuracy of the GW approximation can be expected to improve due to stronger screening of the interaction W and, importantly, provides a framework for computing electron addition and removal energies that captures the nonlocal screening from the GNRs' environment out of the box.

Early GW calculations of GNRs in isolation were performed starting from the orbitals and Kohn-Sham energies in the LDA (G_0W_0@LDA) (Yang et al. 2007). While the GW quasiparticle band structure remains qualitatively similar to the DFT band structure, the electronic gap of AGNRs opens substantially to

$$\Delta_{el}(N_A) \approx \begin{cases} 3.1\,\mathrm{eV\,nm}/w, & N_A = 3p \\ 4.4\,\mathrm{eV\,nm}/w, & N_A = 3p + 1 \\ 1.5\,\mathrm{eV\,nm}/w, & N_A = 3p + 2 \end{cases} \qquad (19)$$

as shown in Fig. 13a. Importantly, the corrections depend on the character of the electronic states (σ-states are more strongly corrected than π-states at the same energy) and result in an increase of dispersion near the Fermi level by 10–20%. This increase in bandwidth is consistent with GW calculations for graphene, where

the resulting increase of the Fermi velocity improves agreement with experiment
compared to the LDA (Grüneis et al. 2008; Trevisanutto et al. 2008).

Unfortunately, there is currently no meaningful reference to validate the accu-
racy of GW calculations for GNRs in the gas phase: the large size of GNRs
prevents experimental studies of the gas phase and makes it challenging to
obtain complementary theoretical values from accurate but unfavorably scaling
quantum chemistry methods. For a meaningful comparison to experiments, be it
photoelectron spectroscopy or scanning tunneling spectroscopy, GW calculations
of GNRs therefore need to consider the substrate, on which the GNRs are adsorbed.
For "simple" substrates like NaCl or graphene, this is feasible with significant
computational effort (Jiang et al. 2013). In the on-surface synthesis approach,

however, GNRs are usually synthesized on the noble metal surfaces Au(111) and Ag(111), whose many electrons pose a major challenge for the convergence of GW calculations (Tamblyn et al. 2011). For AGNRs on metallic surfaces, a simple remedy is to introduce the screening by the substrate into the gas-phase GW calculation via the method of image charges from classical electrostatics: a charge q in the GNR is attracted toward the metal surface as if interacting with an image charge $-q$, mirrored across the image plane. The position of the image plane (Lam and Needs 1993) as well as the adsorption height of the GNR can be computed at the level of DFT, thus making the model free of adjustable parameters (Kharche and Meunier 2016). Given the approximations involved, the excellent agreement with experiment shown in Fig. 13b may however be fortuitous.

Figure 13b illustrates that screening by a metallic substrate reduces the large gas-phase GW bandgaps almost back to the original DFT values, which raises the question whether the same cannot be achieved with less effort by using adequate DFT exchange-correlation functionals. While generalized Kohn-Sham schemes hold some promise in this respect (Stein et al. 2010), the answer is likely negative, since the nonlocal screening depends sensitively on the details of the GNRs' environment (Biller et al. 2011). For example, moving a 7-AGNR from the Au(111) surface onto a NaCl monolayer island already increases Δ_{el} by 0.5 eV (Wang et al. 2016a).

Turning to ZGNRs, GW predicts a substantial gap of the order of $\Delta_{el} \approx 1$eV for widths in the range of $1-2$ nm (Yang et al. 2007) (not shown). Recent measurements of Δ_{el} for zigzag edges on a monolayer of NaCl on Au(111) are compatible with these predictions (Ruffieux et al. 2016; Wang et al. 2016a). It is important, however, to keep in mind that these experiments were carried out at 4 K, i.e., significantly below the temperature at which spin-wave excitations are predicted to start playing a dominant role (Yazyev and Katsnelson 2008). The size of Δ_{el} at room temperature remains to be determined and may be significantly smaller or vanish entirely.

Finally, it is worth noting that most of the GW calculations for GNRs to date involve additional approximations, such as plasmon-pole approximations for the energy dependence of the self-energy (Hybertsen and Louie 1986), a lack of self-consistency (which introduces a dependence on the starting point), and potentially unconverged basis sets. Recent validation efforts rightfully point out the necessity of eliminating these technical approximations (van Setten et al. 2015; Maggio and Kresse 2017), and future calculations will be able to take advantage of the significant progress made in modern GW implementations, which reduce both the computational complexity and the prefactor (Govoni and Galli 2015; Liu et al. 2016; Wilhelm et al. 2018).

3.4 The Bethe-Salpeter Equation: Electron-Hole Interaction

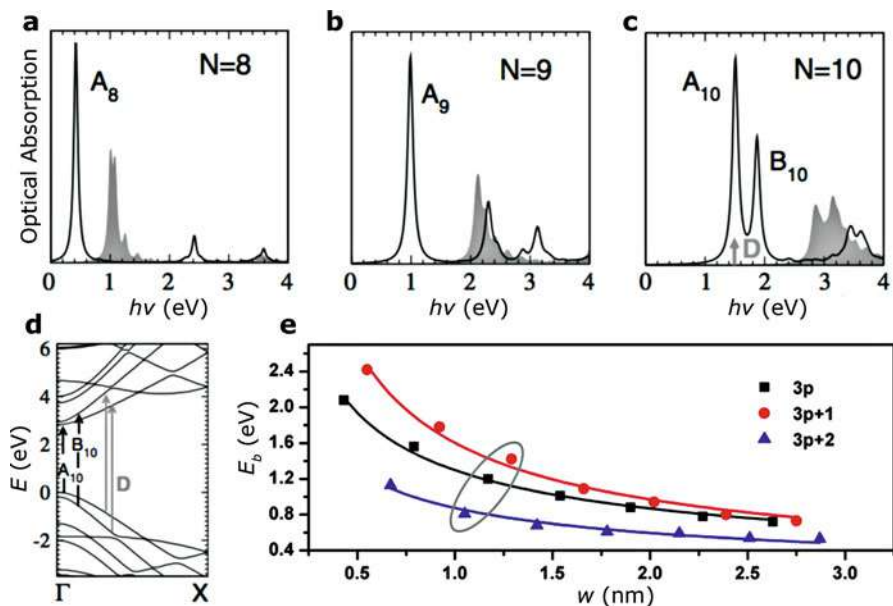
The two-particle Bethe-Salpeter equation (BSE) provides a framework for explicitly describing the interaction between a photoexcited electron and hole. Building on the GW quasiparticle spectrum as well as the screened Coulomb interaction W, the BSE


Fig. 14 Optical absorption spectra of armchair GNRs from GW+BSE. (**a–c**) Spectra for armchair GNRs of width $N_A = 8, 9, 10$ with (black lines) and without (gray) inclusion of electron-hole interaction, computed for linear polarization along the GNR axis. is one of the most accurate methods available for computing optical spectra and exciton binding energies in extended systems; see Onida et al. (2001) and Martin et al. (2016).

Figures 14a–c show the optical absorption spectra of selected AGNRs, as computed by the GW+BSE approach. AGNRs have *direct* bandgaps, and the lowest-energy optical transition involves the valence and conduction band. For $N_A = 8, 9, 10$, substantial exciton binding energies E_b of the order of 1 eV lead to a corresponding reduction of the optical Δ_{opt} with respect to the electronic gap Δ_{el}, thus highlighting the importance of differentiating between ionizing and optical excitations in AGNRs.

Similar to the case of carbon nanotubes (Marinopoulos et al. 2003), optical absorption in GNRs is strongly quenched for light polarized orthogonal to the GNR axis. This is leveraged in reflectance difference spectroscopy (RDS), which measures the difference in complex reflectance for incident light polarized along and across the axis of GNRs aligned on an optically isotropic substrate (see Fig. 3c). For the 7-AGNR, the theoretical value of $\Delta_{opt} \approx 1.9$ eV has been found to agree

reasonably well with the experimental value of $\Delta_{opt} \approx 2.1\,\text{eV}$ from RDS (Denk et al. 2014).

Compared to charged excitations, the effect of substrate screening on optical excitations in AGNRs is significantly reduced. This is a direct consequence of the fact that the corresponding excitons are charge-neutral and do not display a static dipole moment (Garcia-Lastra and Thygesen 2011). Minor renormalization is still expected due to inhomogeneity in the charge distribution, as demonstrated for the case of CNTs adsorbed on metals (Spataru 2013). The increased robustness of the optical transition energies against screening from the environment, however, allows to make contact between the characterization of atomically precise GNRs synthesized on metal surfaces and those synthesized in solution (Vo et al. 2014; Narita et al. 2014).

The $GW + \text{BSE}$ approach is computationally challenging – not only does it require the quasiparticle spectrum as input, an adequate description of the excitonic states requires very dense sampling of reciprocal space, and the computational complexity of solving the BSE is $\mathcal{O}(N^4)$ in the number of atoms N (Martin et al. 2016). In practice, additional approximations are often employed, such as using a static interaction W or neglecting nonresonant coupling (Tamm-Dancoff approximation). In this context, the validation of existing BSE implementations, in analogy to the recent efforts for GW approximation (van Setten et al. 2015), is highly anticipated.

4   Conclusions

Theoretical descriptions of the electronic structure of GNRs have come a long way since the empirical models employed in the twentieth century. Ab initio methods, such as density functional theory and many-body perturbation theory, have become valuable tools that assist in the structural and electronic characterization of atomically precise GNRs in highly controlled experimental settings.

As these GNRs start being incorporated into prototype devices, however, efforts both from the experimental and theory side are needed in order to arrive at a predictive accuracy that allows to point out the best GNR for a given application. While experimentalists will need to find ways of increasing control over the atomic-level environment of the GNR in a device, there are a number of challenges on the theory side waiting to be addressed. This chapter concludes with a "wish list" of these outstanding challenges, the solution of each of which would constitute a significant step forward:

- Vibrational effects on the bandgap of AGNRs at the GW level, including zero-point motion renormalization
- Dispersion-aware DFT that is accurate across interaction regimes, from physisorption over chemisorption to covalent bonds

- Refinement of embedding procedures, for capturing substrate effects beyond classical image charge models and modeling the diverse dielectric environment in devices
- Benchmarking GW calculations of AGNRs in the gas phase against accurate quantum chemistry references
- Elimination of starting-point dependence in GW calculations of GNRs, perhaps via quasiparticle self-consistent GW (QSGW)
- Quantifying the effects of spin-wave excitations on the electronic structure of ZGNRs at room temperature, potentially including substrate-induced enhancement of spin-orbit coupling

Part VI
Thermal Transport

Thermal Transport: Overview

32

Davide Donadio

Contents

Abstract

This chapter focuses on recent progress in the modeling of conductive thermal transport in a variety of systems and materials, from crystalline solids and nanostructures to molecular junctions, composites, and biological systems. Novel emergent technologies in energy harvesting and conversion, microelectronics, phase-change memories, heat-assisted magnetic recording, sensing, and medical therapy and diagnostic have prompted the extension of thermal transport modeling beyond traditional bulk crystalline materials and heavily parameterized models. Major advances have been made possible by the development of fundamental theories and computational approaches, which are discussed in the following chapters.

1   Introduction

The first macroscopic theory of heat transport was put forward by J.-B. Joseph Fourier in his essay *The Analytical Theory of Heat*, published in 1822. The partial differential equation that controls heat propagation in a medium remains the cornerstone of nowadays studies of heat transport. In nature, thermal energy can be transferred through three different mechanisms: conduction, convection, and radiation. Since in condensed phases and at the molecular scale convection and radiation are by far less relevant, chapters in this section focus on conductive heat transfer. According to Fourier's early observations, in stationary conditions conductive heat transport is controlled by a proportionality between the heat current $\vec{J}$ and the temperature gradient in the material ∇T:

$$\vec{J} = -\kappa \nabla T. \tag{1}$$

This simple relation is the well-known Fourier's law. The proportionality factor κ is the thermal conductivity, which is an intrinsic property of the material. To compute κ one needs a microscopic theory that describes the conduction of heat carriers, which are electrons and lattice vibrations, i.e., phonons.

In 1929 Rudolf Peierls formulated a microscopic theory of lattice heat transport, based on the assumptions that phonons obey the Boltzmann transport equation (BTE) (Peierls 1929). Later on lattice thermal conductivity, as well as several other transport coefficients, was expressed within linear response (LR) theory in terms of correlation functions by Green and Kubo (Green 1960; Kubo et al. 1957; Zwanzig 1965). BTE and LR laid the foundations of thermal transport modeling for the years to come. In spite of substantial theoretical advances in lattice dynamics and the rise of molecular dynamics, since the 1960s and for several decades, the calculation of the thermal conductivity of materials was undertaken using kinetic models that heavily rely on empirical parameters (Callaway 1959; Holland 1963).

In the past two decades, following the rise of nanotechnology and its potential application to electronics and energy materials, thermal transport has become the subject of intensive efforts in the communities of condensed matter physicists and materials scientists, with impressive progress on the experimental side (Cahill et al. 2003, 2014). New or significantly improved experimental techniques, such as time-domain thermoreflectance (Cahill 2004), Raman thermometry (Reparaz et al. 2014), scanning thermal microscopy (Grosse et al. 2011), and thermal spectroscopy (Siemens et al. 2009; Minnich et al. 2011), provide novel insight into the physics of heat transport, thus enabling fundamental discoveries and paving the way to the design of materials with tailored thermal conductivity.

Among the most remarkable discoveries in the field of thermal transport in materials in the past two decades, it is worth mentioning the measurement of the thermal conductivity of low-dimensional nanostructures (Li et al. 2003; Pop et al. 2006; Ghosh et al. 2010; Bae et al. 2013); the finding of ultralow thermal conductivity, yet crystalline, materials (Chiritescu et al. 2007); the engineering of

nanostructured materials with low κ for thermoelectric energy conversion (Yu et al. 2010; Biswas et al. 2012); and the design of high thermal conductivity polymers (Shen et al. 2010). Such achievements, which were often the result of combined theoretical and experimental efforts, boosted the development of *phononics* as a research field on its own, which addresses the control of acoustic and thermal vibrations in solids or liquids (Balandin 2005; Maldovan 2013; Volz et al. 2016).

The predictive bottom-up calculation of the thermal conductivity remains a very difficult problem in materials modeling. Modeling efforts were also crowned with success, for example, with the development of first-principles BTE, which enables the calculation of κ for simple bulk crystalline materials (Broido et al. 2007; Ward et al. 2009) and nanostructures, e.g., graphene and other 2D materials (Fugallo et al. 2014). Remarkable progress in molecular dynamics (MD) simulations has allowed researchers to tackle heat transport in complex systems, e.g., nanostructured materials (Selli et al. 2016), biomolecules (Leitner 2008), and polymer composites (Desai et al. 2005). Furthermore, today's high-performance computers and MD codes on the theory side, combined with the refinement of nanoscale fabrication on the experimental side, enable the direct comparison of atomistic simulations to experimental measurements over the same length scales. Yet, modeling heat transport in materials still presents major challenges that need to be overcome, both at a very fundamental level and at the level of addressing the actual complexity of realistic systems for technological applications.

The chapters of this section assess the state of the art of modeling thermal transport in materials. They not only provide an overview of applications to emerging materials and complex systems but also report on recent theoretical and methodological advances, since the former would not have been possible without the latter. The first three chapters address recent advances in theory and methods that enable the calculation of the thermal conductivity and of the detailed phonon properties of relatively simple materials and nanostructures by first principles, utilizing either lattice dynamics or molecular dynamics. The following three chapters address the theory and calculation of the thermal boundary resistance of various types of interfaces. The last three chapters address the application of molecular and mesoscale modeling to complex systems, such as alloys, metamaterials, biomolecules, and polymer composites.

2 Ab Initio Theory of Thermal Transport

Fourier's law clearly indicates that, in order to unravel thermal transport in materials, one has to be able to calculate the thermal conductivity. The microscopic ingredients that determine the thermal conductivity in electronic insulators and semiconductors are outlined by the kinetic theory (Ziman 1960), in which κ is expressed as a sum over the phonon branches and the momenta in the first Brillouin zone of the phonon heat capacity c_μ, group velocity v_μ, and mean free path λ_μ:

$$\kappa = \sum_{\mu}^{N_{phonons}} c_{\mu} v_{\mu} \lambda_{\mu} \tag{2}$$

where μ contracts the phonon branch i index and the momentum $\mathbf{q}$. Yet, a predictive calculation of these properties is far from straightforward.

In bulk crystals at low temperature, it is now possible to rely on lattice dynamics and compute phonon dispersion relations, which give c_{μ} and v_{μ}, by density functional perturbation theory (Baroni et al. 2001). Perturbation theory also allows the calculation of anharmonic force constants, and by projecting on the normal modes, one can get three-phonon scattering rates, which can be used to compute relaxation times by solving the linearized BTE. Using this approach and building on the pioneering work by Omini and Sparavigna (Omini and Sparavigna 1995), Broido and co-workers showcased the first first-principles calculations of the thermal conductivity of silicon and germanium (Broido et al. 2007). This approach has become the state of the art in thermal conductivity calculations of solids, proving efficient and predictive. For example it leads to the prediction of new high thermal conductivity materials (Lindsay et al. 2013), and it can be used effectively for high-throughput screening and materials design (Curtarolo et al. 2013). First-principles BTE also provides a detailed insight into the heat transport, as it breaks down the contribution to κ in single carrier properties, and it aids the interpretation of recent thermal transport spectroscopy experiments: for example, it unraveled the contribution of phonons with very long mean free paths, beyond $1\,\mu m$, to the thermal conductivity of bulk silicon even at room temperature (Regner et al. 2013). The linearized BTE approach has been used to calculate the thermal conductivity of low-dimensional systems. In this context it is essential to consider collective hydrodynamic effects, which lead to non-diffusive behavior over a broad temperature range (Lee et al. 2015; Cepellotti et al. 2015; Cepellotti and Marzari 2016)). These studies ascertained the thermal transport regime and the length dependence of κ in two-dimensional materials, thus resolving discrepancies in experimental measurements (Balandin 2011), indicating a finite theoretical bulk limit for κ in 2D materials, and providing a rationale for the length dependence of κ in graphene (Fugallo et al. 2014). Detailed accounts of first-principles BTE in different contexts are provided in ▶ Chaps. 33, "Thermal Transport by First-Principles Anharmonic Lattice Dynamics" and ▶ 34, "On the Kinetic Theory of Thermal Transport in Crystals" in this section.

Originally the applicability of the BTE approach was limited to crystalline materials at low temperatures, where the lattice dynamics is represented in terms of harmonic normal modes and anharmonic effects can be truncated to three-phonon scattering. However, efforts have been deployed to extend the capability of BTE to nanostructured systems with large unit cells, such as silicon-germanium superlattices and crystalline porous carbon (Savic et al. 2013; Pereira et al. 2013), and promising results have been recently achieved for materials at high temperature (van Roekeghem et al. 2016). Yet, BTE cannot be straightforwardly applied to disordered systems, such as glasses and liquids, for which MD is a more natural choice. Using MD, κ can be computed either from equilibrium (Ladd et al. 1986)

or non-equilibrium simulations (Müller-Plathe 1997). While the two approaches have been proven to be nearly equivalent (Schelling et al. 2002), the former is more suitable to study heat transport in extended systems, while the latter applies straightforwardly to finite systems and interfaces.

Thermal conductivity, as other transport coefficients, can be computed in equilibrium MD simulation through Green-Kubo theory. κ is expressed as the limit to infinite size and infinite time of the integral of the heat current autocorrelation function:

$$\kappa_{\alpha\beta} = \lim_{V \to \infty} \lim_{t \to \infty} \frac{1}{k_B T^2 V} \int_0^t dt' \langle J_\alpha(0) J_\beta(t') \rangle, \tag{3}$$

where κ is 3×3 tensor and $J_{\alpha,\beta}$ are the components of the heat current. Besides carefully taking care of size convergence and sufficient sampling, to calculate κ one needs an expression for the heat current, which is nontrivial for many-body empirical potentials (Fan et al. 2015). While ab initio MD simulations were long deemed unsuitable to evaluate (3), an expression for J was recently derived in the framework of density functional theory (Marcolongo et al. 2015). This breakthrough paves the way to the ab initio calculation of thermal transport in previously intractable materials such as geological fluids, glasses, and dynamically stabilized crystals, as well as condensed matter close to phase transitions. ▶ Chapter 35, "Heat Transport in Insulators from Ab Initio Green-Kubo Theory" reviews these recent advances in ab initio MD calculations of heat transport.

3   Interfaces

Regardless whether they occur spontaneously, e.g., in polycrystalline solids, or they are specifically engineered, interfaces are a distinguishing feature of complex materials. Thermal transport in real materials is often dictated by the thermal boundary resistance (TBR) of interfaces. Moreover, TBR has a major impact on several technologies, such as heat-assisted magnetic recording, heat management in microelectronic devices, and reading and writing processes of phase-change materials (PCM) memories. Heat transport at interfaces between hard and soft matter systems has become a subject of numerous studies in the last decades for its technological and medical implications.

As observed by Kapitza in 1941 (Kapitza 1941), given a thermal current (J) at the ideally abrupt interface between two different materials, a discontinuity ΔT occurs in the temperature profile. The so-called Kapitza resistance (R) is given by the ratio between the temperature drop and the flux:

$$R = -\frac{\Delta T}{J}. \tag{4}$$

Knowing the bulk phonon properties of the two materials forming the interface, it is possible to make an approximate estimate of the thermal boundary resistance via

acoustic mismatch or diffusive mismatch models (Swartz and Pohl 1989). However, these approaches imply severe approximations, and predictions are usually not quantitatively accurate. Furthermore, the definition of Kapitza resistance can be practically extended to more broadly define interfacial regions with finite thickness and even further to open systems in general. These can be generically described as systems in which two semi-infinite periodic thermal reservoirs are connected by a nonperiodic "device," as, for example, in molecular junctions (Galperin et al. 2007).

Hence, concurrently with the development of approaches to calculate the bulk thermal conductivity of extended systems, bottom-up atomistic methods and theories were developed to compute thermal boundary resistance and heat transport in open systems. LD and MD simulations can be exploited to calculate R. LD methods rely either on scattering theory (Young and Maris 1989) or on Green's functions (Fagas et al. 1999). In analogy with electronic transport, these calculations provide frequency-resolved phonon transmission function, which sheds light into the details of heat transport and can be exploited to design the thermal conductance of junctions or interfaces. The total thermal conductance is computed integrating Landauer's expression over the whole phonon spectrum (Imry and Landauer 1999). LD approaches allow one to treat open systems at any temperature, including the correct quantum populations, and can be implemented for large. However, while it is possible to take into account anharmonicity, the involved computational complexity makes LD approaches inconvenient to treat strongly anharmonic systems (Mingo 2006). MD, in turn, can be applied straightforwardly in its non-equilibrium form, and TBR can be computed from Eq. 4 by directly evaluating the heat current and the temperature drop at the interface. It is necessary to point out that classical MD cannot take into account quantum effects, and it is therefore unsuitable to treat systems at low temperatures that are below their Debye temperature. A general overview on heat transport at interfaces, including lattice dynamics models and non-equilibrium MD, is given in ▶ Chaps. 36, "Lattice Thermal Boundary Resistance." and ▶ 37, "Energy Relaxation and Thermal Transport in Molecules," gives a perspective on the use of Landauer's approach in modeling molecular junctions and interfaces between inorganic substrates and self-assembled monolayers. These are systems that have stimulated growing interest among materials scientists and engineers in the past decade (Reddy et al. 2007; Losego et al. 2012; Ong et al. 2013).

Equilibrium MD and the Green-Kubo formalism turns out to be a very versatile tool, and it can be casted in such a way as to calculate interfacial thermal conductance from temperature fluctuations (Chalopin and Volz 2013). Furthermore, linear response theory enables the calculation of the phonon dispersion relations and of the spectral transmission function across interfaces. Equilibrium MD is particularly suitable to simulate not only solid-solid junctions but also interfaces between solids and liquids or soft matter, as it avoids a number of algorithmic issues occurring while establishing a stationary heat flux in non-equilibrium MD, such as thermostatting diffusive regions of the simulation system. ▶ Chapter 38, "A Statistical Approach of Thermal Transport at Nanoscales: From Solid-State to Biological Applications," provides a detailed account of Green-Kubo theory and

calculations of thermal boundary resistance in a variety of complex systems, paving the way to simulations of heat transfer at bio-inorganic interfaces, relevant for medical applications.

4   Toward Advanced Materials and Complex Systems

The methods described in the previous sections allow for accurate and predictive heat transport calculations of the thermal conductivity of systems, for which heat transport had remained poorly understood for several decades. Alloys are a good example of such systems: SiGe alloys have been used since the 1960s by NASA for thermoelectric power generation, but only recent calculations started to unravel heat transport in such systems (Garg et al. 2011). Following the original ideas by Hicks and Dresselhaus (Hicks and Dresselhaus 1993; Dresselhaus et al. 2007), combining alloying with nanostructuring was proposed to lead to ultralow thermal conductivity (He et al. 2011). The thermal conductivity and the thermoelectric performance of silicon-based alloys can be further optimized by engineering their nanoscale structure and their chemical composition. Lattice dynamics calculations can be applied effectively to alloys, nanocomposites, and superlattices as a tool to guide such systematic optimization (Aksamija and Knezevic 2010; Savic et al. 2013; Khatami and Aksamija 2016). ▶ Chapter 39, "Thermal Conductivity of Nanostructured Semiconductor Alloys" reviews progresses in the simulation of binary and ternary Si/Ge/Sn alloys using LD and BTE.

Further refinements in designing materials with tailored phononic properties can be achieved by relying upon concepts like phononic crystals (Gorishnyy et al. 2005) and metamaterials (Pendry et al. 1996). Phononic crystals consist of materials in which regular features, e.g., pores, tailor the dispersion relations of acoustic or supersonic waves. Metamaterials are composite materials that exhibit properties that do not pertain to their single components, or, in general, to natural materials. The concept was originally developed to achieve exotic optical properties, such as negative refractive index (Pendry 2006), and was eventually adopted for acoustic properties (Liu et al. 2000). Both phononic crystals and nanophononic metamaterials were recently proposed as a way to reduce the thermal conductivity of silicon thin films or membranes and to improve their thermoelectric performance (Yu et al. 2010; Davis and Hussein 2014). In the case of thermal transport, metamaterials can be obtained by introducing surface nanostructures (Davis and Hussein 2014; Xiong et al. 2017), so as to induce localized resonances that hybridize with phonons, thus reducing the capability of transferring energy. This approach is discussed in ▶ Chap. 40, "Resonant Thermal Transport in Nanophononic Metamaterials." The concept of nanophononic metamaterials is fascinating, as it may be applied not only to optimize thermoelectric energy conversion but also for phonon cloaking, filtering, and ultimately advanced optomechanical systems.

Thanks to the ever-growing computational power and the development of efficient parallel algorithms, MD simulations with either empirical potentials or classical force fields enable the study of heat transport in systems of up to millions

of atoms, thus allowing one to tackle complex materials such as polymers and their nanocomposites. These simulations allowed researchers to address a long-standing challenge in materials science that is unraveling the design principles to create structural plastics with high thermal conductivity. While polymeric materials normally feature very low thermal conductivity, MD simulations showed that single polyethylene molecular chains have very high κ (Henry and Chen 2008). This result was eventually used to fabricate high thermal conductivity polyethylene nanofibers, in which molecular chains are aligned by drawing (Shen et al. 2010). While these early results are encouraging, simulating heat transport in polymers and their composites still faces several challenges. For example, it is still difficult to obtain representative molecular models of polymer melts, due to the multiple size scales involved in such systems and very long relaxation times. In addition, in the case of composites, the issue of thermal boundary resistance between the solid micro- or nanoparticles and the polymer matrix intertwines with the collective modes of the system. This complex phenomenology, which is so far just partially understood, has hindered the optimization of high thermal conductivity composites. ▶ Chapter 41, "Modeling of Heat Transport in Polymers and their Nanocomposites" provides a detailed overview of successes and open challenges in the simulation of polymers and their composites.

5   Conclusion

In conclusion, this section is a journey through recent achievements in the simulation of heat transport in emergent materials, which have been enabled by major theoretical and methodological developments. Some of the methods and the ideas discussed in the following chapters are very recent, and, so far, we are just scratching the surface of the possibility that they offer. In spite of such advances in both simulation and measurement techniques, several recent experiments raised new questions about the very nature of thermal transport both in nanoscale systems and in complex materials. Similarly, numerical simulations of apparently simple nonlinear models, such as the Fermi-Pasta-Ulam model, suggest universal behaviors of low-dimensional systems, which are difficult to transpose to real materials (Lepri et al. 2003). More fundamental work is needed to unravel issues such as the transport regime at the nanoscale, phonon coherence, energy propagation in amorphous materials, anharmonic effect on thermal boundary resistance, and thermal rectification. In this respect it is still reasonable to say that, as Peierls himself put it in the early 1960s, "it seems there is no problem in modern physics, for which there are on record as many false starts, and as many theories which overlook some essential feature, as in the problem of the thermal conductivity of nonconducting materials."

Abstract

Predictive methodologies for calculating lattice thermal transport and related properties have been recently developed and benchmarked successfully against measurements in a wide range of materials, from bulk to the nanoscale. This chapter presents an overview of the theoretical underpinnings of typical numerical methods for solving the Peierls-Boltzmann equation (PBE) for phonon transport when coupled with density functional theory (DFT). We discuss how these numerical methods may be employed to advance fundamental understanding of

thermal transport, particularly as applied to measurements of anharmonic properties (e.g., linewidths, lattice expansion) in materials. In particular, calculations of interatomic force constants, integration methods, and construction of transport properties will be explained in detail with reference to relevant research in the literature. Furthermore, this chapter will provide an overview of applications and methods for calculations of thermal conductivities beyond perfect infinite crystals (including phonon-defect scattering) and of other measured observables, including mean free path accumulation, linewidths, and densities of states from scattering experiments.

1   Introduction

Lattice vibrational properties of crystals as governed by phonons (normal modes of vibration) play a critical role in the conversion, storage, and transmission of thermal energy, which is of significant importance to a variety of technologies, including thermoelectrics, thermal barrier coatings, electronics packaging, claddings for nuclear technologies, solid-state lighting, and batteries. Of particular relevance here is the characterization of a material's ability to conduct heat via phonons as determined by the lattice thermal conductivity κ. The study of phonons and κ has a long and storied past, yet recent advances in computational power and numerical methods are expanding our ability to predict and develop deeper insights into fundamental physics and still provide novel surprises and new understandings of these behaviors. This chapter aims to provide a basic foundation of the theoretical and computational formalism from which recent κ calculations are built, without adjustable empirical parameters, and to relate these with other experimental observables. Figure 1 gives an example calculation of κ for the rock salt structure KCl as given by the formalism described in this chapter and compared with available measured data.

2   Theoretical Underpinnings

Much of the theory presented here can be pieced together from textbook discussions (Ashcroft and Mermin 1976; Kittel 2005) of lattice dynamical behavior – two foundational resources being *Electrons and Phonons* by Ziman (2001) and *The Physics of Phonons* by G. P. Srivastava (1990). Attempting to build anharmonic lattice dynamical features from a top to bottom approach, this chapter begins with the concept of thermal energy being carried by correlated vibrations of atoms in a crystal, phonons.

2.1   Lattice Thermal Conductivity

To understand the lattice dynamics of crystalline dielectrics, Einstein proposed a theory of atoms as a set of oscillators each independently vibrating (Einstein
Fig. 1 Calculated κ of KCl as a function of temperature for isotopically pure material (red curve) and including naturally occurring phonon-isotope scattering (blue curve). Details of the κ calculations are described in this chapter. Colored circles give various measured κ data for KCl: black (McCarthy and Ballard 1960), green (Walker 1963), blue (Petrov et al. 1976), red (Rosenbaum et al. 1969), orange (Andersson 1985), purple (Slack and Ross 1985), brown (Peech et al. 1967), and light blue (Pettersson 1987)

1911), from which heat could flow via a random walk of thermal energy among them. This theory failed to describe specific heat and thermal conductivity, though a modification of it is often used to describe the minimum thermal conductivity of disordered or amorphous materials (Cahill and Pohl 1989; Cahill et al. 1992). The concept of atoms in the lattice collectively vibrating as coupled harmonic oscillators was introduced by Debye, where the idea of the phonon (normal modes of vibration) began (Debye 1912, 1914). This description has been very successful in describing all sorts of physical phenomena in crystals. One very important success is an accurate description and subsequent understanding of κ for crystalline solids (Srivastava 1990; Ziman 2001).

In general κ can vary spatially and temporally in a material; however, here we will assume infinite crystalline material at a particular average temperature T under the influence of a small temperature gradient $\partial T/\partial \alpha$ in the Cartesian direction α. Under these conditions, a thermal energy current J_α flows from hot to cold and is linearly proportional to the temperature gradient (Fourier's law):

$$J_\alpha = -\kappa_\alpha \frac{\partial T}{\partial \alpha} \qquad (1)$$

with the constant of proportionality being thermal conductivity, an intrinsic material property. In general, κ is a tensor quantity, though is typically described by one, two, or three components depending on crystal symmetry. Note that when discussing the thermal conductivity in general the subscript dependence will be dropped.

Taking a microscopic view, each phonon mode (labeled by wavevector $\vec{q}$ and branch index j) carries a part of the overall J_α, and κ is given as a sum over mode contributions $\kappa_{\vec{q}j\alpha}$:

$$\kappa_\alpha = \sum_{\vec{q}j} \kappa_{\vec{q}j\alpha} = \sum_{\vec{q}j} C_{\vec{q}j} v_{\vec{q}j\alpha}^2 \tau_{\vec{q}j} \tag{2}$$
