Mesoscopic Modelling of Irradiation Damage Processes: Bridging Many-Body Mechanics and Thermodynamics in Rate Processes

92

Chung H. Woo

Contents

Abstract

The integration of atomistic mechanics into the macroscopic modeling of rate-processes in solids should ensure the principles of statistical and thermal physics are not violated. Rate constants are customarily derived based on the transition state theory or its variants such as kinetic Monte Carlo simulation, phase-field model, and classical nucleation theory. In this perspective, we examine the assumptions traditionally made in constructing the mesoscopic connection between molecular mechanics and macroscopic thermodynamics, (1) separability of the reaction path from the noise created by lattice vibrations, (2) validity of classical statistics, and (3) existence of quasi-equilibrium among the reactants, the transition state, and the product. We find that the first assumption excludes rate processes at high temperatures or low reaction barrier, while the second excludes those at low temperatures or low reaction barrier. The third assumption has to reconcile with the nonequilibrium nature of rate processes, such as the neglect of entropy production which is proportional to the reaction rate, and thus

C. H. Woo (✉)

e-mail: chung.woo@polyu.edu.hk

excludes processes proceeding at fast rates. On this basis, the traditional approach in mesoscopic modeling is only reliable for rate processes in irradiation-damage accumulation with a high activation barrier and at not-too-high temperatures. The mitigation of these restrictions and evaluation of consequences due to their neglect can be formulated in a mesoscopic model in which the atomic processes in the many-body system are treated dynamically and energy quantization and quantum uncertainty are taken into account explicitly through the Mori-Zwanzig formalism of nonequilibrium statistical mechanics and the quantum fluctuation-dissipation relation.

Irradiation damage starts with the production of crystalline defects followed by their accumulation and interaction with existing microstructure. To achieve an engineering description, mechanics in the atomistic scales of time and space must be transposed to the macroscopic scales through the laws of thermodynamics. Rate-theory models (Bullough 1985; Ghoniem 1989; Woo and Singh 1992) of irradiation damage, which provide a continuum description of microstructure evolution as a result of the balance of the generation, migration, and annihilation at sinks of crystal defects, have dominated the scene since the early years. This approach is effective in expressing the macroscopic effects due to microstructure changes caused by their reactions with the defects. The integration of atomistic mechanics into rate-theory models is implemented via articulating reaction rate constants derived based on an elastic continuum theory assuming isotropic diffusion-controlled kinetics. Model parameters sometimes may be force fitted to experimental data. Yet, a good physical basis of the model is essential, without which one may just be redistributing errors among different components of the model.

   To overcome the limitations of the continuum model, a mesoscopic formulation of mass transport, which takes into account the discreteness, structure, and interatomic interaction of the static crystal lattice, is incorporated into the reaction constants. The progress of this line of work was reviewed in the context of fundamental mechanisms of irradiation-induced creep and growth (Matthews and Finnis 1988; Eyre and Matthews 1993). To be consistent, the concept of sink bias was generalized to include the effects of diffusion anisotropy difference (DAD) between the vacancies and the SIAs (Woo 1988). Thus, going beyond the isotropic continuum model, effects on the diffusion-controlled kinetics due to interactions with applied fields, implications for the reaction kinetics of low-dimensional diffusers, and stress-induced preferred absorption (SIPA) effects due to elasto-diffusion can be integrated into the rate-theoretic approach. The progress is further updated in the first edition of this *Handbook* (Woo 2005).

   Reaction constants in the foregoing efforts are derived based on quasi-equilibrium classical thermodynamics, neglecting the dynamical and many-body nature of atomistic processes. It is not difficult to imagine the consequence when the activation barrier involved has a magnitude comparable to the energy of the average phonons, a situation often encountered in the kinetics of small interstitial impurity atoms (e.g., helium and hydrogen) and SIAs in the crowdion state (in low-dimension

diffusion controlled reactions). Dynamics of fast-moving dislocations and loops encountered in embrittlement and plasticity constitutes another class of examples where interaction with lattice vibrations plays an important role.

Processes fundamental to the mechanics of irradiation-damage accumulation generally involve the change of the state of crystalline defects during their formation, migration, clustering, and reaction with sinks. The changes can be regarded as mono- or bi-molecular reactions proceeding through a transition state, envisaged as a saddle-point on the potential-energy surface in phase space. The kinetics of the associated rate process may be considered in ways similar to the transition-state theory (TST) (Eyring 1935). Assuming separability of the transition state (activation barrier) from its dynamic environment (lattice vibrations) and as a quasi-equilibrium process, the corresponding reaction rate is expressible in the Arrhenius form as the product of the attempt frequency ν_0 and the probability of formation of the transition state $\exp(-\Delta G_t/k_B T)$ within classical Gibbs-Boltzmann statistics (Glasstone et al. 1941; Laidler and King (1983)). Other methodologies often used in the modeling of rate-processes, including irradiation damage accumulation, such as kinetic Monte Carlo, phase-field model, and classical nucleation theory, are also similarly formulated. Here ΔG_t is the free-energy of formation of the transition state under quasi-equilibrium conditions, which may also be interpreted as the saddle-point energy that must be provided to complete the reaction reversibly, k_B is the Boltzmann constant and T is the absolute temperature.

In the simple example of migration in real space, the point-defect diffusivity D can be written in the Arrhenius form (Vineyard 1957; Mehrer 2007):

$$D = D_0 e^{S_m/k_B} \exp\left(-E_m/k_B T\right), \tag{1}$$

where D_0 is the prefactor that depends on the jump geometry and vibration frequency of the migrating species. S_m and E_m are, respectively, the migration entropy and enthalpy. Since the saddle-point configuration is coupled to the vibrating lattice (and spins) in the neighborhood, the thermodynamics of its formation cannot be isolated from the way the vibration modes are occupied. Proper accounting of the many-body dynamics is required to relate the corresponding atomistic mechanics and thermodynamics.

Indeed, in his critical investigation of the accuracy of models of rate processes such as the TST, Kramers (1940) explicitly showed that the environmental noise derived from many-body dynamics are important controlling factors of the reaction velocity. More recent works also showed that environmental noise has important consequences in a wide scope (Swinburne et al. 2013, 2014, 2017; Pavliotis and Vogiannou 2008; Ala-Nissila and Ying 1992). Accordingly, kinetics of point-defect processes, such as those governing the lifetime of point-defect configurations and the corresponding mobility and diffusional anisotropy, are only sensitive to the static saddle-point configuration when the relative importance of the environmental noise is sufficiently small. This is consistent with the loss of accuracy at high temperatures of the traditional TST which has been shown by Pineda and Schwartz (2006).

In a contemporary study of the many-body effects of lattice vibrations, the statistical occupation of vibration modes has to be accounted for. It is well known that classical statistics is inadequate in explaining the phenomena of the ultraviolet catastrophe, the photoelectric effect, the specific heat, and the associated divergence of the classical entropy. Classical statistics describes lattice dynamics based on a continuous (nonquantized) vibrational energy spectrum, in which all vibration modes are active at any temperature. This is not so where energy levels are discrete (quantized). Indeed, "the granularity of atoms and quantization of energy and how they gives way to apparently continuous and infinitely divisible matter and energy" is how mesoscale science is characterized by Crabtree and Sarrao (2012). In Einstein's model of heat capacity, for example, phonon excitations in bcc iron below 360 K and carbon below 2000 K are basically frozen because the thermal energy needed to excite the average phonon is not available. When the vibration state of the solid becomes dominated by the ground-state phonons, a classical description of the thermodynamics and lattice dynamics can be in significant error if used to interpret experiments conducted at low temperatures, such as resistivity recovery (Dausinger and Schultz 1975; Maury et al. 1978; Fu et al. 2005), electron microscopy (Yi et al. 2015; Sand et al. 2016), and low temperature plasticity (Biget and Saada 1989; Moskalenko et al. 2005).

The situation is even more drastic if the foregoing discussions were to be extended to magnetic metals. An important example is bcc iron, in which the relevant many-body dynamics must also include the spin waves (magnons) (Van Vleck 1945; Van Kranendonk and Van Vleck 1958; Argyle et al. 1963). Based on the experimental spin stiffness of bcc iron from Collins et al. (1969) and Mook and Nicklow (1973), or the magnon DOS calculated from first principles (Halilov et al. 1997), excitation of a magnon mode at low temperatures requires an average energy of ~250–350 meV. The strong energy quantization makes the application of classical statistical distribution to the vibration modes of the spin system untenable for temperatures under ~3000 K.

In addition to energy quantization, effects due to quantum tunneling are also important to reaction rates. Athermal vibrations due to the phonon ground state, the so-called zero-point vibrations, have to be taken into account. The corresponding free energy contributes to rate processes in solids through point-defect formation, migration, and reaction kinetics. Indeed, this athermal component provides the main driving force that (a) effectively lowers the activation barrier via phonon screening and (b) provides the momentum transfer required for the activation jumps, resulting in phonon-assisted tunneling (Flynn and Stoneham 1970; Woo and Wen 2017). More generally, similar athermal field fluctuations have been envisaged as responsible for many physical effects, such as the Lamb shift, the Casimir force, the natural linewidths of energy levels, and the broadening of neutron scattering resonance lines in solids (Milonni 1994).

It is clear that the principles of statistical and thermal physics must be observed in the integration of atomistic mechanics into the macroscopic modeling of irradiation-damage accumulation. TST and its variants, with their well-established physical and

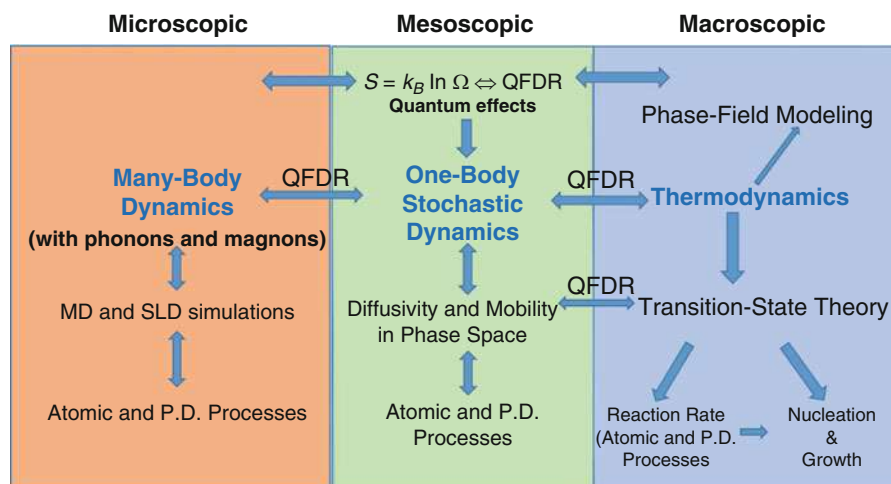
chemical basis, may be ideally suited to provide the rate constants in the formulation of an irradiation-damage model. Yet, according to Pineda and Schwartz (2006) and Miller (1974), traditional TST suffers from the failure of fundamental assumptions pertaining to the separability of the transition state from the environmental noise due to many-body dynamics and the validity of classical mechanics. As we have discussed in the foregoing, the issue of separability sets a high-temperature limit (relative to the activation barrier) beyond which many-body effects cannot be ignored, while the use of classical physics sets a low-temperature limit (relative to the activation barrier) below which quantum effects are important. Further assumption of a quasi-static process has to reconcile with the entropy production, which is proportional to the reaction rate (Kondepudi and Prigogine 1998), and restricts the application to slow reactions. Indeed, weaknesses such as these are also present in traditional irradiation damage modeling, namely, the kinetic Monte Carlo method, the phase-field method, and classical nucleation model. If these fundamental issues are to be addresses, the quantum, many-body, and dynamical nature of the mechanics of the reactions need to be properly introduced. A key concept in such a formulation is the bridge between the quantum mechanical world of discrete energy, space, and configurations and the engineering world of temperatures and thermodynamic functions which is provided by the fluctuation-dissipation relation (see Fig. 1). Progress in the development of this approach will be assessed and issues discussed in Sect. 1. The effects of many-body dynamics and quantum statistics on reaction kinetics will be discussed in Sect. 2. A summary and outlook is provided in Sect. 3.


Fig. 1 (color on line) Schematics to illustrate the implementation of quantum many-body dynamics in thermodynamics and reaction kinetics via the Mori-Zwanzig formalism using quantum fluctuation-dissipation relation (QFDR)

1 Fluctuation–Dissipation Relation: The Bridge between Mechanics and Thermodynamics

The importance of environmental noise in the theory of rate processes is well known since the celebrated work of Kramers (1940). That the many-body effects on the mechanics of a many-body system can be represented as the action of stochastic noise is also well established from the works of Mori (1965) and Zwanzig (1965). It is natural that these effects are considered at a fundamental level in the formulation of irradiation-damage models, or at least the conditions of validity of the models be made clear. This is an important concern because the physical link between the rate processes at the atomistic-scale and their manifestation in the macroscopic scale lies in the relation between the mechanical behavior of atoms and the macroscopic laws of thermodynamics. Similar to the famous Boltzmann relation between the thermodynamic concept of entropy and the mechanical microstates, the fluctuation-dissipation relation (FDR) connects the stochastic mechanics of a many-body system and the thermodynamics of the corresponding process (Kubo 1966).

1.1 Many-Body Mechanics in Terms of the Fluctuation–Dissipation Ratio

In principle, many-body dynamics can be treated by directly solving the coupled equations of motion among all particles of the system, such as achieved commonly in a molecular dynamics or spin-lattice dynamics (Ma et al. 2008; Woo et al. 2015) approach. Alternatively, the equation of motion of a state variable in a many-body system can also be formally expressed through a projection operator formalism in the form of a generalized Langevin equation, with the dissipation and fluctuation terms expressed via the Liouville equation (Liouville 1838; Gibbs 1902). This representation of the many-body problem provides a route to an analytic link between the mechanics and thermodynamics of the system of atoms via a pseudo-one-body scheme in which many-body effects are subsumed into a functional relation between the fluctuation-dissipation ratio and the thermodynamic temperature. Indeed, in the earlier works of Einstein (1905) and Smoluchowski (1906), the many-body environment of a diffusing Brownian particle was already modelled using random forces and associated dissipative friction related through the fluctuation-dissipation theorem (Mori 1965; Kubo 1966). The mobility and diffusivity derived this way has a form not bearing any obvious resemblance to the Arrhenius law. Along a similar route, Munakata and Tsurui (1979) and Combs and Kunz (1987) modelled the many-body dynamics of a highly mobile defect in a crystal as a particle under stochastic forces in a periodic force field.

Based on the Mori-Zwanzig formalism (Mori 1965; Zwanzig 1965), Woo and Wen (2017) analyzed the general mechanics of a system of N atoms in an infinite crystal. The mass of the nth atom is denoted by m_n, its momentum $\mathbf{p}_n$ and position $\mathbf{r}_n$. $U(\{\mathbf{r}_n\})$ is the interatomic potential (many-body) corresponding to the lattice

configuration $\{\mathbf{r}_n\}$, neglecting for the time being the interaction between atomic spins. Following Ehrenfest (1927), these authors expressed the equation of motion for each atom in terms of the expectation values which is denoted by $\langle \ldots \rangle_E$. Assuming that the difference between the quantum and classical forces $\left\langle \frac{\partial U}{\partial \mathbf{r}_n} \right\rangle_E - \frac{\partial U(\mathbf{r}_n)}{\partial \mathbf{r}_n}$ that accounts for the quantum uncertainty due to the noncommutative relation between $\mathbf{r}$ and $\mathbf{p}$ may be subsumed into the Mori-Zwanzig random forces that accounts for the fluctuations due to many-body and quantum effects, the equation of motion of each particle can be formally put in the Langevin form. Within this approximation, coherency of the one-particle wave function of the atoms over different sites is neglected, which is justified by noting that the De Broglie wavelength $\lambda \approx \frac{\hbar}{m v_G} \approx 10^{-12}$m of an atom in crystals is much smaller than the interatomic distances under consideration. Assuming a local memory function, the set of pseudo-one-particle Langevin equations of motion can be written. The random forces on the atom n due to its environment (the rest of the crystal) are characterized by the dissipative friction with drag-coefficient g and delta-correlated remnant fluctuations with strength characterized by s, i.e.,

$$\langle \mathbf{f}_n(t) \rangle = 0 \text{ and } \langle f_{in}(t) f_{jl}(t') \rangle = s \delta_{ij} \delta_{nl} \delta(t - t') \tag{2}$$

Here subscripts i and j denote Cartesian components and $\langle \cdots \rangle$ denotes the statistical mean taken over all the possible realizations of the stochastic forces. The corresponding phase-space probability density $W(\{r_{ni}\}, \{p_{ni}\}, t)$ of the crystal is determined by the Fokker-Planck equation. Woo and Wen (2016) showed that the solution of $W(\{r_{ni}\}, \{p_{ni}\})$ at equilibrium is given by $W = C \exp(-\kappa E)$, where C is a normalization constant, E is the total energy of the system, $\kappa^{-1} = s/2g \equiv \eta$ is the fluctuation-dissipation ratio which defines the Langevin equation representing the mechanics of the atoms subjected to the environmental noise. The corresponding phase-space probability density for energy E can then be obtained,

$$W(\{r_{ni}\}, \{p_{ni}\}) = Z \exp[-\kappa E(\{r_{ni}\}, \{p_{ni}\})]. \tag{3}$$

where Z is a normalizing constant.

1.2   Quantum Statistics and Thermodynamics

The probability of the jth state of the $3N$ independent degrees of freedom of the N-atom system from Eq. (3) can be written as $P_j = Z \exp(-\kappa \varepsilon_j)$, where ε_j is the corresponding energy and $Z = \sum_{j=1}^{3N} e^{-\kappa \varepsilon_j}$ is the partition function. P_j maximizes the corresponding mean entropy per atom $\bar{s} = \sum_{j=1}^{3N} P_j \ln P_j$ (in units of k_B) under

the constraints $\sum_{j=1}^{3N} P_j = 1$ and $\sum_{j=1}^{3N} P_j \varepsilon_j = \bar{\varepsilon} \equiv \frac{E}{3N}$. Z is then linked to the mean energy per atom by $\bar{\varepsilon} = -\frac{\partial \ln Z}{\partial \kappa}$ and to the corresponding entropy by $\bar{s} = \kappa \bar{\varepsilon} + \ln Z$. In this regard, $f \equiv -\eta \ln Z = \bar{\varepsilon} - \eta \bar{s}$ is the corresponding Helmholtz free energy per atom. Since both $\bar{\varepsilon}$ and $\bar{s}$ are functions of κ that dictates the phase-space probability density, we may write $d\bar{s} = \kappa d\bar{\varepsilon} + \bar{\varepsilon} d\kappa + \frac{d \ln Z}{d\kappa} d\kappa$, in which the last two terms cancel, yielding $\frac{d\bar{\varepsilon}}{d\bar{s}} = \eta$. Accordingly, if the functional relation between η and the temperature T is known, the thermodynamics (equilibrium) of the system is completely and uniquely defined as a function of the mean energy $\bar{\varepsilon}$. Noting that the effects of fluctuation and dissipation are balanced at equilibrium, Woo and Wen (2017) obtain the relation $\eta = \frac{2}{3N} E_K(T)$, E_K being the kinetic energy of the ensemble which is a function of temperature. In terms of the system energy and entropy, we may write $E = 3N\eta$ and $S = 3N\bar{s}$.

If quantum effects can be neglected, Equipartition theorem gives $E_K = 3Nk_BT/2$, yielding $\eta = k_BT$, the classical fluctuation-dissipation relation (CFDR) for a system of N particles (Mori 1965; Kubo 1966). In this case, the temperature of the system is given by $\frac{dE}{dS} = k_BT$, which is sometimes used as a thermodynamic definition of temperature. The corresponding Helmholtz free energy is then given by $F = E - k_BTS$, a standard result of classical thermodynamics. The Langevin heat bath can also be defined accordingly.

The Equipartition theorem does not hold in quantum mechanics and $\frac{dE}{dS} \neq k_BT$ in general. When the environmental noise is coming from lattice vibrations, standard quantum theory of phonons (Kittel 2004) yields

$$\eta(T) = \frac{E}{3N} = \frac{1}{3N} \sum_{k} \sum_{\alpha=1}^{3} \hbar\omega_\alpha(\mathbf{k}) \left[\frac{1}{e^{\hbar\omega_\alpha(k)/k_BT} - 1} + \frac{1}{2} \right], \tag{4}$$

from which a *nonlinear* relation between η and T can be defined via the phonon dispersion relation, which is governed by a temperature-dependent spring constant. The associated quasi-harmonic approximation (Woo et al. 2015) will be elucidated in the following subsection. It is clear that the right hand side of Eq. (4) reduces to k_BT in the classical limit when $\hbar \to 0$. This relation between η and T is called the *Quantum Fluctuation-Dissipation Relation* (QFDR) for the lattice system. It then follows that all thermodynamic properties of the crystal are functions of temperature via the QFDR $\eta(T)$ in Eq. (4).

Within the Debye model, $\eta(T)$ can be written in close form as

$$\eta(T) = \frac{3}{8} k_B \Theta_D + 3k_B \Theta_D \left(\frac{T}{\Theta_D} \right)^4 \int_0^{\frac{\Theta_D}{T}} \frac{x^3}{e^x - 1} dx, \tag{5}$$

where Θ_D is the Debye temperature of the crystal. The heat capacity, for example, is given by $C_V(T) = \frac{\partial E}{\partial \eta} \frac{d\eta}{dT} = 3Nk_B f_D \left(\frac{\Theta_D}{T} \right)$, which is precisely the well-known expression for the heat capacity that can be derived within the Debye model

directly from quantum statistics. The vibrational entropy $S = \int_{\eta(0)}^{\eta(T)} \frac{1}{\eta} \frac{dE}{d\eta} d\eta' =$ $3N \ln\left(\frac{\eta(T)}{\eta(0)}\right)$ can be derived from the thermodynamic relation $\frac{dE}{dS} = \eta$ obtained earlier. As $T \to 0$, $S \to 3N\left(\frac{8\pi^4}{15}\left(\frac{T}{\Theta_D}\right)^4\right)$, which obeys the third law, vanishing as T^4. The quantum entropy contrasts the classical entropy derived from the CFDR which diverges as $T \to 0$. At high temperatures, $S \to 3N \ln\left(\frac{8T}{3\Theta_D}\right)$ which is the same as the classical result up to a constant.

At low temperatures, $\eta(T)$ in Eq. (5) has an athermal component $\eta_Q = 3k_B \Theta_D/8$ attributable to the phonon ground state, which has a purely quantum origin from the noncommutative relation between $\mathbf{r}$ and $\mathbf{p}$. In this regard, Van Kampen (1992) interpreted that the ensuing quantum uncertainty is effectively an internal noise. Within this interpretation, the athermal term in the fluctuation-dissipation ratio η is simply a reflection of the contribution of quantum noise on the stochastic dynamics of the ensemble. This term corresponds to the difference between the quantum and classical forces $\left\langle \frac{\partial U}{\partial \mathbf{r}_n} \right\rangle_E - \frac{\partial U(\mathbf{r}_n)}{\partial \mathbf{r}_n}$ we mentioned earlier.

At higher temperatures ($T > \Theta_D$), $\eta(T)$ in Eq. (5) is dominated by the thermal component. With decreasing temperature, the dominance wanes and begins to reverse near $T \approx \Theta_D/3$. Thus, at $\Theta_D/3$, the athermal component is already ~50% larger than the thermal one and becomes 20 times greater at $\Theta_D/5$. Therefore, at temperatures below $\Theta_D/3$, it is the athermal ground-state phonons that control the frequency of the activation jumps by (a) lowering the activation barrier by screening and (b) providing the momentum required for the jumps, which is effectively activation by phonon-assisted tunneling (Flynn and Stoneham 1970).

1.3   Thermodynamics of Ferromagnetic Metals

The methodology of large-scale spin-lattice dynamics simulation was first developed under a classical mechanics formulation in the thesis work of Ma et al. (2008) for the mesoscopic treatment of magnetic metals. This scheme was used by Wen and Woo (2014) to calculate the vacancy migration and formation entropies and enthalpies of BCC iron based on classical thermodynamic integration under a reversible thermodynamic path. The development for the quantum treatment of spin vibrations in ferromagnetic metals was based on the quantum fluctuation-dissipation relation developed for lattice vibrations using a Debye theory modified to take into account magnon softening at the ferro-para magnetic transition point (Woo et al. 2015). Atoms in a ferromagnetic metal are modeled as interacting particles with Heisenberg spins embedded in noisy media that represent thermally connected many-body atomic and spin environments (in thermodynamic equilibrium) within the Mori-Zwanzig's formalism.

This theory was applied to the typical case of BCC iron. The dynamics of the many-body system of atoms and spins is solved numerically in a temperature range between 10 and 1400 K. Thermodynamic functions, namely, vibrational energies, heat capacities, and entropies, were calculated from three models, using (1) spin-lattice dynamics with QFDR (quantum and quasi-harmonic); (2) spin-lattice dynamics with CFDR (classical and quasi-harmonic); and (3) analytic QH model based on the 0 K quantum-harmonic phonons and magnons. In Fig. (2), results for the total (spin + lattice) heat capacity from Wen and Woo (2016) are shown together with the experimental data from Wallace et al. (1960). At low temperatures, excellent agreement can be seen among all the quantum results (QFDR and QH) and experimental ones. The nonlinear temperature dependence of the heat capacities that vanish at 0 K is the consequence of Bose-Einstein statistics used in the quantum models. The vanishing of the heat capacity at 0 K is both experimentally observed and theoretically required. The corresponding classical heat capacity based on CFDR remains nonzero at 4 k_B at 0 K, consistent with the equipartition theorem. Historically, Einstein was the first to show that this can be corrected in a way similar to the problem of ultraviolet catastrophe by taking into account Planck's quantization in the excitations of the vibrational modes of the crystal lattice (Donald 2005).

Accuracy of the QH model deteriorates as spin vibrations become increasingly anharmonic at higher temperatures. The excellent agreement between the QFDR and the experimental heat capacity remains intact even beyond 1000 K, successfully reproducing the characteristic sharp rise near the Curie temperature as the spring stiffness for spin vibrations softens. Indeed, harmonic phonons and magnons do
Fig. 2 (color on line) Total heat capacities of ferromagnetic bcc iron (involving interacting phonons and magnons) calculated from QH, QSLD and CSLD models as a function of temperature. Experimental data of Wallace et al. (1960) are plotted for comparison

not interact, which explains the absence of the peak in the harmonic QH model. The interaction between the lattice and spin vibrations is accounted for, although classically, within the CFDR model. This is what gives rise to the suppressed peak in the heat capacity.

The pioneering works of Ma et al. (2008), Wen and Woo (2014, 2016), and Woo et al. (2015) on bcc iron exemplify the complexity and subtlety of the mesoscopic connection between many-body mechanics in the atomistic scale and macroscopic thermodynamics for rate processes in ferromagnetic metals. More importantly, they also show that quantum effects may be important even at temperatures traditionally believed to be safe for the application of the classical thermodynamics.

2   Formulating Reaction Rates in Rate Processes in a Dynamic Scheme

Christiansen (1936) and Kramers (1940) modelled chemical reactions dynamically as a drift-diffusion process in phase space. In this way they avoided having to use the questionable assumption of quasi-equilibrium among the reactants, the transition state, and the product in a chemical process. In this approach, reactants are brought from a state A with equilibrium energy $-E_A$ to a product represented by state B with equilibrium energy $-E_B$ via the saddle point C (see Fig. 3). In this way, rate processes in a many-body environment may be formally considered as "particles" passing from A to B in phase-space in a noisy medium. The corresponding reaction rate may be measured by the particle flux across the saddle point C in terms of the corresponding mobility and diffusivity. The potential-energy gradient $\Delta E_m/a \equiv (E_B - E_A)/2a$ in phase space can be considered as an applied force $\delta \mathbf{F}$ in the effective one-body Langevin dynamics of the particle. Here $E_m = (E_A + E_B)/2$ measures the height of the activation barrier at the saddle-point. These energies (within the adiabatic approximation) are due to the interactions of the "particle" with a *static* environment (no noise) in the two equilibrium configurations before and after the reaction.

Within this framework, the equations of motion of the "particle" in the Mori-Zwanzig formalism can be written in the Langevin form. The probability density $P(\mathbf{r}, t)$ and particle flux are governed by the corresponding Fokker-Planck equation,

Fig. 3 (color on line) Reactants are brought from a state A with equilibrium energy $-E_A$ to a state B with equilibrium energy $-E_B$ via saddle point C
$$\frac{\partial}{\partial t} P\left(\boldsymbol{r}, t\right) = \nabla \cdot \left[\frac{\nabla U}{m\gamma_L} P\left(\boldsymbol{r}, t\right)\right] + D_{\mathrm{E}} \nabla^2 P\left(\boldsymbol{r}, t\right) \equiv -\nabla \cdot \boldsymbol{j}\left(\boldsymbol{r}, t\right). \qquad (6)$$

Here m, $\boldsymbol{r}$, and the velocity $\boldsymbol{v}$ are, respectively, the effective mass, generalized co-ordinate and velocity of the "particle" in phase space. In its trajectory from A to B, the "particle" is subjected to a generalized force $-\nabla U(\boldsymbol{r})$ due to the potential energy gradient, a viscous drag $-m\gamma_L \boldsymbol{v}$ due to the noisy environment, where γ_L is the corresponding frictional coefficient. The environmental noise takes the form of random forces $\sigma_L \boldsymbol{\zeta}(t)$, where $\boldsymbol{\zeta}(t)$ is a Gaussian noise, i.e., $\langle \boldsymbol{\zeta}(t) \rangle = 0$ and $\langle \zeta_i(t) \zeta_j(t') \rangle = \delta_{ij} \delta(t - t')$, with i, j denote the Cartesian components. In this regard, the "particle" described by Eq. (6) can be likened to a Brownian particle embedded in the phonon gas under the action of an external force field (Kramers 1940). Indeed, $D_{\mathrm{E}} = \eta_L / m\gamma_L$ is the *Einstein diffusivity* for a free Brownian particle subjected to the assumption that $|\gamma_L v| >> |\dot{v}|$.

Modelling the potential experienced by the "particle" with a saw-tooth potential in each of the three Cartesian directions, analytic expressions of the phase-space diffusivity D and mobility μ can be derived by solving Eq. (6). The lengthy derivation has been detailed in the Appendix of Woo and Wen (2017). To first order of Δ, the corresponding mean reaction time $\tau_\pm$, which governs the speed of the forward $(+)$ and backward $(-)$ reactions, is given by

$$\tau_\pm = \frac{a^2 m \gamma_L \left(1 + \gamma_m/\gamma_L\right)}{\eta_L} \left(1 \mp \frac{E_B - E_A}{2\eta_L}\right), \qquad (7)$$

where $2a$ is the distance in phase space between the two equilibrium positions. The ratio γ_m/γ_L measures the relative strength of the resistance due to activation barrier versus that due to the lattice.

Physically, the reduced effectiveness of the activation barrier as temperature increases (ξ decreases) is the result of noise-assisted tunneling (Flynn and Stoneham 1970; Woo and Wen 2017).

The reaction rate constant is the inverse of the reaction time in Eq. (7). It only takes the Arrhenius form when the activation barrier is sufficiently high or when the temperature is sufficiently low. When more than one transition states are involved, the reaction rate is the inverse of the sum of reaction times of all processes involved, and the slowest step is the controlling step as expected.

The foregoing general discussion holds independent of whether classical or quantum statistics are used in the derivation. Since classical results can be recovered from the quantum version by taking the limit $\hbar \to 0$, we only need to continue along the quantum route. When the environment is that of a nonmagnetic metal, the quantum fluctuation-dissipation relation (QFDR) can be evaluated from Eq. (4) using the phonon density of state (DOS) $g(\omega) = \frac{4\pi k^2 \Omega}{(2\pi)^3} \frac{1}{\nabla_{\mathbf{k}} \omega}$ where Ω is the atomic volume and $\mathbf{k}$ the phonon wave vector. The DOS can be obtained from experiments or from first-principle calculations, or by simply using the Debye model as Woo et al. (2015).
Fig. 4 (color on line) ξ as function of temperature based on classical fluctuation dissipation relation (CFDR) $\xi_C = E_m/k_B T$, and quantum fluctuation dissipation relation (QFDR) $\xi_Q = E_m/\eta(T)$, where $\eta(T)$ is given in Eq. (5) and $E_m = k_B \Theta_D = 0.032$eV (From Woo and Wen 2017)

To visualize the effect of quantum statistics on the many-body dynamics, Woo and Wen (2017) plotted the variable $\xi(T) = \frac{E_m}{\eta_L(T)}$ as a function of temperature T in an example where E_m is hypothetically put equal to the Debye energy of BCC W, i.e., $E_m = k_B \Theta_D = 32$meV. The plot is reproduced here in Fig. 4. It can be seen that above the Debye temperature, i.e., $T > \Theta_D$, quantum effects disappears and $\xi_Q \approx \xi_C$. Below the Debye temperature, i.e., $T < \Theta_D$, CFDR overestimates the phonon density, which is reflected in the large difference between $\xi_C \to \infty$ calculated using CFDR and $\xi_Q = 8/3$ calculated using QFDR as $T \to 0$. If ξ_C is used instead of ξ_Q in Eq. (7), γ_m is greatly over-estimated, causing a serious underestimation of the reaction speed. Thus, referring to Fig. (4), at $T = 10$K, QFDR gives a value of $\xi_Q \approx 8/3$ while CFDR gives a value of $\xi_C \approx 40$. This means that significant reactions between molecules may still occur even if there is insufficient energy to overcome the activation barrier. The same quantum effect on the reaction rate has also been found by Masel (1996).

Within the Debye model, classical thermodynamics is applicable well above the Debye temperature. In this case, $\eta_L = k_B T$ and the QFDR is reduced to the classical fluctuation-dissipation relation (CFDR). The traditional Einstein-Smoluchowski relation between the mobility and diffusivity, namely, $D = \mu k_B T$, can also be recovered (Woo and Wen 2017). For sufficient large activation energy, i.e., $E_m >> k_B T >> k_B \Theta_D$, the classical reaction constant is given by

$$k_{\pm} = \tau_{\pm}^{-1} = \frac{E_m^2}{2a^2 m \gamma_L k_B T} \left(1 \pm \frac{E_B - E_A}{2k_B T} \right) e^{-E_m/k_B T}, \qquad (8)$$

which has the Arrhenius form. Many-body effect is manifested in the dependence of the reaction constant on the high-temperature mobility $\mu_{HT} = (m\gamma_L)^{-1}$, which

measures the viscosity of the medium due to the environmental noise encountered by the reactants. This relation with the lattice vibrations is not considered in the traditional TST derived using a static approach.

When the activation energy is small, i.e., $E_m << k_B T$, $\xi << 1$ and $\frac{\gamma_m}{\gamma_L} \approx \frac{\xi}{3} << 1$ according to Eq. (7). In this case, the reaction time is controlled by the environmental noise, i.e., by γ_L. In comparison, the effectiveness of γ_m is reduced because of phonon-assisted tunneling. In this case, the reaction constant from Eq. (7) is reduced to

$$k_{\pm} = \frac{k_B T}{a^2 m \gamma_L} \left(1 \pm \frac{E_B - E_A}{2 k_B T} \right), \tag{9}$$

which is noticeably independent of the activation barrier and has a temperature dependence that deviates completely from the traditional Arrhenius form. Both are many-body effects that originate from the environmental noise which becomes the controlling factor when the activation barrier E_m is sufficiently low. The deviation of both Eqs. (8) and (9) from the traditional transition state theory is expected from Miller's (1974) observation that the separability assumption used in deriving TST is seldom satisfied. Woo and Wen's (2017) results are also consistent with the observation of Pineda and Schwartz (2006) in the simple exchange reaction between diatomic hydrogen and a hydrogen radical. Indeed, when $E_B - E_A << k_B T$, Eqs. (8) and (9) can be combined to give the modified Arrhenius equation, $k \approx B T^n e^{-E_m / k_B T}$ where $-1 \leq n \leq 1$ in the IUPAC Goldbook (IUPAC 2006).

When quantum effects are taken into account, the frequencies of the vibration modes enter the equation. At low temperatures down to 0 K, the density of the phonon gas is low, but does not vanish due to the athermal phonon ground state. This energy still allows the probable appearance of the particle on the other side of the saddle point without thermal excitation, a phenomenon one may describe as ground-state-phonon-assisted tunneling. This can be clearly seen from the Debye model, within which $\eta_L(T) = \left[\frac{3}{8} + \frac{\pi^4}{5} \left(\frac{T}{\Theta_D} \right)^4 \right] k_B \Theta_D$ from Eq. (5). When the temperature T dips below $\sim \Theta_D / 3$, the second term in the square brackets decreases rapidly as T^4, and η_L tends to a constant value of $\eta_L \approx \frac{3}{8} k_B \Theta_D$. Following Eq. (7), the near-zero reaction constant τ_Z^{-1} is related to the high-temperature mobility μ_{HT}.

Thus, below $\sim \Theta_D / 3$, the reaction constants become temperature independent and is nonzero even at 0 K. The complete departure from both the Arrhenius behavior and the Einstein-Smoluchowski relation is obvious. In particular, when $E_m << \frac{3}{8} k_B \Theta_D$, the reaction constant is also independent of the activation energy and is completely controlled by the drag due to the ground-state phonons, a pure quantum effect. The nonzero reaction rate at 0 K is a consequence of phonon-assisted tunneling resulting from the uncertainty-principle. In addition, below the Debye temperature, the conventional Einstein relation $D = \mu k_B T$ no longer holds due to quantum effects.

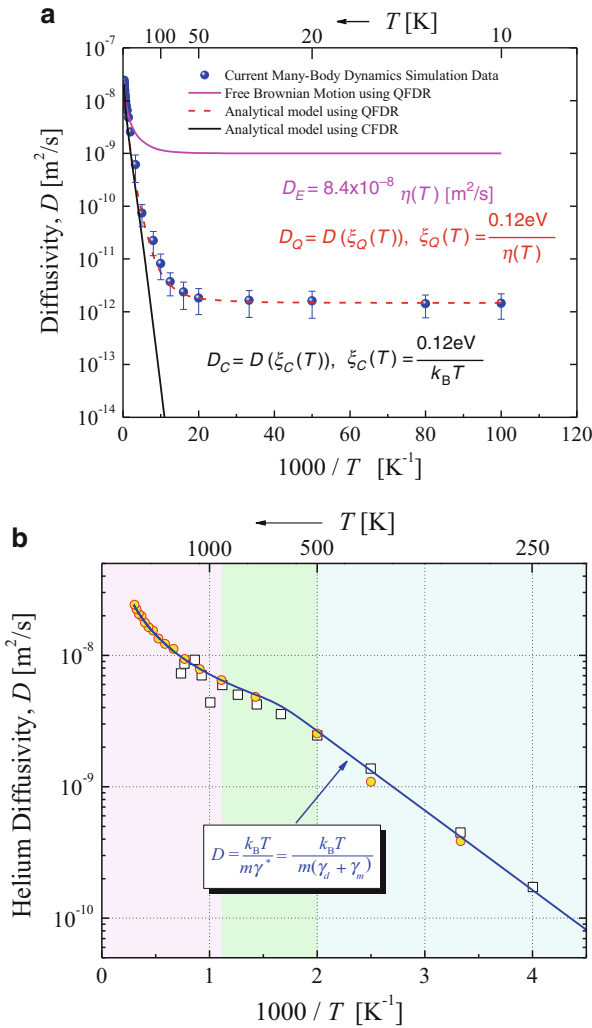
The accuracy of the foregoing Langevin-equation approach has been verified by comparing with results from MD simulation (Woo and Wen 2017). In Fig. 5, the


Fig. 5 (color on line) Diffusivities of He in BCC W at temperatures from 10 to 3300 K, calculated from analytical model (Eq. (8)) based on QFDR and CFDR, comparing with corresponding MD results. (**a**) for low temperatures (From Woo and Wen 2017); (**b**) for high temperatures (From Wen et al. 2017)

diffusivity of He in bcc W obtained from MD simulation is shown to only follow the Arrhenius law in a narrow temperature range between ~300 and ~700 K and tends to a constant on the low-temperature side while obeying Einstein's theory and becoming a linear function of temperature on the high-temperature side.

The kinetic description of cluster nucleation and growth may be described as an evaporation-condensation process in which particles are randomly added to or removed from the clusters one at a time. Within the Becker-Döring model (Becker

and Döring 1935), the evolution kinetics can be expressed in terms of a system of hierarchical conservation equations for clusters of increasing sizes. Fluctuations due to lattice vibrations are neglected. If the size of the fluctuations is sufficiently small compared to the size of the cluster, this set of equations may be approximated by the corresponding Fokker-Planck (F-P) equation which is formally a drift-diffusion equation in the cluster-size space (Kelton and Greer 2010). The drift term represents the deterministic (macroscopic) growth rate of the clusters and the diffusion term represents the statistical spread of cluster sizes due to the random fluctuations in the chemical potential. It is on this basis that the well-known Zeldovich-Frenkel equation in classical nucleation theory was derived (Zeldovich 1942; Frenkel 1946). Inherent assumptions made in the Becker-Döring model (1936) from which the Zeldovich-Frenkel equation is derived are the same as that of the TST due to Eyring (1935), namely, separability, quasi-equilibrium, and classical mechanics. The Arrhenius temperature dependence of the nucleation rate so obtained is affected in a similar way when many-body dynamics is taken into account.

3   Summary and Outlook

In a previous contribution to the First Edition of this Handbook, we assessed the efforts seeking to overcome the limitations of modeling irradiation damage based on the continuum theory. The atomistic description of reactions among crystalline defects was integrated into the macroscopic rate-theory model via rate constants derived using a mesoscopic model based on the Gibbs-Boltzmann statistics. The present article continues in this direction but with emphasis on the fundamental principles that can bridge the scales between atomistic mechanics and macroscopic thermodynamics which can then provide a new basis for the various irradiation-damage modeling methodologies. We focus on the shortcomings of the three basic assumptions: (1) separability of the reaction path from the environmental noise, (2) validity of classical statistics, and (3) quasi-equilibrium between the reactants, products, and the transition state. The first assumption prevents rate processes at high temperatures or those with low reaction barrier to be treated properly. The second excludes processes at low temperatures or those with low reaction barrier. The third assumption ignores processes with low activation barrier. As a result, the traditional approach is only reliable for rate processes with a high activation barrier and at intermediate temperatures. To mitigate the limited applicability of the reaction constants so derived, we consider a dynamical approach using a Langevin equation scheme in the Mori-Zwanzig formalism. The many-body dynamics is solved and linked to the thermodynamics and reaction kinetics using the quantum fluctuation-dissipation relation via the Debye theory. Both analytical and MD results are consistent and demonstrates significant effects of lattice and spin dynamics on the reaction rates. One can expect improved accuracy in the descriptions of the kinetics of the general, anisotropic, and low-dimensional diffusion-controlled reactions, clustering of small interstitial atoms (He, H) and self-interstitials, the interpretation of low-temperature experiments, plasticity and dislocation dynamics.

Temperature dependence is clearly central to the theory of rate processes, the issue having been studied for well over a century, as witnessed by the dominant role of the Arrhenius law. Based on similar assumptions, Eyring's equation of TST and the Zeldovich-Frenkel equation of classical nucleation theory also had the Arrhenius form. Given the basic nature of thermodynamics and reaction kinetics, the universality of the environmental noise, quantization and quantum uncertainty, and significance of the effects due to quantum many-body dynamics discussed here, the awareness of a science frontier at the mesoscale (Crabtree and Sarrao 2012; Yip and Short 2013) is a noteworthy development with relevance to radiation damage (Short and Yip 2015). This provides a window to a more fundamental and mechanism-based understanding of reaction and nucleation kinetics (diffusion- or reaction-controlled), all sink biases, production bias, point-defect configurations, diffusivities and mobility, isochronal annealing rates of irradiation damage. The new frontiers tend to be in regimes characterized by extreme environments where temperatures can be very high or very low, activation energies can be low, e.g., self-interstitial migration, and when ferromagnetic metals are involved. While the present discussions are concerned with crystalline materials, the general responses considered, classical versus quantum treatment, low and high activation barriers, and dynamics of many-body interactions have counterparts for amorphous or other states of matter.

Contents

Abstract

The materials used in nuclear fuel elements and other structural components within a nuclear reactor are subjected to an aggressive operating environment that subjects them to challenging physical conditions and leads to changes to their microstructure and engineering properties over time. Numerical simulation is increasingly used to characterize the response of these materials at both engineering and material scales. Many problems of interest in nuclear systems inherently require a capability to solve for multiple physics systems in a coupled manner. This chapter provides a summary of the governing equations for some of the

physics that are typically of interest for these problems, numerical discretization techniques, and methods for solution of the resulting systems of equations. In addition, it provides examples of three important nuclear material simulation applications: engineering-scale nuclear fuel performance, hydride formation in zirconium alloy cladding material, and UO_2 microstructure evolution.

The operating environment of nuclear reactors presents many unique challenges both for the materials comprising fuel elements (Olander 1976) and other structural components within and surrounding the reactor (Zinkle and Was 2013). These environmental challenges are due to the simultaneous exposure to conditions from multiple physical systems, including high temperatures, high radiation fluxes, aggressive chemical environments, and mechanical loading.

Numerical simulation has been used for multiple decades as a tool for understanding the behavior of various components in this environment. As these tools have been developed to increasing levels of sophistication, they have been used increasingly both for engineering analysis of components and for simulating the processes of microstructure evolution, which leads to changes in the engineering properties of interest in the materials used in these components.

In some cases, the behavior of a single physics can be considered independently, simply because the response of one system does not change the conditions a component or material is subject to in other physical systems. For example, a component may be subjected to mechanical loading and thermal expansion due to elevated temperatures, but often, the mechanical response has a negligible effect on the thermal environment, so the temperature field can simply be imposed as a boundary condition to the mechanical model. However, there are also many scenarios in which the response to one physics has a strong effect on other physics. In the thermal/mechanical example, if the mechanical response of that component significantly changes its configuration, that could alter paths for heat transfer and have a dramatic effect on the thermal field. In such a case, the simulation should account for two-way feedback between the models of these physical systems to accurately represent its response.

There are many cases in which significant feedback occurs between physical systems within the nuclear reactor environment. These occur at length scales ranging from that of the full reactor system to the material level.

At the reactor scale, there is two-way feedback between the neutron transport and the thermal conditions within the nuclear fuel, which is volumetrically heated by the process of fissioning atoms under neutron flux. The nuclear cross sections, or probabilities of interaction between a nucleus and an incident neutron, are dependent on the temperature. Because of the temperature dependence of the cross sections, the fission rate is dependent on the fuel temperature.

Even if the fission rate is taken as a prescribed condition, computing the temperature in nuclear fuel is a complex multiphysics problem. In light water reactor (LWR) fuel, cylindrical uranium dioxide fuel pellets are stacked within long metallic fuel rods. Heat transfer from the fuel to the coolant outside the fuel rod is highly dependent on the size of the gap between the fuel and cladding, which can evolve

due to the mechanical response of the system. Computing the thermal response of a fuel rod thus necessarily involves solving coupled equations of mechanics and heat conduction.

At the material scale, within ceramic nuclear fuel, exposure to irradiation and elevated temperatures causes significant changes in the grain structure of the fuel. Gaseous fission products diffuse through the solid material and form bubbles. These bubbles, along with larger pores, have a tendency to migrate up the temperature gradient. At high temperatures, grain growth occurs either in an equiaxial or columnar fashion, depending on the local conditions.

Similarly, phenomena affecting the material performance of the zirconium alloys used for cladding in LWRs are driven by multiple interacting physics. Exposure to coolant water causes atomic hydrogen to diffuse through the cladding. Some of this hydrogen precipitates in the form of hydrides, which can form, dissolve, reprecipitate, and change their orientation depending on the temperature and stress state. Under a constant temperature and far-field stress, the process of hydride formation is itself a multiphysics problem, as hydride formation induces local stresses due to the volumetric expansion that occurs during the phase change, and the process of that phase change is affected by the stress state.

Away from the fuel elements, the integrity of the structural elements comprising the reactor system is challenged by exposure to the reactor environment. These elements include core supporting structures, pressure vessels, control rods, piping, steam generators, and concrete structures such as biological shield walls and containment vessels.

Material evolution can be considered at many length and time scales. When considering phenomena of interest at the engineering scale, material behavior can often be homogenized and represented as continuous behavior. When understanding of the processes of microstructure evolution is needed, simulations can be performed at the mesoscopic scale and explicitly include features of the material structure, such as individual grains or constituents of a composite material. At lower scales, other modeling techniques can explicitly include features in crystal structures such as dislocations, voids, self-interstitial atoms, or other matrix defects.

The discussion here is focused on modeling techniques for aspects of material behavior that vary spatially in a relatively continuous manner, so that the problem to be solved is to find spatially resolved field variables whose behavior is governed by partial differential equations (PDEs). The techniques for solving such problems are applicable at a wide variety of length scales, but are not applicable for modeling every aspect of multiphysics material response.

This chapter will first present a brief overview of the characteristics of the major physics affecting fuels and structural components in the nuclear reactor environment. This is followed by a discussion on the techniques used to numerically simulate these coupled systems. This includes both the discretization techniques and techniques for solving the resulting coupled systems of equations. Finally, several representative examples of coupled physics problems relevant to the performance of engineered systems and materials in a nuclear reactor environment are presented, along with details on the numerical simulation of those systems.

1   Characteristics of Physics

Multiple physical systems can potentially have a significant impact on the performance of nuclear reactor components and materials. These include mechanical deformation, heat transfer, species diffusion and reactions, phase change, fluid dynamics, and neutron transport. The characteristics of the physical systems that are typically most relevant to simulation of materials in nuclear reactors are summarized here.

1.1   Solid Mechanics

Materials and structures can experience mechanical deformation due to either external loading or intrinsically generated strains, such as those due to thermal expansion. The primary solution variable is the displacement vector $\boldsymbol{u}$, which varies spatially over the domain and contains components for its values in the directions of the coordinate system employed.

Deformation is governed by stress equilibrium within the volume of the domain:

$$\nabla \cdot \boldsymbol{\sigma} + \boldsymbol{b} = \boldsymbol{0} \tag{1}$$

where $\boldsymbol{\sigma}$ is the stress tensor and $\boldsymbol{b}$ is a vector of body forces (such as gravity loads). These tensors and vectors consist of components in the coordinate system of the model.

The strain tensor, $\boldsymbol{\varepsilon}$, is related to the gradient of the displacement field through a kinematic relationship, shown here for the small-strain case:

$$\boldsymbol{\varepsilon} = \frac{1}{2}\left(\nabla \boldsymbol{u} + (\nabla \boldsymbol{u})^T\right) \tag{2}$$

The treatment for finite strains is considerably more complex (Rashid 1993) and not covered here.

The stress is computed from the strain through a constitutive relationship, the details of which are material-specific. Under low stresses, many materials exhibit elastic behavior, in which the stress is linearly related to the applied strain through the elasticity tensor, $\boldsymbol{E}$:

$$\boldsymbol{\sigma} = \boldsymbol{E} : \boldsymbol{\varepsilon} \tag{3}$$

Intrinsically generated strains (also referred to as eigenstrains) are subtracted from $\boldsymbol{\varepsilon}$ before applying Eq. 3. Under higher stresses, materials often exhibit nonlinear inelastic behavior in the form of creep or plasticity. This is usually represented by using an incremental form for stress computation, where stress is a function of the increment in the strain between the current and previous time steps (Simo and Hughes 1998).

The equations shown here are for the quasistatic case, where the deformation occurs slowly or, in other words, when the time derivatives of $\boldsymbol{u}$ are very small, so

that inertial effects are assumed to be negligible. This is often the case for steady-state conditions in nuclear reactor components and materials. Additional terms for the effects of inertia and damping should be included in Eq. 1 if these are important.

1.2   Diffusion Processes

Many physical systems are governed by diffusion processes. Heat transfer and species transport in solids are two such systems of interest in nuclear reactors. These are commonly represented by Fickian diffusion (Fick 1855), in which the change in local concentration of a given species, ϕ over time, t, is governed by the gradient of that concentration:

$$\frac{\partial \phi}{\partial t} = D\nabla^2 \phi \tag{4}$$

where D is the diffusion coefficient. This PDE can be solved for the concentration ϕ, which is the primary solution variable. The flux vector J of a system following this process is expressed as:

$$\boldsymbol{J} = -D\nabla\phi \tag{5}$$

Heat transfer within a solid (in the absence of advection) is governed by Fickian diffusion. In this case, the concentration variable is the temperature, T. The energy balance equation governing heat transfer within a volume, including a source term due to an applied volumetric heating rate $\dot{Q}$, is expressed as:

$$\rho C_p \frac{\partial T}{\partial t} = k\nabla^2 T + \dot{Q} \tag{6}$$

where ρ is the density, C_p is the specific heat at constant pressure, and k is the thermal conductivity. The coefficients C_p and k can depend on temperature, making this a nonlinear equation.

Many diffusion systems of interest are also affected by the Soret effect (Rahman and Saghir 2014), where the concentration of a species is a function of both the concentration gradient and the temperature. An example of such a system in a nuclear environment is hydrogen concentration in LWR fuel cladding (Stafford 2015). Heat and moisture transport in concrete are affected by both the Soret effect and its counterpart, the Dufour effect, in which temperature is affected by the concentration gradient (Bažant et al. 1981).

1.3   Phase-Field Microstructure

In ideal solutions, the diffusive driving force is represented by the concentration gradient, and species concentrations can be computed using diffusion models as described in the previous section. However, in systems other than ideal solutions, where the chemical potential is not a linear function of the concentration, the

diffusive driving force is given by the gradient of the chemical potential rather than the concentration gradient. The modeling of species transport and phase changes on the mesoscale in these systems thus requires knowledge of the system's thermodynamic potential and its kinetic coefficients.

The phase-field method is a well-established tool for simulating the coevolution of microstructure and physical properties at the mesoscale. In the phase-field method, the microstructure is described by a system of continuous variables, also called order parameters. Microstructure interfaces are approximated using a finite width, and the order parameters vary smoothly over those interfaces. The evolution of non-conserved order parameters η_j (e.g., phase regions and grains) is governed by the Allen–Cahn (1972) equation (7), and the evolution of conserved order parameters c_i (e.g., concentrations) is governed by the Cahn–Hilliard (1958) equation (8):

$$\frac{\partial \eta_j}{\partial t} = -L_j \frac{\delta F}{\delta \eta_j}, \qquad\qquad j = 1, \ldots, N_\eta \qquad (7)$$

$$\frac{\partial c_i}{\partial t} = \nabla \cdot \left(M_i \nabla \frac{\delta F}{\delta c_i} \right), \qquad\qquad i = 1, \ldots, N_c \qquad (8)$$

Here, F is the total free energy of the system, which can be formulated as a volume integral

$$F = \int_\Omega \left(f_{\text{loc}} + f_{\text{gr}} + E_{\text{d}} \right) \, \mathrm{d}V, \qquad (9)$$

where Ω is the simulation domain,

$$f_{\text{loc}} \equiv f_{\text{loc}}(\eta_1, \eta_2, \ldots, c_1, c_2, \ldots) \qquad (10)$$

is the local free energy density, and

$$f_{\text{gr}} \equiv f_{\text{gr}}(\nabla \eta_1, \nabla \eta_2, \ldots, \nabla c_1, \nabla c_2, \ldots) \qquad (11)$$

is the gradient energy contribution.

In isolated systems, the evolution of these variables leads to a monotonically decreasing free energy as a function of time. The phase-field method has been used to model a large range of physical phenomena, including solidification, phase transformation, and grain growth.

2   Discretization Techniques

The behavior of physical systems is continuous in both space and time. To make the solution amenable to numerical solution, it is necessary to approximate the continuous response of the actual system using a finite number of variables. This process, known as discretization, allows the model to be solved using an algebraic system of equations. Discretization is used both in space and time – spatial

discretization is used to describe the spatial variation of field quantities, while time discretization is used to solve for the system's response at a fixed number of times.

2.1 Finite Element Method

The finite element method (FEM) is widely used as a discretization technique for solving a variety of PDEs (Zienkiewicz et al. 2013). In FEM, the solution domain is represented by a mesh, which is a collection of connected primitive geometric elements. Associated with these elements is a set of nodes, which are located at the vertices of elements, and can also be located on edges or faces, or within the volume of elements. Continuity of the solution between neighboring elements is enforced when those elements share common nodes.

FEM is used to solve a discretized form of the governing PDEs, which are enforced in a weak, or integral, form at the finite element degrees of freedom. The solution is locally interpolated over individual elements using a set of shape functions, which are associated with the degrees of freedom in the discrete system. A number of different types of shape functions can be used. Lagrangian shape functions are among the most commonly used and interpolate between degrees of freedom directly associated with the nodes of a given element.

The solution field, denoted here as $u(x)$, is interpolated at any point x within the domain by a set of interpolation or shape functions ϕ_i. Lagrangian shape functions are associated with the finite element nodes, so that for node i, $\phi_i = 1$, and at all other nodes, $\phi_i = 0$. At any location within an element, the sum of the shape functions is 1. The solution and its gradient can be expressed at any location in the domain as a function of the shape functions and their gradients:

$$u(x) = \sum_i \phi_i(x) u_i \tag{12}$$

$$\nabla u(x) = \sum_i \nabla \phi_i(x) u_i \tag{13}$$

where u_i are the values of u at the nodes of the element containing point x.

To solve a PDE using FEM, it must be cast in a variational or weak form. This involves pre-multiplying each term of the PDE by a test function and expressing the PDE as a domain integral. In the Galerkin method, these test functions correspond to the shape functions. The divergence theorem is then applied to integrate terms with divergence operators into two separate terms involving a volume and a surface integral and which can be represented using gradients of the shape functions.

Finally, the weak form of the governing equation is integrated numerically. The integrals over the domain are performed by taking a summation of the integrals over individual elements, and the individual elements are integrated using numerical quadrature, typically Gaussian quadrature. An arbitrary function $f(x)$ is integrated numerically over the domain of an element Ω_e as:

$$\int_{\Omega_e} f(\boldsymbol{x}) \approx \sum_q f(\boldsymbol{x}_q) w_q \qquad (14)$$

where q are the quadrature points, $\boldsymbol{x}_q$ are the coordinates of the quadrature points, and w_q are the weights of the quadrature points for an element.

An important side effect of the use of quadrature is that while solution variables can be interpolated anywhere in the domain, coefficients in the PDE that are computed at quadrature points are only available at those locations, and extrapolation to other locations is somewhat problematic.

One of the advantages of FEM is that it is very flexible. It has become widely used for solving PDEs associated with a variety of physics. Finite element meshes can be constructed to conform to the shapes of very general domain geometries, so it can be used for modeling a variety of engineering components. The flexibility in mesh generation also readily permits local refinement in regions where increased fidelity is needed.

2.2 Other Methods

FEM is the most widely adopted technique for multiphysics PDE solvers and is the basis for the methods discussed here. However, a number of other PDE solution techniques can be used for solving multiphysics problems, and a few of them are briefly discussed here.

2.2.1 Finite Difference Method

The finite difference method is a technique for discretizing PDEs in either space or time and was developed independently of FEM. FDM also uses a mesh to represent the solution domain, but the mesh must be topologically regular. It can be adjusted to fit domains with curved surfaces, but it does not have nearly the flexibility that FEM meshes do to conform to parts with complex geometry.

FDM is much simpler than FEM. FDM approximates the spatial derivatives of solution field variables by computing the differences between values of those variables on opposing sides of a given node in each coordinate direction. It does not rely on quadrature or interpolation functions in the way that FEM does.

FDM can be very numerically efficient, and although it is limited in the geometries that it can represent, it is very well-suited to material-scale modeling where the solution domain commonly consists of periodic representative volume elements.

2.2.2 Spectral Methods

Rather than discretizing the domain using degrees of freedom tied to specific material points, as is done in the FEM or FDM, the spatial variation of the solution field can be represented using a Fourier series expansion (Chen and Shen 1998). This technique is widely used in phase-field simulations of periodic representative volume elements and is very efficient.

2.2.3 Peridynamics

Peridynamics is another method for solving governing equations. Peridynamics is a nonlocal meshfree method that solves integral rather than differential equations (Silling 2000). Its development was driven by a need to better handle fracture in solid mechanics simulations. Using PDEs, along with the solution methods developed to solve PDEs, to represent mechanical deformation is problematic when material fractures, because the response is no longer continuous. Peridynamics overcomes some of the shortcomings of FEM in this area by allowing connections between material points to naturally break. It has since been generalized to other physics, and has been applied to coupled physics models, including nuclear fuel applications (Oterkus and Madenci 2017).

3 Solution Techniques

These discretization methods for PDEs all result in the representation of the system as a set of coupled algebraic equations. The integration of these equations in time can be done using explicit methods, in which no equation solution is needed, or implicit methods, which require the solution of a system of linear or nonlinear equations at each time step. Many of the materials challenges in nuclear reactors involve slowly evolving processes, which are more amenable to solution using implicit techniques, so those are the focus of the present discussion.

Typically, Newton's method or a variant thereof is used to solve the nonlinear system of equations for a given physics. The goal of the nonlinear solver is to obtain the solution vector x for which the associated residual r is zero:

$$r(x) = 0 \tag{15}$$

The Jacobian matrix J is:

$$J(x) = \frac{\partial r(x)}{\partial x}. \tag{16}$$

In Newton's method, the following procedure is iteratively repeated to update the solution until Eq. 15 is met within an acceptable tolerance:

$$\text{Compute } J(x_k), r(x_k) \tag{17}$$

$$\text{Solve } J(x_k)s = -r(x_k) \text{ for } s \tag{18}$$

$$x_{k+1} = x_k + s \tag{19}$$

where s is the iterative update to the solution vector and k is the nonlinear iteration index.

Solving coupled physics systems introduces many mathematical and software engineering challenges that are not encountered in solving single physics equations.

For multiphysics simulations, the complexity of solving the system is increased significantly because the solution vector x contains the unknown degrees of freedom for all of the physical systems modeled. To solve the system for all those physics using Newton's method requires forming the full Jacobian matrix for that coupled system. This can be quite challenging, because computing the terms related to the interactions between the physics can be very complex.

To avoid this difficulty, it is common to solve coupled physics problems in a loosely coupled fashion, where the systems of equations for the individual physics are solved independently. The results from the solutions of individual physics models are sequentially transferred to the other models. Fixed point iterations can be performed to iterate between these models until they reach a converged solution. Alternatively, if there is weak coupling between the systems, it may be acceptable to simply transfer the solutions from the other physics from the previous time step and skip these iterations entirely.

This loose coupling approach allows for the individual physics models to be based on completely different solution and discretization schemes. The individual simulation codes and discretizations can be optimized for specific physics, and all that is required is a means to transfer results between the models. This approach is widely used in practice to couple physics codes that were developed independently.

For coupled physical systems with significant feedback, however, loose coupling approaches often suffer from decreased performance relative to tight coupling. A study performed by Novascone et al. (2015) compared the performance of loose and tight coupling approaches for thermal/mechanical systems. It was found that for weakly coupled systems, there were no significant benefits to using a tightly coupled solution strategy, but using tight coupling significantly improved performance for problems with strong two-way feedback between the physics.

The Jacobian-free Newton-Krylov (JFNK) method, which is a variant of the Newton method that does not explicitly require the Jacobian (Knoll and Keyes 2004), has great utility for solving multiphysics problems as a single coupled system of equations since it alleviates some of the burden of forming the coupling terms in the Jacobian matrix. This algorithm employs a Krylov iterative method, such as GMRES (Saad and Schultz 1986), to compute the Newton iterative update in Eq. 18:

$$s = a_0 r_0 + a_1 J r_0 + a_2 J^2 r_0 + \cdots + a_l J^l r_0 \qquad (20)$$

where r_0 is the initial residual and a_i are the series of coefficients computed in the individual Krylov iterations.

The Krylov algorithm only requires the action of the Jacobian on a vector v, which can be approximated with the finite difference expression:

$$J(x_k)v \approx \frac{r(x_k + \epsilon v) - r(x_k)}{\epsilon}. \qquad (21)$$

where ϵ is a small number that reflects a perturbation from the last iterative solution. As long as the Krylov iterations in Eq. 20 are sufficiently converged, this technique

has the same nonlinear convergence characteristics as Newton's method. There are two primary advantages to not explicitly forming a Jacobian: it can require significant computational resources to store and solve using the Jacobian, and it can be challenging to compute the off-diagonal coupling terms in the Jacobian.

Although the full Jacobian matrix is not strictly required in the JFNK algorithm, The Krylov iterations converge much more rapidly if the system is well-conditioned, so preconditioning is typically used with this approach. Using the exact Jacobian matrix for preconditioning will yield best convergence rates for the Krylov iterations, but an approximation of it often performs quite well.

In multiphysics simulations, it is often fairly straightforward to compute the residual for physics as a function of the state of another physics, but computing the derivatives with respect to that other physics can be much more difficult. Hence the JFNK algorithm can be very attractive in that those derivatives are not strictly required. A working initial capability can be rapidly developed without those derivatives, and then they can be developed later as needed to optimize the algorithm.

An alternative approach to deal with the complexity of forming the Jacobian is to use automatic differentiation (AD) techniques to automatically compute the derivatives needed for the Jacobian from the code that computes the residual (Pawlowski et al. 2012a). The residual evaluation code can be broken down into basic mathematical operations with known rules for computing derivatives. AD can be used to compute an exact Jacobian matrix for an entire equation system, which can be applied very effectively to obtain the solution. The main drawback to AD is that it requires sophisticated software engineering. For the derivatives to be evaluable from the code that computes residuals typically requires quite invasive changes to be made to that code.

A number of commercial and open-source codes and frameworks supporting multiphysics simulations are available, based on a variety of designs. A few notable examples, all based on FEM, are mentioned here.

Many commercial codes such as Abaqus (Dassault Systemes 2016), which started out as single-physics solid mechanics codes, now support coupling with multiple physics. COMSOL (COMSOL, Inc 2017) is a commercial product specifically targeted at multiphysics simulation and which permits adding user-defined physics. It has been used as the basis of a nuclear fuel simulation tool (Liu et al. 2016).

Multiple frameworks have been developed with an explicit goal of being the basis for developing multiphysics simulation capabilities, with very different philosophies. A few examples of such frameworks are mentioned here.

The SIERRA framework (Stewart and Edwards 2004) is an example of a software framework based on the use of loose coupling to handle the solution of multiphysics models. It does this by providing common finite element data structures and services to transfer solutions between applications, which solve their individual physics equations independently.

Other frameworks solve multiphysics models using a single coupled system of equations. One such framework is MOOSE (Gaston et al. 2009), which provides a pluggable set of interfaces to define individual physics models, and manages the

FEM assembly of the residuals from those models, using preconditioned JFNK and other techniques to solve the physics models as a single, tightly coupled system. MOOSE is notable in the context of this chapter because its development was motivated specifically for the solution of simulation problems in nuclear energy. Multiple applications based on that framework have been developed for various aspects of nuclear energy simulations and are used as the basis for the results shown here. Other open-source frameworks that solve a single system of equations are Trilinos (Pawlowski et al. 2012b), FEniCS (Logg et al. 2012), and Life (Prud'homme 2006). These also provide pluggable interfaces to define physics models and solve the coupled physics equations in a single tightly coupled system, but they focus on using AD techniques to automate the construction of the Jacobian matrix.

4   Applications

4.1   Fuel Performance

A wide variety of nuclear reactors, with specialized nuclear fuels, have been designed or proposed. These include light water reactors (LWRs), research reactors employing plate fuel, fast reactors, high temperature gas reactors, and others. The discussion here focuses on the fuel performance of UO_2/zirconium alloy fuel rods for LWRs. These rods consist of hundreds of UO_2 pellets atop one another encased in a zirconium alloy cladding with a gas-filled plenum at the top of the cladding.

The fundamental quantity of interest in LWR fuel performance analysis is the fuel center-line temperature. This quantity is critical due to its effect on neutronics and other fuel performance behaviors.

Considering Eq. 6, for steady operation, the important parameters are the volumetric heating rate and the thermal conductivity. The volumetric heating rate directly depends on the fission rate, which is given as in input for fuel performance analysis. The thermal conductivity of the ceramic fuel is quite low, whereas the thermal conductivity of the zirconium alloy cladding is fairly high given that the cladding is a metal. Thus the more important quantity is the fuel thermal conductivity.

Fuel thermal conductivity is temperature dependent (Fink 2000) as well as dependent on irradiation effects (Lucuta et al. 1996). This being the case, the thermal conductivity of the fuel varies across the fuel pellet due to the temperature gradient in the pellet and also varies in time. The heat transfer equation is therefore nonlinear.

The heat in the fuel passes through the gap between the fuel and the cladding before passing through the cladding and then to the coolant. The gap between the fuel and cladding is filled with helium gas when the rod is fabricated. The ease at which heat passes through the gap is governed by the size of the gap; the thermal conductivity of the gas in the gap; pressure due to mechanical contact, if any, between the fuel and the cladding; and radiative heat transfer effects. The size of the gap depends on the initial geometry and the deformation of the fuel

and cladding, which ties the mechanical response of the fuel rod to the thermal response. In addition, one product of nuclear fission is gas (primarily xenon and krypton) that will accumulate in the gap over time. These gaseous fission products affect the internal pressure of the fuel rod (the mechanical response) and the thermal conductivity of the gas mixture (the thermal response).

Conductance across the gap due to the gas follows Eq. 22:

$$h_{\text{gap}} = \frac{k_g(T_g)}{r_c - r_f + d} \tag{22}$$

where h_{gap} is the gap conductance; k_g is the gas thermal conductivity; T_g is the temperature of the gas; r_c and r_f are the radial positions of the cladding and fuel, respectively; and d is an additional distance that accounts for roughness of the surfaces, for example. The need to calculate the distance between the cladding and the fuel clearly shows a dependence on the mechanical solution.

Other important fuel behaviors include densification, swelling, cracking, and creep. Early in life in the reactor, pellets densify and shrink slightly. Fuel swelling happens continuously under irradiation and is of two types. The first is solid fission product swelling and occurs in a linear relationship with irradiation. The second is due to gaseous fission products and is much more difficult to predict. Gaseous swelling depends on the diffusion of gas atoms and bubbles within grains, the accumulation and interconnection of gas bubbles at grain boundaries, and the eventual release of fission gas to the gap and plenum.

When a fuel rod is initially brought to power in the reactor, the temperature gradient causes the pellet to crack due to thermal stresses. This cracking relieves stress and allows the pellet to move outward, slightly, in the radial direction. (This also affects temperature predictions because of the effect on the gap size.) Cracking also greatly influences the creep of the fuel pellet due to its effect on the stress state.

Thermal and irradiation creep, along with irradiation growth, of the zirconium alloy cladding are other behaviors that must be modeled. The coolant pressure in LWRs engages creep mechanisms in cladding, causing the cladding to move inward toward the pellet, affecting internal rod pressure, gap size, and, once again, temperature.

The effects of several sources of eigenstrains must be accounted for in the computation of the stress. For an example of how this is done, the elastic stress computation takes these into account as:

$$\sigma = E(\varepsilon - \varepsilon_T - \varepsilon_{sw} - \varepsilon_d - \ldots) \tag{23}$$

where σ is the stress, E is the elasticity tensor, ε is the total mechanical strain, ε_T is the thermal strain, ε_{sw} is the strain due to swelling, and ε_d is the swelling due to densification. Given that stress is dependent on the thermal strain, the displacement solution has a direct dependence on the temperature solution.

Other behaviors of interest in fuel performance modeling include the shift of power toward the outer rim of the fuel pellet, the thermal boundary condition on the

exterior of the cladding, corrosion of the cladding, thermal expansion, the evolving internal rod pressure, mechanical contact between the fuel and cladding, and mass diffusion.

Most, though not all, fuel performance codes resolve the thermal and mechanical physics with a loose coupling approach. In this approach, the temperature at the grid points is computed based on a fixed set of displacements, and then the displacements and stresses are computed based on those temperatures. The new stress state and displacements are then used to update the temperature, and the process is repeated until a satisfactory condition is met. It is worth noting that this approach can be nested. For example, the displacements may be computed using a fixed internal rod pressure. With new displacements, the internal rod pressure can be recomputed and the two steps repeated to reach a final converged displacement solution.

Fuel performance codes are used to compute fuel center-line temperatures when comparing against experimental data, for postulated conditions, or when coupling with other (e.g., neutronics) codes. There is particular interest in using fuel performance codes to simulate abnormal, or accident, conditions. Because the fuel properties and behavior are outside normal regimes and can exhibit highly nonlinear behavior, this can be particularly challenging for fuel performance analysis.

For example, in a loss of coolant accident, the supply of coolant to the reactor is interrupted. This results in increased fuel rod and coolant temperatures. If coolant flow is not restored, the coolant will change to steam, and the fuel rod temperatures will continue to rise. A lack of external pressure in conjunction with increased temperatures can cause the cladding to creep outward. This outward motion may result in a ballooned section of the fuel rod and in cladding burst.

This situation requires more advanced thermal boundary conditions for the fuel performance code (often taken from the output of a dedicated thermal-hydraulics package). In addition, creep models for the cladding appropriate for this temperature regime are needed. Fission gas release and other fuel-specific models must also be appropriate for these conditions.

Other challenging conditions to analyze, all of which require a multiphysics approach, include reactivity insertion accidents, so-called missing pellet surface defects (a chipped pellet that creates high localized stresses), and stress corrosion cracking of cladding.

Examples of fuel performance codes in use today include TRANSURANUS (Lassmann 1992), ENIGMA (Rossiter 2011), DIONISIO (Soba and Denis 2008), ALCYONE (Michel et al. 2013), FRAPCON (Berna et al. 1997), FALCON (Yagnik et al. 2004), and Bison (Williamson et al. 2012). Bison is based on the MOOSE framework discussed in Sect. 3.

Example calculation results for layered 1D (stacked radial slices of fuel and cladding), 2D axisymmetric, and 3D fuel analysis are shown in Fig. 1. Low dimensionality models are useful for rapid evaluation of the global fuel rod response, while higher dimensionality models can be used to study local behavior in detail. These models were all run using the Bison code, which uses the same set of computational models with arbitrary dimensionality.
Fig. 1 1D (left), 2D (center), and 3D (right) nuclear fuel models. The 1D model is a set of slices of fuel with radial 1D elements representing fuel and cladding at a given elevation. The 2D model uses an axisymmetric representation and can include individual fuel pellets as shown. The 3D model uses a symmetry plane through the center of the rod and can be used to study local effects such as the behavior around a defective pellet on upper right side of center pellet

4.2   Hydride Formation

Zirconium (Zr) alloys are a well-established light water reactor fuel cladding material due to the low neutron capture cross section of zirconium, its mechanical strength, and good corrosion resistance up to high temperatures.

Fuel elements are in constant contact with the water coolant medium during both reactor operation and wet storage, and one of the main challenges facing these alloys is that Zr has an undesirable reaction with water. At the clad surface, H_2O molecules are split and zirconium oxides are formed. A portion of the remaining hydrogen (H) atoms diffuse through the oxide layer forming on that surface into the bulk of the

cladding. Continued H uptake pushes the material past the H solubility limit, at which point a phase change to a thermodynamically more stable hydride phases is initiated.

Hydride formation has a substantial impact on the engineering-scale mechanical properties of the clad material. The low fracture toughness of the ZrH phases causes clad embrittlement and can lead to clad failure due to fracture.

This solid-state diffusion and phase change reaction lends itself to modeling using the phase-field method. Required parameterization includes the bulk free energies of the various ZrH phases, the interfacial free energy between phases, and the kinetic coefficients, i.e., interfacial and species mobilities. Data for this can be found in the literature.

The multiphysics aspects of this problem arise from the fact that the hydride phase transformations result in lattice changes that exhibit volume changes and thus misfit strains with respect to the Zr matrix. These strains result in elastic stress fields, which in turn affect the stored mechanical energy of the system. This mechanical energy contributes to the total free energy of the system, the chemical potentials of the diffusing species, and as a result, the microstructure evolution. Further complications can arise from local plastic deformations due to dislocations emitted at points of stress concentrations at developing hydride precipitates.

The mechanism of delayed hydride cracking is a diffusion-limited time-dependent crack formation mechanism in which ZrH platelets are constantly formed at the tip of a crack. The crack propagates in steps through the newly formed hydride as soon as a critical condition, relating to hydride size and stress intensity factors, is met. Inherent to this mechanism is the multiphysics coupling of diffusive species transport, phase transformation, and mechanical state changes.

A comprehensive model for ZrH formation needs to combine the chemical free energy contributions and the mechanical interactions of the various phases. The resulting coupling in practice is twofold. On the one hand, the evolving phase-field microstructure variables will affect the mechanical properties of the system by means of variable-dependent eigenstrains as well as variable-dependent elasticity tensors. On the other hand, the elastic stress state gives rise to an elastic energy $\frac{1}{2}\sigma\epsilon$ which needs to be added to the thermodynamic free energy density used in the phase-field evolution equations. The elastic free energy is a function of a subset of the phase-field order parameters though the mechanical properties, which depend on the microstructural state. As a consequence, driving forces for these phase-field order parameters emerge from the variational derivative of this free energy contribution.

The phase-field and mechanics equations can be solved implicitly in a tightly coupled system using the finite element method. Figure 2 shows a representative coupled phase-field and mechanical finite element simulation of hydride precipitation. In periodic systems under the small-strain assumption, spectral methods can solve this system effectively as well.

Fig. 2 Stress field and concentration contours of three differently oriented γ hydride precipitates
4.3   UO$_2$ Microstructure Evolution

Uranium dioxide (UO$_2$), a common light water reactor fuel, is a polycrystalline ceramic material. For reactor applications, the fuel is synthesized in powder form and pressed into cylindrical pellets with a diameter and height of about a centimeter. These pellets are then sintered under a reducing atmosphere and loaded into zirconium alloy cladding tubes. Under operation conditions in a critical nuclear reactor, fission of the ^{235}U nuclei generates fission fragments, neutrons (which keep up the fission reaction), prompt γ-rays, and, through decaying fission products, β^--particles, delayed γ-rays, and heat due to neutron capture. As a consequence the nuclear fuel heats up, incurs lattice damage from collision cascades, and is doped with a broad variety of new chemical species – the fission fragments. About 80% of the heat is deposited during the stopping process of the fission fragments, and roughly 15% of the fission products deposited in the fuel are insoluble gases.

These harsh conditions result in driving forces that strongly impact the microstructural evolution of the fuel. The techniques described in Sect. 4.1 are necessary to compute the temperature and stress conditions in the fuel. Thermal and stress gradients affect the migration of both chemical species and irradiation-generated point defects and defect clusters in the fuel. This requires solving a diffusional or phase-field problem.

Beyond these basic mechanisms, which already form a connected multiphysics problem, are the advanced mechanisms of irradiation effects, added chemical species, creep, and fracture. The constant internal irradiation generates a defect population far above the thermal equilibrium. Defects interact with each other to
Fig. 3 3D simulation of increasing fission gas grain boundary coverage with progressing burnup in UO_2 (From Aagesen et al. 2017)

form complex defect structures such as loops or voids, and they interact with solute species such as fission gas atoms to form trap sites or gas bubbles. The irradiation also forces chemical mixing through ballistic displacements of atoms leading, for example, to resolution of fission gas out of the precipitated bubbles. Chemical species intentionally added to the fuel affect its composition and must be taken into account. Figure 3 shows a simulation of the evolution of fission gas bubbles at grain boundaries.

At the mesoscale level, radiation effects can be simulated with varying levels of fidelity. If the primary concern is the non-equilibrium defect population, phase-field simulations can include source terms for the vacancy and interstitial fields. These source terms can be homogeneous, to represent mean field defect production, empirical distributions fitted to typical collision cascade dimensions, or data obtained from a coupled damage calculation code. The most established code for ion transport in matter and the generation of point defects is the binary collision Monte Carlo (BCMC) code TRIM/SRIM (Ziegler et al. 2010), which is based on a scattering integral approximation of the Ziegler-Biersack-Littmark potential. BCMC data can also be used to introduce ballistic mixing contributions to a phase-field microstructure evolution simulation.

At the grain level, recrystallization can occur in nuclear fuel as the existing grains acquire a free energy contribution from stored defect populations, such as dislocations. In absence of a fast mechanism to relieve the grains of the stored defects by annihilation or diffusion into sinks, new, defect-free grains with a lower free energy may spontaneously nucleate and form small-grained microstructures. This process can be captured by phase-field simulations.

4.4   Summary

Many aspects of the behavior of components and materials in the nuclear reactor environment are fundamentally affected by phenomena involving the coupled response of multiple physical systems. Including this coupled multiphysics behavior in simulation models is essential for accurately representing many problems of engineering significance.

This chapter provides an overview of the main governing equations involved, the techniques for discretization and solution of these equations, and the software algorithms, frameworks, and codes used for solving multiphysics problems. It also provides an overview of important aspects of a few areas of interest in multiphysics simulation of nuclear reactor components and materials. This is a broad and constantly developing field. The algorithms, codes, and applications described here are not intended to be a comprehensive listing, but are representative of the current state of the art.

Phase-Field Modeling of Microstructure Evolution in Nuclear Materials

94

Karim Ahmed and Anter El-Azab

Contents

Abstract

Irradiation is a unique driver for microstructure evolution in nuclear materials. It produces high concentrations of point defects and extended defects that trigger the formation of microstructural features such as voids, bubbles, precipitates and dislocations agglomerates. The evolution of such features significantly impacts the properties of materials, thus requiring careful modeling. The phase-field method has demonstrated its capability of simulating microstructure evolution in nuclear materials. Although the method does not yield as of yet quantitative results in various aspects of microstructure evolution, the community is working with the premise that the method will be a standard predictive tool in the future. The objective of this chapter is thus to present a concise summary of the status of

development of the phase field approach for nuclear materials applications, with a special focus on the quantitative results obtained by following this approach. The strengths and limitations of the application of phase-field modeling of microstructure evolution in nuclear materials are discussed, and a summary of possible future research directions is presented.

1   Introduction

Nuclear reactor materials are often exposed to harsh conditions during service. In addition to high temperatures and stresses in corrosive environments, these materials are constantly bombarded with different types of energetic particles. The interactions of such particles with materials produce high concentrations of defects including vacancies, interstitials, and small defect clusters. These defects eventually nucleate extended defects such as dislocation loops, voids, bubbles, and solid-phase precipitates and lead to evolution of grain boundaries. All of these microstructural features drastically change the thermal and mechanical properties of materials and hence limit their performance (Olander 1976; Short and Yip 2015; Was 2017; Olander and Motta 2017). Hence, understanding how microstructure evolution takes place in nuclear materials is of paramount importance.

Due to the inherent multi-physics and multi-scale nature of radiation effects in materials, several computational modeling techniques were employed to simulate the resulting microstructure processes (Was 2017; Short and Yip 2015; Olander and Motta 2017). These techniques include density functional theory and molecular dynamics at atomic scale, kinetic Monte Carlo and cluster dynamics at intermediate mesoscale, and phase-field and sharp-interface models at the microstructure scale, to homogenization models such as rate theory. All of these models were utilized to investigate different aspects of the complex problem.

While rate theory and cluster dynamics models have a long history in modeling irradiation effects in materials at mesoscale (Brailsford and Bullough 1972; Was 2017; Olander and Motta 2017), the phase-field method is a relatively newcomer to the field (Millet and Tonks 2011; El-Azab et al. 2014; Y Li et al. 2017). Nonetheless, its unparalleled success in simulating microstructure evolution in all types of materials in other environments made its use in the field of radiation effects inevitable. The phase-field method has clear major advantages that render it uniquely suitable for simulating irradiation-induced microstructure evolution. It can account for several species and microstructural features simultaneously, it has both spatial and temporal resolution, it can account for different driving forces concurrently, it can account for all stages of phase transition from separation/nucleation to growth to coarsening, and it is relatively easy to implement numerically even for complex microstructures in 3D. Indeed, the method was able to successfully simulate different microstructural evolution processes in irradiated materials and their effect on the degradation of physical properties of such materials (Millet and Tonks 2011; El-Azab et al. 2014; Y Li et al. 2017). This success resulted in the sponsorship of the Nuclear Energy Advanced Modeling and Simulation

(NEAMS) program funded by the Department of Energy (DOE) to develop the phase-field-based mesoscale simulator MARMOT (Tonks et al. 2012) to facilitate the implementation of new models for existing and advanced fuel and cladding materials. MARMOT results will be integrated into the fuel performance code BISON (Williamson et al. 2012) to enhance its predictive capability by providing physics-based constitutive laws instead of frequently used empirical relations.

In this communication, we give an overview of the application of the phase-field method to simulate irradiation effects in nuclear materials at the mesoscale. We discuss its advantages and shortcomings and propose ways to mitigate its limitations. In addition, we highlight possible future progress areas. The organization of this manuscript is as follows. Following a brief introduction of the phase-field method in Sect. 1, we summarize in Sect. 2 the current commercial and open-source frameworks available for solving the phase-field kinetic evolution equations. In Sect. 3, we discuss the application of the phase-field modeling technique to nuclear materials, focusing on problems where the method yields quantitative results. Lastly, concluding remarks and suggestions for future research directions are presented in Sect. 4.

2   Background to the Phase-Field Modeling Approach

Phase-field modeling is now recognized to be the approach of choice for modeling microstructure evolution in materials (Boettinger et al. 2002; Chen 2002; Moelans et al. 2008; Emmerich 2008; Provatas and Elder 2010; Ahmed 2011; Ahmed 2015; Biner 2017). Its unique feature is the treatment of interfaces in heterogeneous systems as diffuse. The material properties of different phases, which are represented in terms of phase-field variables, then change continuously across the interface. Such treatment obviates the necessity of tracking the interfaces, as opposed to the classical sharp-interface models that give rise to moving/free boundary problems in which the interface tracking is necessary. Not having to track interfaces in the phase-field approach facilitates the numerical implementation even in cases where complex 3D geometries are involved. This clear advantage of the method is the primary reason for its widespread adaptation in the field of materials science and engineering. Moreover, the technique is now finding ever-expanding applications in other fields such as earth sciences, biology, and medicine (Provatas and Elder 2010; Biner 2017).

Historical developments of the diffuse-interface concepts can be traced back to the works of Van der Waals on gas condensation (Rowlinson 1979), Landau and Ginzburg on phase transitions (Ginzburg and Landau 1950), and Cahn and Hilliard on the thermodynamics of heterogeneous systems (Cahn and Hilliard 1958). In all of these treatments, suitable phase-field variables (or order parameters) are identified to simulate the material and phase transition of interest. Thus, the phase-field variables can be thought of as an extension of the state variables concept in classical thermodynamics.

A typical procedure for constructing a phase-field model is as follows. First, the free energy of the heterogeneous system is expressed in terms of the phase-field variables and their gradients. If one considers only one conserved variable (c) such as concentration and one non-conserved variable (η) such as spin direction or grain orientation, such model usually referred to in literature as model C in analogy to the stochastic models of dynamic critical phenomena (Hohenberg and Halperin 1977), the total isothermal free energy functional becomes:

$$F = \int \left[f\left(c(r), \eta(r)\right) + \frac{\kappa_c}{2}|\nabla c(r)|^2 + \frac{\kappa_\eta}{2}|\nabla\eta(r)|^2 + E\left(c(r), \eta(r)\right) \right] d^3r. \tag{1}$$

Here, $f(c, \eta)$ is the short-range chemical free energy density, and $E(c, \eta)$ is a long-range energy contribution from elastic or electrostatic forces. The chemical free energy can be obtained from thermodynamic databases such as CALPHAD (Moelans et al. 2008). The elastic or electrostatic energies have their regular forms where here the material properties such elastic/dielectric constant or magnetization may be phase-dependent. The gradient terms account for the interfacial energies. The evolution equations for the phase-field variables are then derived following the standard procedure of irreversible thermodynamics (De Groot and Mazur 1962), i.e., the evolution equations are constructed so as to monotonically decrease the free energy while ensuring nonnegative entropy production. A non-conserved order parameter evolves according to the Allen-Cahn/Ginzburg-Landau equation (Allen and Cahn 1979):

$$\partial_t \eta = -L \left[\partial_\eta f + \partial_\eta E - \kappa_\eta \nabla^2 \eta \right], \tag{2}$$

where L is Allen-Cahn mobility. The evolution of the conserved order parameter is governed by Cahn-Hilliard equation (Cahn 1961):

$$\partial_t c = \nabla \cdot M \nabla \mu, \tag{3}$$

$$\mu = \partial_c f + \partial_c E - \kappa_c \nabla^2 c. \tag{4}$$

In Eq. (3), M is the chemical mobility and μ is the chemical potential. If only non-conserved or conserved order parameters and kinetics are present, the phase-field models are called models of type A or B, respectively. If elastic and electrostatic energies are taken into account, their balance laws must be solved simultaneously with Eqs. (2) and (3). The kinetic evolution equations can also be derived from integrating some approximate master equations. In such scenario, the phase-field models are considered the coarse-grained/continuum version of the discrete kinetic Ising models (Glauber 1963, Kawasaki 1966).

In this general phase-field model C type (sometimes called WBM model after Wheeler, Boettinger, and McFadden work on solidification (1992)), the interfacial

energy and interface width can be estimated from the model parameters as (Cahn and Hilliard 1958, Wheeler et al. 1992, Moelans et al. 2008, Ahmed et al. 2013):

$$\gamma \approx \sqrt{f^* \left(\overline{c}, \overline{\eta} \right)} \sqrt{g \left(\kappa_c, \kappa_\eta \right)}, \tag{5}$$

$$\ell \approx \sqrt{\frac{g \left(\kappa_c, \kappa_\eta \right)}{f^* \left(\overline{c}, \overline{\eta} \right)}}. \tag{6}$$

Here is $f^* \left(\overline{c}, \overline{\eta} \right)$ the value of the bulk free energy calculated at the middle of the interface where the phase-field variables take on intermediate values between the two equilibrium values representing the two phases, and $g(\kappa_c, \kappa_\eta)$is some linear function of the gradient coefficients. These simple relations, however, highlight a major limitation of this formulation, which is the coupling between interfacial and bulk properties. The two forces cannot be independently specified. Also, the numerical value of the interface width for realistic values of bulk chemical energy is on the order of nanometer rendering large-scale simulations unfeasible. Nonetheless, other phase-field formulations that overcome this problem were proposed. The most notable ones are the Kim-Kim-Suzuki (KKS) model (Kim et al. 1999) and the grand potential-based phase-field model by Plapp (2011). These two versions are now widely utilized to conduct quantitative phase-field simulations. The phase-field model summarized above is for a simple binary two-phase system. Nevertheless, multiphase and multicomponent phase-field models have also appeared in literature (Moelans 2011; Steinbach 2009).

The diffuse-interface (phase-field) models can also be directly compared to the classical sharp-interface models (Pego 1989; Elder et al. 2001; Emmerich 2008; Provatas and Elder 2010; Ahmed and El-Azab 2018). Such connection is important for two main reasons. First, it demonstrates the thermodynamic and kinetic consistency of new phase-field models. Second, it establishes a direct relation between the phase-field model parameters and the regular thermodynamic and kinetic material properties that appear in the sharp-interface models, which is crucial for enabling quantitative phase-field simulations. The sharp-interface limits of phase-field models can be deduced using formal asymptotic analyses based on singular perturbation theory (Fife 1992).

3   Numerical Implementation of Phase-Field Models

In order to track the microstructure evolution using the phase-field approach, the phase-field kinetic equations, which are partial differential equations (PDEs), must be solved numerically. Most of the well-established methods for solving PDEs such as finite-difference, finite-volume, finite-element, and spectral methods were used for obtaining solutions of such models (Provatas and Elder 2010; Biner 2017). Each method has its strengths and limitations. Initially, the community opted for using their in-house codes written in Fortran90, C++, Python, etc., but recently the

utilization of commercial and open-source software for solving PDEs has gained momentum. This new direction has several advantages such as minimizing code duplication, reducing time and effort of implementing new models, decreasing the time required for obtaining solutions, and increasing the precision and accuracy of these solutions, allowing modelers to focus more on developing physics-based models rather than numerical algorithms and facilitating multi-physics and multi-scale coupling.

Examples of popular codes adopted by the community are the following. For commercial codes, the Microstructure Evolution Simulation Software (MICRESS 2017) and COMSOL (COMSOL 2017) are the most used. For open-source codes, the list is growing rapidly; the ones readily available for download are MOOSE (MOOSE 2017), FEniCS (FEniCS 2017), PRISMS (PRISMS 2017), FiPY (FiPy 2017), and OpenPhase (OpenPhase 2017).

The phase-field community seems more inclined to utilize the open-source codes for two main reasons. First, of course, they are free to use. Second, in contrast to commercial software that are usually black box, they provide complete access to the source code. Such access makes these codes extensible and encourages collaborative work. Moreover, this facilitates code verification and validation. In fact, the community has recently established a set of benchmark phase-field problems to test existing and emerging codes against. This was part of an effort by the Center for Hierarchical Materials Design (CHiMaD 2017) that aims to accelerate materials discovery through integration of theory and computational methods. Representatives of most of the developers of the abovementioned codes were invited to participate in workshops and hackathons to solve these problems and upload the solutions. The benchmark problems and their solutions are hosted on the Phase Field Community Hub website (PF Hub 2017) and summarized in the publication by Jokisaari et al. (2017).

Out of the open-source codes listed before, the one utilized the most by the nuclear materials community is the Multi-Physics Object-Oriented Simulation Environment (MOOSE) developed by Idaho National Laboratory (MOOSE 2017; Gaston et al. 2009). This is due to the fact that MOOSE framework is the building block of the new nuclear fuel performance codes MARMOT (Tonks et al. 2012) and BISON (Williamson et al. 2012). These codes are part of a toolkit that is being developed by the Nuclear Energy Advanced Modeling and Simulation (NEAMS) program funded by the Department of Energy (DOE) to accelerate the development and deployment of new nuclear technologies (NEAMS 2017). In addition, MOOSE has several features that make it appealing to different types of researchers. It facilitates solving multi-physics and multi-scale problems in a fully coupled or weakly coupled approach. Explicit and fully implicit schemes can be used. It provides built-in mesh and time adaptivity. It is dimension independent and readily parallel.

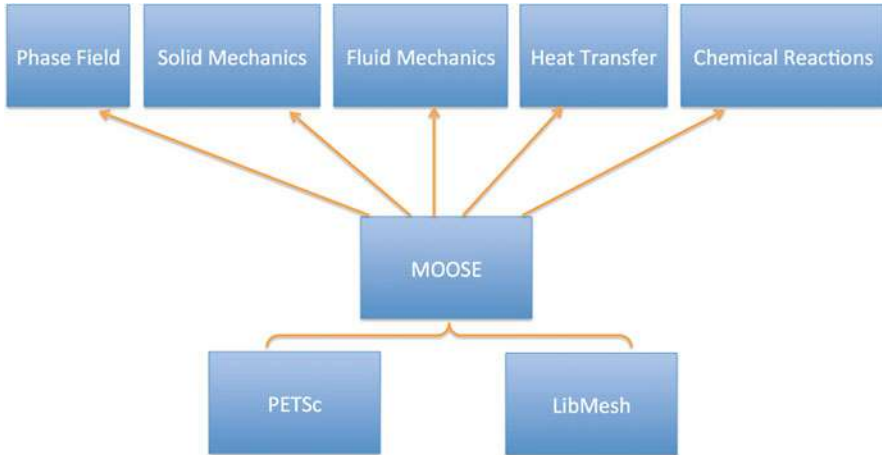
MOOSE has a convenient modular structure that leverages existing codes and simplifies implementation of new models. A schematic of the main structure of MOOSE is shown in Fig. 1. It provides a high-level interface to the finite-element library LibMesh developed by the University of Texas at Austin (LibMesh 2017)


Fig. 1 A schematic illustration of the main structure of the Multi-Physics Object-Oriented Simulation Environment (MOOSE) developed by Idaho National Laboratory (MOOSE 2017). MOOSE is built on top of the finite-element library LibMesh (LibMesh 2017) and the scientific computing toolkit PETSc (PETSc 2017). MOOSE contains modules designed for solving different types of physics, where each module includes several kernels representing the most frequently used models, boundary conditions, initial conditions, etc. in that field. Note that we only highlighted the main modules here; MOOSE has more modules with potential for even further extension. There is also a combined module where all the kernels from different modules can be accessed and multi-physics simulations can be conducted

and the nonlinear solvers in the scientific computing toolkit PETSc developed by Argonne National Laboratory (PETSc 2017). As can be seen from Fig. 1, at its highest level, it consists of different modules targeting different types of physics such as solid mechanics, heat transfer, fluid mechanics, chemical reactions, and phase-field. Each module contains several kernels representing terms that appear in the frequently used PDEs in that subject area. For example, the phase-field module includes the weak forms of Allen-Cahn (Allen and Cahn 1979) and Cahn-Hilliard (Cahn 1961) equations:

$$(\partial \eta / \partial t, \phi) + L\,(\partial f / \partial \eta, \phi) + L\left(\kappa_\eta \nabla \eta, \nabla \phi\right) - <\kappa_\eta \nabla \eta \cdot \mathbf{n}, \phi> = 0, \qquad (7)$$

$$(\mu, \phi) - (\partial f / \partial c, \phi) - (\kappa_c \nabla c, \nabla \phi) + <\kappa_c \nabla c \cdot \mathbf{n}, \phi> = 0, \qquad (8)$$

$$(\partial c / \partial t, \phi) + (M \nabla \mu, \nabla \phi)\ - <M \nabla \mu \cdot \mathbf{n}, \phi> = 0. \qquad (9)$$

In the above, ϕ is a test function, $(\cdot, \cdot)$ stands for interior integration, and $< \cdot, \cdot >$ stands for boundary integration (Tonks et al. 2012; Ahmed et al. 2017). Here, the fourth-order Cahn-Hilliard equation is transformed into two coupled second-order equations which was shown to be a good compromise between accuracy and efficiency (Zhang et al. 2013). The user can then simply code in a specific free

energy form and its derivatives or even take advantage of the newly developed automatic differentiation capabilities Schwen et al. 2017). Of course the user can also call different modules at the same time (from the same input file) to enable multi-physics simulations.

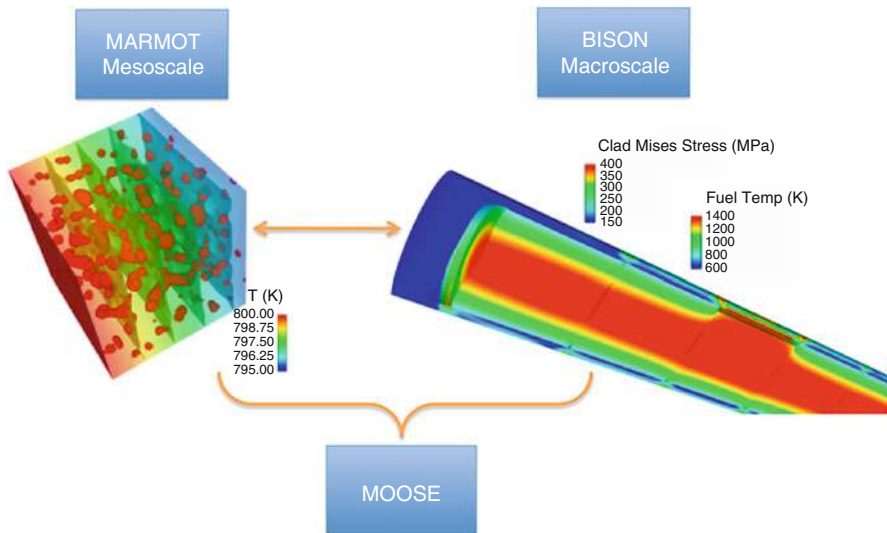
In addition to being a finite-element framework, MOOSE is also an application programming interface (API). It assists developers in launching their own applications that can take advantage of all capabilities present in MOOSE. These applications could be designed to solve advanced specific engineering or physics problems. This unique feature of MOOSE was added by design to facilitate the development of various codes for simulating all aspects of nuclear reactors operation, which is the ultimate goal of the NEAMS program (NEAMS 2017). Based on that philosophy, the MARMOT-MOOSE-BISON framework is currently being utilized to investigate fuel performance under both normal and accidents conditions (Gaston et al. 2015; Tonks et al. 2017). A schematic illustration of that framework is depicted in Fig. 2. In this framework, both MARMOT and BISON are MOOSE-based applications used to simulate fuel and cladding materials response to radiation, stresses, and temperature gradients in the entire fuel rod with spatial resolution down to the size of nanometer bubbles. MARMOT is a phase-field-based code with optional coupling to other thermal, mechanical, and irradiation


Fig. 2 An illustration of the concept of multi-scale modeling of nuclear fuel performance using MOOSE. The phase-field-based mesoscale simulator MARMOT (MARMOT 2012) and the finite-element-based engineering/macroscale simulator BISON (BISON 2012) are used to study fuel behavior under normal and transient conditions across multiple length and time scales. MARMOT is used to evolve the microstructure and quantify its features such as grains and bubbles sizes and distributions, and BISON calculates the global stress and temperature in the fuel rod. Since both codes are MOOSE-based applications, transferring data back and forth can be done in an efficient and a straightforward manner (Gaston et al. 2015). Furthermore, multi-scale simulations can be conducted in a hierarchal or concurrent setting

driving forces (Tonks et al. 2012). BISON is a finite-element-based code that solves the regular mass, momentum, and heat balance equations to find the global stress and temperature profiles (Williamson et al. 2012). Therefore, the coupling between MARMOT and BISON helps in improving the understanding of the unique phenomena that take place in nuclear materials that usually span multiple length and time scales. Furthermore, there are other MOOSE-based applications concerned with other types of physics and aspects of nuclear power plants, the mention of which is beyond the scope of this chapter.

4   Applications of Phase-Field Models to Nuclear Materials

Over the last decade, the phase-field modeling approach has been used to investigate irradiation effects in materials (Millet and Tonks 2011; El-Azab et al. 2014; Y Li et al. 2017). Studies of voids and bubbles formation and growth (Yu and Lu 2005; Hu et al. 2009; Hu and Henager 2009; Semenov and Woo 2012; Rokkam et al. 2009; Millett et al. 2009, 2011a, b; Li et al. 2013; Xiao et al. 2013), voids migration under temperature gradient (Hu and Henager 2010; Li et al. 2010; Zhang et al. 2012), bubble/void superlattice development (Yu and Lu 2005; Hu et al. 2016a, 2016b), growth of dislocation loops (Li et al. 2012; Rouchette et al. 2014), grain growth and recrystallization (Ahmed et al. 2014, 2016a, 2016b; Tonks et al. 2014; Liang et al. 2016; Mei et al. 2016), and segregation and precipitation (Badillo et al. 2015; Biner et al. 2016, Li et al. 2014) have appeared in literature. Moreover, studies of the effect of the formation and evolution of these microstructural features on the degradation of nuclear materials were conducted. For example, phase-field simulations of the effect of irradiation-induced microstructure evolution on swelling (Chang et al. 2016), thermal conductivity (Millet et al. 2012), and fracture (Chakraborty et al. 2016) were carried out.

In the phase-field formulation of irradiation effects, all types of equilibrium and non-equilibrium microstructural features such as grains, precipitates, voids, bubbles, cracks, and dislocation loops are treated as second phases that nucleate from the metastable solid phase under irradiation. The irradiation conditions are simulated by the production, diffusion, and reaction of point defects and gas atoms. A general phase-field model formulation of irradiation effects in solids can be described as follows. First, sets of order parameters representing defects concentrations $\{x_1, x_2, ..., x_k\}$, species concentrations $\{c_1, c_2, ..., c_m\}$, and microstructural features $\{\eta_1, \eta_2, ..., \eta_n\}$ of interest are selected. Second, the total free energy functional of the system, postulated to be of the Ginzburg-Landau/Cahn-Hilliard type, is expressed as (recall Eq. (1)):

$$F = \int f_{\text{bulk}} + f_{\text{int}} \ dV, \tag{10}$$

where f_{bulk} is the thermodynamic bulk free energy containing both the short-range chemical free energy and the long-range contribution due to elastic, electrostatic, or magnetic interactions. It is in general a function of all order parameters. f_{int} is

the interfacial free energy of the system. It is usually expressed as the sum of the square gradients of all order parameters (as in Eq. (1)). Lastly, the kinetic evolution equations are derived following the principles of irreversible thermodynamics. The effect of irradiation conditions is directly accounted for by adding terms that represent the defects production and loss rates into the kinetic eqs. A typical phase-field model of irradiation effects in nuclear materials includes the following kinetic equations for the order parameters (phase-field variables):

$$\partial_t x_i = P_i - \nabla \cdot \mathbf{J}_i - L_i \quad \forall i, \tag{11}$$

$$\partial_t c_i = -\nabla \cdot \mathbf{J}_i \quad \forall i, \tag{12}$$

$$\partial_t \eta_i = -M_{\eta_i} \left[\partial_{\eta_i} f_{\text{bulk}} - \kappa_{\eta_i} \nabla^2 \eta_i \right] \quad \forall i. \tag{13}$$

In the above, P_i is the production rate of defects that can be estimated from dose/fission rate, $\mathbf{J}_i$ is the corresponding flux of species/defects, and L_i is the loss due to defects recombination and defects losses to sinks. The fluxes are related to the gradients of the corresponding chemical potentials. Note that due to the coupling between defects and species through the bulk free energy, coupling of their fluxes naturally occurs. Hence, these models can directly take into consideration defects/species segregation or desegregation at interfaces. The strain energy is usually included in these models to account for the stress effect of point defects, gas atoms, bubble pressure, and microstructural features on the overall kinetics. In such case, the stress equilibrium equation is solved simultaneously with the phase-field kinetic equations (Aagesen et al. 2017).

In spite of the success of phase-field models in simulating microstructure evolution in nuclear materials, only a few quantitative investigations were carried out. Most of existing investigations only present qualitative results that cannot be compared with experiments. However, this is not a limitation of the model since, as discussed earlier, the model parameters can be uniquely identified in terms of thermodynamic and kinetic material properties using a formal asymptotic analysis. Such procedure for the case of nuclear materials was conducted recently by Ahmed et al. (2016a, 2016b; Ahmed and El-Azab 2018). In the following, we highlight some of the quantitative results obtained from phase-field simulations of microstructure evolution in nuclear materials.

4.1 General Void Growth Kinetics

The problem of voids/bubbles formation and growth was the first example of the usage of the phase-field method in simulating irradiation effects in materials (Yu and Lu 2005; Hu et al. 2009; Rokkam et al. 2009; Millett et al. 2009). Several physical characteristics of the process such as the existence of incubation period before nucleation, existence of void denuded zones near grain boundaries, dependence

of growth and coarsening rates on dose rate, and the reduction of void number density during coarsening were correctly captured, though only qualitatively, by the phase-field model. However, two different types of the phase-field model for void growth were utilized without rigorous analysis of their differences. Models of type B only used the concentrations of point defects as the phase-field variables/order parameters, while models of type C combined the defects concentrations with a non-conserved order parameter representing the void as a microstructural feature. Moreover, most of the simulations conducted in these studies used unrealistically high defects concentrations on the order of 0.1 (10%).

Furthermore, the results of the void/bubble dynamics are usually presented qualitatively using non-dimensionalized time and length scales. All these limitations clearly prevent model verification and validation.

Ahmed and El-Azab (2018) have recently demonstrated that quantitative phase-field models of void growth in irradiated solids can be constructed in a systematic way using a formal asymptotic analysis. The analysis showed that phase-field models of type B can only capture diffusion-controlled kinetics and are equivalent to the well-known rate theory description of the problem (Olander 1976; Was 2017). On the other hand, phase-field models of type C are capable of describing general void growth kinetics from which diffusion-controlled and surface-controlled arise as limiting cases. The generality of model C was found to be the result of the extra Allen-Cahn equation that acts as an interfacial constitutive law that guarantees nonnegative interfacial entropy production. Therefore, it was concluded that the Allen-Cahn mobility is directly connected to the surface mobility/kinetic barrier through a regular Arrhenius-type relation. The analysis also matched the phase-field model of type C to the recently developed sharp-interface model of void growth (Hochrainer and El-Azab 2015). This matching facilitates fixing the phase-field model parameters in terms of the regular thermodynamic and kinetic data. This was demonstrated by investigating void growth in copper. The quantitative predictions of the model are captured in Figs. 3, 4, and 5. Figure 3 depicts the evolution of vacancy concentration during void growth from a slightly supersaturated copper matrix (with realistically low vacancy concentration). The different types of void growth kinetics are captured in Figs. 5 and 6. As the surface kinetic barrier (Δg) increases relative to the bulk migration energy (E_{m}),
Fig. 3 Snapshots of the evolution of the vacancy concentration during the growth of a void from a supersaturated copper matrix. Note that the vacancy concentration here does not have to be artificially high as in most of existing phase-field models

Fig. 4 The chemical potential across the centerline of the domain in Fig. 3. Large gradient develops across the domain for the case of diffusion-controlled growth, while the chemical potential is almost constant in the entire domain for the interface-controlled case
Fig. 5 Effect of the surface kinetic barrier (Δg), assumed here to be a multiple of the bulk migration barrier (E_m), on the overall void growth kinetics in a supersaturated copper at 800 K. The void growth kinetic diminishes as the surface migration barrier increases. Moreover, the kinetics of the process transforms from diffusion-controlled to surface-controlled with increasing the surface barrier

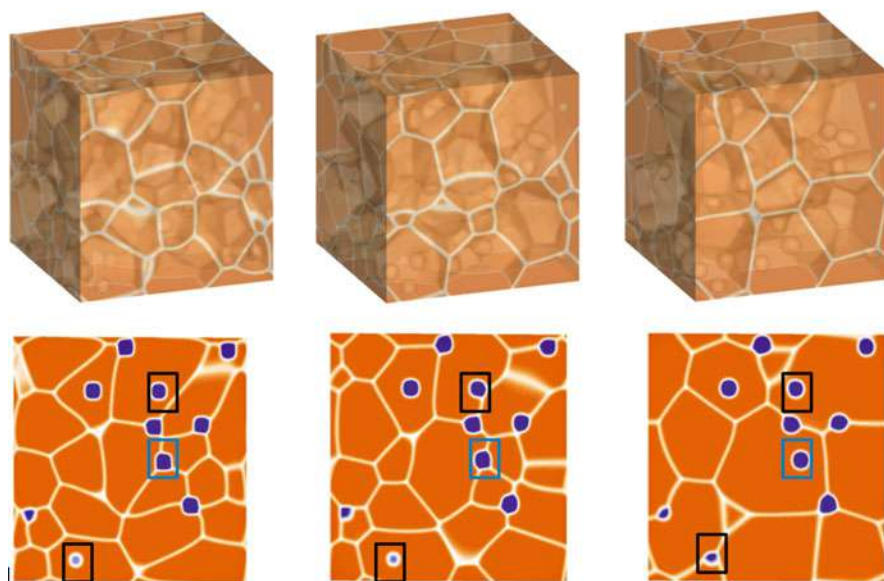
the overall kinetics changes from diffusion-controlled to surface-controlled. This is evident from Fig. 4, where the chemical potential as function of position is plotted. High gradients of the chemical potential are established for the case of diffusion-controlled, while negligible gradients of chemical potential exist during surface-controlled growth. Moreover, the overall kinetics of the void growth process slows down with increasing the kinetic surface barrier as quantitatively represented in Fig. 5.


Fig. 6 Snapshots showing the different pore-grain boundary interactions during grain growth of a porous polycrystalline UO_2 at 2000 K. Pore breakaway is evident from the 3D snapshots (upper row). The model is clearly capable of capturing all possible pore-boundary interactions simultaneously as obvious from the 2D cross-sectional images (lower row). Pores can move along with or detach from a migrating boundary. Moreover, initially isolated pores can get attached to a moving boundary. Furthermore, a specific pore can go through a series of attachments and detachments

4.2   Grain Growth in Porous Uranium Dioxide

It is well known that most of the physical properties of polycrystalline solids are strongly dependent on the grain size (Rahaman 2003). Moreover, the behavior of such materials under harsh conditions such as irradiation, high temperature, and high stresses is also highly influenced by grain size. For instance, it was shown that fission gas swelling and release rates decrease with increasing grain size (Turnbull 1974). This has motivated several experimental, theoretical, and computational works for investigating the kinetics of grain growth in the main nuclear fuel.

For the case of porous ceramics such as UO_2, the pore-grain boundary interactions must be taken into account to appropriately model grain growth in such materials (Ahmed 2015). Second-phase particles such as precipitates, bubbles, inclusions, and pores exert a drag force on the migrating grain boundary that retards the grain growth process and may completely stop it as was predicted by the famous Zener's pinning model (Rahaman 2003). However, mobile particles such as pores can move along with the migrating boundary if any of the mass transport mechanisms such as bulk diffusion, surface diffusion, or vapor transport is active. It was shown that most of existing data on grain growth of UO_2 is consistent pore migration via surface diffusion (Bourgeois et al. 2001).

A detailed phase-field model of pore-grain boundary interactions and its effect on grain growth in ceramics was developed by Ahmed et al. (2013, 2014, 2016a, 2016b; 2017). The model takes into consideration the coupled curvature-driven motion of grain boundaries and pore migration by surface diffusion. The phase-field model relaxes the restrictive assumptions on the pore and boundary geometries and motion in the classical models (Nichols 1968, Brook 1969, and Carpay 1977) and obviates the numerical difficulties of the sharp-interface models (Hsueh et al. 1982; Spears and Evans 1982; Svoboda and Riedel 1992; Riedel and Svoboda 1993). Using a formal asymptotic analysis (Ahmed et al. 2016a, 2016b), it was shown that the phase-field model recovers the sharp-interface description of the problem, which facilitates quantitative simulations of grain growth in different porous ceramics (Ahmed et al. 2013, 2014).

The phase-field model of grain growth in porous ceramics was used to simulate grain growth in UO_2 (Ahmed et al. 2014). The model was successfully able to account for all possible pore-grain boundary interactions in such material as obvious from Fig. 6 that captures these different scenarios. A migrating grain boundary can drag mobile pores along with it. It could also break away from less mobile pores. The presence of large number of immobile pores may lead to the cease of grain growth process. The prevailing type of interaction depends on the grain boundary and pore/surface mobilities and the grains and pores sizes and morphologies. However, in a heterogeneous microstructure, all different types of interactions may occur simultaneously as demonstrated in Fig. 6. Moreover, the 3D simulations revealed that boundary breakaway is artificially suppressed in 2D simulations due to the implied assumption of cylindrical pore shape that exaggerates pore drag. An excellent agreement between model predictions and experimental data was found as shown in Fig. 7.

Fig. 7 Comparison of phase-field model predictions and experimental data of grain growth porous polycrystalline UO_2 at 2000 K. The direct comparison was carried out by extrapolating the model results and fitting the experimental data as discussed in Ahmed et al. (2014). Note that such high-fidelity model verification is only possible for quantitative phase-field models (with no arbitrary model parameters)
4.3   Hydride Precipitation in Zircaloys

Zirconium alloys are widely used as cladding materials for water-cooled reactors. However, it is known that zircaloys tend to pick up hydrogen during service which, due to the low hydrogen solubility in zirconium, leads to the formation of zirconium hydrides (Carpenter 1973). The precipitation of these hydrides is detrimental to the mechanical integrity of the cladding because hydrides are brittle. Accumulation of these hydrides facilitates crack initiation and propagation that eventually leads to the rupture of the cladding. A few stable and metastable hydrides that precipitate from the hexagonal $\alpha - $ Zr were identified (Carpenter 1973). The most investigated ones are the FCC δ hydride and the FCT γ hydride. The former is the stable configuration usually observed in cladding, and the latter is a metastable phase that forms under high cooling rates. The misfit strains for both hydrides were determined by Carpenter (1973).

A few phase-field models of hydrides formation and growth were proposed in literature (Ma et al. 2002a, 2002b, 2006; Guo et al. 2008a, b). Most of them focus on either δ or γ hydride, but a recent multiphase-field model (Bair et al. 2017) was introduced to simulate all phases of hydrides and the possibility of γ to δ transition. In these models, the misfit strain tensors are usually expressed in terms of phase-field variables to capture their variation with phase. The stress equilibrium equation is then solved concurrently with the phase-field evolution equations.

For the case of γ hydride, phase-field simulations demonstrated, in agreement with experiments, the equilibrium needle shape of these hydrides. Since they have anisotropic misfit strain in the basal plane, their variants with 120° angles between each other can form during an HCP to FCT transition. In the absence of external stress, all variants are likely to precipitate with equal probability. However, under applied stress, the variant normal to the direction of applied stress has lower nucleation barrier. This results in a preferential precipitation of that variant. These results are demonstrated in Fig. 8, which captures the precipitation of these hydrides in the absence and presence of applied stress. The preferential precipitation of hydrides was suggested as possible mechanism of hydride reorientation that takes place under cyclic temperature and stress conditions (Ma et al. 2002). A threshold stress value of 200 MPa was found to be necessary for hydride reorientation. This value lies well within the range reported in literature (Ma et al. 2002a, 2002b).

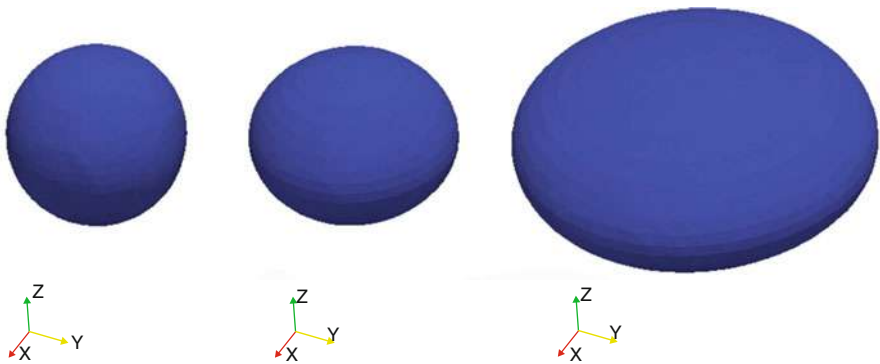
On the other hand, for the case of δ hydride, the misfit strain is isotropic in the basal plane with the elastically hard direction being normal to that plane. Therefore, the equilibrium shape of these hydrides is a platelet. A 3D phase-field simulation showing the development of that equilibrium shape is presented in Fig. 9. However, their reorientation cannot simply be explained by preferential precipitation as in the case of γ hydrides. It is believed that the 3D stacking of microscale hydrides and plastic effects may hold the key for their reorientation. Nonetheless, a detailed theoretical or computational model that accounts for these effects is still lacking.
Fig. 8 Snapshots of the precipitation process of γ hydrides under no external load (upper row) and 200 MPa vertical tensile load (lower row). In the absence of applied stresses, all variants of hydrides precipitate out with equal probability. In the presence of an applied load, preferential precipitation of the variant perpendicular to the direction of the applied load takes place


Fig. 9 Snapshots of the development of the equilibrium platelet shape of δ hydrides as observed in experiments. The z-axis here is assumed to coincide with the elastically hard eigen/misfit strain direction [0001]

5   Conclusions and Outlook

Based on its success in simulating microstructure evolution in different materials, the phase-field method was adapted by the nuclear materials community to investigate irradiation effects on materials. The phase-field models of nuclear materials account directly for the production, diffusion, recombination, and reaction

of point defects. Moreover, other extended defects and microstructural features are also included and naturally represented by phase-field variables/order parameters. Furthermore, thanks to its thermodynamic formulation, different types of driving forces such as irradiation, thermal, and mechanical can be considered and coupled in a straightforward manner. In addition, thanks to their spatiotemporal nature, phase-field models inherently account for the effect of microstructure and species heterogeneity on the kinetics of evolution. All these features of the phase-field method enable it to give a more complete picture of microstructure evolution in irradiated materials than other competitive techniques such as rate theory or Monte Carlo. This has led the NEAMS program under DOE to foster the establishment and development of the phase-field-based mesoscale simulator MARMOT to model microstructure evolution in fuel and cladding materials (NEAMS 2017).

Phase-field models were successfully utilized to simulate irradiation-induced microstructure evolution in materials. Phenomena such as irradiation-induced segregation and precipitation; irradiation-induced voids and bubbles formation; growth, coarsening, and dislocation loops; and grain growth were investigated using the phase-field method (Millet and Tonks 2011; El-Azab et al. 2014; Y Li et al. 2017). However, most of these studies only presented qualitative results that cannot be used for predicting material behavior. Nonetheless, as discussed here, this is not an inherent limitation of the method, and a few quantitative investigations were carried out. The construction of such quantitative models requires careful thermodynamic and mathematical formulation of the free energy functional (Moelans 2011; El-Azab et al. 2014). In addition, the sharp-interface limits of these diffuse-interface phase-field models must be obtained in order to directly connect the model parameters to the regular thermodynamic and kinetic material properties (El-Azab et al. 2014; Hochrainer and El-Azab 2015; Ahmed et al. 2016a, 2016b; Ahmed and El-Azab 2018).

Of course, as with any modeling technique, phase-field methods have their limitations. Similar to any coarse-grained modeling approach, their predictive capability is limited by the availability of thermodynamic and kinetic data. There is a clear shortage of such data for nuclear materials. Nonetheless, such limitation can be overcome by conducting lower-scale simulations and/or experiments to obtain these data. Also, parametric studies and uncertainty quantification techniques may be used to assess the effect of missing data on the model predictions. The second major limitation is the high numerical cost of these models. Phase-field simulations scale linearly with number of variables and domain dimension, which make them difficult to implement in 3D for multiphase and multicomponent systems. However, this limitation can be mitigated by using efficient multigrid solver methods and adaptive mesh and time-step techniques. The advancement of sophisticated frameworks such as MOOSE/MARMOT will definitely help in that regard.

There are three main future directions that can be pursued to advance the construction and implementation of phase-field models of irradiation effects in nuclear materials. First, model verification and validation must be a high priority. In order to accomplish this goal, only quantitative phase-field models (having no arbitrary model parameters) should be used. Developing such models is possible through matching with thermodynamically consistent sharp-interface models. The

model predictions can then be directly compared with experiments. Some simplified separate-effects experiments may be designed to facilitate model validation. For instance, experiments that only demonstrate the effects of dose/fission rate, temperature, and total dose/burnup will be invaluable not just to evaluate model predictions but also to enhance model design by pinning down which parts of the model need further improvements. Only then we can start validating more advanced models with coupled driving forces. However, developing and validating such generalized models that account for different aspects of irradiation effects simultaneously must be the ultimate goal. Second, modelers should try to mitigate the limitations of the phase-field method discussed above. Such task requires collaborative community work to expand the thermodynamic and kinetic data of nuclear materials, preferably also to be organized into an accessible online library and improve/develop robust and efficient numerical algorithms. Third, the phase-field models of irradiation effects should be coupled to lower-scale models such as MD, DFT, and KMC to account for both stages of irradiation damage and irradiation effects. Since those stages usually span order of magnitudes with different length and time scales, only a true multi-scale modeling approach can elucidate material behavior in such challenging environment. Innovative theoretical and numerical schemes are required to achieve this goal.

Abstract

Thermodynamics is essential, fundamental information for understanding the behavior of any system. For nuclear materials, the situation is even more critical. The fuel in particular becomes highly multicomponent with burnup and is constantly evolving from beginning to end of life. Calculation of Phase Diagram (CALPHAD) modeling gives a continuous thermodynamic description of a system and allows coupling of the information to other phenomena facilitating multiphysics simulations.

1   Introduction

The combined first and second laws of thermodynamics give us the extremum principle. Stated simply, an isolated system will maximize its entropy and minimize its free energy. As will be discussed later, the Gibbs energy has temperature and pressure as natural variables and is therefore generally the most convenient thermodynamic function to use for treating chemical equilibria. Mathematically, the equilibrium state of a multicomponent isolated system at constant temperature and pressure is the assemblage of phases and their respective compositions that correspond to the global constrained minimum of the total Gibbs free energy.

A nuclear fuel system is continuously evolving due to transmutations and fission product (FP) generation. Because of the high temperatures, there is a rapid approach to equilibrium; therefore, thermodynamic arguments are often sufficient to predict many phenomena and are, at a minimum, necessary to understand more complex, dynamic physics such as corrosion, heat transfer, and mass transport. While the structural materials for reactors can benefit from thermodynamic insight, the emphasis here is reserved for the fuel since it is the fuel that generates the heat and experiences the highest temperatures and evolves to a multicomponent system of up to 60 elements.

A major issue for fresh light water reactor (LWR) fuel is it can have variable initial composition. It is therefore a complex system even before irradiation. All fuels become even more so with burnup as fission and transmutation products are generated. Some of these dissolve into the parent phase while others form secondary ones, for example, the five-metal white phase (molybdenum, rhodium, palladium, ruthenium, and technetium) and perovskites in oxide fuels. Therefore, thermodynamic representations of the system must capture the important complex behavior, for example, nonstoichiometry of the crystalline structures, ordering in ionic melts, and dissolution of elements into the original and secondary phases. Fortunately, there are models available that incorporate these characteristics; they are discussed in Sect. 5.

Finally, while thermodynamics does not explicitly include the physics of time evolution to equilibrium, the tendency of a system to evolve to its lowest energy state and to balance potentials does provide driving forces for many kinetic phenomena within certain formalisms, for example, the *theory of irreversible processes*

(De Groot and Mazur 2013). As mentioned, fuel experiences high temperatures. Thus, the assumption of local thermodynamic equilibrium (LTE) is useful for predicting the chemical state of the elements and the material properties of the fuel; these are important inputs for representing many kinetically driven processes like phase transformations, microstructural evolution, and transport phenomenon.

2   Classical Thermodynamics

Thermodynamics can be viewed as the study of the manifestations of energy and its transformations. The fundamental mathematical relations were empirically derived from the necessity of describing the operation of steam engines (J.M Smith et al. 1996), and the theory was essentially complete at the end of the 19th century (DeHoff 2006).

The first law captures the essence of the science through the following statement:

Although energy assumes many forms, the total quantity of energy is constant, and when energy disappears in one form it appears simultaneously in other forms. (J.M Smith et al. 1996)

Expressed mathematically:

$$dU = \delta Q - PdV \tag{1}$$

where U is internal energy, Q is heat, P is pressure, and V is volume. The δ symbol signifies that Q is a process functions, i.e., the integral of δQ depends not only on the initial and final state, but also on the path.

The second law asserts there is a proper direction for transformation of energy from one form to another. It is the statement of the principle of entropy increase given as:

$$dS \geq 0 \tag{2}$$

A consequence of Eq. 2 is that an isolated system, if left alone, may never decrease in entropy. The combined first and second laws, formulated in Eq. 3, give the fundamental relation of thermodynamics (Willard 1961).

$$dU \leq TdS - PdV \tag{3}$$

where the S and V are the natural variables of U. It is often desirable to represent Eq. 3 as a different thermodynamic potential dependent upon another set of more experimentally useful natural variables; this can be accomplished by performing a partial Legendre transform on Eq. 3 to obtain the Helmholtz (F) and the Gibbs (G) energies.

$$G = U + PV - TS \tag{4}$$

$$F = U - TS \tag{5}$$

Equations 4 and 5 yield all the information contained in Eq. 3, but with natural variables (T,P) and (T,V), respectively. Upon differentiation, Eqs. 4 and 5 become:

$$dG = dU + VdP + PdV - TdS - SdT \tag{6}$$

$$dF = dU - TdS - SdT \tag{7}$$

Applying Eq. 3 means that the G and F must never increase at constant (T,P) and (T,V), respectively.

$$dG \leq 0 \tag{8}$$

$$dF \leq 0 \tag{9}$$

Representing any real irreversible process with a reversible path underpins calculations made within the framework of *Classical Thermodynamics*; therefore, the equality will strictly apply and Eq. 8 will be used from here on to define equilibrium, i.e., $dG = 0$.

Despite significant advances in science since the advent of *Classical Thermodynamics*, only a minor modification to the first law has been introduced and no experiment has ever directly or indirectly provided evidence that contradicts the second law (Van Wylen et al. 1994). The famous Einstein equation, $E = mc^2$, effectively combines the laws of conservation of mass and energy such that mass is simply yet another manifestation of energy and the first law remains soundly intact. There is a zeroth law that states that two bodies in thermal equilibrium with a third are themselves in thermal equilibrium (Van Wylen et al. 1994). The third law will be discussed later on as it applies to modeling, but the fundamentals of *Classical Thermodynamics* can be applied based on the first and second laws alone.

3   The Ideal Gas

A natural didactic and utilitarian companion to the *Classical Thermodynamics* framework is the equation of state (EOS) for an ideal gas derived from combination of Charles', Boyle's, and Avogadro's laws (Chang 1998); it is mathematically expressed as:

$$PV = nRT \tag{10}$$

where n is number of moles and R is the ideal gas constant. Dalton's law states that ideal gases are noninteracting and every gas behaves as a vacuum unto every other gas (Chang 1998). This leads to an important simplification for low pressures and/or high temperatures with very convenient and useful consequences for thermodynamic calculations; the sum of partial pressures equals the total pressure (Eq. 11):

$$P \equiv \sum_i p_i = \sum_i x_i P = \sum_i \frac{n_i}{N} P \tag{11}$$

where n_i is the number of moles of component i, N is the total number of moles of the system, and x_i is the mole fraction of component i. The change in the Gibbs energy at constant temperature can be shown to be:

$$dG = V dP \tag{12}$$

Employing Eq. 10 as the EOS, the familiar equation for the pressure effect on the Gibbs energy of an ideal gas is recovered.

$$G = n^\circ G + nRT \ln \frac{P}{1bar} \tag{13}$$

Here, $^\circ G$ is the molar Gibbs energy of the ideal gas at the temperature of the system referenced to a standard pressure of 1 bar. Furthermore, upon application of Dalton's law of partial pressures, the entropic effect on the Gibbs energy from the mixing of ideal gases is included in Eq. 14.

$$G = \sum_i n_i G^\circ_i + \sum_i n_i \ln x_i + NRT \ln \frac{P}{1bar} \tag{14}$$

where the change in entropy, or the entropy of mixing, S^{mix}, is:

$$S^{mix} = R \left(\sum_i n_i \ln x_i \right) \tag{15}$$

4   Ideal Mixing: The Statistical Mechanics Approach to Entropy

Pioneered by Ludwig Boltzmann and J. Willard Gibbs, statistical mechanics provides a link between the energy states described by quantum and classical treatments and the macroscopic observable properties of thermodynamics described earlier. Entropy is best defined using statistical mechanics and, according to the Boltzmann equation, is:

$$S = k_B \ln \Omega(U) \tag{16}$$

where k_B is the Boltzmann constant, and $\Omega(U)$ is the number of microstates with energy U. Assuming no interactions between solution components, Eq. 16 is used to derive the *ideal entropy of mixing* (S^{id}) for condensed phases resulting in exactly the same expression given by Eq. 15 for an ideal gas mixture.

$$S^{id} = S^{mix} = R \left(\sum_i n_i \ln x_i \right) \tag{17}$$

Although approximate and generally an overestimate, Eq. 17 is widely applied in the field of thermodynamic modeling and is a convenient, utilitarian way of representing the entropy of mixing resulting from solution formation. It is used directly in the regular solution model and with modification in the sublattice model for ionic crystalline material discussed later. It is worth noting that S^{id} is used to distinguish from S^{mix} since S^{mix} provides an exact description of the configurational entropy from the mixing of ideal gases and is an exceptionally accurate approximation for *actual* gases within the limit that Dalton's law may be applied. The word *actual* is purposely used here in lieu of *real* since the term *real gas* is the conventional way of referring to gases that deviate from ideal behavior, i.e., Dalton's law is inapplicable and significant interactions are present.

It is well established that the phenomenological relations of *Classical Thermodynamics*, such as the pressure effect on the Gibbs energy and the entropy of mixing of an ideal gas, can be derived from quantum and classical statistics using many of the same simplifying assumptions that led to the development of the empirical laws that underpin Eqs. 10 and 11. This fact validates the statistical mechanics approach to entropy and helps to establish a link between the micro- and macroscopic quantum and classical treatments of thermodynamics.

5   Thermodynamic Models

A useful form of the Gibbs energy equation is obtained by defining a new potential, the enthalpy, H. The definition of H is given as:

$$H = U + PV \tag{18}$$

Enthalpy has natural variables S and P as can be seen from the differential form:

$$dH = TdS + VdP \tag{19}$$

It is one of the four fundamental thermodynamic potentials along with U, G, and F. Here, H is introduced since a very convenient and widely applied from of G is given by:

$$G = H - TS \tag{20}$$

While the third law of thermodynamics establishes the concept of absolute entropy, there is no such assertion for enthalpy (H); therefore, Gibbs energy functions rely on energy differences between references taken at a standard temperature and pressure (STP) generally 298 K and 1 bar. The convention is to use the elements as references with zero H in their stable form at STP. This gives rise to the concept of a standard enthalpy of formation ΔH_f, alternately referred to as the stable element reference and denoted H^{SER}. Using Maxwell's relations and assigning $H_{298} = \Delta H_f$, the functions for H and S with temperature can be defined as (E Brian Smith 2013):

$$H = H_{298} + \int_{298}^{T} c_p dT \tag{21}$$

$$S = S_{298} + \int_{298}^{T} \frac{c_p}{T} dT \tag{22}$$

where c_p is the heat capacity at constant pressure. The Gibbs energy is expressed as a temperature dependent polynomial of the general form:

$$G = a + b + cT \ln T + dT^2 + eT^3 + fT^{-1} \ldots \tag{23}$$

The ellipsis denotes that additional terms can be added to achieve a better representation when compared to experimentally determined values, but these are rarely needed.

The heat capacity can be found from the G by utilizing the following relation (Prausnitz et al. 1998):

$$c_p = -T \left(\frac{\partial^2 G}{\partial T^2} \right) \tag{24}$$

resulting in:

$$c_p = -c - 2dT - 6eT^2 - 2fT^{-2} \ldots \tag{25}$$

While c_p can always be calculated from the Gibbs function, the reverse is not true due to the creation of integration constants thus underscoring the importance of knowing a standard enthalpy and absolute (or standard) entropy. It is worth noting that differences in standard states can have small but serious computational consequences and this can arise when utilizing data from different sources.

5.1   Pure Elements and Stoichiometric Compounds

For a pure element or a stoichiometric compound, Eqs. 23 and 24 are sufficient for describing the Gibbs energy and heat capacity. The deconvolution of Eq. 23 gives S_{298} and H_{298} and therefore contains all of the thermodynamic information illustrating the importance of its potential in computational thermodynamic applications.

5.2   The Regular Solution Model

The ideal solution model is given by Eq. 14 for a gas but can be extended to condensed phases by assuming negligible pressure dependence, which is generally true in practice; therefore, Eq. 14, in terms of mole fractions, reduces to:

$$G^{total} = N \left(\sum_i x_i \, ^\circ G_i + \sum_i x_i \ln x_i \right) \tag{26}$$

Eq. 26 can be expressed in terms of the molar Gibbs energy, G, as:

$$G = \sum_i x_i \, ^\circ G_i + \sum_i x_i \ln x_i \tag{27}$$

The ideal solution model assumes no interaction between end-members that constitute the phase. The Gibbs energy of many liquid and solid mixtures can be sufficiently represented with Eq. 27, particularly within the limit of dilute solutions. For solutions that exhibit strong interactions, an additional term is added and Eq. 27 becomes the well-known regular solution model given by:

$$G = \sum_i x_i \, ^\circ G_i + \sum_i x_i \ln x_i + {}^{xs}G \tag{28}$$

where ${}^{xs}G$ is termed the excess Gibbs energy. A common form of ${}^{xs}G$ is the Redlich-Kister polynomial (Redlich and Kister 1948) that yields interaction energies as a function of composition (Prausnitz et al. 1998). To illustrate, for a binary system, a Redlich-Kister excess Gibbs energy is given as:

$$^{xs}G = x_1 x_2 \sum {}^i L (x_1 - x_2)^i \tag{29}$$

where the ${}^i L$ terms are the ith order interaction energies and are commonly represented as a function of temperature following the form:

$$^i L = {}^i A + {}^i BT + {}^i CT \ln T + {}^i DT^2 \ldots \tag{30}$$

Gases that deviate from ideality are treated differently, due primarily to pressure effects, but the idea that interactions between unlike components generate an excess Gibbs energy contribution is the same. Eq. 14 can still be used for a *real gas* by correcting the pressure term in Eq. 10 using the fugacity coefficient, φ, given by:

$$\phi = e^{\int_0^P \left(\frac{z-1}{P}\right)dP} \tag{31}$$

where z is known as the compressibility factor given by:

$$z \equiv \frac{PV}{NRT} \tag{32}$$

When a *real gas mixture* description is warranted, φ is modified to $\widehat{\phi_i}$, or the fugacity coefficient of species i in solution, which is a function of the interaction between components that reduces to φ for pure i as the composition of i approaches unity. Finally, the excess function for a real gas can be characterized by Eq. 33 below.

$$^{xs}G = \sum RT \ln \widehat{\phi_i} \tag{33}$$

5.3   The Associate Species Model

To represent the thermodynamics of nonstoichiometric solution phases or the short range order (SRO) in some liquids, the associate species model uses fictive or fictitious molecule-like species as end-members in a regular solution model. As an example, to represent the oxygen potential of the $U_{1-y}Gd_yO_{2 \pm x}$ phase, Lindemer and Sutton (Lindemer and Sutton Jr. 1988) used the U_2O_5 and $UGdO_4$ associate compounds in a regular solution model framework. To illustrate the SRO in a generic liquid mixture of components A and B with a tendency to form AB associates, the appropriate model is given by:

$$G^{total} = n_A G_A + n_B G_B + n_{AB} G_{AB} + NRT \left(x_A \ln x_A + x_B \ln x_B + x_{AB} \ln x_{AB}\right)$$
$$+ G^{xs} \tag{34}$$

The major drawback to Eq. 34 is that it does not reduce to the regular solution model when there is no tendency for association, i.e., $\Delta G_{AB} = 0$ for the so called pair exchange reaction given by Eq. 35 below.

$$(A - A) + (B - B) = 2(A - B) \tag{35}$$
5.4   Sublattice Models

The modeling of complex interstitial and substitutional solutions of crystalline phases can best be accomplished with a sublattice approach using either a reciprocal solid solution (RSS) or compound energy formalism (CEF) model. The two are not easily distinguishable as the RSS is a special case of the CEF. The major difference lies in the fact that the CEF is a broadly applied formalism approach for which the RSS, depending on the stoichiometry of the crystal, could be a model within the CEF framework.

Since the CEF assumes the general form of the sublattice model, it will be used from here on to generate a description. The long range ordering (LRO) of a crystal with multiple sites, or sublattices, on which mixing takes place gives rise to a modification of the entropic term and, according to the CEF, it becomes:

$$S^{CEF} = -R \left(\sum_s \sum_J n^s y_J^s \ln y_J^s \right) \tag{36}$$

where y_J^s is the site fraction of constituent J on sublattice s and n^s is the stoichiometric coefficient of sublattice s. There is a mechanical mixture of all the end-member *compounds*, called a surface of reference ($G^{s.r.}$), that is, all possible combinations of the members from different sublattices. Here, the term *compound* is italicized and loosely applied since some combinations may be unphysical or fictive, meaning that they only exist in solution and not as a pure compound. The surface of reference is described in general mathematical terms as:

$$G^{s.r.} = \sum_k {}^{\circ}G_k \prod_s y_J^s \tag{37}$$

where ${}^{\circ}G_k$ is the Gibbs energy for the end-members and the $\prod_s y_J^s$ term accounts for all the sublattices that contain components of end-member k, the end-member being operated on by the summation. Combining Eqs. 37 and 38 and adding ${}^{xs}G$ gives the common form of the molar Gibbs energy CEF expression:

$$G^{CEF} = \sum_k {}^{\circ}G_k \prod_s y_J^s + RT \left(\sum_s \sum_J n^s y_J^s \ln y_J^s \right) + {}^{xs}G \tag{38}$$

Liquid mixtures can be represented with a regular solution model, but a tendency for ordering necessitates a more sophisticated approach that directly treats interactions among constituents. While the technique of including associates discussed above was originally developed for this purpose, an alternative is the two-sublattice liquid model (TSLM) that can be used to describe the ordering in ionic liquids (Hillert et al. 1985). The TSLM is based on the concept first proposed by Temkin (Temkin 1945) for salt melts where each atom is practically surrounded by unlike

atoms and cations mix at random only with each other while anions randomly reposition exclusively with other anions. The situation is conveniently represented with two sublattices, one for the cations and one for anions, and the melt is described with the same approach used for crystalline phases with LRO (Hillert et al. 1985).

Hillert et al. (Hillert et al. 1985) made modifications to extend the application of the TSLM to include components with multiple valences by allowing the stoichiometry to vary. Vacancies and associates, both neutral and charged, were also introduced to describe nonstoichiometric melts. While this may not always be a physical reality, it is an expedient way of representing the Gibbs energy of liquids ranging from a purely metallic-like solution to one with short range ordering from ionic interactions. This approach has since come to be known as the partially ionic TSLM and within its framework electroneutrality is defined as:

$$P = \sum_j v_j y_{A_j} + Q y_{Va} \tag{39}$$

$$Q = \sum_i v_i y_{C_i} \tag{40}$$

where v_j and y_{A_j} are the charge and site fraction of the anion species and v_i and y_{C_i} are the charge and site fraction of the cation C, respectively; y_{Va} is the site fraction for a vacancy of charge Q-, thus.

$$G = \sum_C \sum_A y_C y_A {}^{\circ}G_{C:A} + Q y_{Va} \sum_C y_C {}^{\circ}G_C + Q \sum_B y_B {}^{\circ}G_B - TS + {}^{xs}G \tag{41}$$

where ${}^{\circ}G_{C:A}$ is the Gibbs energy of the liquid constituent corresponding to the formula $C_{v_A} A_{v_C}$ and ${}^{\circ}G_C$ is the Gibbs energy of element C. The symbols y_B and ${}^{\circ}G_B$ correspond to the site fraction and the Gibbs energies of neutral B associates.

The configurational entropy term S is given by:

$$S = -R \left[P \sum_C y_C \ln y_C + Q \left(\sum_A y_A \ln y_A + y_{Va} \ln y_{Va} + \sum_B y_B \ln y_B \right) \right] \tag{42}$$

5.5   Quasichemical and Modified Quasichemical Models

A quasichemical treatment of SRO in liquids is an alternative to the associate species and the TSLM approaches. The model was developed by Fowler and Guggenheim who based the configurational entropy on a one-dimensional lattice. Pelton and coworkers introduced modifications to the model in order to permit the composition

of maximum SRO to vary and to extend the application to multicomponent systems (AD Pelton et al. 2000; Arthur D Pelton and Chartrand 2001).

The modified quasichemical model (MQM) is best illustrated first with a generic binary example consisting of components A and B which are distributed over a one-dimensional quasilattice. The pair approximation is used, that is, only nearest neighbor pairs are considered to interact and this interaction is independent of the other pairs. As such, the driving force for ordering is the pair exchange reaction given by Eq. 35:

This can be viewed as a *quasi*-chemical reaction with an energy, ΔG_{AB}. The Gibbs energy of the solution is modified by ΔG_{AB} and becomes:

$$G^{total} = n_A \, ^\circ G_A + n_B \, ^\circ G_B - T S^{config} + \left(\frac{n_{AB}}{2} \right) \Delta G_{AB} \tag{43}$$

where n_A, n_B, and n_{AB} are the number of moles of component A, B, and AB pairs, respectively, and these quantities are bound by the relations:

$$Z_A n_A = 2 n_{AA} + n_{AB} \tag{44}$$

$$Z_B n_B = 2 n_{BB} + n_{AB} \tag{45}$$

Here Z_A and Z_B are the coordination numbers of A and B and $n_{AB} = n_{BA}$. In the quasichemical model after Guggenheim and Fowler (Fowler and Guggenheim 1949), $Z_A = Z_B = Z$; however, by allowing these to be chosen independently, the composition corresponding to maximum ordering is determined by the ratio Z_B/Z_A and can therefore be adjusted to fit the behavior of the system.

The pair fractions are defined as:

$$X_{ij} = \frac{n_{ij}}{n_{AA} + n_{BB} + n_{AB}} \tag{46}$$

while the coordination equivalent fractions are given as:

$$Y_A = \frac{Z_A n_A}{Z_A n_A + Z_B n_B} \tag{47}$$

$$Y_B = \frac{Z_B n_B}{Z_A n_A + Z_B n_B} \tag{48}$$

A correction is added to configurational entropy since it is no longer given by the random mixing assumption from Eq. 17; therefore, S^{mix} becomes:

$$
\begin{aligned}
S^{mix} = -R \Bigg[&(n_A \ln X_A + n_B \ln X_B) + \left(n_{AA} \ln \frac{X_{AA}}{Y_A^2} + n_{BB} \ln \frac{X_{BB}}{Y_B^2} \right. \\
&\left. -n_{AB} \ln \frac{X_{AB}}{2Y_A Y_B} \right) \Bigg]
\end{aligned}
\tag{49}
$$

The quantities Y_A^2, Y_B^2, and $2Y_A Y_B$ represent the probability of finding AA, BB, an AB, respectively, and this corresponds to pair fractions from random mixing. The pair fractions, X_{ij}, are bound by the law of mass action relation:

$$
\frac{X_{AB}^2}{X_{AA} X_{BB}} = 4e^{\left(\frac{-\Delta G_{AB}}{RT} \right)}
\tag{50}
$$

If $\Delta G_{AB} = 0$, each pair is associated with the same energy and there is no tendency for ordering. When this happens $X_{AA} = Y_A^2$, $X_{BB} = Y_B^2$, and $X_{AB} = 2Y_A Y_B$ and Eq. 49 reduces to Eq. 17 for S^{id}.

Finally, ΔG_{AB} can be expanded in terms of coordinate equivalent fractions, for example, using a Redlich-Kister polynomial, in order to achieve a good fit to experimental data.

For multicomponent quasichemical models, assessed binary subsystems are used to construct higher order representations. The coordination number is compositionally dependent via:

$$
\frac{1}{Z_i} = \frac{1}{2n_{ii} + \sum\limits_{j \neq i} n_{ij}} \left(\frac{2n_{ii}}{Z_{ii}^i} + \sum\limits_{j \neq i} \frac{n_{ij}}{Z_{ij}^i} \right)
\tag{51}
$$

The composition of maximum SRO for each binary subsystem is determined by the ratio $\left(Z_{m,n}^m / Z_{n,m}^n \right)$. The multicomponent analogue to Eqs. 44 and 45 can be written as:

$$
Z_i n_i = 2n_{ii} + \sum\limits_{j \neq i} n_{ij}
\tag{52}
$$

Combining Eqs. 51 and 52 results in the relation:

$$
n_i = \frac{2n_{ii}}{Z_{ii}^i} + \sum\limits_{j \neq i} \frac{n_{ij}}{Z_{ij}^i}
\tag{53}
$$

Eqs. 46–48 can be generalized as

$$
X_{ij} = \frac{n_{ij}}{\sum\limits_{k} n_{kk} + \sum\limits_{k} \sum\limits_{l=k+1} n_{kl}}
\tag{54}
$$

$$X_i = \frac{n_i}{\sum_k n_k} \tag{55}$$

$$Y_i = \frac{Z_i n_i}{\sum_k Z_k n_k} \tag{56}$$

The Gibbs energy of solution and the configurational entropy terms now become:

$$G = \sum n_i {}^\circ G_i - T S^{config} + \sum_i \sum_j \left(\frac{n_{ij}}{2}\right) \Delta G_{ij} \tag{57}$$

$$S^{config} = -R \left[\sum n_i \ln X_i + \sum_i n_{ii} \ln \frac{X_{ii}}{Y_i^2} + \sum_i \sum_{j=i+1} n_{ij} \ln \frac{X_{ij}}{2Y_i Y_j} \right] \tag{58}$$

The technique of predicting multicomponent thermodynamic behavior by using assessed binary and/or ternary subsystems can be applied since ΔG_{ij} is a function of two body interactions only.

5.6 Excess Functions

The random mixing assumptions form the base for Eq. 28, 34, 38, 41, and 57. In order to model observed thermodynamic behavior, an ^{xs}G term is included. An important part of modeling efforts is the expedient choice of an excess function that facilitates extrapolation from binary and ternary subsystems to multicomponent mixtures. For this reason, ^{xs}G is generally chosen as a function of binary interactions only. There are more sophisticated representations for ^{xs}G, such as the three-suffix Margules and Whol's equations that are applied to liquid regular solution models, which likely better reproduce observed experimental behavior. However, these expressions suffer from the fact that interaction parameters between all components starting from binary up to the formal order of the system are included. In general, for practical purposes, the ^{xs}G equation should be chosen such that it is defined in terms of binary components or truncated to include only ternary interactions. This allows higher order systems to be extrapolated from binary and/or ternaries and therefore minimizes the experimental effort required to fit the adjustable parameters and describe the system. Higher order interactions are included as needed. This is known as the Muggianu method.

6 Data Sources

Tabulated data have been developed based on experimental measurements spanning several decades. For pure substances, that is the elements, stoichiometric compounds and their compositionally equivalent liquids, and molecular gases, good resources exist such as *NIST-JANAF Thermochemical Tables* (1998) and *Thermochemical Data of Pure Substances* (Ihsan 1995). The data are presented as tabulated Gibbs free energy, enthalpy, entropy, and heat capacity values in increments of temperature. Care must be taken to ensure consistency of standard states. For example, it is customary to use either 1 bar or 1 atm pressure as a reference; there is therefore the potential for small but important errors that can influence calculations if data are mixed between databases that use differing reference conventions.

Perhaps the international standard for thermochemical reference data and solution descriptions is that of the Scientific Group Thermodata Europe or SGTE (SGTE Substances Database Version 2). The SGTE is a well-established and respected organization. Their work is highly cited particularly within the CALPHAD (CALculation of PHAse Diagrams) community. The SGTE continually evaluates and revises the values within the existing database as needed and updates it with new species and phases when new studies identify the need for their inclusion. One limitation is the solution phase models are generally restricted to binary systems.

The Thermodynamic of Advanced Fuels-International Database (TAF-ID) program managed by the Nuclear Energy Agency (NEA) within the Organization of Economic Cooperation and Development (OECD) is an endeavor to model highly complex nuclear fuel systems with burn-up, for example, by including fission and transmutation products. The TAF-ID effort uses the CALPHAD method (detail in Sect. 7.2), whereby fundamental unaries, binaries, and ternaries subsystems are first assessed and then combined to simulate the thermodynamic behavior of multicomponent systems. An international team of researchers and engineers are compiling and assessing the available information on the most significant compounds and solution phases in order to define the multicomponent interaction behavior. Data are either mined from the open literature and checked for consistency or generated through carefully crafted experimental measurements within existing national programs. Other information that may be cost prohibitive or difficult to assess experimentally may possibly be determined from first principles calculations. Advances in theory and computational capabilities allow for calculating thermodynamic properties in this way, for example, lattice stabilities using Density Functional Theory (DFT). Estimation techniques are also useful and can be remarkably accurate in many cases. One example is the Neumann-Kopp rule, postulated more than 140 years ago. It states "*Each element (in the solid state) has essentially the same specific or atomic heat in compounds as it has in the free state*" (*Leitner* et al. 2010). Neumann-Kopp is often modified, for example, computing the overall heat capacity of a multicomponent compound by summing the individual heat capacities of constituent simpler compounds in appropriate ratios that result in the correct

stoichiometry for the complex phase of interest. This has been done with some success for oxides (Leitner et al. 2010). The enthalpy of formation of analogue compounds often follows a linear relationship with atomic number (Konings 2012). Other trends can be identified through systematic evaluation. For example, the standard state entropy and enthalpy of formation for a series of stoichiometric oxides in the Pr-O system show a linear relationship with composition (McMurray 2016). Generalized methods for particular systems are discussed at length by Kubaschewski et al. (1993) and Spencer (1998).

7   Computational Thermodynamics

The essence of computational thermodynamics (CT) is the use of computer codes and numerical techniques to find the constrained global minimum of the total Gibbs energy of a heterogeneous system. This results in an assemblage of stable phases, their elemental composition, and their relative amounts. At the heart of this technique is the Gibbs energy models discussed earlier, many of which are quite sophisticated which, ironically, has restricted successful implementation. For example, the sublattice model has existed for quite some time but use was not practical until the advent of affordable high speed computing and the development of robust minimization routines. For this reason, CT represents a significant scientific step forward by facilitating the thermodynamic representation of multicomponent systems with a high order of possible phase assemblages using complex liquid and crystalline models. The results of CT equilibrium calculations are currently used to construct unary, binary, and ternary phase diagrams and provide thermodynamic properties and potentials that are vital for understanding material behavior.

7.1   Phase Diagrams

Phase diagrams are graphical representations of the thermodynamically distinct phases that are stable at equilibrium. A unary phase diagram is completely defined by two natural variables, usually T,P. An example for H_2O is given in Fig. 1. For a binary system, a complete diagram requires the use of three dimensional (3-D) space since it is necessary to define the system in terms of one independent compositional variable in addition to the two natural variables. For convenience, a temperature composition (T-c) plot of a two component system is sectioned along an isobar, typically 1 atm, to construct a two-dimensional (2-D) T-c binary phase diagram. An example for the Cu-Ni system is given in Fig. 2. Ternaries are even more complex since it is necessary to specify two compositional and two natural variables to define the system, thus requiring the use of four dimensional (4-D) space to completely represent the phase equilibria. An isobaric section reduces this to 3-D that can be represented by a prism as shown in Fig. 3. Here, temperature is plotted along the vertical axis and the base of the prism is formed by an equilateral compositional triangle, the so-called Gibbs triangle.

Difficulties arise when using 3-D representations on 2-D media; it is therefore useful to reduce ternary phase space plots to 2-D by sectioning. If a slice is excised along the horizontal plane of the 3-D space, i.e., the system is at a constant temperature, then an isothermal diagram results such as that shown for the Mo-Si-C system in Fig. 4. These are typically the most useful since they
Fig. 1   Temperature-pressure phase diagram for H_2O in the vicinity of the triple point
Fig. 2   The Cu-Ni binary phase diagram

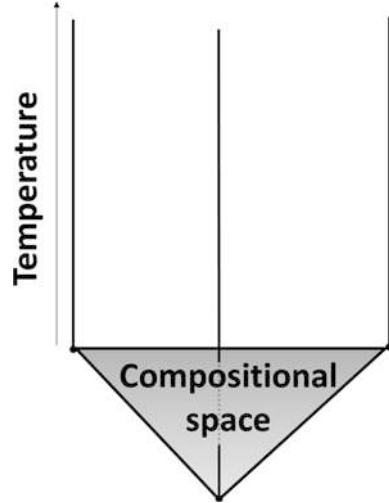
Fig. 3 The constant pressure prism representing temperature along the vertical axis and composition within the so called Gibbs triangle


Fig. 4 Ternary isothermal section of the Mo-Si-C at 1590 °C

allow for compositional analysis while the alternatives do not (Campbell 2012). An isoplethal diagram follows a constant variable, usually composition of one (or more) component. An example of the isopleth is shown in Fig. 5.

Higher order phase diagrams are extremely difficult to visualize and plot and are therefore not very utilitarian; however, one technique is to fix the compositions of
Fig. 5 Pseudobinary phase diagram of the Mo-Si-C system along the C-MoSi$_2$ isoplethal section

enough of the components to generate a pseudo-ternary isotherm or a pseudo-binary isopleth for 2-D renderings. While most systems do not attain equilibrium, phase diagrams are important since they show where nature would like to move the system given enough time to evolve, with increasing temperature generally moving systems more rapidly to equilibrium. They are a core part of developing thermodynamic models that can be used to compute chemical potentials that are fundamental for simulating many kinetic processes such as microstructural evolution based on phase-field methods.

7.2   CALPHAD Methodology

Over 40 years ago, Larry Kaufman and Himo Ansara organized the first CALPHAD (**CAL**culation of **PHA**se **D**iagrams) (Spencer 2008) meeting with the aim of developing a framework for self-consistent modeling of combined thermodynamic properties and phase equilibria – this became known as the CALPHAD method. Since then, CALPHAD has become more of a movement than a method. There is a membership organization growing in both the number of scientists employing the approach and the scope of materials to which the methodology is applied as well as a flagship journal *CALPHAD – Computer coupling of phase diagrams and thermochemistry*. Advances in science and computing performance have facilitated the implementation of theoretical first principles calculations into thermodynamic assessments and the development of sophisticated commercial computational thermodynamic software packages like Factsage and Thermocalc. These achievements have grown from and form a fundamental part of present day CALPHAD.

In the CALPHAD approach, all available data are critically assessed and utilized to build the most accurate and comprehensive representation of the phases in a system. The aim is self-consistent models that predict thermodynamic properties and equilibria to be used for phase diagram construction that can be confidently extrapolated beyond the range of experimental validation. The ultimate goal is the development of databases for specific components that form systems of technological importance that can be extended to include higher order systems ad hoc. This is facilitated by developing models based on the physical and chemical properties of the phases, for example, the crystallography, bonding, order-disorder transitions, and magnetism (CALPHAD 2014). Of course, extensions and extrapolations are just that and a core tenet of the CALPHAD methodology is the periodic re-assessment of systems, a re-examination of the existing data from which they are determined, and new experiments for validation of the models in extrapolated regions; therefore, databases and models should be constantly updated and improved.

The use of first principles methods, particularly density functional theory (DFT) (Lukas et al. 2007), has come to play an increasingly important role in CALPHAD modeling to supplement efforts to develop thermodynamic data or to determine thermodynamic values that are difficult or otherwise impossible to obtain experimentally, such as properties of meta-stable or unstable phases. The structure of crystalline materials should inform the selection or development of models that can represent the defects and site occupancy of the species comprising the solid; this information can generally be determined from neutron and X-ray diffraction techniques. Once a model is chosen to represent the phase, thermodynamic data determined from experimental measurements or ab initio simulations are used to optimize the adjustable parameters of models using a computational software package.

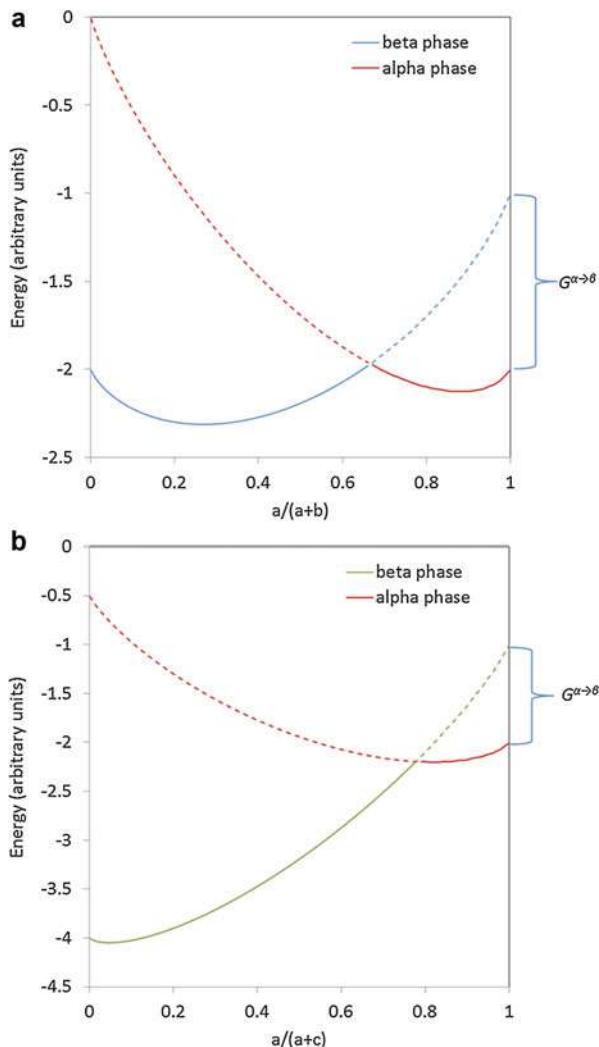
7.3   Lattice Stabilities

A fundamental CALPHAD concept is *lattice stability* (Saunders and Miodownik 1998). It comes from the idea that the Gibbs energy descriptions can be represented for all elements in every phase of a system, that is, it can be extrapolated into regions of instability, expressed graphically in Fig. 6. Lattice stabilities can be obtained by traditional CALPHAD techniques or from first principles calculations such as DFT.

7.3.1   Lattice Stabilities from Extrapolation

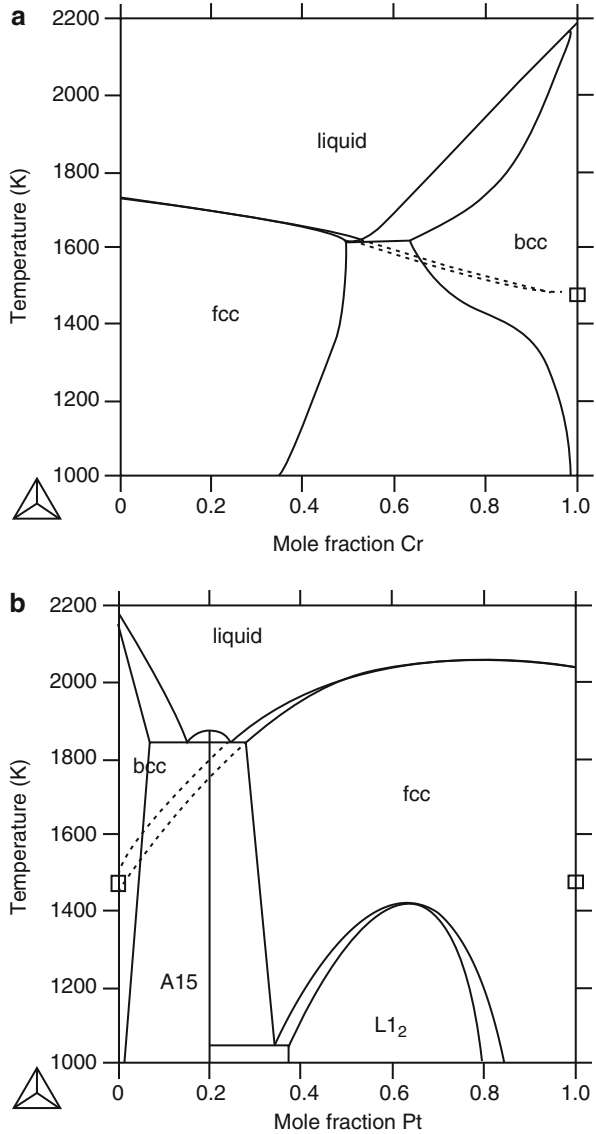
Most CALPHAD lattice stabilities can be deconvoluted into H and S components as follows:

$$G^{\alpha \to \beta} = H^{\alpha \to \beta} - T S^{\alpha \to \beta} \tag{59}$$

Fig. 6 Gibbs curves from the ideal solution model as a function of composition for the α and β phases in the hypothetical a-b and a-c systems. The dashed lines represent "extrapolations" into the unstable phase regions. The difference between the extrapolated end points and the pure stable phase is the lattice stability. Note that the lattice stability for pure *a* in both the *a-b* and *a-c* binaries are the same, i.e., the $G^{\alpha \to \beta}$ value is independent of the system


where $G^{\alpha \to \beta}$ is the lattice stability and $H^{\alpha \to \beta}$ and $S^{\alpha \to \beta}$ are the transition enthalpy and entropy for unstable β relative to the stable α phase, respectively. One common and convenient approach assumes the c_p to be the same for both phases; therefore, G^{β} can be obtained by adjustment to G^{α} with an $a-bT$ term. One technique is to estimate the entropy and hypothetical melting temperature of the unstable phase; an example is seen in Fig. 7 where the melting temperature is determined by extrapolation shown as the dashed line. Using the following relations:

$$H_{Cr}^{L} - H_{Cr}^{bcc} = S_{Cr}^{L \to bcc} \left(T_f^{bcc} - T \right) \tag{60}$$

Fig. 7 Melting temperature extrapolations (dashed line) of bcc Cr in the Cr-Ni and Cr-Pt systems from (Lukas et al. 2007)


$$H_{Cr}^{L} - H_{Cr}^{fcc} = S_{Cr}^{L \to fcc} \left(T_{f}^{fcc} - T \right) \qquad (61)$$

where T_f is the melting temperature and $H_{Cr}^{fcc \to bcc}$ can be obtained by subtracting Eq. 60 from 61. The credibility of this approach is established by multiple phase relations that yield self-consistent extrapolated values (Lukas et al. 2007). Another

technique is the direct extrapolation of the Gibbs energy for a component in solution in two isostructural parent materials. For consistency, the same type of model is be used to describe the behavior for both phases and requires the end-member energies of the solute must be consistent between systems. This is illustrated graphically in Fig. 6. Finally, further confidence is established if the values for $H^{\alpha \to \beta}$ are consistent with 0 K total energy differences calculated from DFT methods.

7.3.2 Lattice Stabilities from First Principles Calculations

Ideally, DFT can provide the relative enthalpy for various crystal structures and thus the $H^{\alpha \to \beta}$ component of the lattice stability. This is accomplished by computing the total energy, E, at absolute zero for an assemblage of particles by solving the time-independent Schrödinger equation using simplifying assumptions and approximations (Lukas et al. 2007). Equations 62 and 63 show the lattice stability is, to a first approximation, the difference in E values between two distinct crystallographic arrangements.

$$\Delta E = E^{\alpha} - E^{\beta} \tag{62}$$

where

$$\Delta E \approx \Delta H \tag{63}$$

Eq. 63 is assumed to be valid since at 1 atm pressure $P\Delta V \approx 0$. These results can then be compared to estimated $H^{\alpha \to \beta}$ based on extrapolations, used directly to determine the $S^{\alpha \to \beta}$ for stable phases, or serve as an initial value for applying lattice stability in an optimization procedure.

7.4 Computational Thermodynamic Codes

In the 1950s, White et al. (2004) developed an algorithm for minimization of the Gibbs energy of multicomponent gas mixture for computer implementation using a method of steepest descent. While techniques have evolved over the years for thermodynamic equilibrium calculations for ever more complex solution phases and multicomponent systems, most are variations of the method of White et al. and all are based on one fundamental concept, which is attaining the global minimum of the total Gibbs energy satisfying the condition of conservation of mass (Piro 2011).

The two most robust and widely cited computational thermodynamic software packages in the open literature are Factsage® and Thermocalc®. Factsage uses an equilibrium solver developed by Eriksson that was the basis of his original SOLGASMIX code (Eriksson 1971, 1975; Eriksson and Rosen 1973; Piro 2011), while the Thermocalc code is based on an algorithm after Hillert and Jansson (JO Andersson et al. 2002). The fundamental operation of both programs is essentially the same allowing for versatile thermodynamic properties output and phase diagram construction. They also include an optimization module for fitting adjustable

parameters of Gibbs functions and solution models using thermodynamic values and phase equilibria data. Both Factsage and Thermocalc have an established record of use for modeling of nuclear materials systems and are capable of handling at least 48 and 20 components respectively (Piro 2011). Other commercial thermodynamic packages include Thermosuite, MTDATA, PANDAT, HSC, and MALT to name a few (Konings 2012). The software facilitate the use of the sophisticated models needed to describe many of the solution phases discussed earlier.

8 Fuel Systems

8.1 Ceramic Fuels and Ionic Crystalline Phases

Uranium monocarbide (UC_{1-x}), UC_{2-x}, and UN are of interest as advanced fuels. Urania, or $UO_{2 \pm x}$, is the most widely used commercial nuclear fuel and is interesting because of its complex oxygen chemistry. The U cation exhibits 3+,4+,5+, and 6+ oxidation states. This, along with the structure of the fluorite crystal, allows for oxygen interstitials and vacancies in $UO_{2 \pm x}$ and permit formations of a wide oxygen homogeneity as can be seen in Fig. 8. While UC_{1-x}, UC_{2-x}, and UN are all modeled with CEF, the CEF for $UO_{2 \pm x}$ developed by Guéneau et al. (2002, 2011) is used here as an example for modeling complex crystalline phases.

As can be seen in Fig. 9, the CEF provides a description of the oxygen potential, heat capacity, and point defect chemistry of $UO_{2 \pm x}$. These are critical values for understanding the behavior of the fuel in a reactor. In particular, oxygen redistributes and affects the local thermal conductivity of the phase creating a temperature-composition feedback loop. The CEF cannot, however, address the likely clustering

of oxygen interstitials in the hyperstoichiometric oxide (D. A. Andersson et al. 2009; Brincat et al. 2015) and thus the inclusion of such defects awaits further model development.

8.2   Metallic Fuels and Metallic Phases

It is standard practice to use sublattice models like the CEF to represent interstitial solutions. One example is for O dissolution in hcp Zr. The crystal structure influences the degree of solubility of interstitials and this is captured with the CEF. For example, there is one octahedral site in both the fcc (face centered cubic) and hcp (hexagonal close packed) metals. However, for the hcp structure, there are shorter distances between these sites. It is therefore generally accepted that only one-half

can be occupied (Grundy et al. 2001). The sublattice model $(M)_1(I)_{0.5}$ where M represents the metal and I the interstitial species well reproduces the solubility limit of O in both hcp Ti (Waldner and Eriksson 1999) and Zr (Wang et al. 2004).

When mixing occurs on only one sublattice and the others are either fully occupied or totally vacant, the CEF reduces to the regular solution model, sometimes called the RKMP because of the Redlich-Kister-Muggiano polynomial formalism based on Eqs. 29 and 30 that is used to define the interaction terms. The U-Th system was assessed by Li et al. (2009) and the binary phase diagram is reproduced in Fig. 10. Here, the CEF is used for the crystalline metallic solutions but with vacancies exclusively on the anion sublattice. While this is tantamount to simply using the RKMP, it is good practice to apply the CEF as it allows extension of the models into higher order component space. For example, in the ternary U-Th-O or U-Th-C systems, the O and/or the C would likely dissolve and be accommodated on the interstitial sites.

It is worth pointing out that the database focused on metallic fuels are few with limited thermochemical information, for example that of Kurata (Kurata 1999). Another, dedicated to Zr alloys of interest for nuclear applications, is ZIRCOBASE (Dupin et al. 1999) concentrating on Zr containing binary systems and some ternaries
Fig. 10 Computed Th-U binary based on the models from (Li et al. 2009)

8.3   Ionic and Metallic Liquids

The MQM and the two-sublattice ionic liquid model (TSLM) are extensively used within the CALPHAD community to represent melts like ionic liquids such as molten salts. Of the two, the MQM incorporates more physics and better describes the configurational entropy by accounting for nearest neighbor short range ordering, as described in detail in Sect. 5.5. However, the TSLM is convenient to use and can do as well as the MQM in representing the Gibbs energy of both ionic and metallic melts. In the latter case, the TSLM reduces to the regular solution model. Molten salt phases are most often represented with the MQM. Modeling efforts based on the MQM for nuclear-related fluoride systems have been significant (Capelli et al. 2015; Capelli et al. 2014) and efforts are expanding to use the MQM for chloride based molten salt fuels as well.

While ionic liquids can certainly be represented with the MQM, the TSLM is also commonly used as is the case for the U-O system (Guéneau et al. 2002; Guéneau et al. 2011). For metallic melts, the RKMP is sufficient. However, just as for purely substitutional crystalline solutions, the TSLM is preferred to allow for extension into multicomponent space. A caveat is, for the TSLM both FactSage and Thermocalc currently have issues representing a liquid metal without a constituent on the anion sublattice; therefore, both TSLM and RKMP models are sometimes included in multicomponent assessments as a work around.

9   Outlook

Thermodynamics of nuclear fuels is an important and continuing area of intense research. It has broad based utility in developing new materials, designing of processes, and in predicting and optimizing reactor performance. The current state of the science can be summarized as: Much has been accomplished, but more is needed. Understanding the fundamental thermochemistry of fuel systems with burnup continues to be a challenge for two reasons. First, including actinides makes measurements required for model development costly and difficult. Second, fuel systems become highly multicomponent and inhomogeneous with burnup and are constantly evolving from beginning to end of life. To attack these challenges, over the past decade efforts have been devoted to developing multiscale-, multiphysics-based computational capabilities that couple thermodynamic inputs to transport, phase field, and continuum mechanics simulations to predict the chemical, thermal, and structural behavior of reactor core components (Devanathan et al. 2010). This is the future of fuel performance modeling. At the beating heart is thermodynamics.

Part XIV
Radiation Damage

Modeling of Radiation Damage in Materials: Best Practices and Future Directions

96

Kai Nordlund and Michael P. Short

Contents

Abstract

In this section of the *Handbook of Materials Modeling*, modern methods to model radiation damage in materials are considered. This introductory chapter puts the topic into context, briefly overviews the multiscale nature of radiation effects, and surveys most important methods used to advance this field of physics. Emphasis is given to advances from the past 10 years, highlighting specific bodies of work, some of which are reviewed in this section, which have advanced both our scientific understanding of and best practices for simulating radiation damage. This section differs somewhat from that of Devanathan and Marian entitled "Nuclear Materials," in that this section focuses more on modeling techniques for radiation damage as applied to pure materials, not necessarily nuclear materials. However, much can be learned from reading the shared perspectives in both

sections, as many similar topics are addressed from different points of view. The more specific chapters in this part are introduced in this overview, with emphasis on predicted directions in the field for the next 10 years.

1 Introduction: A Historical Perspective

The history of the human race is closely linked with developments in materials processing. Societal development is routinely divided into the Stone Age, Bronze Age, and Iron Age, and sometimes the last half century is characterized as the silicon age. The varieties of materials processing that enabled the first three ages are of course traditional and can be characterized in terms easily understood to a layman: chiseling, cracking, melting, cooling, and so on. In a physicist's terminology, these can be characterized as being equilibrium or near-to-equilibrium processes.

In this range of ages, the silicon age brought with it a fundamentally different way of processing materials: ion irradiation enabled by particle accelerators. Taken into use in the industry in the 1960s, it is an inherently far-from-equilibrium process. In fact, during the very first stages, when atoms ballistically collide two at a time (a process known as a collision cascade), classical thermodynamics does not in fact apply at all. Even the very idea of temperature requires an ensemble of atoms, which does not really exist at this stage. Later on, after about 0.2 ps or so, the initially energetic atoms have slowed down to kinetic energies comparable to the chemical bond energy (still tens of thousands of Kelvin, thermodynamically speaking), and atomic motion becomes many-body in character. At this stage, thermodynamic concepts like temperature and pressure become meaningful (Diaz de la Rubia et al. 1987), and the system can be characterized as in a far-from-equilibrium thermodynamic state. After another 10 ps or so, all atoms have thermalized to temperatures close to that of the surrounding material, and regular thermodynamics and kinetics, such as the heat diffusion equation, can be used to characterize the system.

Although the silicon semiconductor industry is by far the most economically important user of ion irradiation for materials modification, it did not invent the technology. Radiation does of course occur everywhere in nature due to radioactive decay and cosmic radiation. The first reported human-controlled use of irradiation effects for materials modification was in 1852, when Sir Grove built a metal needle in a vacuum chamber and charged it up from a coil (Grove 1852). This caused visible surface modifications, which in retrospect were deduced to be due to rest gas atoms being ionized and hitting the surface, causing sputtering or implantation and a color change associated with that – essentially a very early precursor to the field ion microscope (Mueller and Bahadur 1956).

The experimental and theoretical developments of the study of radiation effects in materials are proceeded by famous scientists like Rutherford, Curie, Bohr, Fermi, and Oppenheimer (Rutherford 1911; Bohr 1913; Fermi and Teller 1947). Initially the efforts were largely focused on understanding the slowing-down mechanisms of the energetic ions and neutrons that were obtained first from radioactive sources,

and later from particle accelerators. Without much exaggeration, one can say that the basic physics of the ion slowing down was understood by the 1960s, when Jens Lindhard (a student of Niels Bohr) and coworkers formulated a coherent theory of the nuclear and electronic stopping powers and their energy deposition in materials (Lindhard et al. 1963). This leads soon to a predictive simulation capacity regarding some aspects of radiation effects, such as calculating within 10% or so the penetration depth profile of keV or MeV ions in amorphous materials (Robinson and Torrens 1974).

The efforts to understand how materials are actually modified by energy deposition from ionizing radiation started to become more systematic around the same time, as nuclear fission reactors became widely used, and the idea to use ion implantation for semiconductor processing arose. However, it turned out that reaching a predictive capability for damage production was a much harder problem than that of ion passage in materials, and the efforts to achieve this understanding are still underway. This collection of chapters in the *Handbook of Materials Modeling* is in essence a description of the state of the art of attacking this complex problem, which even now is far from solved. Similarities will be noted in the part by Devanathan and Marian entitled "Nuclear Materials," though theirs focuses more on actual nuclear materials while this part focuses squarely on model materials to illustrate modeling techniques. Nevertheless, the reader is referred to the part by Devanathan and Marian for different perspectives on many similar modeling issues, as seeing similar high-level concepts from different points of view, or as applied to different materials systems, is often highly instructive.

The chapters in this part are largely written with examples focused on the studies of ion and neutron effects in metals. However, we emphasize that this is not the only regime where the methods are applicable. All the same physics and approaches can also be used to study semiconductors (Chason et al. 1997), ceramics (Meldrum et al. 1998) and carbon-based materials (Krasheninnikov and Nordlund 2010), and to some extent also damage in organic materials (Polvi et al. 2012). The radiation damage in biological materials is, however, quite different in that the damage on the biologically active molecules, such as DNA and proteins, seems to be to a large extent a secondary effect from radicals formed in the water surroundings. Discussion of the last case is beyond the scope of this part.

2   Radiation Effects as a Multiphysics and Multiscale Problem

The evolution of radiation damage in the bulk is an inherent multiphysics and multiscale problem. The physical nature of this evolution is illustrated schematically in Figs. 1, and 2 provides an overview of the length and time scales involved.

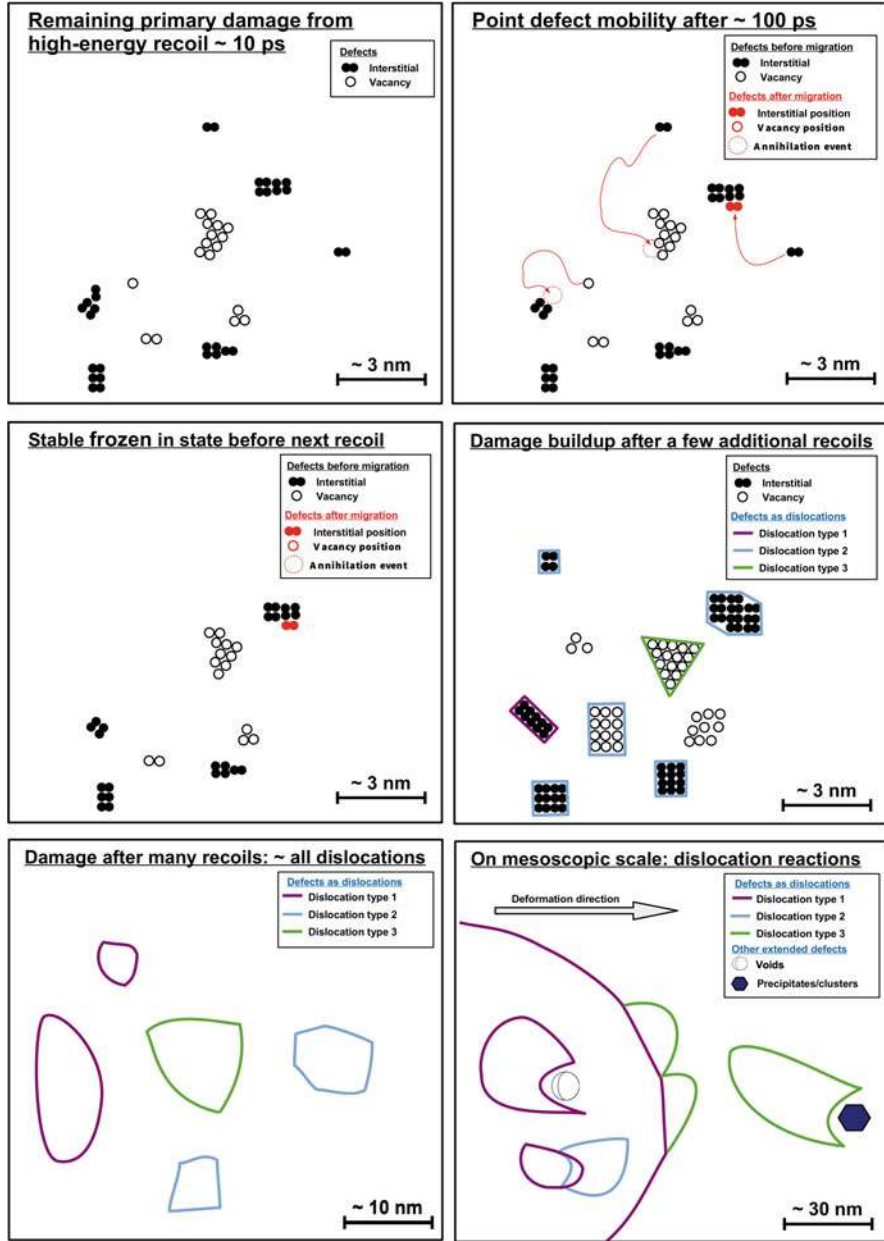
Before proceeding with the discussion of this, it is worth noting that not all aspects of radiation effects, however, are multiscale in character. Clear examples of this are the ion penetration depth problem mentioned in the historical overview above and sputtering (energetic particle-induced atom erosion from surfaces) and ion beam mixing (relocation of atoms by irradiation) at low temperatures. Both


Fig. 1 Graphical illustration of radiation damage production physics
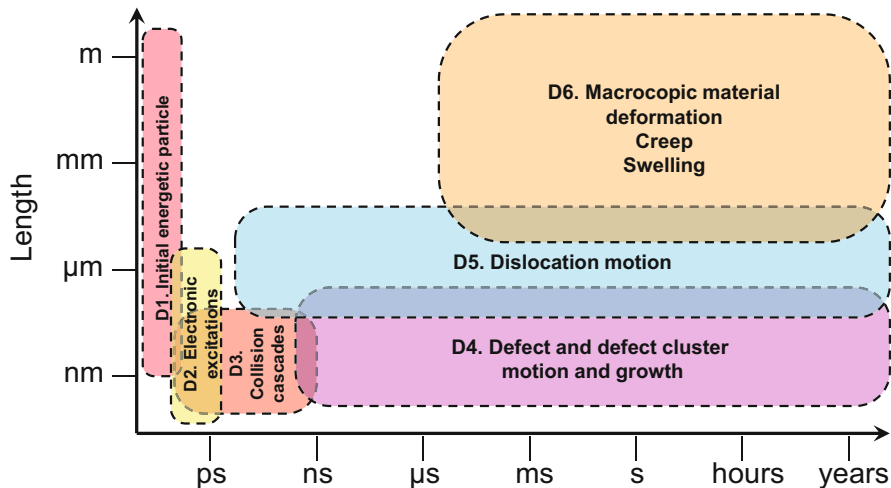

Fig. 2 Multiple levels of physics involved in radiation effects. The codes D1–D6 are used as cross-references in the main text. The box limits in space and time are very rough and should not be taken as any kind of sharp limits

effects are under typical ion or neutron fluxes caused by atom movement in the collisional and heat spike stages of single collision cascades, which are over in less than 10 ps. Hence they in essence do not involve multiscale physics, nor is multiscale modeling needed to describe these effects. Indeed, the phenomena have – at least in a few simple materials – been very well described by a single simulation technique, molecular dynamics (Gades and Urbassek 1995; Nordlund et al. 1998).

In the multiphysics regime, achieving a predictive description level of radiation effects is very challenging and has not been achieved yet. In this chapter, we describe very briefly the different levels of physics known to be involved and, in the next ones, the modeling tools used to study them, pointing out which chapter belongs to which method.

The initiator of a "radiation event" is an energetic (ionizing) particle, **box D1** in Fig. 2. These can, for instance, be fission fragments from radioactive decay of natural or man-made isotopes, neutrons from a nuclear reactor, ions from a particle accelerator, electrons from an electron gun, or photons from a synchrotron. These slow down by different mechanisms involving interaction with the electrons and nuclei in the materials. While the slowing-down mechanisms are beyond the scope of this chapter, the important physics point is that for an individual energetic particle, the slowing down to thermal energies is a very rapid process, occurring on femtosecond to picosecond time scales. Due to the energy transfer, the struck electrons and nuclei can in turn gain high kinetic energies, which in turn leads to material damage.

In this section, we focus on the damage caused by the nuclei that have gained a recoil energy from any kind of initial energetic particle. The damage by electronic excitations (**box D2**) is discussed in a separate chapter by Djurabekova and Nordlund (▶ Chap. 88, "Molecular Dynamics Simulations of Non-equilibrium Systems"). Regardless of the type of the initial particle, after a nucleus in the material has received a recoil kinetic energy, the damage production mechanism is the same. This motivates that the remainder of this chapter is a thorough discussion of damage production by atomic recoils.

After an atom has obtained a recoil energy, higher than the threshold displacement energy of the material (Nordlund et al. 2005), it will collide with atoms in it, giving over some of its kinetic energy to these. Thus these atoms in turn become recoils themselves and can lead to further collisions. The sequence of collisions is called a collision cascade (**box D3**). What is very important to realize, however, is that in dense materials, eventually the different branches of a collision cascade almost always overlap, and the process becomes a set of simultaneous many-body collisions known as a heat spike (Seitz and Koehler 1956). In the heat spikes, the damage produced is not only single Frenkel pairs (pairs of interstitials and vacancies) but can be clustered (Kojima et al. 1989), regions that have undergone a phase transition (Meldrum et al. 1998), or, in the case of amorphizing materials, an amorphous zone (Ruault et al. 1984).

The collision cascades cool down rapidly (the cooling rate of heat spikes in metals is of the order of 10^{15} K/s, which is an amusing number from a macroscopic point of view). After they have cooled down to the ambient temperature, which occurs in 10–100 ps, the system can be considered an equilibrium thermodynamic system, albeit with a high local defect concentration. In most materials, at least one of the single point defects (vacancies or interstitials) is mobile already at room temperature. Hence, after the athermal collision cascade, thermal motion of defects will occur (**box D4**). This occurs until either a next cascade hits the same region or all defects have recombined.

In many materials, and especially in metals, the damage typically takes the form of dislocations after a few damage overlaps (illustrated in lower part of Fig. 1), **box D5**. In fact, in some metals where the heat spikes are dense, such as Cu, Ni, and W, already the primary damage state may include dislocations (Kojima et al. 1989; Nordlund and Gao 1999; Yi et al. 2015). Since the mechanical properties of metals under deformation are completely dominated by dislocations, understanding the high-dose damage in metals requires good understanding of how dislocations form and develop under irradiation conditions and how they behave after the irradiation is finished.

Macroscopic materials modification after high-dose irradiation may take many forms (**box D6**). The buildup of high dislocation concentrations by irradiation generally speaking tends to harden metals, but also makes them more brittle. In the case that vacancy mobility leads to their coalescence into voids, the material will swell – and this effect can be very strong, tens of percentages of volume change. Moreover, especially at elevated temperatures, both point defect and dislocation mobility can lead to permanent shape changes of the material, an effect known as creep.

3   Modeling Methods for Studying the Multiple Scales

In this chapter, we very briefly introduce the basic ideas of the key multiscale simulation tools used in radiation effects modeling and point to which physics levels and separate chapters in this section they relate to. The reader is also referred to the part entitled "Atomistic Simulations and Extensions Towards Multiscale" in Vol. 1 of this handbook for a more general overview of modern methods for atomistic-based multiscale modeling.

The initial penetration of energetic (energies of keV or higher) particles in matter can be calculated with various codes that treat the particle as moving in straight paths between collisions. For neutrons, the collisions occur only with nuclei, and the collision probability can be obtained from nuclear reaction cross sections. Such **neutronics** calculations were actually the first Monte Carlo computer simulations ever performed, in the Manhattan Project (Fermi and Richtmyer 1948). For ions, the collision cross section is much larger, but can be well modeled with the **binary collision approximation (BCA)** method (Robinson and Torrens 1974). The movement of electrons and gamma particles is interlinked at MeV energies and can be described well with so-called **electron-gamma cascade** codes (Nelson 1978). Since all of these methods are well established in their basic formulations on one hand, and do not directly predict damage production on the other, there are no detailed articles related to them. The most popular BCA method by far to simulate radiation damage is SRIM, or the Stopping and Range of Ions in Matter , by Ziegler et al. (1985). This approach, while simple and very easy to use, fails to describe the interaction of radiation damage cascades with material structures of a similar length scale. ▶ Chapter 97, "More Efficient and Accurate Simulations of Primary Radiation Damage in Materials with Nanosized Microstructural Features or Ion Beams," by Li, Yang and Short shows a new approach to directly simulating the interaction of swift ions and neutrons with nanostructures, both isolated and within materials, showing that they are more resilient to damage by many orders of magnitude. Because radiation interactions with nanostructures form more of the underpinnings of material behavior, from structural composites to nanotube-based detectors, this ability is projected to be increasingly important in the years to come.

Reality is of course fundamentally quantum mechanical, and thus all dynamic materials properties are in principle determined by the Schrödinger equation (or for heavy elements its relativistic equivalent to the Dirac equation) for the system of all electrons and all nuclei. Unfortunately solving the true Schrödinger equation for a many-atom system is, even with current computer capacity, intractable. However, the approximate quantum mechanical method, **density functional theory (DFT)**, has proven to be quite accurate and efficient enough to handle system sizes of a few hundred atoms (Jones and Gunnarsson 1989). Hence it is very well suited to examine the properties of point defects and small defect clusters and also defect production dynamics in the smallest collision cascades (Holmström et al. 2008; Olsson et al. 2016). The method is very widely used and reviewed elsewhere for defect calculations (Freysoldt et al. 2014) and hence there is not a separate chapter for this topic.

The few hundred atoms, to which DFT is limited, are certainly not enough to describe full collision cascades. For simulating these, **molecular dynamics (MD)**

simulation utilizing classical potentials is a very appropriate method, as it can easily handle millions of atoms to nanosecond time scales, In MD, Newton's equation of motion is solved for forces acting between atoms, obtained from analytically or numerically defined interatomic potentials. If the interatomic potential is accurate and the electronic stopping power known, MD can describe perfectly the atom motion in collision cascades all the way from the initial high-energy collisions down to the final thermalization to the ambient temperature. Use of MD for collision cascade studies is discussed further in the chapter by A. E. Sand et al., ► Chap. 98, "Incorporating Electronic Effects in Molecular Dynamics Simulations of Neutron and Ion-Induced Collision Cascades"

The thermally activated defect motion between collision cascades can occur on time scales from 10 ps to years. While both DFT and MD can be useful methods to obtain the migration activation energy and Arrhenius equation prefactor for individual defects, they are too slow to simulate the evolution of a complex defect ensemble over long time scales. The **kinetic Monte Carlo (KMC)** method, on the other hand, is very useful for simulating the long-term defect dynamics and is first addressed in the part entitled "Long Timescale Atomistic Simulations: Accelerated Molecular Dynamics and Adaptive Kinetic Monte Carlo" of the MTM set of this handbook. This method needs as input the defect migration rates and a full description of defect reactions (e.g., recombination radius between a vacancy and an interstitial, emission of point defects from clusters, even extended defect reconfigurations and rotations). If all of these are known, the KMC algorithm can describe defect evolution perfectly with the correct time scale and correct relative jump rates of all defects. The object simulated can be atoms (atomic KMC, AKMC) or "defect objects" (object KMC, OKMC). ► Chapter 99, "Atomistic Kinetic Monte Carlo and Solute Effects," by Becquart et al., describes the use of AKMC for simulating solute evolution in metals, a notoriously difficult problem. Multibody potentials must be utilized to enumerate solute-defect reactions, and many solute-defect effects take place at fantastically low concentrations of tens of parts per million, such as the slowdown of vacancy migration by tiny amounts of carbon in iron (Takaki et al. 1983).

Solid links between such disparate length/time scales such as DFT and KMC have characterized progress in the past 10 years, as exemplified by Martinez et al., ► Chap. 100, "DFT-Parameterized Object Kinetic Monte Carlo Simulations of Radiation Damage" This chapter details the use of OKMC as informed by lower length scale simulations from DFT describing precise defect reactions and energetics. This direct link between the atomic/femtosecond scales and the micron/millisecond scales is a prime example of what has only been possible in the past 10 years, as computational power increases enough to parallelize both DFT wave function calculations and larger/longer OKMC simulations, allowing the inclusion of more and rarer transitions between defect states.

The dynamic behavior of dislocations, in turn, can be modeled at a higher length scale with a method known as **discrete dislocation dynamics (DDD)**, addressed in "Advances in Discrete Dislocation Dynamics Simulations" by LeSar

and Capolungo. In this approach, dislocations are described as a chain of connected dislocation segments, each of which giving rise to its own strain field. In the simplification of elastically isotropic materials, these strain fields are known exactly from classical dislocation theory (Hirth and Lothe 1992). Each segment interacts with each other in the system, and their motion is described for forces derived from the strain fields, similar to the basic molecular dynamics equation. The big challenge in DDD is being able to describe all possible reactions of dislocations with each other, voids, and precipitates, for all stresses and temperatures. Such information can be derived from MD, and while serious efforts are underway to do this (Queyreau et al. 2010; Terentyev et al. 2009; Byggmästar et al. 2017), much clearly remains to be done.

Both KMC and DDD can handle micrometer length scales. However, for a large, complicated defect population where the balance of defects is important, neither method can handle a sufficiently large amount of defects. The **cluster dynamics (CD)** method as presented in ▶ Chap. 101, "Rate Theory: Cluster Dynamics, Grouping Methods, and Best Practices"by Jourdan et al., is an efficient rate theory approach, which can describe the time evolution of even very complicated defect populations. It does not have a length scale explicitly; however, from the nature and concentration of defects it describes, one can nevertheless give a rough description of its range of validity in length scales, as shown in Fig. 3. The inputs to CD can be obtained from DFT or MD and are often the same as the inputs needed for KMC. Jourdan's chapter details critical lessons learned since the inception
Fig. 3 Multiscale modeling methods for radiation effects in materials. *DFT* density functional theory. The limits in the figure are very rough and indicative only of the typical most relevant time and length scales of the method. In some cases the methods can be applied on a much smaller scale; for instance finite element methods can for linear elastic properties often used down a nm length scale

of cluster dynamics, in terms of how best to run stable and efficient large-scale simulations. This is especially enabled by grouping sets of similarly behaved defects into single ensembles, ensuring that total fluxes between sizes and types of defects are conserved while reducing the number of differential equations required by factors of thousands or more.

Structural engineering materials, especially metals, are almost always polycrystalline, with grain sizes typically in the 1–100 μm. It is well known that grain boundaries can be sinks for point defects; dislocation movement follows crystal direction and is hindered by grain boundaries. Hence a complete description of these materials should also include the effect of different crystal orientation in different grains and grain boundary effects. While grain boundary effects can be described by DFT, MD, KMC, and DDD, these methods are too slow or small-scale to describe the deformation of a large number of differently oriented grains adjacent to each other. The **crystal plasticity (CP)** approach deals with this well (Lebensohn and Tomé 1993) and is discussed thoroughly in the part entitled "Crystal Plasticity: From the Atomic Scale to the Macroscale" in Vol. 1 of this handbook.

In the scale of simulation methods mentioned in this overview, we must address **finite element modeling (FEM)**. In this approach, space is divided into a set of elements, typically triangular (2D) or prism-shaped (3D), all connected to each other in the corners, and a given equation system is solved in this grid. The solution can be either static or dynamic. For the purpose of this chapter, the most relevant use of FEM is the solution of elastoplastic equations describing the response of a material to external forces, as it is widely applied for structural design in mechanical engineering. FEM is, because of this wide use, very reliable for describing stresses and deformation in standard engineering materials (steels, aluminum, etc.) under usual processing conditions. However, the radiation condition is not a usual one, and due to all the physics effects described above, the elastoplastic response (constitutive equations) of a material will be significantly different from the initial one after a prolonged exposure to radiation. Thus, from a nuclear (fusion or fission) development point of view, the ultimate aim of the entire multiscale modeling can be considered to be obtaining both understanding and predictive modeling capability in all the lower levels, which enable formulating physics-based input laws including all radiation effects for FEM.

Finally, we mention a very interesting method that can be used on many different levels of modeling (and hence is not explicitly shown in the multiscale modeling schematic): **artificial intelligence (AI)**. This topic is more generally addressed in the part entitled "Materials Informatics" in Vol. 1 of this handbook. Although the exact definition of the term varies, in modern usage it generally means algorithms that have self-reinforcing or iterative features that enable a program to mimic human learning. With this definition, the term is almost identical to **machine learning (ML),** such as is discussed in Chap. 88, "Machine Learning and Big-Data in Computational Chemistry" in Vol. 1 of this handbook. AI or ML approaches can be useful in many ways in materials modeling, starting from optimizing DFT wave functions, to crafting more accurate MD interatomic potentials, even to mapping out potential defect reactions in KMC. In the future, AI approaches may become

crucial for transferring large data sets on one multiscale level to another one effectively. ▶ Chapter 103, "Modeling Radiation-Induced Segregation and Precipitation: Contributions and Future Perspectives from Artificial Neural Networks" by Castin and Malerba, describes one fairly well-established application of AI in materials modeling, predicting diffusion barriers efficiently using trained neural networks. Such examples are rare so far, as most parameters regarding activation energies, defect reactions, and even structures of defects themselves have been painstakingly acquired through a combination of single simulations and well-crafted validation experiments. Thus ML/AI represent a fundamental paradigm shift, where unleashing automated pattern recognition can point the human investigators toward potentially useful parameters and information far quicker than they could achieve by themselves.

Although this book series deals with materials modeling, it is of course very important to always keep **experimental inputs** in mind. The only theory of all those mentioned above that is known to be exactly correct at all relevant levels of accuracy needed for materials modeling are the Schrödinger/Dirac equations (which as noted are not practically usable for materials). All higher levels involve approximations, and sometimes also assumptions. Due to the rapid emergence of complexity in materials modeling when going up from a single atom, the accuracy of the higher-level methods is difficult to assess from theory alone. Hence it is crucial to utilize the available experimental knowledge and data for formulation and testing of the higher-level models. When the models develop, it is also natural to formulate and perform well-defined experiments that can be used to test the models. ▶ Chapter 102, "Experimental Validation of Models: *In Situ* TEM for Radiation Damage," by Arakawa and Short, deals with the experimental validation of models of radiation damage by *in situ* transmission electron microscopy experiments as an exemplar of how to elegantly confirm key simulations of radiation effects in materials.

4   Conclusion

In conclusion, this introductory article has presented an overview of the physics of radiation effects in solids, as well as the perhaps most widely used models for studying them. The aim was solely to put the following articles into a perspective and indicating how the different levels of modeling contribute to the whole.

More Efficient and Accurate Simulations of Primary Radiation Damage in Materials with Nanosized Microstructural Features or Ion Beams

97

Ju Li, Yang Yang, and Michael P. Short

Contents

Abstract

Primary radiation damage, resulting from the direct ballistic collisions of energetic particles with matter, is the starting point for all of radiation damage. It has traditionally been simulated using binary collision approximations (BCA) Monte Carlo (MC) method in bulk or layered materials, which has served the community well until now. The introduction of nanosized features into materials, whether as 0D dispersoids to pin grain boundaries, 1D dispersoids for removal of helium and sinking defects, or other nanosized features, introduces major errors into conventional bulk/multilayer BCA-MC simulations. This is due to an inability to simulate the exchange of ions at internal/external phase boundaries and the creation of struck atoms with ranges larger than or comparable to the

2381

smallest microstructural feature. We first review the fundamentals of BCA-MC simulations with continuous electronic slowing down for energetic ions, followed by identifying where the traditional approaches fail, and ending with a new full-3D simulation capability to correctly model such features. Such simulations drive the planning and interpretation of radiation exposure campaigns, ion implantation, ion modifications, and even the basic definition of radiation damage. A comparison to more accurate but computationally more expensive, molecular dynamics (MD) simulations of radiation damage will be discussed.

1   Introduction to Primary Radiation Damage

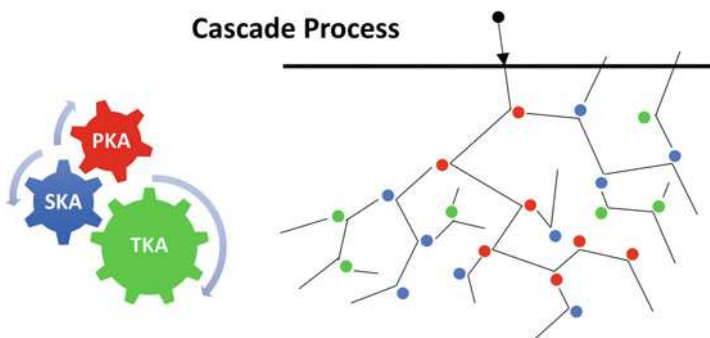
Radiation damage, by nature, refers to permanent atomic displacements in solid matter caused by energetic particles, including neutrons, charged particles (e.g., electrons, protons, and α particles), and photons. During the interaction between radiation and solids, a series of atomic displacements may arise, creating damage in materials that impacts their material properties. For example, energetic particles create abundant vacancies and interstitials in materials that may lead to swelling (Short et al. 2015) and embrittlement. Understanding the interplay between radiation and matter is vital not only for designing materials and systems with improved radiation damage tolerance, but also for creating novel devices by defect engineering (Yang et al. 2018a). Atomic displacements start as primary damage, on a timescale of femtoseconds, with the phase known as "primary radiation damage" lasting roughly ∼10 ps until all atoms ballistically come to rest. Figure 1 illustrates the primary damage process where a series of knock-on atoms are generated: primary knock-on atoms (PKAs), secondary knock-on atoms (SKAs), tertiary knock-on atom (TKAs), and so on. Once the kinetic energies of the incident ions and all the knock-on atoms are low enough (usually much lower than the threshold displacement energy (Crocombette 2005)), then primary radiation damage is said to be complete.


Fig. 1 Illustration of the PKA/SKA/TKA during the radiation damage cascade process. Once all knock-on atoms come to rest, then the radiation damage cascade, known as "primary radiation damage," is complete

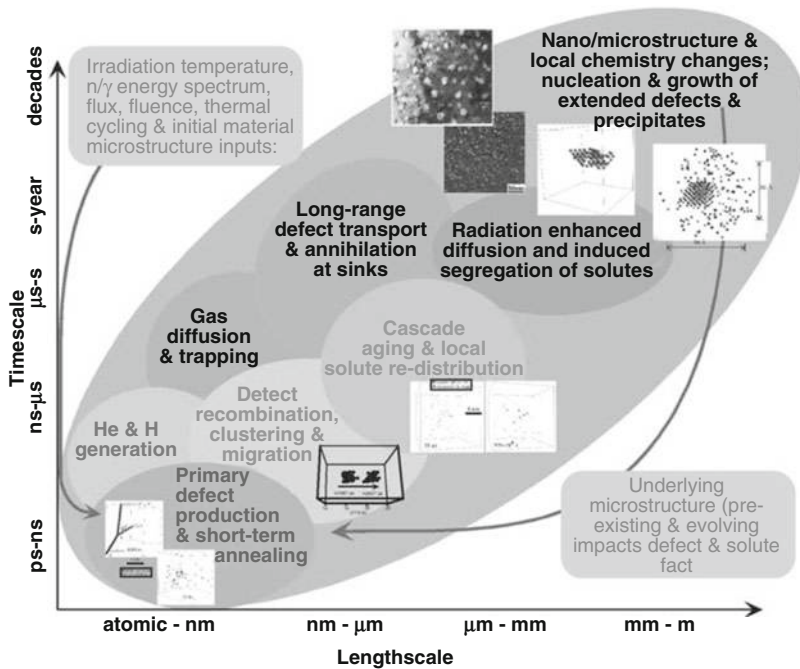
A PKA is born when an incident energetic particle bombards a native atom of the material, transferring kinetic energy T to the native atom above its threshold displacement energy E_d. Multiple PKAs ("generation 1") can be created by the same energetic particle ("generation 0"), and these can be considered the generation-1 leaves of the generation-0 root node of a collision cascade tree. A SKA("generation 2")/TKA ("generation 3")/ . . . is generated by collisions between a PKA/SKA/ . . . and a native atom with the same energy threshold criterion. The whole process is called a "cascade" and terminates when the kinetic energy of every struck atom is below its displacement threshold energy. Rigorously speaking, PKAs, SKAs, TKAs, etc., are not mutually exclusive, since a native atom can in principle be first displaced by an external particle, settle down, and later become displaced by another SKA, although such probabilities are exceedingly small. Along with the cascade process, there is spontaneous recombination (athermal process) which happens below the timescale of picoseconds (Li et al. 2015). Above that, the defects generated will migrate and interact with each other as well as dislocations and different microstructural damage sinks, leading to microstructural evolution and modification of bulk-scale material properties. The time and length scales of these interactions are outlined in Fig. 2. Radiation damage in materials is an inherently multiscale, multiphysics problem (▶ Chap. 96, "Modeling of Radiation Damage in Materials: Best Practices and Future Directions").


Fig. 2 Illustration of the length and timescales (and inherent feedback) involved in the multiscale processes responsible for microstructural changes in irradiated materials (Odette and Wirth 2005)

Neutrons are the main source of atomic displacement damage in nuclear reactors. Although transmutation can create charged particles such as alpha particles in reactors, this is considered as a second order effect (Woo 2005). A neutron may interact with atoms in multiple ways: elastic scattering (n, n), radiative capture (n, γ), inelastic scattering (n, n'), fission (n, f), and charged particle emission (Yip 2014). Among these mechanisms, elastic and inelastic scattering are the main ways to transfer kinetic energy to target atoms. By contrast, a charged particle may interact with materials in four different ways: (a) elastic collision with electrons, (b) inelastic collision with electrons, (c) elastic collisions with atomic nuclei, and (d) inelastic collisions with atomic nuclei (Yip 2014). (b) and (c) are the main driving forces to stop the transport of charged particles, while (d) is often called "bremsstrahlung" and only becomes prominent for charged particles at very high energy. In BCA-MC simulations, it is often assumed that (a) will only change the kinetic energies of charged particles, while it has no effect on the speed direction. In this context, (c) is the leading term for changing the direction of charged particles and creation of atomic displacements in materials.

In this chapter, we will only focus on the simulations of primary radiation damage. These atomic-scale simulations provide details of the displacement process as well as input parameters for larger scale simulations. These are used as direct inputs for longer timescale models of defect migration, clustering, elemental segregation or dealloying, and evolution of microstructure, mechanical properties, and thermal, electronic, and magnetic properties of irradiated materials. For example, primary radiation damage simulated by BCA-MC codes is used as input for point kinetics simulations of radiation-induced void swelling (Short et al. 2015), MD simulation of the re-dissolution of Xe fission gas bubbles in uranium dioxide (Schwen et al. 2009), cluster dynamics simulations of nanoscale defect agglomeration (Xu et al. 2012), and so on. Also, it is often required in the planning process of irradiating materials for performance analysis, and its high importance is underscored by being the root of all follow-on simulations. Thus, it is critical that these simulations are as accurate as possible, for as many types and forms of materials as possible. The reader is referred to all other chapters in this part of the Handbook for more information about the subsequent stages of radiation damage and the best practices with which to model them.

2 BCA-MC Simulations of Primary Radiation Damage under Ion Irradiation

In this part of the chapter, we will briefly review what BCA-Monte Carlo (BCA-MC) simulations are, followed by examples of current methods and codes to carry them out, and concluding with the common shortcomings of non-full-3D simulations. This will set the stage for the required modifications to BCA-MC models to accurately model radiation damage in certain types of irradiation scenarios – those with nanosized features (in target materials or/and incident radiation beam) smaller than or comparable to the mean free path of the ionizing radiation.

Generally, there are two types of BCA simulations for ion irradiation, classified by the assumption of target structure: (1) crystalline structure, simulated by codes such as MARLOWE (Robinson and Torrens 1974); (2) amorphous structure, simulated by codes such as SRIM/TRIM. The latter is simpler and more computationally efficient, and has been more widely used in the past decade. In the following text we will focus on BCA-MC codes based on the random phase approximation (RPA), assuming the target is in amorphous structure. MC simulations based on BCA models are robust methods to understand the detailed cascade process of primary radiation damage (Gilmer and Yip 2005). A BCA-MC simulation tracks all collision events along the trajectories of incident ions. The trajectory of each ion is called a "history." By computing random trajectories of incident ions (usually about 10^4–10^8 atoms), a MC simulation presents statistically meaningful data about the spatial distribution of the injected ions, primary radiation damage in the form of Frenkel pair defects, and energy deposition. The histories of the incoming neutrons and photons ("generation 0") are often modeled using MCNP (Briesmeister 1986), Geant4 (Agostinelli et al. 2003), and so on, while for incoming ions (generations-1 and above, considered native) the most famous and widely used tool is TRIM/SRIM (Ziegler et al. 2008). This chapter will focus solely on modeling ion-matter interactions, as the damage and defects produced by neutrons and photons are so sparse compared to ions (typically millimeter to centimeter between events, owing to far lower cross sections) that very different methods must be used. Note that in accelerator tests, the external ion accelerated by the accelerator is also considered "generation 0," whereas the displaced native ions are considered generation 1 and above.

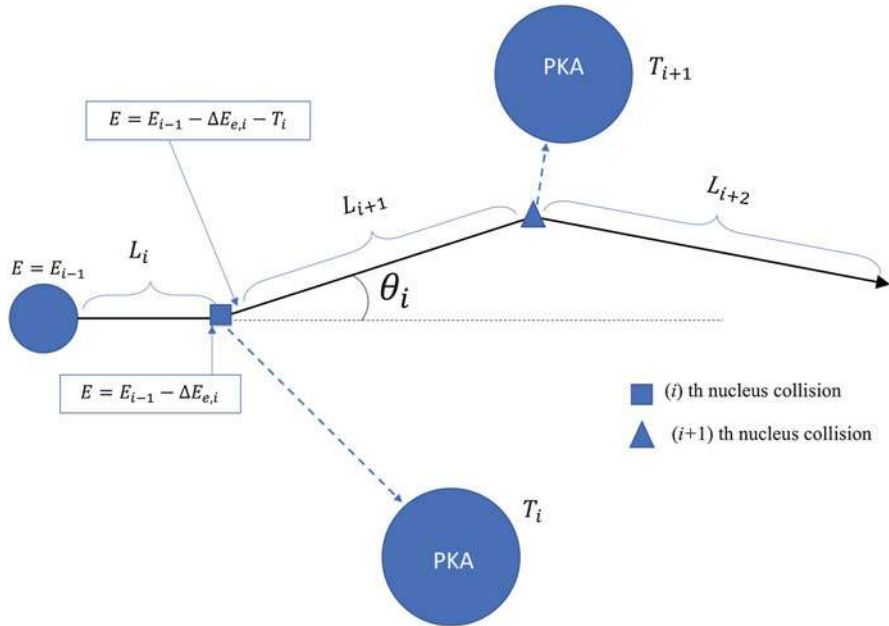
Assumptions are vital for the simplification of the full breadth of interactions to make the physical process more easily computable. Most simulation frameworks to compute primary radiation damage make these same assumptions, so they will be introduced as a common starting point for understanding the simulation process. The cascade processes induced by different ions (generations 0, 1, 2, …) are considered to be independent, and only two-body interactions are considered for elastic scattering with target nuclei. The target atom is usually assumed to be stationary before the collision. It is further assumed that ions always travel in straight paths between two binary collisions. The line segment between two successive collisions is called the "free-flight-path," within which only inelastic scattering with electrons contributes to the change in ion energy, known as electronic energy loss. Therefore, the trajectory of each ion is composed of a series of successive free-flight-paths with elastic nuclear scattering, as depicted in Fig. 3, changing the particle's energy and direction. The moving direction of ion can only be changed during an elastic scattering event with a nucleus; thus, it is assumed that electronic interactions change the direction of the particle so little that its direction of travel is essentially unchanged. A particle's history is terminated when it exits the target with zero possibility of reentry, or its energy falls below a pre-defined cutoff energy, which is set depending on the situation being simulated. A proper cutoff energy is important for enhancing the simulation efficiency. The reader is referred to Sect. 6.2.1 in Eckstein (1991) for more details about how to set an appropriate cutoff energy. Bremsstrahlung is usually ignored.


Fig. 3 Schematic of the modeling process. L is the free-flight-path length, $\Delta E_{e,i}$ is the electronic energy loss in L_i, and T_i is the kinetic energy loss during the i-th nuclear collision

A basic algorithm of the BCA-MC simulation modified from (Yang et al. 2018b) is shown in Fig. 4 in the form of pseudocode, to elucidate the general algorithm of BCA simulations while avoiding confusion and unnecessary details. A more detailed program flowchart showing the different treatments of the quick Kinchin-Pease (KP) mode and the full cascade (FC) mode can be found in the documentation of IM3D (Li et al. 2015).

There are four key ingredients which one needs in order to compute in a BCA-MC simulation, which are the free-flight-path length (L), the stopping power (determines $\Delta E_{e,i}/L_i$), the scattering angle θ_c (determines the direction of L), and the nuclear scattering energy loss (T_i). The reader is referred to existing references for the calculation of many of these parameters, such as the introduction of the algorithms in TRIM (Biersack and Haggmark 1980), a review of the computer simulation for ion-solid interactions (Eckstein 1991), textbook of SRIM (Ziegler et al. 2008), and recent corrections of stopping powers in the case of high-Z ions damaging low-Z materials (Jin et al. 2014). It is the chosen of the ion-matter interaction models and the numerical methods that differ between legacy and newer BCA-MC simulations. These differences manifest themselves not only in the sampling methods for the free-flight-path length L and the impact parameter P (Biersack and Haggmark 1980) according to the ion and target properties but also

in computational approaches to efficiently evaluate scattering angles and stopping powers. Below we briefly review different schemes based on these two aspects, so the reader can appreciate what has evolved in the past decade.

TRIM/SRIM (Biersack and Haggmark 1980; Ziegler et al. 2008), the most widely used tool for BCA simulations, uses semi-empirical relations to compute the electronic and nuclear stopping of ions and struck atoms. These take root in "reduced energies" (ε), by which the physical model of the ion-matter interaction is chosen. The ion energy space is further divided into three regions (low, intermediate,

and high) or four regions (very low, low, intermediate, and high), with each region assigned a unique set of semi-empirical equations for the evaluation of the impact parameter P, the free-flight-path length L, and the electronic stopping power S_e. The impact parameter P is sampled using this reduced energy, which changes its form depending on whether the ion's energy is low, intermediate, or high by assuming hard sphere collisions, a random nonlogarithmic impact parameter, or a random natural log-based impact parameter, respectively. The electronic stopping power in the early version of TRIM (Biersack and Haggmark 1980) is described by two different sets of semi-empirical relations based on different physical models in the low and the high energy regions, while in the intermediate energy region an interpolation method is used. For the ease of computation, fitting formulas for the electronic stopping power are used. A later version of SRIM provides a stopping power database using experimental results, containing over 28,000 stopping values (Ziegler et al. 2010). The scattering angle θ_c relies on the chosen interatomic potential and the impact parameter P as sampled. A key challenge here is the computationally heavy evaluation of the scattering integral (Eckstein 1991), for which various numerical recipes are applied in different codes, such as the so-called "MAGIC" fitting formula in SRIM/TRIM (Biersack and Haggmark 1980), Gauss–Legendre and Gauss-Mehler quadratures reviewed in Ref. (Eckstein 1991), the latest "fast indexing" approach in Corteo (Schiettekatte 2008), and IM3D (Li et al. 2015). In terms of the free-flight-path length L, a random impact-parameter-dependent $L(P)$, a constant L equal to the mean atomic distance in the target, or a randomly energy-dependent $L(\varepsilon)$ is applied at low, intermediate, and high energies, respectively. Two newer frameworks, Corteo (Schiettekatte 2008) and IM3D (Li et al. 2015), sample L over all energies according to a Poisson distribution, with a random inverse-logarithmic sampling of the impact parameter different from that found in SRIM. Otherwise, the basic physics of the older and newer frameworks are quite similar.

One of the major variations among the legacy and newer BCA-MC simulations is the assumption of beam shape and target geometry. SRIM/TRIM, for example, assumes a point incident beam (or "pencil beam") with bulk/multilayer target. The newer codes, however, enable the consideration of arbitrary beam profile (shape and size) as well as 3D target morphologies. The frameworks that is restricted out of the full-3D scope break down in the case of nanoscale microstructural features and radiation beams, or more generally speaking whenever ions encounter features in either the beam or the target that are close to or smaller than the mean free path of the ions. In these cases, codes like SRIM, which can only model bulk or multi-layered materials, fail to account for ions which laterally exit/enter any phase boundary and for a nanoscopically focused beam. This can result in a gross overestimation of primary radiation damage in nanosized features, whether in a radiation mask with pinholes (Bayn et al. 2015), lone carbon nanotubes, microsized mechanical test specimens, oxide dispersion strengthened (ODS) particles, or any other submicron features in materials (Yang et al. 2018a). Thus, more advanced features must be added to BCA codes to accurately simulate primary radiation damage. It should also be noted that complexity often hinders performance, so such features must be added while keeping computational efficiency in mind.

3   The Necessity of Full-3D BCA-MC Simulations

While SRIM/TRIM can perform 3D simulations, it is based on several assumptions on the beam profile and target structure. First, the beam source is assumed to be a pencil beam, meaning that ions enter the target via a single point on the surface of target all with identical velocities. Second, the target is at most a multilayered structure with interfaces perpendicular to the longitudinal (i.e., depth) direction, indicating no physical boundaries in the lateral directions. Its 1D output is the most widely used for engineering purposes. If the defect distribution in 3D has a functional form of $F(x, y, z)$, then the 1D output along depth direction z is computed by:

$$f(z) \equiv \iint_{-\infty}^{\infty} F(x, y, z)\, dx dy \tag{1}$$

$f(z)$ ignores the lateral straggling of ions, which usually ranges from a few nanometers to a few microns. However, it works as a good approximation for the traditional bulk scale experiments, where both the ion beam and the target size are larger than tens of microns (Yang et al. 2018a). Recently, nanoscale ion implantation (nanosized ion beam or target, or both) has drawn expanding interest, facilitating the fabrication of novel devices, such as quantum computers (Shinada et al. 2005; Bayn et al. 2015), magnetometers (Maletinsky et al. 2012), nanowire p-n junctions (Hoffmann et al. 2009). An excellent review about the progress (before 2011) of engineering 0D or 1D nanomaterials using ion radiation has been provided by Krasheninnikov and Nordlund (2010).

3.1   Examples Where Full 3D BCA Simulations Are Required

Because of the breakdown of several key assumptions, these traditional restricted 3D simulations as well as their 1D outputs may be misused, leading to significant errors when predicting defect distributions. Three nanosized effects of ion radiation for MC simulations have been reported, namely, the nano-beam, nano-target (Yang et al. 2018a), and nano-energetic effects (Li et al. 2015), calling for full-3D simulations. The difference between nano-beam and nano-target experiments is illustrated in Fig. 5a.

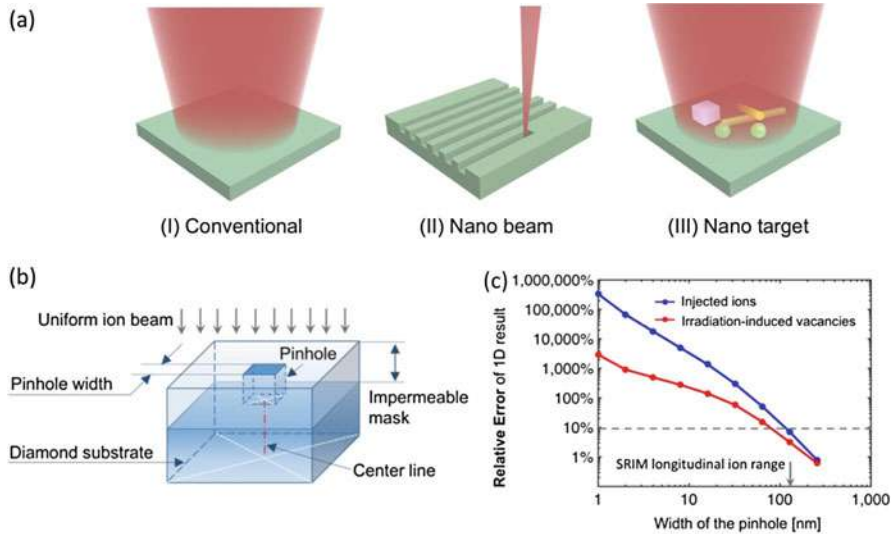
   The nano-beam effect arises where the beam size is small and thus the assumptions of 1D output, especially the pencil beam assumption, lose validity. This effect has important implications in nanofabrication, where precision and accuracy relies heavily on beam size. Advanced implantation systems (Watt et al. 2007; Tan et al. 2011; Economou et al. 2012; Yao et al. 2013; PEKIN et al. 2016) and implantation masks with nanoapertures (Pezzagna et al. 2010, 2011; Toyli et al. 2010; Bayn et al. 2015; Scarabelli et al. 2016) have been extensively developed to precisely control the width and position of ion beams. Examples include MeV proton beams with a beam-width below 14 nm (Yao et al. 2013) and silicon masks with pinholes for the creation of nitrogen-vacancy color centers (Bayn et al. 2015). The relative error of the 1D output of TRIM/SRIM in the application of nanosized ion-beam has been


Fig. 5 (**a**) Schematic illustration of the difference between a conventional bulk-scale experiment, a nano-beam experiment, and a nano-target experiment. (**b**) Schematic diagram of the NV center creation experiment. (**c**) Relative error of the 1D output by SRIM compared to the full-3D simulation. Reproduced from Ref. (Yang et al. 2018a) with permission from The Royal Society of Chemistry

quantified using an example of implanting $^{15}N^+$ ions into diamond for the creation of NV centers (Yang et al. 2018a), as shown in Fig. 5b, c. In this case, the effective beam width is equivalent to the width of the square pinhole in the silicon mask. It is shown that the relative error of the traditional 1D output increases dramatically as the width of the pinhole decreases. A full-3D simulation is required to take into account the beam shape information (i.e., the 2D ion density distribution at entrance).

The nano-target effect, on the other hand, becomes prominent when the target size is small, leading to the breakdown of both the pencil beam and multilayer target assumptions. SRIM/TRIM ignores heterogeneity in the lateral directions, failing to consider ion exchange at physical boundaries of the target. Here we take implantation in nanowires as an example (see Fig. 10), which can be used to make nanowire-based devices such as p-n junctions (Hoffmann et al. 2009) and mechanically test ion-irradiated samples (Liontas et al. 2014). The traditional restricted 3D simulations and 1D output are incapable of considering ion leakage from surfaces, overestimating the defects accumulated in the nanowire. Meanwhile, as the target size shrinks, the shape of the defect distribution evolves accordingly, with its peak shifting to a shallower place (Yang et al. 2018a), as shown in Fig. 6b, c.

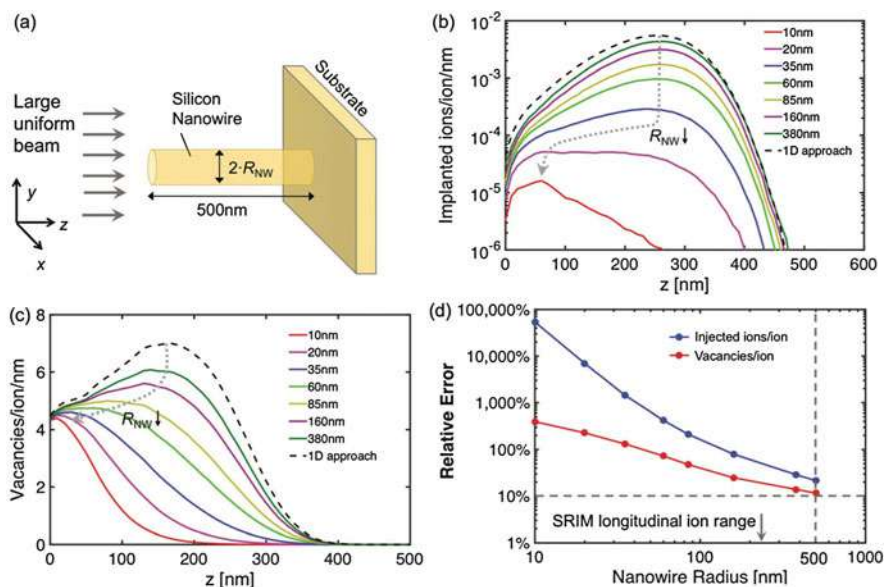
Another example of the nano-target effect is shown in Fig. 7, where the sputtering yield of spherical Au nanoparticles under the irradiation of Ar^+ and Ga^+ is shown to be enhanced when the nanoparticle radius is small (Holland-Moritz et al. 2015) by *iradina* (Borschel and Ronning 2011) simulations, in agreement with experimental


Fig. 6 (**a**) Schematic diagram of the head-on ion implantation experiment. (**b**, **c**) Distribution of point defects along *z* axis as the nanowire radius decreases. results. The enhanced sputtering in nanostructures can be attributed to a large surface-to-volume ratio which allows more ions to exit the target, as illustrated in Fig. 7c, d. Figure 7a, b shows the energy dependence of sputtering yield in bulk and Au nanoparticles, whose diameter follows a Gaussian-shaped distribution with a mean size about 56 nm. Figure 7e, f shows the effect of nanoparticle size on the sputtering yield. The bulk-scale simulation is found to significantly underestimate the sputtering yield, while failing to predict the diameter of the nanoparticle that yields the most sputtering.

The nano-energetic effect is related to the loss of validity of bulk physical parameters at small scales due to quantum confinement, surface stress, and elastic image interactions. These fundamental parameters include electronic stopping power and the threshold energy, which could depend on the sample size. The number of athermal recombinations (Nordlund et al. 2018) could have an even stronger dependency on the size and geometry of the sample, since the sample surface and interfaces provide different venues for knock-out and recombination compared to the bulk. Figure 8 shows an example of the nano-energetic effect for the ion implantation of Ar into 3–4 nm diameter GaN nanowires. It is known that both the Kinchin–Pease (KP) and full-cascade (FC) modes in SRIM-like MC codes will over-estimate vacancy creation in solids (Stoller et al. 2013); therefore, it is particularly surprising that MC methods underestimate vacancy creation for the nanowire implantation cases, if bulk physical parameters are used (see the difference

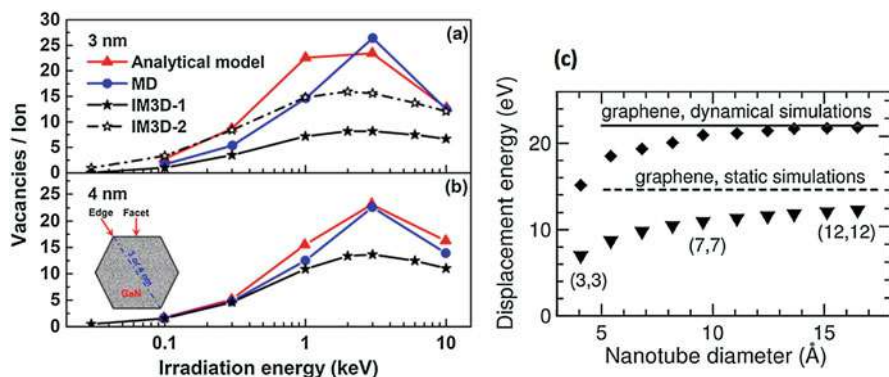
between MD and IM3D-1 in Fig. 8). By reducing the displacement threshold energy by half, the result of MC simulation (IM3D-2 in Fig. 8) agrees better with that of MD. Comparing Fig. 8a, b, it is also found that the nano-energetic effect is less prominent when the size of nanowire increases. The reader is referred to the supplementary document in Ref. (Li et al. 2017) for more details about this nano-energetic effect. Another example is shown in Fig. 8c, where researchers found the displacement energy of carbon nanotubes has a dependence on the diameter (Krasheninnikov and Nordlund 2010).


Fig. 8 Illustration of the nano-energetic effect. (**a**, **b**) The difference between IM3D-1 and IM3D-2 is that the former adopts the bulk energy thresholds, while the latter adopts half values of the bulk thresholds. Figure reprinted from (Li et al. 2015) with permission. (**c**) Dependence of the displacement energy on the carbon nanotube diameter (Krasheninnikov and Nordlund 2010)
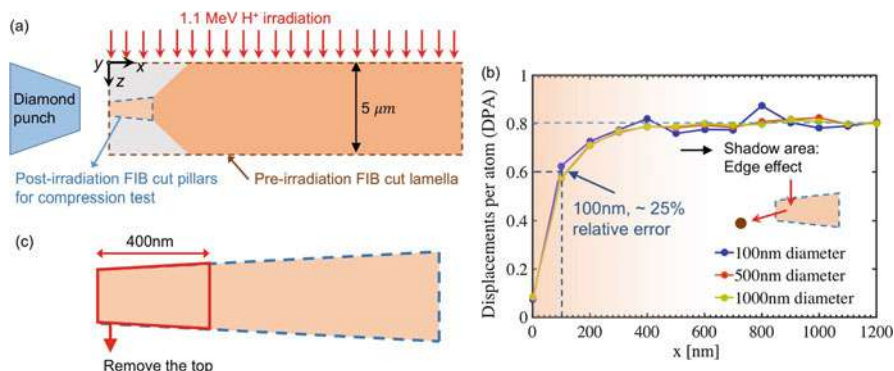

Fig. 9 (**a**) Schematic drawing of the experimental setup. (**b**) Radiation damage as a function of the distance to the edge along *x* axis. (**c**) Schematic drawing about the removal of the top of the pillar (Yang et al. 2018a)

Although the nano-beam and nano-target effects can be simulated conveniently in full-3D simulation codes such as IM3D, the nano-energetic effect requires corrected physical parameters usually obtained by MD/DFT simulations. It is recommended to consider the nano-energetic effect when the characteristic length of the target is below 20 nm, as the thermodynamic properties vary less sensitively with object sizes above 20 nm (Li et al. 2015 and 2017).

In addition to the three nanosized effects above, researchers also found an "edge-attenuation" effect and a "surface roughness" effect that require full-3D simulations, although their beam/target sizes or surface features are comparatively large. The "edge-attenuation" effect should be considered when the edge of the target is important during a traditional bulk-scale experiment. Figure 9 shows an example

(Yang et al. 2018a). Because ion radiation has very limited penetration capability, one has to perform small-scale mechanical experiments to understand the radiation hardening effect of ion irradiated samples. Researchers first irradiated a 5 µm thick Cu thin film by 1.1 MeV protons and then used a focused ion beam (FIB) to cut a small pillar at the edge for small-scale mechanical experiments, as illustrated in Fig. 9a. It is vital for the pillar to have a uniform distribution of radiation damage. However, a full-3D simulation performed in IM3D revealed that there is an "edge attenuation" of radiation damage along the x axis from the inner to the edge. Therefore, one should remove the top (i.e., from the $x = 0$ to 400 nm) to avoid uneven radiation dose distributions in the pillar. This is an absolutely critical finding for those undertaking microscale compression pillar irradiation experiments, as without these 3D BCA-MC simulations this effect would not have been discovered and would have continued to alter the consistency of microcompression experiments under irradiation compared to bulk experiments.

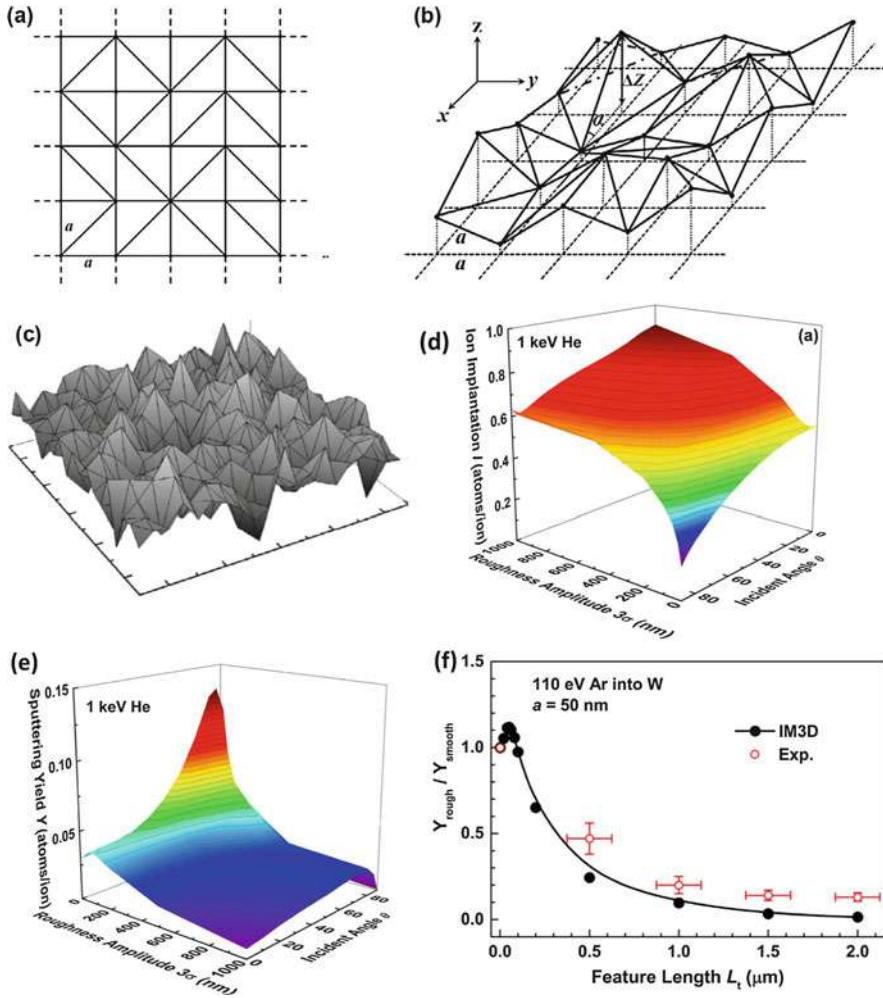
The "surface roughness" effect has important implications in the study of ion-surface interactions. For example, in fusion reactors, the plasma facing materials (PFMs) suffer from the impact of low energy (10–1000 eV) and high fluence (up to 10^{24} particles/m^2-s) D/T/He ions, which lead to sputtering and ion retention (Nordlund et al. 2014). The surface morphology of PFMs can be modified by the plasma. As a result, a series of surface features are formed, including fuzz (Baldwin and Doerner 2010) and surface blisters (Wang et al. 2001). Surface roughness evolution will in turn have a significant effect on sputtering and ion retention. Traditional SRIM/TRIM is only designed for bulk targets with smooth, nonevolving surfaces; thus, it will fail to predict this surface roughness effect. Previously, simulation codes based on fractal surface geometry models, such as VF-TRIM (Ruzic 1990), ACAT (Kenmotsu et al. 2005), and ITMC-F (Hu and Hassanein 2012), have been developed to understand this effect. Recently, a rough-surface geometry model based on finite element triangular mesh (FETM) method has been developed using the IM3D framework (Li et al. 2017). Since the FETM method is simpler and more realistic than the fractal model in terms of validation with experimental atomic force microscopy (AFM) images, here we will only introduce the former. In the FETM model, the surface is first divided into square pixels with a side-length of a and then subdivided into triangles by randomly selecting one diagonal of each pixel, as shown in Fig. 10a. The height Z of each point in the mesh is sampled using a truncated Gaussian distribution $f(Z) \propto \exp(-Z^2/(2\sigma^2))$, where $Z \in [-3\sigma, 3\sigma]$. Therefore, the surface roughness can be adjusted conveniently and intuitively by controlling the surface roughness amplitude 3σ and square mesh size a. The primary ion retention and sputtering yield as a function of surface 3σ and ion incident angle are shown in Fig. 10d, e. It is found that as the surface roughness increases, the primary ion retention will increase while the sputtering yield will decrease. A comparison of the experiment and IM3D simulation is provided in Fig. 10f, showing significant improvement of sputtering yield by making the surface smoother. However, it is surprising that the highest sputtering yield occurs before the surface roughness reaches zero, indicating an optimum surface roughness leading to the highest sputtering yield.


Fig. 10 (a–c) Schematic illustration of the surface roughness generated by the FETM method. Dependence of the ion retention (d) and sputtering yield (e) on the roughness amplitude and incident angle (1 keV He → W). (f) Effect of the surface roughness on the sputtering yield and validation of the IM3D simulations (1 keV He → W) (Li et al. 2017)

3.2 3D Geometry Representation and Ray Tracing in Full-3D BCA-MC Simulations

A key step in full-3D simulation is to build the 3D structure of target. It is significant for the "language" of 3D geometry description to be general and flexible. Also, during the simulation, after sampling the free-flight-path L to travel in the next step, one should determine if the projectile will enter another material or not during the

path L. If a boundary is crossed, the electronic energy loss will need correction because the free-flight-path L covers regions of different materials with different stopping capabilities. Such treatment is involved in the process called "particle tracking" or "ray tracing," and its method varies in different codes. For example, in IM3D (Li et al. 2015), the program follows a similar methodology to CD-SEM (Li et al. 2008). It calculates the sub-free-flight-path length L_i (where $L = L_1 + L_2 \sim + L_i \sim + ... + L_n$, and L_1 is the distance to the closest boundary along the direction of the ion's path at the starting point of L) in each region covered by L, according to the electronic stopping power ratios between different regions. The total electronic energy loss is corrected accordingly. Besides, the FETM module in IM3D accounts for refraction at each interface, *i.e.*, change of flight path direction due to entering different materials. In *iradina* (Borschel and Ronning 2011), the correction of electronic stopping is ignored because their free-flight-paths and ion energies are so small that nuclear stopping is the dominant mechanism of energy loss. In neutron transport simulation codes such as OpenMC (Romano and Forget 2013; MIT 2011), the free-flight-path is updated to be the distance to the closest boundary, followed by moving the ion to the intersection between the boundary and the free-flight-path, and then re-sampling L using the new material's properties. The readers are referred to Chap. 8.3 of Bielajew (2001) for details about the treatment in such neutron simulations. The selection of the 3D geometry representation model and the ray-tracing method are closely related. Here we will briefly introduce two kinds of 3D geometry representation methods with some common practices of ray-tracing.

1. The voxel method. First define the whole target space as a rectangular box, then subdivide it into equal-sized rectangular voxels (cells). Each cell is assigned to a pre-defined material, which may be a vacuum. In this case, a curved surface is approximated by a stepped surface. The progression of the ion along a path L is composed of a sequence of finding the intersection of rays with the next surrounding voxel, followed by moving the ion to the next voxel until the entire path length L is finished or a "boundary crossing" event occurs. A "boundary crossing" event means that the path L passes though voxels of different materials. The simulation accuracy of these methods increases with the number of voxels, while the computation load increases at the same time. Note that there is a lower limit of the voxel size in TRI3DRYN because of the consideration of dynamic evolution (Möller 2014). The voxel method has the advantage of easy implementation of dynamic evolution. For example, the formation of voids in the bulk can be simulated by reducing the density of certain voxels through some preset criteria. However, the voxel method may lead to unavoidable artifacts. For instance, when predicting the sputtering yield of the stepped planes, ions that have exited may re-enter and create further unphysical sputtering/cascades. Also, there is still a lack of understanding about the correction of electronic stopping power at the step edges (Li et al. 2015). Last but not least, domain size adaptivity and scaling issues should also be considered (Borschel and Ronning 2011; Möller 2014), adding to the complexity of simulations.

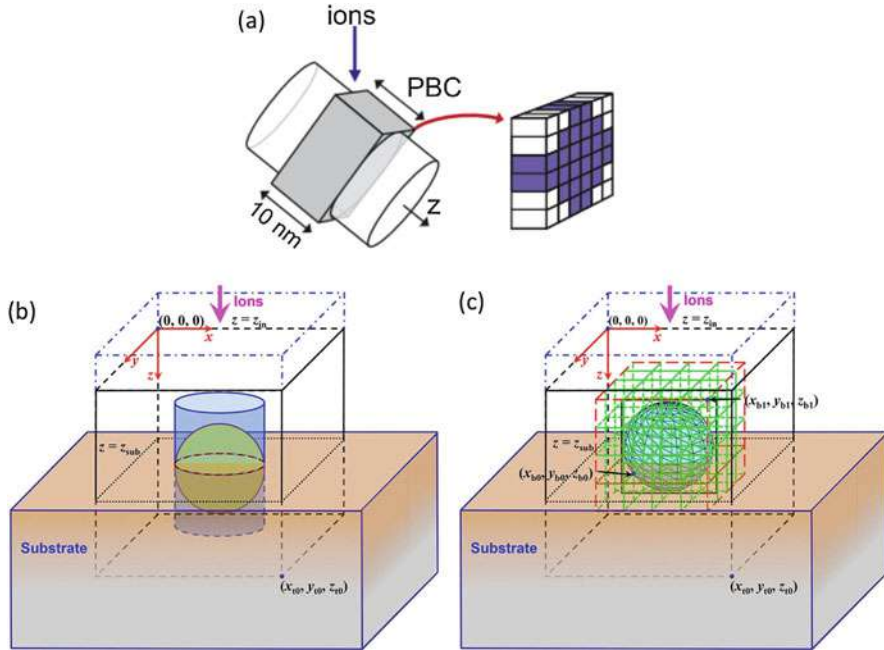
2. The surface method. The 3D structure is constructed by defining the surfaces of the target in real-space (x, y, z) using mathematical (vector) descriptors. For example, the vector descriptor for the surface of a spherical nanoparticle centered at the origin with radius R is $x^2 + y^2 + z^2 = R^2$. If an ion is at position (x_0, y_0), then $x_0^2 + y_0^2 + z_0^2 < R^2$, $x_0^2 + y_0^2 + z_0^2 = R^2$ and $x_0^2 + y_0^2 + z_0^2 > R^2$ means the ion is inside the nanoparticle, at the surface of the nanoparticle and outside the nanoparticle, respectively. Suppose an ion bombards an atom at (x_0, y_0), after which the new speed of the ion is $\vec{v} \equiv (u, v, w)$. We then sample the distance to travel next with a result of L. To determine if the ion will enter or exit the surface, one should first compute the minimum distance to the surface of the nanoparticle using (x_0, y_0) and $\vec{v} \equiv (u, v, w)$ as $d = -\Lambda \pm \sqrt{\Lambda^2 - \varpi}$, where $\Lambda = x_0 u + y_0 v + z_0 w$, and $\varpi = x_0^2 + y_0^2 + z_0^2 - R^2$. If there is no real solution, it means that the ray will never intersect the sphere, no matter how large L is. If $\varpi < 0$, the ion is inside the sphere at the beginning, so there will be two solutions (one positive and one negative). If $\varpi > 0$, the ion is outside the particle; thus, the solutions are both positive or negative. If $L > d > 0$, a "boundary crossing" event will occur. When the target structure is more complicated, more surfaces (mathematical descriptors) are required. If there is more than one surface, one should compute the minimum distance to each surface along the ray and sort them in order to identify the sequence of surfaces that the ion will intersect along the path L. There are several ways to construct arbitrary target structures using the surface method, here we will just briefly introduce two of them: the constructive solid geometry (CSG) method (Li and Ding 2006) and the previously introduced FETM method (see Sect. 3.1) (Zhang et al. 2012). IM3D supports both the CSG and the FETM methods. The CSG method constructs the complicated target surfaces by Boolean operations on simple geometries (such as the sphere, tetrahedron, cuboid, ellipsoid, and taper). These operations include union, difference, and intersection. Therefore, for simple nanostructures such as nanoparticles or nanowires, it provides the best balance between convenience and accuracy. The reader is referred to the documentation webpage of OpenMC (MIT 2011) for details about the CSG method. The FETM method, on the other hand, is more suitable for building arbitrarily complex structures. The triangular mesh for a complicated structure can be easily generated by programs such as Gmsh (Geuzaine and Remacle 2009). Also, triangular mesh enables easier determination of intersection points of a straight line with surfaces. The FETM method is further aided by a spatial subdividing technique (Li et al. 2008) to avoid the computation of intersections with all triangular meshing surfaces. Only the surfaces contained in the cubes along the path L are considered for such intersection searching and distance computation. For complicated geometries, the number of times for finding the intersection points with surfaces on a free-flight-path L using the FETM method is usually much smaller than that using the CSG method, leading to a higher computational efficiency. The FETM method can be extended to the finite element tetrahedron method for easier implementation of dynamic evolution in materials during irradiation.


Fig. 11 Schematic illustrations of different geometry construction method: (**a**) voxels (Borschel and Ronning 2011); (**b**) CSG and (**c**) FETM (Li et al. 2015)

The differences between the voxel method and the surface method are illustrated in Fig. 11. Currently, available full-3D MC codes for the simulation of energetic particles in matter include MCNP (LANL 2018), OpenMC (Romano and Forget 2013; MIT 2011), Geant4 (Agostinelli et al. 2003), *iradina* (Borschel and Ronning 2011), TRI3DYN (Möller 2014), IM3D (Li et al. 2015), MyTRIM (Schwen et al. 2009 and 2018), and Corteo 3D (Schiettekatte and Chicoine 2016). The reader is referred to the documentation of these codes for more details about their methods for particle tracing and 3D geometry construction.

3.3 Dynamically Evolving Full-3D BCA Simulation Structures

Under high fluence of ion beam radiation, the target can be modified, leading to changes in the morphology and density in material due to sputtering and relocation of atoms by atomic collisions. A "dynamic" code is designed to take into account this evolution of the target during ion implantation, with well-documented application examples where such dynamic evolution is absolutely necessary to correctly simulate experimental results. Examples include the secondary ion mass spectrometry (SIMS) depth profiling technique, plasma–wall interactions in fusion reactors, and magnetron sputtering for thin film processing. TRIDYN (Möller and Eckstein 1984) (1D simulation) and TRI3DYN (Möller 2014) (full-3D simula-

Fig. 12 Schematic of the voxel types in TRI3DRYN. *Dark blue*, *light blue*, and *white* represent bulk, surface, and vacuum voxels, respectively (Möller 2014)
tion) have been developed to model this dynamic evolution under ion radiation. TRI3DYN uses the voxel method (see Sect. 3.2) for the construction of target 3D structures. Here we will briefly introduce TRI3DYN, for more details please refer to Möller (2014).

In TRI3DYN, the voxels are classified into three types: bulk, surface, and vacuum, as shown in Fig. 12. The neighborhoods of a voxel (say "voxel 1") are classified by the distance between voxel 1 and its neighborhood voxels. There are 6 first neighbors, 12 second neighbors, and 8 third neighbors. A lower limit for the voxel size is set ($\lambda < \min(\Delta x, \Delta y, \Delta z)$), where λ is the mean free path and $\Delta x, \Delta y, \Delta z$ are the size of voxel along the x, y, z directions, respectively, so that the path length L between two successive collisions always ends within the volume that is composed of the 26 first-to-third nearest neighbors. Suppose there are N_c types of component in the material, then the partial atomic density of a component l ($1 \leq l \leq N_c$) in the voxel with spatial index (i, j, k) is $n_l(i, j, k)$. TRI3DYN and TRIDRYN both assume that after the relaxation, a constant atomic volume is reached with the following relation:

$$\frac{1}{n} = \sum_l \frac{q_l}{n_l^0} \tag{2}$$

where n, n_l^0, and q_l denote the total atomic density, a predefined atomic density of component l and atomic fractions of component l ($0 \leq q_l \leq 1$), respectively. With this condition at a relaxed state, one can define a reduced partial density:

$$d = \sum_l d_l = \sum_l \frac{n_l}{n_l^0} \tag{3}$$

where d_l is the partial density of the component l. When $n_l = q_l \cdot n$, a "nominal" density is reached such that $d = 1$. Based on this, $d = 0$, $d > 1$, and $0 < d < 1$

represent "vacuum," "over-dense," and "under-dense," respectively. The simulation procedure is an iteration of the following pseudocode steps:

1. Perform a SRIM/TRIM-like BCA simulation for the cascade resulting from one (default) or more incident ions. Record point defect distributions (interstitial atoms and vacancies).
2. Compensation and recombination of interstitials and vacancies. First, the interstitials and vacancies within the same voxel will recombine. Next, the program will search for neighboring voxels within a predefined recombination radius and enable recombination.
3. Incorporation of the remaining point defects from step (2) into the voxels.
4. Relaxation of the voxels, so that nominal density ($d = 1$) is obtained for each bulk voxel, while the surface voxel is permitted to be under-dense ($d < 1$).
5. "Local surface smoothing" will be performed if this kernel is activated. Examples of smoothing methods are illustrated in Fig. 13.
6. Optionally, adjust the surface layers so that the top two layers are kept a vacuum.

Ion implantation is a popular tool to tailor the composition and morphology of materials (Krasheninnikov and Nordlund 2010; Borschel et al. 2011) and is promising to improve the functional properties of nanostructured materials, such as using Ar^+ to modify the electronic properties of single-wall carbon nanotube (Gómez-Navarro et al. 2005) or single layer MoS_2 (Chen et al. 2018). An example of the simulation by TRI3DRYN is shown in Fig. 14, where P^+ at 10 keV is modifying the morphology and composition gradually. The 3D surface morphology evolution of the nanoparticle (changing from a sphere to pillar) can be well captured by the TRI3DYN simulation.

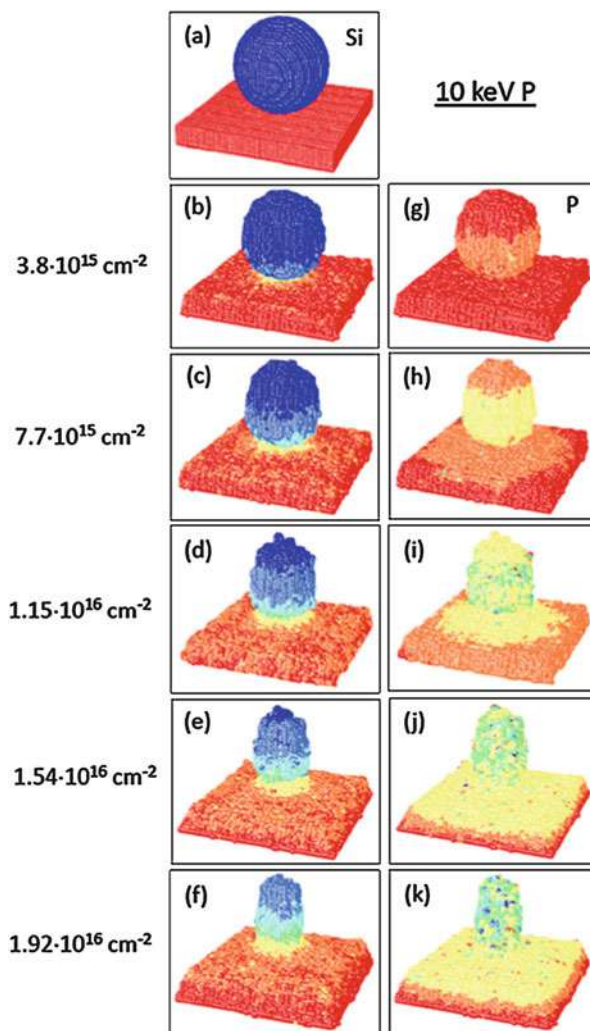
(**a–f**) Si atomic fraction. Color coding: 0.333 (*red*) → 1 (*blue*). (**g–k**) P atomic fraction. Color coding: 0 (*red*) → 0.1 (*blue*) (Möller 2014)


3.4   Maintaining 3D Simulation Efficiency

The usage of full-3D simulations and consideration of dynamic evolution will potentially increase the computational load. The increase of computational time can be 10–10,000× for a 3D target with a complicated surface morphology. Therefore, it is vital to enhance the efficiency of the simulation codes. Here we will briefly introduce the methods adopted in static BCA-MC simulations (such as Corteo and IM3D) for the improvement of computational efficiency.

One of the most computationally expensive parts in the simulation of radiation damage cascade is the sampling of θ_C. Traditionally, this requires one to solve the scattering integral equations, leading to a significant computational load. SRIM uses the so-called "MAGIC" formula to sample the scattering and azimuthal angles for better efficiency. Based on it, a "fast indexing" technique using database evaluation was latter proposed (Yuan et al. 1993) to further enhance the efficiency to about 18 times faster than the "MAGIC" formula. Instead of computing directly from the "MAGIC" algorithm, this method utilizes interpolated tables for the scattering angle $\sin^2(\theta_c)$ and looks up the needed values in the tables. It is worthwhile to note that the table is indexed using the binary representation of floating point numbers so that computing logarithms can be avoided (Schiettekatte 2009). This method also improves accuracy and memory usage. Similarly, one can obtain the electronic stopping power using precalculated tables (generated using "SRModule.exe" (Ziegler 2004)). This "fast indexing" method is now available in Corteo (Schiettekatte 2009), *iradina* (Borschel and Ronning 2011), and IM3D (Li et al. 2015). A comparison of the efficiency is provided in Fig. 15. The readers can refer to Schiettekatte (2009) for more details about this method. In addition, a ray-tracing technique based on the FETM 3D geometry representation and spatial subdivision is introduced in IM3D (Li et al. 2015), boosting the computational efficiency of complex 3D geometry simulations to a level similar to that in bulk simulations.

For a static BCA Monte Carlo simulation, the history of each ion is independent. Therefore, it is well suited for parallel computation. IM3D (Li et al. 2015) in particular is implemented with the Message Passing Interface (MPI) library. Its parallel scaling performance, as shown in Fig. 16, shows a greatly enhanced speed, up to 10^5 faster than SRIM.

3.5   Open Sourcing and Stopping Power Databases

An open source code can greatly facilitate the development of advanced codes, as it allows an open inspection and validation of the underlying algorithms. More and more codes have joined the open-source family, including Corteo (Schiettekatte 2009), *iradina* (Borschel and Ronning 2011), MyTRIM (Schwen 2018), Mat-TRIM (Yang et al. 2018b), and IM3D (Li et al. 2015), etc. One of the main advantages of open-source is that one can easily modify or incorporate new stopping power data into the code. It is known that the accuracy of BCA Monte Carlo simulation codes for ion radiation rely greatly on the accuracy of the stopping power data. Although SRIM has provided a powerful stopping power database (Ziegler 2004), it was recently shown to be inaccurate in several circumstances. For example, for the case of very heavy ions into a light element target, a large discrepancy is shown between the ion ranges predicted by SRIM and experimental results (Behar et al. 1985; Grande et al. 1988; Friedland et al. 1998; Zhang et al. 2009, 2010; Jin et al. 2014) due to errors in the stopping power database. An example of heavy ions into SiC is shown in Fig. 17. Because of this, M-TRIM (Jin et al. 2014) has been developed based on an early version of TRIM (Ziegler et al. 1985) with updated stopping power data for Cl, Br, I, and Au ions into SiO_2 and SiC. The comparison between the ion distribution simulated by SRIM and M-TRIM and the experimental results obtained by Rutherford backscattering spectrometry (RBS) and secondary ion mass spectrometry (SIMS) are shown in Fig. 17a.

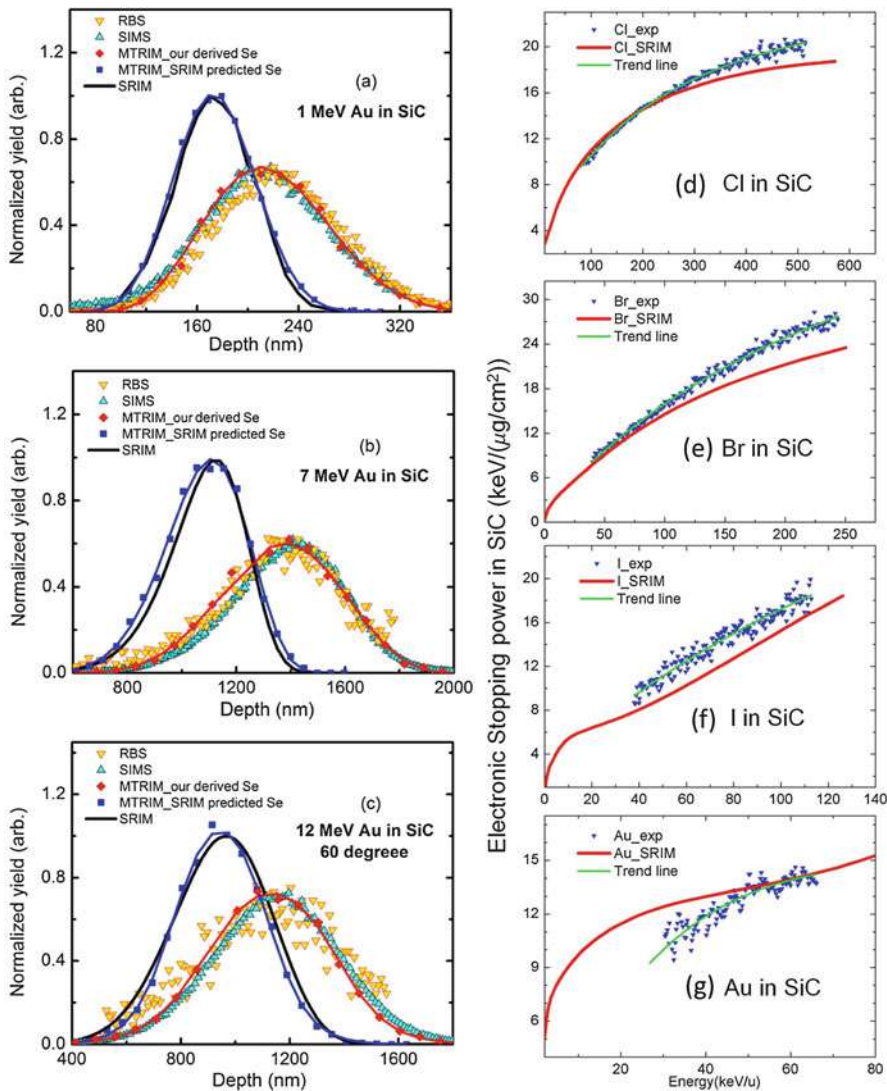
Electronic stopping powers for bulk materials may also need to be corrected for nanostructured materials. Recently, the electronic energy loss for graphene (see Fig. 18) and boron nitride (BN) sheets have been studied (Zhao et al. 2015) using time-dependent DFT. However, there is still a lack of study of the applicability of


Fig. 17 (**a–c**) Injected ion distribution of 1 MeV, 7 MeV, and 12 MeV Au into SiC: a comparison between the simulations and experimental results. (**d–g**) Comparison of the electronic stopping power of Cl, Br, I, and Au into SiC between the experimental results and SRIM database (Jin et al. 2014)

bulk stopping power database in nanostructured systems. Currently, Corteo, *iradina*, and IM3D use the same stopping power tables generated by Corteo using the "SRModule.exe" (Ziegler 2004). Since these codes are open-source, in principle it is possible to generate new stopping power tables. However, there is still a need

Fig. 18 Comparison of transferred energy as a function of proton energy. The target is graphene and the collision site is point C (Zhao et al. 2015)
of a friendly user-interface (UI) that can help generate and conveniently manage the stopping power data for these codes.

4   Comparisons Between MC and Molecular Dynamics (MD)

Radiation damage in nanostructured materials can also be simulated by MD (Jin et al. 2018). Here we will briefly review the difference between MC and MD simulations. MC codes are generally based on more assumptions than MD. MC codes usually only consider two-body interactions and use universal potentials in many cases. Because of its high computational efficiency, MC simulations of ion irradiation serve as convenient engineering tools for the prediction of ion ranges and vacancy/energy-deposition distributions. On the other hand, MD simulations are based on solving equations of motion (Li 2005), which is in general more accurate as they consider many-body interactions and can provide more details about the cascade process; however, MD is much more computationally intense than MC, limiting the time and length scales simulated. It should be noted that the accuracy of MD relies on the accuracy of the interatomic potential used. Also, it has recently been shown that the electronic energy loss should be taken into account in MD simulations, while the majority of MD studies on radiation damage cascades ignore this effect (Rutherford and Duffy 2007; ▶ Chap. 98, "Incorporating Electronic Effects in Molecular Dynamics Simulations of Neutron and Ion-Induced Collision Cascades"). For nanostructured materials whose size is less than the mean-free-path of ions, it was recently shown that electronic stopping is the dominant energy loss mechanism for incident ions (Yang et al. 2018b), indicating the necessity of considering electronic energy loss in MD simulations. The results of MD also depend on the simulation temperature, which is difficult to consider in BCA-MC codes. Almost no BCA-MC simulations consider defect

diffusion and defect-sink interactions (kinetics at longer timescales), while MD simulations more systematically model kinetic processes (especially annealing) in materials if the time and length scales are within computable limits. For instance, previous MD simulations showed that defect production can be greatly enhanced by a large surface-area to volume ratio in nanostructured materials at low incident ion energies (Hoilijoki et al. 2011; Sun et al. 2012), which BCA-MC simulations usually fail to predict. However, the primary radiation damage estimated by MC simulations still has broad and significant engineering implications.

MC simulation is a useful and rapid method to calculate the Norgett–Robinson–Torres (NRT) displacements per atom (DPA), a standardized radiation exposure parameter. The definition of DPA is based on $T = 0$ K MD simulations, using the following procedure: First, give a selective incident particle an initial energy E_0. The particle will collide with multiple atoms in the target until its energy is small enough. Every time when it collides an atom in the lattice, if the kinetic energy transferred to the target atom exceeds the threshold energy E_d, the atom will be knocked out (at $t = t_I \sim$ fs). After t_I, there is spontaneous recombination of the Frenkel pairs if the distance between a vacancy and an interstitial atom is within a certain limit. At $t = t_F \sim$ ps, this athermal dynamic recombination/transient annealing process is finished. After that, long-term defect evolution occurs, which depends on thermal activation.

Among all MC codes, SRIM (Ziegler et al. 2008) is the most widely used for the estimation of DPA because of its powerful stopping power database and its ease of use. SRIM offers two ways for the calculation of NRT DPA: (1) The quick Kinchin–Pease (K-P) mode, where defect production by generation-1 ions are tallied by using the K-P formula instead of explicitly calculated and (2) the full-cascade (FC) mode, where generation-2, -3, -4, . . . ions are also explicitly accounted for by BCA calculations. It has recently been found that the displacements calculated by both modes are significantly larger than the results of MD at ten picoseconds after a PKA when the thermal spike has largely disappeared (Stoller et al. 2013) (Fig. 19a). Also, the displacements by the FC mode are twice of that by K-P mode (Fig. 19a–c). Thus, Stoller et al. questioned the FC mode in SRIM, exposing a fundamental problem in this *closed-source* code. Recently, this discrepancy between K-P mode and FC modes has reproduced by IM3D (Li et al. 2015), a new open-source code.

It is also worthwhile to note that MC codes usually overestimate the number of radiation defects by three times compared to MD, while only capturing 1/30th of the atomic mixing (replacement) events (Nordlund et al. 2018), as shown in Fig. 20a, b. As a result, Nordlund et al. proposed two new complementary displacement production estimators to quantify the radiation damage more realistically: (a) Athermal recombination corrected dpa, namely, "arc-dpa"; and (b) replacements per atom, namely, "rpa." Both quantities rely on parameters gained by fitting MD simulation results. Helpful discussions about the difference between MC and MD for radiation damage studies can also be found in ▶ Chap. 88, "Molecular Dynamics Simulations of Non-equilibrium Systems" within this Handbook.

5   Outlook for the Next 10 Years

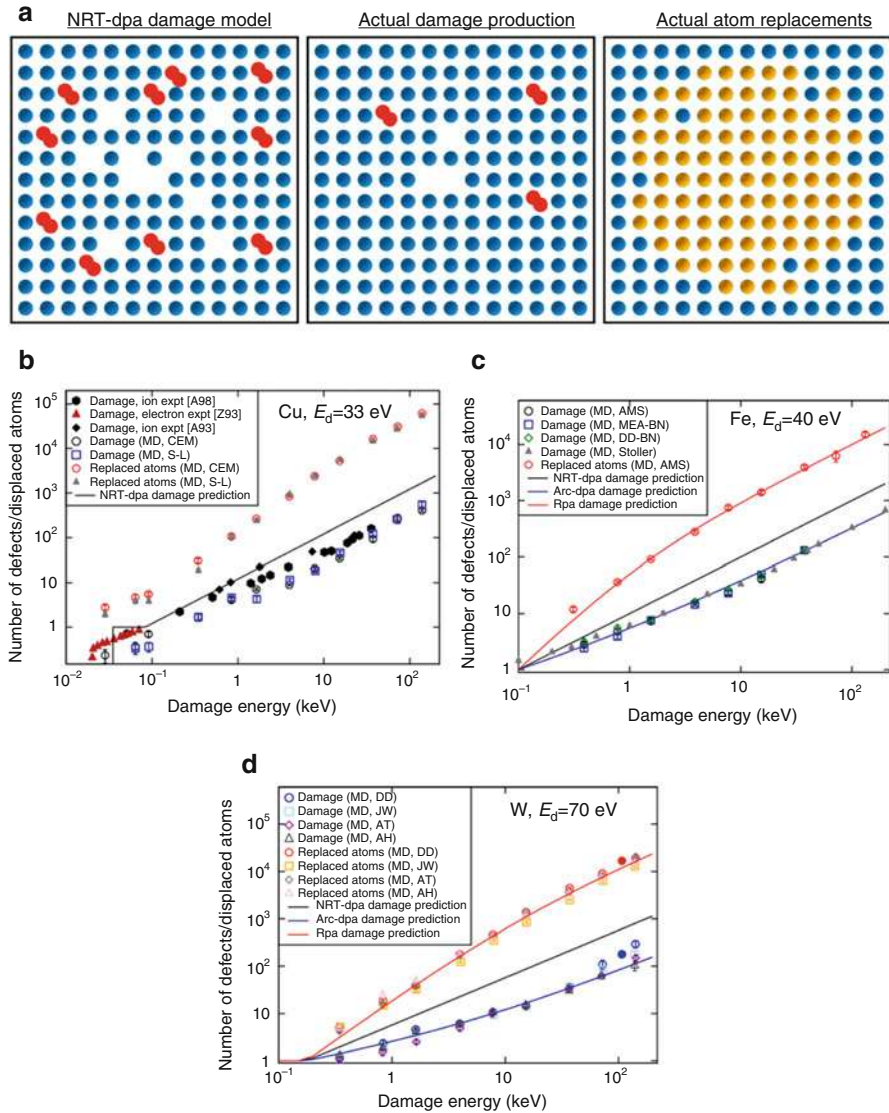
In summary, Monte Carlo simulation of ion radiation based on a BCA model is an efficient tool for the prediction of primary damage in materials. A series of advanced codes have been recently developed, enabling full-3D simulations, which can consider arbitrarily complex target morphologies, arbitrary beam shapes/sizes, and even dynamic evolution. The speed of these codes is also greatly enhanced by the fast indexing method of scattering angle sampling and highly parallel computation. Also, more and more advanced codes are becoming open-source, allowing verification of the algorithms and the underlying physics engine. What


Fig. 20 (**a**) Schematic illustration of the problem of the NRT-dpa damage model. (**b**) Comparison of MD simulation and NRT-dpa model. (**c**, **d**) Two new quantification standards: Arc-DPA and RPA agree well with MD simulations. Reproduced from Ref. (Nordlund et al. 2018), which is licensed under CC BY 4.0

is more, maintaining an open-source code policy will facilitate the incorporation of BCA-MC simulations into the framework of multi-scale and multi-physics frameworks such as MOOSE (Gaston et al. 2009), dynamically providing primary radiation damage data as input for larger time- or length-scale simulations. Besides,

it has been shown that legacy codes such as SRIM will lead to significant errors in many applications, such as nano-beams, nanostructured materials, and rough-surface. However, the traditional closed-source code SRIM still enjoys a relative monopoly due to its long history, its relative accuracy for bulk-scale simulation, and especially its simple and intuitive user interface. It is important for new codes to have such a friendly user interface, allowing not only the easy input of complex target morphologies, but also convenient updates of the stopping power database. Last, but not least, increasing doubt exists on the NRT-DPA model when comparing MC to MD simulations, while the applicability of newly proposed damage units is still under exploration.

Incorporating Electronic Effects in Molecular Dynamics Simulations of Neutron and Ion-Induced Collision Cascades

98

Andrea E. Sand

Contents

Abstract

Molecular dynamics offers an ideal method for investigating the evolution of collision cascades and the formation of the resulting primary radiation damage. However, several modifications to classical molecular dynamics are needed in order to facilitate simulating the highly non-equilibrium cascade process. One such modification, which is still a point of active research, concerns methods by which electronic effects, which are expected to be important in collision cascades, can be included in molecular dynamics simulations, where a priori atoms are treated as classical particles and electrons are only present implicitly

through the atomic interactions represented by the interatomic potential. This chapter describes current methods by which electronic effects can be accounted for in cascade simulations, with special focus on the developments in the field that have taken place over the last 10 years.

1   Introduction

Irradiation by energetic particles, such as neutrons or ions, can in crystalline materials give rise to various forms of damage in the atomic structure, through collisions with atoms in the target material. Such irradiation events can give rise to what is known as a collision cascade: a series of elastic collisions between atoms in the material, resulting in the permanent displacement of a potentially large number of target atoms. This chapter deals with atomic-scale simulations of such cascades, and current state-of-the-art methods by which electronic effects can be explicitly included in such simulations, beyond the bonding effects which are implicitly captured in the fitting of the semiempirical interatomic potentials.

In cascade events, most of the initial energy of the incident ion, or the recoiling atom, is transferred to the atoms of the target material through the nuclear stopping process, and only a small fraction, typically around 20%, is absorbed by the electronic system. For ions with higher kinetic energy, of the order of MeV, the collision cross section decreases to the point where interaction with atoms of the target becomes negligible, and the energy of the ion is mainly absorbed by the electronic system. Heavy particles in this energy regime are known as swift heavy ions, and while electronic effects are highly relevant in the formation of damage from such particles (Toulemonde et al. 1992; Leino et al. 2015), the damage is not produced through collision cascades, due to the negligible nuclear stopping at higher velocities, and hence this phenomenon lies outside the scope of the current article.

From the first atomistic simulations of cascades in solids in 1960 (Gibson et al. 1960), molecular dynamics (MD) simulations have uncovered many important mechanisms of radiation damage formation, including the different stages of cascade development (Calder et al. 2010), defect recombination during the heat spike phase (Diaz de la Rubia et al. 1987), and athermal defect cluster formation (Diaz de la Rubia and Guinan 1991). As the interatomic potentials that describe the forces between the atoms have improved, the predictive power of MD simulations has increased (Nordlund and Dudarev 2008). As a simulation method, molecular dynamics offers the most complete picture of the processes leading to cascade damage while still being able to treat the full system of up to millions of atoms that is required to capture the whole cascade event.

In many cascade simulations to date, electronic effects have been neglected, either in part or fully. While the potential importance of such effects on the highly non-equilibrium cascade event has been recognized early on (Flynn and Averback 1988; Caro and Victoria 1989), the interactions between the atomic and electronic systems during the cascade evolution are the result of processes occurring over many orders of magnitude in energy, and capturing the behavior in a simple, physically motivated yet computationally expedient model remains a challenging

task. Nevertheless, the past 10 years have seen significant development in this area, due in part to a continued increase in computer capacity. On the one hand, modern supercomputers facilitate performing increasingly large simulations and hence investigating more energetic cascades, where the electronic effects become ever more pronounced. On the other hand, with developments in quantum mechanical techniques of simulating electron dynamics, it is now possible to explicitly follow the dynamics of the interactions between moving ions and electrons. Although full cascades are still out of reach of ab initio calculations, a number of studies of cascade relevant conditions have been performed with different methods (see, e.g., Race et al. 2010), providing insight into the nonadiabatic quantum mechanical effects. Most ab initio studies have focused on predicting electronic energy losses in various projectile-material combinations (Mao et al. 2015; Mason et al. 2007; Race et al. 2012), although the effect of electronic excitations on the interatomic forces has also been investigated (Correa et al. 2012). The initial stages of full cascades have been studied using a time-dependent tight-binding scheme (le Page et al. 2009), providing a method for assessing the accuracy of various approximations of electronic energy losses employed in MD simulations. Together, these developments in computational methods and resources have opened up new avenues for investigating the nonadiabatic effects in collision cascades.

1.1   Phases of Cascade Dynamics

A collision cascade refers to the process of displacing atoms, which is initiated by an energetic projectile undergoing an elastic collision with an atom in the target material, called the primary knock-on atom (PKA). If the kinetic energy acquired by the PKA is above a certain threshold value, termed the threshold displacement energy (TDE), the atom will leave its place in the lattice. When the kinetic energy of the PKA is significantly above the TDE, then as it collides with other atoms in the lattice, it will transfer energy to these atoms, giving rise to secondary, tertiary, etc. recoils. This constitutes the ballistic phase of the cascade, which is characterized by energetic projectiles penetrating undisturbed lattice and undergoing individual energetic collisions with atoms in the matrix as they expand the volume of material affected by the cascade. During the ballistic phase, the volume and structure of the cascade are determined, including possible splitting into subcascades. The energy at which cascades begin to split is material dependent and occurs at lower energies for materials with lower atomic mass. Splitting is a gradual transition, but as examples, in Fe and Ni, cascades begin to split at 20–30 keV, while in W and Au, splitting begins at around 150–200 keV.

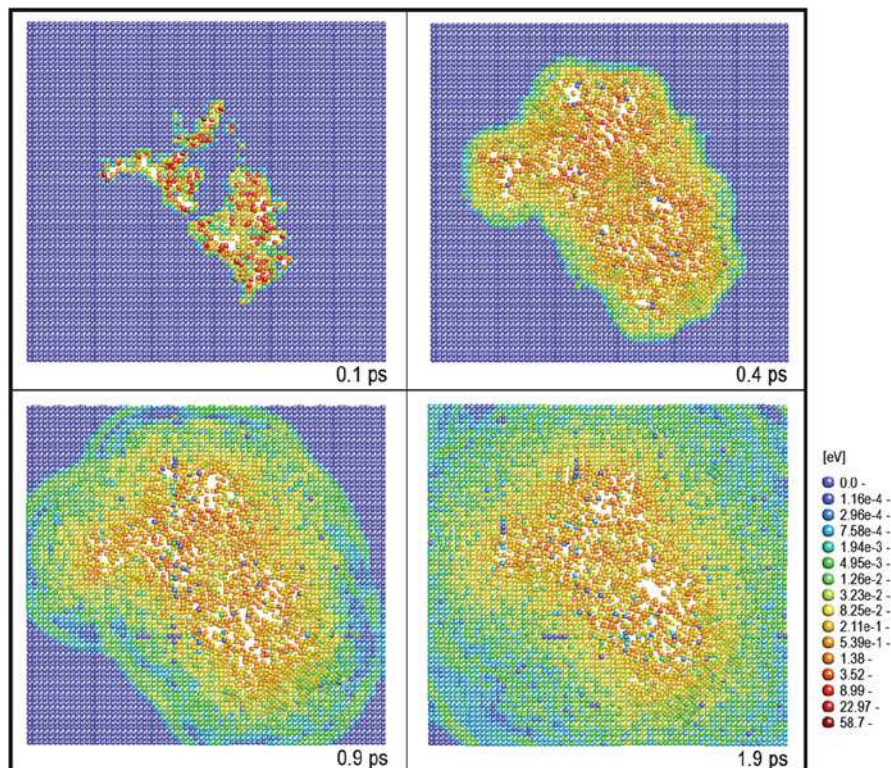
In dense materials, from energetic PKAs, the disturbance of the surrounding lattice by the recoils will eventually give rise to a heat spike. This stage of the cascade evolution occurs at the end of the ballistic phase (at around 100–300 fs depending on PKA energy), when the ballistic recoils have lost most of their kinetic energy through collisions with other atoms. The heat spike phase is characterized by a highly disordered, underdense liquid-like volume (or several separate volumes if the cascade has split into subcascades), which persists for several picoseconds.


Fig. 1 The disordered core of a 150 keV cascade in W. Atoms shown are from a 2 Å thick slice through the cascade core and are colored according to their kinetic energy (scale in eV)

At this point, energetic projectiles have ceased to exist, and the cascade volume ceases to expand. During the heat spike phase, energetic atoms move randomly in the core of the cascade, resulting in total displacements which are the main causes of ion beam mixing observed in experiments (Kim et al. 1988). Figure 1 shows the disordered core of a cascade in W during the heat spike phase from a 150 keV PKA.

The disordered core eventually cools and recrystallizes, resulting in the recombination of most of the damage in the case of metals and leaving individual point defects and defect clusters as the final products. These defects, which form as a direct result of the athermal processes of the cascade but are subsequently subject to thermal evolution, are termed the primary radiation damage (Was 2007).

1.2 Electronic Effects in Collision Cascades

The ballistic phase of the cascade is dominated by the processes associated with energetic ionic projectiles in matter. It is well established, both theoretically and experimentally, that electrons play a part in the slowing down of such ions (see,

e.g., Ziegler et al. 2010). The electronic contribution to the slowing down of ions is known as electronic stopping. A detailed treatment of the various theories behind the processes involved in electronic stopping is beyond the scope of this chapter. For ion energies relevant in cascade simulations, with velocities smaller than that of the Fermi velocity of electrons, it is given, e.g., by the theory of Lindhard and Sharff (1961) as

$$S_e = \frac{\partial E}{\partial x} = \lambda E^{1/2} \tag{1}$$

where E is the energy of the ion and λ is a material-dependent proportionality factor. For our purposes, we note that the theoretical treatment is based on the assumption of an energetic particle traveling through ground-state pristine material. The SRIM software package (Ziegler 2008) provides plots of the stopping power for any projectile-target combination. The data in these plots are derived from the theoretical models, with various correction terms, and fitted to available experimental data. In many cases, the predictions of the model in SRIM are within a 10% error margin to experiments, but notable exceptions exist. The two scenarios that are most relevant to cascade simulations, where SRIM predictions fail, are in the case of channeled ions and in the low velocity limit.

In the first of the abovementioned cases, predictions fail since SRIM does not account for the crystal structure nor the dependence of the stopping power on the electron density and hence on the ion trajectory. Channeled ions experience a stopping power which may in some cases be significantly lower than that experienced by ions traveling in a random direction or through amorphous material. This has been shown experimentally for a number of cases, including for various projectiles and channels in Si (Wilson et al. 1986) and in W (Eriksson et al. 1967) and in explicit ion range simulations where electron density-dependent stopping was implemented (Cai et al. 1996; Sillanpää 2000). This spatial dependence is not of immediate concern in cascades, where secondary, tertiary, etc. recoils travel in highly random directions in the lattice. Hence the atoms visit varying regions of electron density along their path through the material, and an average stopping power is therefore representative of the average interaction with the electrons. However, as will be explored in later sections of this chapter, the question has bearing on the full treatment of the ion-electron interactions during the complete cascade evolution, including that of the later cascade phases.

In the second case, for the low velocity limit, the model assumes a linear interpolation of the average stopping power down to zero, at zero velocity, which is in good agreement with predictions at slightly higher velocities. However, such behavior is not experimentally verified for very low velocities, and in fact a clear deviation from linear dependency on velocity is seen, both experimentally and in ab initio simulations, in the form of a low-energy threshold for the stopping power of H and He in a number of materials, including insulators (Markin et al. 2009a; Pruneda et al. 2007), but also in metals such as Au and Cu (Markin et al. 2009b; Zeb et al. 2012). The existence of a threshold was predicted early on, based on considerations

of electronic densities of state (Semrad 1986). Surprisingly, recent investigations of the low-energy behavior of the stopping of Si in Si (Lim et al. 2016) have found a non-zero stopping below the band gap threshold, explained by an "electron elevator" effect due to an intermediate electron state within the band gap, induced by the projectile itself.

Another effect of electrons in cascades follows from the electron-phonon coupling, which describes the interactions between thermal ions and electrons. During the initial ballistic phase of the cascade, it is assumed that electronic transport is efficient enough in the pristine lattice to justify instantaneously removing the energy obtained by the electronic system as a result of the electronic stopping of individual recoils. However, during the heat spike phase, the precise mechanisms of energy transfer between the atomic and electronic systems, and the rate of heat dissipation from within the hot, disordered heat spike region, are less obvious. The coupling strength between electronic and ionic systems and the mean free path of electrons in the hot cascade core determine whether or not the electronic system achieves equilibrium with the ionic system during the heat spike phase (Flynn and Averback 1988). However, the energy transfer between electrons and ions in the heat spike does not lend itself well to experimental investigation, and as a result, the potential importance of the coupling on cascade evolution is not known. Early investigations in Cu and Ni (Finnis et al. 1991) indicated that the strong electron-phonon coupling in Ni will quench the cascade and result in fewer defects in total. In contrast, other cascade simulations in Ni, Pd, and Pt, where electronic stopping was included but electron-phonon coupling was disregarded, showed agreement with experiments of ion beam mixing (Nordlund et al. 1998b), a mechanism which is sensitive to the lifetime of the heat spike. These results were interpreted as an indication that electron-phonon coupling effects are negligible in cascades in these materials.

Finally, the contribution of the electrons to thermal diffusion is the dominant method of thermal conduction in metals yet is completely absent in classical molecular dynamics. Hence the heat conduction in the electronic system surrounding the cascade region will contribute to removing heat from the cascade region (Finnis et al. 1991).

2   Electronic Effects in MD Cascade Simulations

2.1   Cascades as a Function of Damage Energy

According to the theories of stopping of ions in matter, an ionic projectile is slowed down in a material through two different mechanisms: the nuclear and the electronic stopping. This allows separating the initial projectile energy into two parts. The energy lost by the ion in collisions with electrons does not directly contribute to the displacement of atoms, and hence only the remaining energy, which is available for elastic collisions with atoms, is taken as the cause of the damage and thus termed the "damage energy," T_{dam}. Especially in early cascade simulations, the energy losses due to electronic stopping were most often disregarded during the simulation but

were instead taken into account in comparisons to real irradiation events. When relating cascade simulation results to actual damage produced by ions or neutrons, the energy of the projectile in the simulation is then labeled $E_{MD} = T_{dam}(E_{PKA})$, with the corresponding (experimental) projectile energy given by E_{PKA} (Stoller et al. 1997). The difference between E_{MD} and E_{PKA}, i.e., the energy lost to electronic stopping, can be calculated, e.g., using the approximation to Lindhard's theory (Lindhard and Sharff 1961) given in (Norgett et al. (1975)). The quantity T_{dam} is also the energy used in the NRT (Norgett-Robinson-Torrens) equation (Norgett et al. 1975) for the displacement damage, $N_{dspl}^{NRT} = 0.8T_{dam}/2E_d$, i.e., the basis for the *dpa* ("displacements per atom") measure of radiation exposure (Nordlund et al. 2015). Here N_{dspl}^{NRT} is the number of defects, or displaced atoms, and E_d is the (material-specific) threshold displacement energy.

To date, many studies employ this method, in part to facilitate comparison with previously published results. While effects on the predictions of the primary damage in lower-energy cascades in many cases may be below the statistical uncertainties, recent results show that in dense, energetic cascades, such as those occurring in the heavier element W, the numbers and sizes of defects in the primary damage are clearly affected by the electronic stopping energy losses (Sand et al. 2016b). Figure 2 illustrates the increasing effect on the fraction of clustered defects that electronic stopping has for increasing PKA energy in W. The effect is strongest on the clustering of vacancies. As cascades of ever-increasing energy are being studied in various materials, given the growing power of massively parallel supercomputers able to simulate ever larger systems, including electronic stopping dynamically becomes increasingly important.

2.2 Electronic Stopping as a Nonlocal Friction Force

A straightforward method of including the electronic stopping dynamically during cascade simulations is to apply a friction force on the moving atoms. From the electronic stopping $S_e = \frac{dE}{dx} \sim v$, one arrives at an additional term in the equations of motion:

$$m = \frac{d^2\mathbf{x}}{dt^2} = \mathbf{F} - \beta\mathbf{v} \tag{2}$$

Applying such a friction term in molecular dynamics simulations is computationally efficient, and the method has been used for numerous studies of cascade damage (see, e.g., refs Zhong et al. (1998), Nordlund et al. (1998a, b), and later work by these authors).

There are a number of uncertainties pertaining to the use of a nonlocal, average stopping power (such as that given by SRIM) in classical MD cascade simulations. As mentioned earlier, the local stopping power depends on the local electronic density. For most recoils in cascades, the trajectories occur in random directions, and the average electronic stopping predicted by SRIM is largely applicable. This, however, does not hold for channeled ions, for which the nonlocal friction force may be an overestimate.
Fig. 2 The fraction of defects in clusters predicted by simulations without electronic stopping S_e and with electronic stopping included for different cutoff energies T_c (see Sect. 2.2 for details). In simulations with no S_e, the value of E_{PKA} is calculated from the initial recoil energy E_{MD} in the simulation (which in this case represents the damage energy) using an approximation to Lindhard's theory (Lindhard and Sharff 1961). In simulations with electronic stopping, E_{PKA} is the initial recoil energy in the simulation

A more serious shortcoming of the average friction term in cascade simulations is the practice of setting a cutoff T_c for the kinetic energy, below which the frictional force is not applied. This is necessary in order to avoid quenching all thermal modes, since the energy lost to electrons is simply extracted from the system. Since such a threshold in most metals is not directly motivated by any physical theory, various different ways of choosing a value of T_c can be found in the literature, including taking twice the value of the material's cohesive energy (Duffy and Rutherford 2007) or a value of 10 eV independently of the material (Zhong et al. 1998;

Nordlund et al. 1998a, b). Recent investigations of the effects of different values for the threshold in W (Sand et al. 2014) and Ni, Pd, and Pt (Sand and Nordlund 2015) have shown an effect of the choice of T_c on both the damage production and atomic mixing resulting from cascades.

Although the energy lost to collisions with electrons from an ion with low velocity becomes increasingly tiny, especially in relation to the initial PKA energy, the total number of atoms in cascades with energies of the order of the threshold value can reach into the thousands during the heat spike phase. The total energy losses therefore add up, resulting in a very large difference in the final amount of energy extracted from the atomic system, depending on the cutoff value. As an example, in tungsten it was found that a cutoff value of $T_c = 1$ eV results in roughly 40 keV of excess energy lost from the atomic system during the heat spike phase of the cascade, compared to negligible energy losses during the heat spike phase if the cutoff is set to $T_c = 10$ eV. This is illustrated in Fig. 3. The additional energy losses roughly equal the amount of energy lost to electronic stopping during the ballistic phase of the cascade, giving a total of 80 keV energy lost to electrons from 150 keV PKAs, for $T_c = 1$ eV. This does not agree with the SRIM prediction of the proportions of electronic and nuclear stopping of ions at that energy and is in contradiction also with the predictions of Lindhard's theory. The difference in the resulting primary radiation damage from such simulations is drastic, with no large clusters forming when $T_c = 1$ eV. In contrast, regularly occurring large clusters are predicted in simulations with $T_c = 10$ eV.

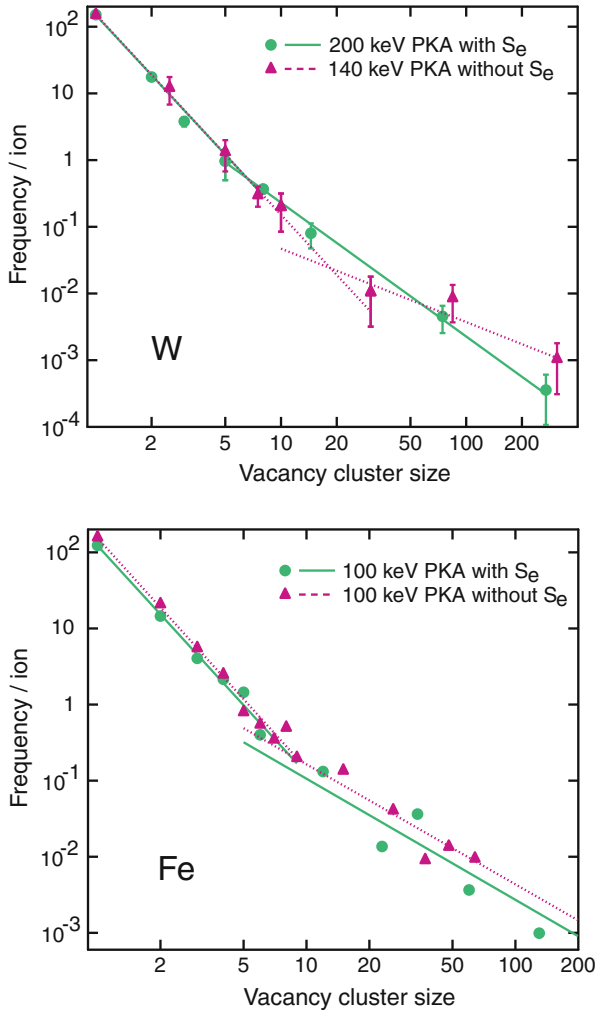
The impact of the electronic energy losses on predictions of the primary damage is dependent on material, with a more pronounced effect in materials with larger atomic mass. Figure 4 shows a comparison of the effects in the bcc materials W and Fe. Including electronic stopping during the simulation affects the slope of the
Fig. 3 Cumulative energy losses to electronic stopping during the evolution of 150 keV cascades in W, for different cutoff values. (Reproduced with permission from Sand et al. 2014)


Fig. 4 Size-frequency distributions of vacancy clusters in Fe and W, with and without electronic stopping. For W, PKAs with the same damage energy are shown, while for Fe the difference in overall frequency is due to the difference in damage energy for the two cases that are plotted. (Reproduced with permission from Sand et al. 2016b)

distribution of defect cluster sizes in W quite strongly, while in Fe the slope of the distribution is largely unaffected by whether or not electronic stopping is included. This holds when the threshold T_c is set sufficiently high to leave the heat spike unaffected (for Fe the value $T_c = 5$ eV was used). This material dependence can be related to the increasing impact of electronic stopping on cascades of increasing energy, through the phenomenon of subcascade splitting. For materials with smaller atomic mass, cascades split at a relatively low energy; hence compact energetic cascade regions occur seldom in such materials, even for higher-energy PKAs.

It should be noted that because of the threshold effect, the damage energy T_{dam} associated with a given projectile energy E_{PKA} is not a well-defined quantity, when electronic stopping is included explicitly through a friction term as the sole electronic effect in cascade simulations. While the energy lost to the electronic friction during the simulation can be easily traced, the final value depends sensitively on the chosen cutoff T_c. The plots in Fig. 5 show the dependence of the "damage energy" on the cutoff value for a range of materials, with a comparison to the predictions of Lindhard's theory. While Lindhard's prediction lies within the range of these simulations, it becomes clear that relating a damage energy to a cascade simulation is rather ad hoc, and the electronic effects in the heat spike, which both Lindhard's theory and the electronic friction method fail to properly capture, potentially affect a rather large proportion of the PKA energy in the higher cascade energy regime.

Fig. 5 Energy losses to electronic stopping as a function of cascade energy in Ni, Pd, and Pt, compared to the damage energy calculated from Lindhard's theory. (Reproduced with permission from Sand and Nordlund 2015)
2.3 Electron-Phonon Coupling and Two-Temperature Molecular Dynamics

The issues with tuning a threshold T_c for electronic stopping are due to the fact that electronic stopping theories no longer apply once the cascade transitions into the heat spike phase. At that stage, the dynamics of the atomic system become more phonon-like, and energy transfer between ions and electrons is more correctly described by electron-phonon coupling.

A simple model which introduced electron-phonon coupling based on the method by Hou et al. (2000), as an additional damping term which tends to zero as the ionic temperature approaches a set temperature for the electronic system, was investigated for cascade simulations in Fe by Björkas and Nordlund (2009). Results showed an effect on the numbers of defects but not on the fraction of defects in clusters. However, using a time constant for the electronic stopping derived from the Sommerfeld free electron theory resulted in an underestimation of the atomic mixing with this method.

A method that explicitly includes the electronic system in molecular dynamics simulations, and accounts for both the electronic stopping and electron-phonon coupling, was pioneered for cascade simulations by Duffy and Rutherford (2007) and Rutherford and Duffy (2007). The method uses a stochastic force to represent the energy transfer from the electronic system back to the ionic system, an idea which was first suggested by Caro and Victoria (1989). The Langevin equations of motion for the ionic system are then given by

$$m\frac{\partial \mathbf{v}_i}{\partial t} = \mathbf{F}_i(t) - \gamma_i \mathbf{v}_i + \mu(t), \tag{3}$$

where $\mathbf{v}_i$ is the velocity of the ion; μ is a stochastic force, the strength of which is determined by the strength of the electron-phonon coupling; and $\gamma_i \mathbf{v}_i$ is a friction term associated with the electronic stopping. The formalism builds on the two-temperature model (Lifshits et al. 1960) (TTM), where the atomic and electronic subsystems are assumed to be separately in internal equilibrium, with different defined temperatures, which evolve toward the same value through the coupling between the subsystems. The electronic system in the MD simulation is represented by a continuum thermal bath at temperature T_e, coupled to the ionic system with temperature T_i, and governed by the heat diffusion equation:

$$c_e \frac{\partial T_e}{\partial t} = \kappa_e \Delta T_e - g_p (T_e - T_i) + g_s T_p \tag{4}$$

where c_e and κ_e are the specific heat and heat conductivity, respectively, of the electrons. Note that the corresponding lattice thermal diffusion is accounted for explicitly in the atomic MD system. The parameters g_p and g_s are related to the coefficient γ_i in the friction term in Eq. 3 and determine the strength of the coupling for the electron-phonon interaction and electronic stopping, respectively.

The second term on the right-hand side of Eq. 4 describes the heat exchange between electrons and lattice, while the third term on the right balances the energy lost from the ions through the electronic stopping friction term. The parameter T_p is determined by energy balance equations.

Although the Duffy and Rutherford model includes a description of both electronic stopping and electron-phonon coupling and allows exchange of energy both ways between the electronic and ionic subsystems, it still suffers from an unphysical cutoff parameter for electronic stopping. The model treats the two energy loss mechanisms separately, with electronic stopping applied only above an arbitrarily chosen velocity v_0. Hence the coupling term γ_i in Eq. 3 is given by

$$\gamma_i = \gamma_p + \gamma_s \quad \text{for} \ \ v_i > v_0 \tag{5}$$

$$\gamma_i = \gamma_p \quad \text{for} \ \ v_i \leq v_0 \tag{6}$$

where γ_p is the friction coefficient for the electron-phonon coupling and γ_s is the coefficient for the electronic stopping friction term. An additional uncertainty pertaining to the model is the need for a well-defined lattice temperature. In the initial stage of the cascade, a local temperature is not well-defined, leading to the choice by authors to "turn on" the electron-phonon coupling after 300 fs of the initial cascade evolution (Zarkadoula et al. 2014).

The TTM-MD method has been implemented in in-house versions of DL_POLY but is not yet available in the general DL_POLY distribution (Todorov et al. 2006). It has been used in a number of investigations of cascade damage in metals, including both Fe and W, and in some Ni- and Fe-based alloy systems (see, e.g., Zarkadoula et al. (2017) and references therein). Early investigations with the model in Fe (Rutherford and Duffy 2007) showed a sensitivity of results to the strength of the coupling parameter, with an initial increase in the number of defects with increasing coupling strength, due to a more rapid cooling rate at the later phase of the cascade evolution, resulting in less recombination at later stages (see Fig. 6). As the coupling strength was increased further, the number of residual defects decreased to below the numbers predicted in simulations without electronic effects. This was explained by the rapid early quenching of the cascade, which inhibited the initial formation of the heat spike. Later studies of energetic cascades in Fe (Zarkadoula et al. 2014) used a coupling constant derived from DFT and found little effect on the average numbers of residual defects but instead saw a discernible effect on the degree of clustering of the defects. In energetic cascades in W (Zarkadoula et al. 2015), on the other hand, the TTM-MD method predicts fewer final defects when electron-phonon coupling is included, as compared to simulations where only electronic stopping is included as a friction term.

A slightly modified version of the TTM-MD, which corrects for an energy drift in Duffy's and Rutherford's model (Phillips and Crozier 2009), has been implemented in the LAMMPS code (LAMMPS 1995; Plimpton 1995) and is freely available for use. However, this implementation enforces periodic boundary conditions in
Fig. 6 Defect numbers predicted in cascades in Fe using TTM-MD with a range of coupling strengths. (Reproduced with permission from Rutherford and Duffy 2007)

all dimensions and hence removes the spatially extended borders of the electronic system, which the original TTM-MD used in conjunction with a heat sink at the electronic system borders, to facilitate electronic thermal diffusion away from the hot cascade region. A thorough investigation of the effects of boundary conditions on the cascade evolution and damage formation has not been carried out. For a perspective on the energy increase associated with cascades, one can consider a 200 keV cascade, which would require a 20 million atom system simulated in the NVE ensemble in order to maintain the average temperature to within 100 K of the initial ambient temperature. While this is well within the capacity of today's supercomputers and in pure MD simulations, such a small temperature difference would not result in significant differences in the outcome of cascades, indications are that damage production is more sensitive to temperature effects when electronic interactions are included (Zarkadoula et al. 2015). Due to this, the applicability of a periodic electronic system for energetic cascade simulations may be somewhat restricted. The method has nevertheless been used for lower-energy cascade simulations in α-quartz (Phillips et al. 2010), silicon carbide (Zhang et al. 2013), and in a pyrochlore system (Ismail et al. 2010).

These TTM-MD studies rely on a number of assumptions concerning the electronic effects, including, among others, a constant value of the coupling strength, an electronic thermal conductivity which is independent of the atomic disorder in the heat spike (and in many studies also independent of temperature), and the various thresholds such as the cutoff for electronic stopping and the time at which to include the electron-phonon coupling. The time of turning on the electron-phonon coupling was shown to affect the numbers of residual defects (Zarkadoula et al. 2017). The investigations to date have mainly been concerned with the differences in predictions of the various models and sensitivity of the TTM-MD

to the coupling constant. As no quantitative comparisons of these simulation results with experiments have been reported, the conclusions to date mainly amount to an indication that electron-phonon coupling likely has an effect on the final damage from cascades.

Mason et al. (2014) recently developed an alternative approach to including electron-ion energy transfer in both the electronic stopping and electron-phonon coupling regimes in cascade simulations, which avoids the necessity of a nonphysical cutoff. Instead, a transition between electron-phonon coupling and electronic stopping is determined based on band structure. In this model, the transition regime is found for atoms with kinetic energies on the order of hundreds of eV. Mason's model also accounts for the effects of disorder on the electronic thermal conduction. While this model has not yet been used extensively for cascade simulations, the results presented in Mason et al. (2014) demonstrate a similarity with the method of including only an electronic friction term above a cutoff set to $T_c = 10$ eV, when looking at electronic energy losses over time as the cascade develops. The observed behavior, where energy losses level off at the end of the ballistic phase (see Fig. 7, showing energy losses in 25 keV cascades in W, where the ballistic phase ends roughly after the first 100 fs), can in Mason's model be traced to the significant decrease in electronic conduction due to the disorder in the cascade core, effectively trapping the energy in the heat spike. This leads to the same qualitative behavior as that achieved artificially by a cutoff T_c of the electronic stopping, when T_c is set to a value such that energy losses cease during the transition between the ballistic and heat spike phases. The longer-term energy loss from the atomic system in the plots with a kinetic energy cutoff k_c in Fig. 7 is due to heat dissipation through the borders of the cell (by the use of a thermostat).
Fig. 7 Energy losses from the atomic system during 25 keV cascades in W using various methods of energy transfer. 2TMD refers to Mason's method, 2TMD $(\overline{B}, \overline{\kappa})$ refers to Duffy's model with fixed electronic thermal conductivity and electron-phonon coupling constant, and $k_c = 1$ and $k_c = 10$ refer to a model with only a friction term and cutoff at 1 and 10 eV, respectively. 3   Quantitative Comparisons with Experiment

While it is currently impossible to experimentally observe the collision cascade itself, there are a number of ways in which the effects of cascades can be measured experimentally, and quantitative comparisons with these can be used to guide simulations and give an indication of the validity of various simulation methodologies. Due to the large variability between individual energetic cascades and the wide spectrum of energies of the PKAs in, e.g., irradiation experiments with energetic noble gas atoms, a large set of cascade simulations is needed for any comparison to be possible.

Although MD simulations incorporating electronic effects can be compared to a wide variety of experiments, such as swift heavy ion tracks, ion projectile ranges, short-range and long-range disorder (applicable to alloys), and laser heating, we present here two examples that specifically address collision cascade phenomenon and are applicable also to pure materials, namely, the atomic mixing in heat spikes (captured experimentally by the use of a separate marker species) and the residual defects, or primary damage, of the cascade.

3.1   Ion Beam Mixing

As a result of cascades, atoms are displaced from their original positions, coming to rest some distance away from where they originated. In metals, displaced atoms often come to rest on a lattice site and hence do not contribute to the final damage but have nevertheless traveled a certain distance. This atomic mixing can be divided into two parts – the ballistic mixing and the heat spike mixing. The physics underlying these two mechanisms are different, and while they cannot be separated experimentally, theoretical predictions of the magnitude of ballistic mixing indicate that the total mixing in ion-irradiated metals is mainly due to heat spike mixing (Kim et al. 1988), which occurs as a diffusive process in the disordered, liquid-like core of energetic cascades, before the core recrystallizes. Simulations support this conclusion (Nordlund et al. 2015). Since the level of atomic mixing thus depends on the duration of the heat spike, a suitable choice for the cutoff energy in the electronic friction model can be found empirically from cascade simulations, by comparing with ion beam mixing (IBM) experiments.

The total atomic displacements R_{sim} can be extracted from cascade simulations as long as atoms are indexed and thus traceable. The square of the displacements $R^2{}_{sim}$ can be fitted to a function Nordlund et al. (1998b) of the form

$$R^2(E) = a \frac{E^{c+1}}{b^c + E^c},$$
(7)

where a, b, and c are fitting parameters and E is the PKA energy. The mixing efficiency derived from simulation is then obtained by integrating R^2_{sim} over the whole PKA energy range, weighted by the energy spectrum of the recoils from the

incident ion (Nordlund et al. 1998b):

$$Q_{sim} = \frac{\int_0^{E_0} R^2(E)n(E)dE}{6n_0 E_{D_n}}. \tag{8}$$

Here E_0 is the initial ion implantation energy, n_0 is the atomic density, and E_{D_n} is the damage energy of the ion beam.

As seen in Fig. 3, the choice of the cutoff T_c affects the amount of energy losses during the heat spike phase. This, in turn, affects the lifetime of the liquid core and hence the amount of mixing that takes place. The effect of the threshold is strongest in the more energetic cascades, and these are also the cascades that dominate the total mixing from the range of recoil energies produced by the impacting noble gas ions in IBM experiments. Hence the predicted mixing efficiency from cascade simulations is sensitive to the cutoff energy used for the electronic stopping.

When comparing MD cascade simulations in a pure material with experimental ion beam mixing results, the effects of impurities, varying heats of mixing and miscibility of the marker layer and substrate, and other chemical effects in the real material combination must be taken into account (Paine and Averback 1985). High-quality IBM experiments which minimize chemical effects have been performed in the metals Ni, Pd, and Pt (Nordlund et al. 1998b), and comparison of the mixing efficiencies for these materials with the predictions of cascade simulations shows that a cutoff at $T_c = 1$ eV underestimates the mixing in all cases, while a value of 10 eV gives better agreement, although in Pd and Pt, it is then slightly overestimated (Sand and Nordlund 2015).

These results, combined with the observation that raising the cutoff energy slightly above 10 eV has little or no effect on the final damage nor on the overall energy losses (Sand et al. 2013, 2014), while a lower value of 1 eV has a clear effect on both, and considering the fact that electronic stopping theory does not directly apply in the heat spike regime, conclude that erring on the side of a higher cutoff is perhaps to be preferred over introducing excessive energy losses through an electronic stopping friction term active during the heat spike (Table 1).

Table 1 Simulated and experimental values for the mixing efficiency Q.[a] Nordlund et al. (1998b),[b] Kim et al. (1988),[c] Fenn-Tye and Marwick (1986). (Reproduced with permission from Sand and Nordlund 2015)

Material beam		Q_{sim} (Å^5/eV)$T_c = 1$ eV	Q_{sim} (Å^5/eV)$T_c = 10$ eV	Q_{exp} (Å^5/eV)
Ni	600 keV Kr	2.9 ± 0.1	4.7 ± 0.1	4.8 ± 0.5[a]
Ni	650 keV Kr	3.1 ± 0.2	5.1 ± 0.1	5.0 ± 0.7[b]
Pd	600 keV Kr	6.2 ± 0.2	14 ± 1	8.4 ± 0.8[a]
Pd	400 keV Kr	6.1 ± 0.2	13.7 ± 0.5	9 ± 1[c]
Pt	1 MeV Kr	6.1 ± 0.3	20 ± 3	14 ± 2[b]

3.2   Primary Damage in TEM

It has been noted in several studies, both with the TTM-MD method and with purely electronic stopping, that the magnitude of electronic energy losses from ions affects the clustering of defects in the final damage (Zarkadoula et al. 2014; Sand and Nordlund 2015). Put in different terms, one finds that the distribution of the sizes of defect clusters in the primary damage is affected. A high fraction of clustered defects is seen in terms of the size-frequency distribution as the occasional occurrence of large clusters, with the distribution closely following a power law (Sand et al. 2013). On the other hand, a low fraction of clustered defects corresponds to a completely different distribution. Figure 8 shows the size-frequency distributions for SIA clusters in 200 keV cascades in W obtained with electronic stopping using different values of T_c. While the distributions predicted both without electronic stopping and with electronic stopping and a threshold of $T_c = 10$ eV fit well to a power law, the lower $T_c = 1$ eV inhibits all formation of larger clusters, and the size-frequency distribution tails off exponentially.

In materials where the primary damage contains defects large enough to be visible in an electron microscope, transmission electron microscopy (TEM) can be used for direct comparison between MD predictions and irradiation experiments. Such a comparison has been carried out for self-ion-irradiated tungsten (Yi et al. 2015), where irradiations were performed at cryogenic temperatures and defects observed *in situ*, thus minimizing the microstructural evolution which could take
Fig. 8 Size-frequency distributions of SIA clusters, as predicted by MD simulations of 200 keV cascades in W, simulated with different cutoff values for the electronic stopping friction term but otherwise identical conditions. The defect distribution in the case of $T_c = 1$ eV is fitted to an exponential function, while the distributions predicted with the other methods fit well to power laws

place during the irradiation and between the time of irradiation and the time of observation. In particular, it was observed during the course of the measurements that loops did not visibly grow but appeared instantaneously from one frame to the next. (This is in contrast to higher temperature *in situ* irradiation experiments, where gradual growth of loops is apparent (Yi et al. 2013).) Hence the large clusters visible in the micrographs were concluded to be the products of athermal defect formation in individual cascades. The size-frequency distribution of the TEM-visible defects was extracted from the micrographs using an automated method (Mason et al. 2018) and shown to be in good quantitative agreement with MD predictions from cascades where electronic stopping was included as a friction force with $T_c = 10$ eV (Sand et al. 2017). Comparing Fig. 9 to the predictions plotted in Fig. 8, it is clear that a value of $T_c = 1$ eV leads to a direct contradiction with the experimental observation of TEM-visible loops in W.
Fig. 9 Defect cluster size-frequency distribution as predicted by MD, compared to TEM observation. The experimental defect count is shown as black circles, while the blue squares were obtained with MD. The thick black line is a fit of the MD data to a full model for the size distribution of defects, where subcascade splitting is also taken into account (see Ref. Sand et al. (2017) for details). Accounting for the expected (and observed) loss of loops to the surface yielded the dotted black line, with no fitting to experiment. (Reproduced with permission from Sand et al. 2017)

4   Outlook

Historically, perhaps two factors lie most strongly behind the tendency to widely disregard electronic effects in MD cascade simulations. On the one hand, these effects are rather poorly known for the complicated processes at play in energetic collision cascades. But in addition, most early MD cascade studies were restricted to relatively low PKA energies, where the complicated processes of energy transfer at lower velocities and in the disordered cascade core are largely negligible in relation to the overall energy losses during the cascade. Today, with the continued increase in computer power, increasingly energetic cascades can be simulated with MD, with enough statistics to capture the fluctuations in the damage production. This allows investigating the sensitivity of predictions to effects of electronic energy losses in energetic heat spikes and, most importantly, of validating proposed models by comparison of the statistics of the primary damage with direct experimental observations. In addition, the relatively new time-dependent density functional theory (TDDFT) method provides novel ways of investigating the ion-electron energy transfer under various conditions and opens the way for probing unexplored regions of cascade dynamics, offering a way toward a deeper understanding of electron excitation processes in highly disordered systems and facilitating the direct parameterization of new energy transfer models.

Recently, the power of TDDFT has been put to use toward realizing the ideas originally put forward almost 30 years ago by Caro and Victoria (1989) of expressing the high-energy electronic stopping and low-energy electron-phonon coupling within one formalism in MD cascade simulations. The motivation behind this approach is the understanding that the two limiting models of energy transfer – in the high-energy and low-energy limits – are essentially due to the same physics (Koponen 1993). The proposed method has the advantage of eliminating the need for an arbitrary threshold imposed on the electronic stopping but introduces the need to parameterize the energy transfer for the whole range of electron densities visited by the recoil. Caro and coworkers (Caro et al. 2015) demonstrate the feasibility of doing this within TDDFT, with the help of modern computer capacity. They show the effect of electron density on the stopping of a moving ion and argue that low-energy thermal ions will effectively be embedded in an electron density more like that of a vacant lattice site, rather than that experienced by an interstitial atom or energetic recoil. This approach yields levels of energy transfer from ions to electrons in the two limiting regimes of an energetic recoil and a thermal ion, which correspond well to the magnitudes of the friction terms normally used for the electronic stopping and electron-phonon coupling, respectively. Figure 10 shows the dependence of the energy of the electronic system on the atom position during a TDDFT simulation of an Ni atom traversing a vacant site in the Ni lattice, representing the energy losses experienced by a thermal ion. Based on these calculations, they present an electron density-dependent stopping $dE/dx = \beta (\rho)v$ that can be conveniently introduced into MD simulations and treated with the same computational method as that used for calculating EAM-type interatomic potentials. At the time of writing, this approach has yet to

Fig. 10 The energy of the electronic system during a TDDFT simulation of a Ni atom traversing an empty site in the Ni fcc lattice. The dashed blue line shows the difference in energy between the TDDFT electronic states and the corresponding Born-Oppenheimer energy. The slope of the curve is the instantaneous rate of energy loss of the ion. (Reproduced with permission from Caro et al. 2015)
be implemented in cascade simulations but offers an intriguing possibility for overcoming many of the weaknesses of current models.

Ultimately, the question of validating ion-electron energy transfer models in MD cascade simulations will overlap with the question of the accuracy of interatomic potentials in describing the cascade dynamics (Sand et al. 2016a). For this reason, validation of models such as the TTM-MD will necessarily need to be supported by comparisons with experiments also of other phenomenon, where predictions are less sensitive to the choice of potential.

1 Introduction

The kinetics of alloy microstructures under nonequilibrium conditions such as irradiation is driven by the evolution of the population of point defects introduced by the energetic particles impinging the materials. Being capable of predicting such evolution is an important academic as well as industrial issue that needs to be tackled starting at the atomistic level. For this purpose, Atomistic Kinetic Monte Carlo (AKMC) is a very versatile method that can be used to simulate the evolution of complex microstructures at the atomic scale, dealing with elementary atomic mechanisms. It was developed more than 40 years ago to investigate diffusion events triggered by the motion of a single vacancy (Young and Elcock 1966) in a binary alloy. Since then, hetero-interstitials (Clouet et al. 2006; Hin et al. 2008) and self interstitials (Ngayam-Happy et al. 2010) have been introduced in the models and alloys of more complex nature have been investigated (Cerezo et al. 2003; Liu et al. 1997). The purpose of this chapter is to discuss how the effect of solutes can be taken into account in this approach. We will first start by describing briefly the basis of the AKMC method and its key ingredients. In the following sections, we present and discuss the different strategies available to build Hamiltonians that take into account solute atoms as well as the techniques used to estimate the activation barriers. We conclude by discussing the outlooks and perspectives of the different approaches described in the previous sections.

2   AKMC Method

Kinetic Monte Carlo (KMC) methods are techniques intended to simulate the time evolution of processes that occur with a given known rate, used as inputs to the algorithm (Voter 2007). It is usually applied at two scales: the atomistic scale, where processes that can take place are the ones atoms undergo during the evolution of a microstructure, and the mesoscopic scale, where the microstructure is coarse grained into objects that can evolve on a lattice or not. The first papers presenting a kinetic Monte Carlo approach were published by Young and Elcock (1966) and by Bortz et al. (1975), the first dealing with the kinetic of the vacancy diffusion in ordered alloys, the latter dealing with the kinetic evolution of an Ising spin system. A full theoretical description and formalization of the AKMC algorithm was proposed by Fichthorn (Fichthorn and Weinberg 1991). The most important feature of the AKMC technique – as compared to atomistic Metropolis Monte Carlo (MMC) simulations (Metropolis 1953) – is the fact that a time step can be related to each simulation step, i.e., for instance, the jump of a point defect. In AKMC simulations, configurations are not generated as a Markov chain and sampled respecting a given probability distribution (usually a thermodynamic equilibrium distribution) – as it is done in the MMC approach; rather, the configuration at step i is obtained from configuration at step $i\text{-}1$ by realizing a point defect or an atom move, i.e., the Markov chain is constructed taking into account the kinetics of the system.

We will not give an extensive description of the KMC algorithm which can be found for instance in (Voter 2007) but rather focus on its applications to model alloys and solute effects. We will remain in the context of diffusion controlled phase transformation under classical conditions (for instance under thermal aging) or in the presence of external forcing: here irradiation. A review of AKMC applied to precipitation can be found in Becquart and Soisson (2018). Atomistic kinetic Monte Carlo models are based on the residence time algorithm (Young and Elcock 1966) sometimes referred to as the BKL approach (Bortz et al. 1975). The elementary mechanisms are the point defect jumps or the interstitial jumps in the case of C or other hetero-interstitials. In the rigid lattice approach, which is the approach most used so far, vacancies and interstitials (dumbbells or mixed dumbbells) can jump from one lattice site to another lattice site (typically first nearest neighbor sites). If hetero-interstitial atoms are included in the model, they lie on an interstitial sublattice and jump on this sublattice. Typically one atom is assumed to move and the rates of possible transitions are determined from the local environment around the moving atom. According to harmonic standard transition state theory (Vineyard 1957), the frequency of a thermally activated event such as a vacancy jump in an alloy can be expressed as:

$$\Gamma = \nu e^{-\frac{E_a}{k_B T}} \tag{1}$$

where ν denotes the attempt frequency and E_a corresponds to the activation energy of the jump or the migration energy obtained as the difference between the energies

of the system at the saddle-point and in its initial configuration. Such a description is derived from the theory of thermally activated processes and is justified when the thermal fluctuations are smaller than the activation energies: $k_B T \ll E_a$. The attempt frequency can be expressed as:

$$\nu = \frac{\prod_{j=1}^{3N-3} \nu_j}{\prod_{j=1}^{3N-4} \nu_j^*} \qquad (2)$$

where ν_j and ν_j^* are the normal frequencies for vibrations at the local minimum and saddle states, respectively, and N is the number of atoms. Note that, at constant pressure, one should consider the enthalpies and free enthalpies of migration, but the difference is often negligible in solids. The jump frequencies obtained using this theory appear to be a very good approximation for the real jump frequencies up to at least half the melting point in most solid materials (Voter 2007).

For sake of simplicity, constant prefactors of the order of Debye's frequency are used most of the time (typical values for transition metals are 10^{12}–10^{13} s^{-1}). This commonly chosen assumption is based on the fact that small variations of the activation energy are more likely to have a greater impact on the transition probability than variations of the attempt frequency which are second-order effects (because of the exponential dependency of the former). This assumption is supposed to be valid especially for systems where all species have similar sizes such as 3d transition metal typical alloying elements in steels (Fe, Ni, Cr, Mn). However, it has been shown recently (Lazauskas et al. 2014) using Vineyard approach (Vineyard 1957) that the prefactor has an impact on the primary damage evolution and that the use of a constant prefactor, as is done in many lattice KMC simulations, may change the self interstitial atom (SIA) migration mechanisms, the amount of vacancy SIA recombinations, and enhance the difference between the diffusion rates of vacancies and interstitials. This work also concluded that the vibrational internal energy contributes little to the attempt frequencies of small point defect cluster migration mechanisms in Fe and that Vineyard approach was thus accurate enough to obtain them for each of the defects simulated.

At each KMC step, the algorithm determines the jump frequencies of all possible jumps in the system, chooses one of them according to its probability, and evaluates the time that the system would have taken to do the jump. The associated time-step length δt and average time-step length Δt is given by:

$$\delta t = \frac{-\ln r}{\sum_n \Gamma_X} \quad \Delta t = \frac{1}{\sum_n \Gamma_X} \qquad (3)$$

where r is a random number between 0 and 1.

The key issue of this method is the estimation of the jump frequency and the activation barrier, E_a, which, when the local chemical environment is complex, i.e., when the system is composed of several atomic elements, is not straightforward to calculate.

Three kinds of methods have been used, so far, to obtain E_a:

(i) **Direct calculation of E_a**: This approach is possible for simple cases, for
example, in the study of solute transport mechanisms where only one solute and
one point defect (vacancy or interstitial) are considered, i.e., when the number
of different barriers to determine is small. Such a study was performed by Costa
(2012), using an empirical potential and assuming a limited range of interaction,
e.g., first and second nearest neighbor interactions, to study thermal aging and
spinodal decomposition in the FeCr system, or, more recently, Messina et al.
(2015) using ab initio-computed binding energies and migration barriers in the
FeMnNi system. Usually, the activation energies are tabulated, to speed up
the calculations; however, it is also possible to obtain them on-the-fly, using
approaches such as k-ART (El-Mellouhi et al. 2008) or SEAKMC (Xu et al.
2015) discussed elsewhere in this volume (Chaps. 34, "Off-Lattice Kinetic
Monte Carlo Methods" and 32, "Computational Methods for Long-Timescale
Atomistic Simulations").

Another possibility to obtain E_a is to perform a cluster expansion (CE) at
the saddle point, as proposed in Rehman et al. (2013) again when the system
is not too complex or to use machine learning method based methods, such as
artificial neural network, that can be trained to estimate the activation energy as
a function of the local environment as proposed 10 years ago by Djurabekova
(Djurabekova et al. 2007), see Behler (2016) for a review.

(ii) **Broken bond or cut bond models** (Soisson et al. 1996): In these models, the
activation energy is given by the difference between the energy at the saddle
point position and the energy due to the interactions of the bonds broken during
the jump. The activation/migration energy is obtained as:

$$E_a = e_k^{sp} - \sum_j \varepsilon_{k-j} - \sum_{j \neq k} \varepsilon_{PD-j} \qquad (4)$$

where e_k^{sp} is the binding energy of atom k at the saddle point position and where
the summations over j extend over all the broken bonds of the migrating atom
k and of the moving point defect (PD). This scheme is illustrated in Fig. 1.
Another form of cut bond model has been developed in Vincent et al. (2008a).
In this method, it is considered that the migrating atom jump does not lead to
the destruction of the bonds with the point defect but that the bonds between
the migrating atom and its neighbors are replaced by bonds with the PD and the
same neighbors. The activation energy is then given by:

$$E_a = \sum_j \varepsilon_{k-j}^{sp} + \sum_j \varepsilon_{PD-j} - \sum_j \varepsilon_{k-j} \qquad (5)$$

(iii) **Methods based on the energy of the final and initial states:** They require
that a Hamiltonian is available to obtain the energy of any equilibrium
Fig. 1 Illustration of the broken bond model. The green lines represent the bonds around the jumping point defect and the blue lines the bonds around its final position

configurations and can be used with any Hamiltonian (simple ones like pair interactions or more complex ones). The kinetically resolved activation (KRA) according to van der Ven (Van der Ven et al. 2001), or final initial state energy (FISE) approximation, according to the terminology adopted by Vincent et al.(2008a) in the context of Fe-cu alloys, is based on the Kang and Weinberg decomposition of migration energy barriers (Kang and Weinberg 1989), which consists in computing the migration energy as follows:

$$E_a = E_a^0 + \frac{\Delta E}{2} \tag{6}$$

where E_a^0 depends usually on the migrating atom type but not on the chemical environment. The method, originally applied to vacancies, can be easily extrapolated to the migration of SIAs or foreign interstitial atoms (FIAs).

Whatever the method chosen to determine E_a, it must fulfill the detailed balance. Broken bond and FISE/KRA approaches have been compared in a study of FeCu alloys thermal aging (Vincent et al. 2008a), and it was found, not very surprisingly, that it is the parameterization rather than the method which impacts the most on the results, i.e., the density and mean precipitate radii.

The next section describes the different approaches used to determine the activation energies as well as build the energetic model of the system. The energetic model has to be built on a compromise between the complexity of the system (e.g., the number of solutes to treat) and the combinatorial increase of parameters to

determine and adjust, as well as a computational simplicity in order to be able to perform a very large number of KMC steps to simulate the target microstructure evolution.

3   Hamiltonians for AKMC Simulations

3.1   Exact Hamiltonians Based on DFT and Empirical Potentials

The evolution of the microstructure is driven by the point defects and the hetero-interstitials motions in the lattice. The key issue in these models is, as already mentioned in the previous section, the calculation of the jump probabilities. In the case of perfect and pure elements with simple defects, jump probabilities are not difficult to determine as it is easy to calculate the migration barrier and the attempt frequency using density functional theory (DFT) (i.e. *ab initio* or first principles approaches) calculations. However, in reals systems, solute atoms and strains will impact the activation barriers as described for instance in Tchitchekova et al. (2014) which can lead to incorrect predictions for the barriers even with a highly accurate energy calculation. The ideal way to compute jump frequencies would be to use a first principles approach on a box sufficiently large to limit size effects. Even though first principles calculations are not strictly exact, since they are based on a certain number of approximations which are more or less well controlled according to the different cases, its use represents, at the moment, the most reliable approach to obtain the potential energy for a given atomic distribution. Many methods for finding barriers exist and are implemented in DFT-based codes to determine activation barriers or migration energies. They include the nudged elastic band (NEB) (Henkelman et al. 2000), the growing spring method (Peters et al. 2004), the dimer (Henkelman and Jónsson 1999), autonomous basin climbing (ABC) (Fan et al. 2010) or eigen-vector following methods such as ART-nouveau (Barkema and Mousseau 1996; El-Mellouhi et al. 2008). However, these methods are computationally very demanding when applied to DFT calculations, and they have been used so far only in simple cases such as the estimation of tracer diffusion coefficients that require the calculations of only a few jump frequencies (Mantina et al. 2008; Messina et al. 2014). This is why it is often necessary to turn to empirical potential or force field approach to assess energy barriers. While these potentials are cheap enough to avoid strain artefacts due to small boxes, one of their recurring problems is their transferability, and more precisely their ability to correctly model the desired material under conditions far from the conditions used when adjusting the parameters. Even with empirical potentials, methods such as "on-the-fly" AKMC simulations that can require billions of point defects, jumps remain time consuming without additional tricks (Athènes and Bulatov 2014). Furthermore, the empirical potentials available at the moment are mostly limited to binaries, a few ternaries and even less quaternaries. Often, therefore, simpler models based on strong approximations typically associated with rigid lattices that are described in the following subsections, and illustrated with a few applications, must be used.

3.2 Effective Hamiltonians Based on Cluster Expansions

Cluster expansion methods provide a formalism to derive Hamiltonian, based on a decomposition of the interaction into pairs (that can be between different nearest neighbor distances), triplets (ε_{ijk}), quadruplets (ε_{ijkl}), quintuplet, and so on (Sanchez et al. 1984). The total energy of the system is obtained as:

$$E_{tot} = \sum_i \varepsilon_i + \sum_i \sum_{j<i} \varepsilon_{ij} + \sum_i \sum_{j<i} \sum_{k<j} \varepsilon_{ijk} + \sum_i \sum_{j<i} \sum_{k<j} \sum_{l<k} \varepsilon_{ijkl} + \cdots \quad (7)$$

3.2.1 Pair Models

The simplest approach is to use pair interaction models (Fig. 2). These models, based simply on the presence or absence of a given atom, require a rigid lattice and are often parameterized on experimental or DFT thermodynamical data.

In the case of an Fe alloy containing vacancies, the total energy of the system can be obtained as:

$$
\begin{aligned}
E = &\sum_j \varepsilon_{(Fe-Fe)}^{(i)} + \sum_k \varepsilon_{(V-V)}^{(i)} + \sum_l \varepsilon_{(Fe-V)}^{(i)} + \sum_m \varepsilon_{(Fe-X)}^{(i)} \\
&+ \sum_n \varepsilon_{(V-X)}^{(i)} + \sum_p \varepsilon_{(X-Y)}^{(i)}
\end{aligned}
\quad (8)
$$

where V stands for the vacancy, X and Y are solute atoms.

When interactions are limited to first nearest pairs, the thermodynamical properties of the system are easily determined using the Bragg Williams approximation. This approach has been applied for instance to study the precipitation of Cu in Fe, either using a broken bond model (Soisson et al. 1996) or FISE model (Vincent et al. 2008a) to determine E_a. This is the approach also chosen by Liu et al. to investigate complex Fe-CuNiMnSi alloys (Liu et al. 1997) using only first nearest neighbor parameters adjusted on binary mixing enthalpies. It has since then been shown that in bcc metals, one needs to go beyond the first nearest neighbor interaction to correctly reproduce the interaction of solutes with vacancies or to describe properly solute transport mechanism predicted by DFT calculations (Olsson et al. 2010) (Vincent et al. 2006; Messina et al. 2014).

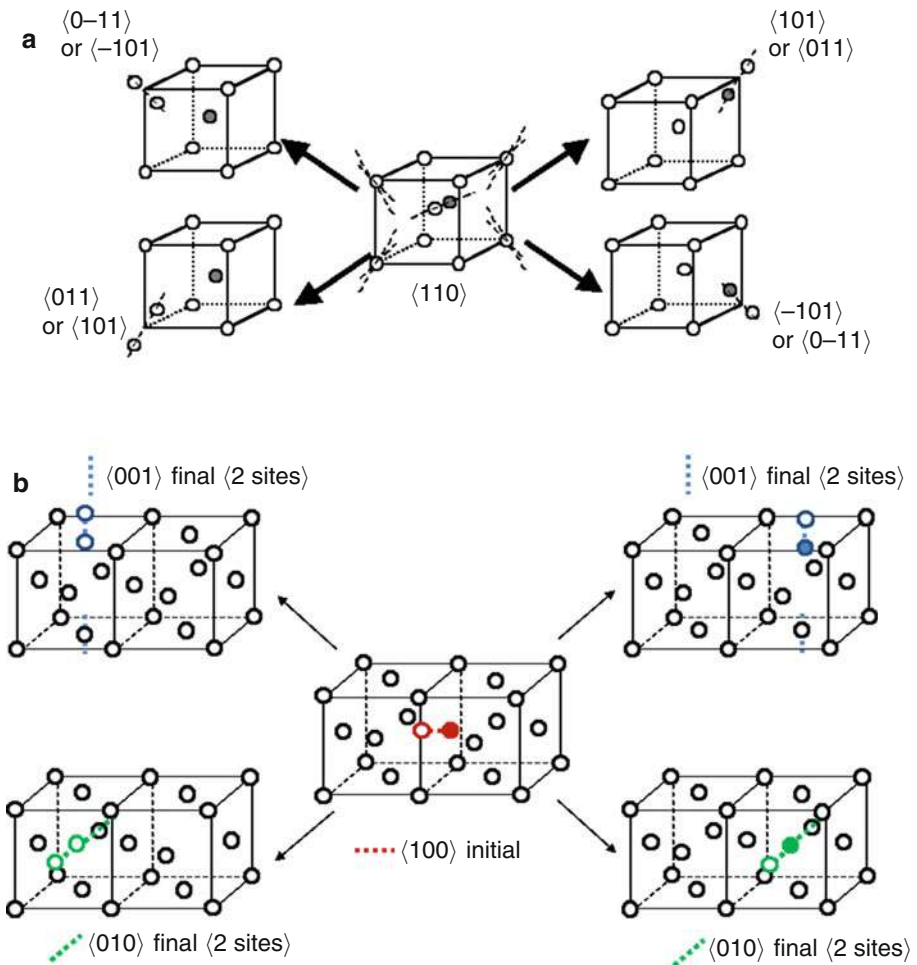
Fig. 2 Illustration of a pair interaction model
Hamiltonian-based pair models have also been derived for SIAs. These defects are more complex than vacancies: different dumbbells form in fcc or bcc metals, with off-lattice positions. The models have to be simplified as in Soisson (2006) or Soisson and Jourdan (2016) for which only the elements of the dumbbell X–Y are stored without considering the detailed migration mechanism and the dumbbell orientation or adapted on the main diffusion mechanisms as in Vincent et al. (2008b). In bcc Fe, most of the time, only the ⟨110⟩ dumbbell is considered, with eight possible jumps (Fig. 3a). It migrates in general according to the Johnson mechanism (Johnson 1964; Vincent et al. 2008b; Ngayam-Happy et al. 2010). In fcc


Fig. 3 SIA migration mechanisms considered (a) in bcc Fe, (b) in fcc Ni, Ni alloys, FeNiCr model fcc alloys

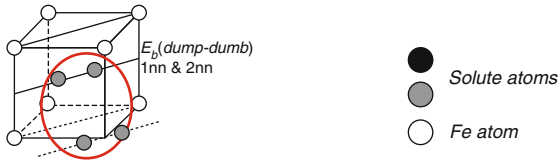
solute - dumbbell
dumbbell - dumbbell


Fig. 4 SIA-solute pair interaction model proposed by Vincent et al. (Vincent et al. 2008b). Three kinds of interactions are considered: dumbbell-dumbbell, dumbbell-compression, and dumbbell-tension sites interactions

alloys such as Ni, Ni alloys or FeNiCr model fcc alloys used to simulate austenitic materials, the $\langle 100 \rangle$ dumbbell is considered with eight possible translation rotation jumps (Fig. 3b).

One possible approach decomposes the SIA interaction into pairs that take into account the different nearest neighbor sites and the sign of the strains of these sites as illustrated on Fig. 4. Using this approach, the dumbbell contribution to the total energy of the system can be obtained as (Vincent et al. 2008b):

$$
E_{\text{dumb}} = \sum_i \left(E_f + \sum_j E_l^{1nn\text{Comp}} \left(\text{dumb}_i - X_j \right) + \sum_j E_l^{1nn\text{Tens}} \left(X_j \right) \right.
$$

$$
\left. + \sum_{i,j} E_l^{\text{mixte}} \left(X_j - X_k \right) + \sum_l E_l \left(\text{dumb} - \text{dumb} \right) \right)
$$

where three kinds of interactions are considered: dumbbell-dumbbell, dumbbell-compression, and dumbbell-tension sites.

FIAs can also be introduced on a sublattice as shown in Hin et al. (2008), where the precipitation of carbides in Fe and FeNb alloys has been modeled under thermal aging using a broken bond model.

Pair interactions and a broken bond model have been used, for instance, to study radiation induced segregation by electrons and neutrons in Fe-15 at %Cr alloys (Soisson and Jourdan 2016) taking into account replacement collision sequences and ballistic mixing as well as the migration of both vacancies and $\langle 110 \rangle$ dumbbells. Hocker et al. (Hocker et al. 2014) used a similar approach to study precipitation in FeCuNiMn alloys whereas Vincent and coworkers (Vincent et al. 2008b) chose the FISE/KRA approach and pair interactions to model FeCuNiMnSi alloys under irradiation.

Fig. 5 Most compact
structure for a triplet and a
quadruplet in a bcc lattice
3.2.2   Higher Order Cluster Expansion Models

When expanding the model beyond pair interactions, complexity increases rapidly
as different geometries must be defined for all n-uplets. The most compact ones, as
illustrated for bcc in Fig. 5, can be privileged in order to limit the possible choices
to the most significant interactions – with the selection, in general of solute atoms
close to each other.

Since each triplet has a different energy contribution, function of the three species
considered, the number of energy parameters (i.e., n-uplets containing combinations
of all the solutes) that need to be defined increases exponentially as the number
of solute species increases (Fig. 6). As in the case of pair interaction models,
parameters can be adjusted on experimental thermodynamical data and/or DFT
calculations. This method can be easily used in conjunction with the FISE/KRA
method as done in (Nguyen-Manh et al. 2008) to model thermal aging in FeCr
alloys or more recently to simulate thermal annealing in Fe–20Cr–xW alloys at
773 K (Bonny et al. 2017). The same approach was used to study ordering in
NiCr fcc alloys by Barnard et al. (2014) who used the CASM package (CASMcode
2017; CASM Developers 2016) to build their cluster expansion Hamiltonian which
was then used with the FISE/KRA approach to follow the formation of the Ni_2Cr
ordered phase under thermal aging. Van de Walle has developed the Alloy Theo-
retic Automated Toolkit (ATAT) (2017) that builds cluster expansion Hamiltonian
interfaced with DFT. ATAT includes tools for thermodynamical analysis and Monte
Carlo simulation but cannot perform kinetic Monte Carlo.

Note that even with simple pair models, the number of parameters required
increases very quickly with the amount of species that needs to be modeled as
can be seen from Fig. 6. Modelling realistic steels for instance remains a not
straightforward task, especially if the adjustment of the parameters is done "by
hand."

3.3   Neural Network and Machine Learning Methods

One promising approach by taking into account the local environment influence on
the migration energies is the use of artificial neural network (ANN) as proposed
by Djurabekova et al. 10 years ago (Djurabekova et al. 2007). The more accurate
the training sets, the better the predictions, thus building training sets from DFT
calculations appears to be the direction to take, as long as elastic effects are
correctly accounted for. For accuracy the training set should cover a large set of
configurations. This starts now to be possible with DFT, despite requiring large
Fig. 6 Evolution of the number of parameters versus the number of species for different approaches

computing resources. Castin et al. (2017) and Messina et al. (2017) combining DFT and ANN proved this approach to be manageable to accurately model the thermal aging of two very well-known systems: FeCr and FeCu. The training sets have been limited to 2,000–10,000 configurations, with extra care taken to choose different environments in order to reproduce both the solid solution and the vacancy environment close to a precipitate. Another possible approach is genetic algorithm implemented for instance in the open source code *potfit* that constructs force matching empirical potentials (Brommer et al. 2015).

4 Taking into Account Solute Effects in the Activation Barriers

The effect on the local atomic environment on the migration barrier can be introduced using different approaches that are discussed in that section.

A first approach is to have E_{sp} or E_a^0 depend on the local environment, and in a first-order approximation on the number of solute atoms in the vicinity of the jumping atom. In a typical FISE/KRA approach, such as the one employed in (Vincent et al. 2008b), all the effects of the environment on the migration barrier are carried by the ΔE term. This simple model can be improved by introducing a dependence of the E_a^0 term on the local atomic environment. In particular, an explicit dependence of E_a^0 on the migrating atom's saddle point local atomic environment – whose effect on the vacancy migration energy is particularly strong (Nguyen-Manh et al. 2008; Costa et al. 2014; Bouar and Soisson 2002), can be easily introduced. This has been done, with the FISE/KRA model, to study Cu precipitation in FeCu (Bouar and Soisson 2002) with a broken-bond model, thermal

aging in FeCr (Nguyen-Manh et al. 2008) or the spinodal decomposition in the same system (Costa 2012). All studies show, however, that saddle point energies are very sensitive to both the nature of the jumping atom and that of the first neighbors of the saddle point. As a result, the kinetics pathways are changed and, for instance, in the FeCu study, Le Bouar et al. observed that the dependence of the saddle-point binding energies on the local atomic configurations modifies the relative mobility of small Cu clusters and Cu monomers.

A more sophisticated model to take into account the LAE in a pair interaction model has been proposed by Martinez et al. (Martínez et al. 2012) to study FeCr alloys. In this approach, the pair interactions are fitted on DFT data and depend on the local concentration as well as temperature. This allows a much better description of the FeCr phase diagram and its miscibility gap.

Recently, this method has been adapted for multi-component dilute alloys and, more precisely, to model the Fe-CuNiMnSi system representative of Reactor Pressure Vessel (RPV) steels (Pannier 2017). In a first and second nearest neighbor pair interaction model, the pair interaction values depend on whether the vacancy is in a solid solution or in a precipitate. This method introduces some additional degrees of freedom as compared to the original method proposed in Vincent et al. (2008b) with a limited increase of the number of parameters that need to be adjusted ($2\times$ more compared to the original pair model).

The cluster expansion method can also be applied to determine the activation barrier. In their study of Li diffusion in Li_xCoO_2 oxides, Van der Ven et al. (Van der Ven et al. 2001) added a cluster expansion contribution to the first term (i.e., E_a^0 in Eq. 6) of the FISE /KRA equation, introducing a dependence of E_a^0 on the local environment, independently of the jump direction. Rehman et al. (Rehman et al. 2013) proposed a procedure based on cluster expansion to obtain directly the migration barriers encountered during diffusion of Ag on Ag(100) surfaces. They trained the cluster expansion on activation barriers obtained using the NEB method and found that they were able to generate an accurate process rate catalogue using this approach.

A mean field approach to include the influence of the local environment in the migration barrier has been proposed recently to study the diffusion of H in zircaloy (Zhang et al. 2017). At each KMC step, the migration barrier of each jump, E_a, is modified as:

$$E_a = E_a^0 + E_t^i \text{ if } R < c_t^i$$

where E_a^0 is the barrier without trapping, i.e., the activation energy in pure Zr. E_t^i is the binding energy of H at a trapping site t with a concentration c_t^i induced by solute i, the concentration of which is c_i. R is a random number drawn each time the jump rate is evaluated.

A last approach uses many body potentials or DFT calculations, recognizing that they take into account naturally the effects of mean local solute concentrations. Potentials based on the embedded atom method (EAM) (Daw and Baskes 1984) are

usually a good compromise to describe metals and their alloys. Such potentials, with additional refinements, have been used to describe the evolution of FeCr systems during short range ordering (Pareige et al. 2009) and spinodal decomposition (Pareige et al. 2011). In Kushima and Yildiz (2010), a database of migration barrier energies as a function of lattice strain for a set of representative defect distributions in the vicinity of the migration path in yttria stabilized zirconia was constructed using DFT and the NEB.

5 Specific Issues Linked to Irradiated Microstructures

Real microstructures contain interfaces such as grain boundaries, phase boundaries, and so on. They are important to take into account as segregation or depletion of solutes can take place in their vicinity because they can act as sinks or traps.

In the AKMC approach, grain boundaries can be modeled using different methods. They can simply be introduced as an atomic plane in the simulation boxes that has perfect sink properties for vacancies and SIAs (Soisson and Jourdan 2016) or with specific trapping properties in the energetic model (Soisson and Jourdan 2016; Piochaud 2013).

Another issue is the impact of energetic particles impacting alloys as in the case of irradiation. Depending on the energy of the incident particle, isolated Frenkel pairs (e.g., with electron irradiation) or displacement cascades with the formation of vacancies and self interstitials isolated and in clusters in a localized zone, few nanometers large (e.g., for high energy ions and neutrons) are created in a few pisoseconds. The associated time scale being much smaller than the atomic migration time scale, the point defects associated to one energetic particle interaction can be introduced between two atomic migration kinetic Monte Carlo steps.

Different approaches are possible to model such events which, in the case of a pure metal, can lead to similar microstructures; however, in alloys, they are not equivalent. In the case of Frenkel pairs, one can either introduce a vacancy and a SIA, at with or without a correlation distance between them, randomly in the simulation box as in Ngayam-Happy et al. (2010) or introduce a series of replacements ending by one vacancy and one SIA at the other end as in Soisson and Jourdan (2016). In the case of displacement cascades, they can be simulated by introducing, in the simulation box, the positions of vacancies and SIAs from a cascade database debris obtained by MD (Vincent et al. 2008b) or they can be obtained as a superposition of channeling sequences (along the <111> direction in bcc crystals for instance), replacement collision sequences (with a specific length), and replacement cascades, i.e., the introduction of vacancies and SIAs within the volume of a sphere (Soisson and Jourdan 2016). When replacements are made in alloys, solute mixing can occur, which may be important in concentrated alloys as they can lead to precipitation or ordering (Lear et al. 2017).

6   Future Directions and Perspectives

Modeling the microstructure evolution of alloys, during thermal aging, irradiation, or under any external constrain, is a difficult task as one has to deal with multiple solutes and/or several point defects. A balance between the computational cost, the cohesive model accuracy and the number of input parameters to build it, the chemical complexity (e.g., multi solute treatment) has to be found. This is why, even as off-lattice AKMC methods are introduced, the need will remain for lattice-based approaches as these are much faster and can achieve the billions of time steps required to understand the physics of defects and alloys in complex environments.

There is still considerable place for improvements, and we consider, in this section, a few directions that must be considered.

For dilute alloys, methods that estimate the activation energies in a specific local environment as a correction of the activation energy in a perfect unary matrix as in Zhang et al. (2017) can be used as long as the local environment remains dilute. These methods are thus appropriate to determine for instance the diffusion coefficients in dilute alloys but not precipitation or solute segregation.

Without a doubt, the most urgent advance must come from force field developers particularly when it comes to complex alloys and solutes. Since, *ab initio* approaches will remain confined to relatively small systems for the foreseeable future, we must turn to approximation. As far as the cohesive model is concerned, machine learning methods that are under development to build improved empirical potentials or cohesive models are currently the most promising path to provide a satisfactory solution both in terms of computational costs and precision. "Quantum accurate interatomic potentials" such as the Gaussian approximation potentials (GAP) (Bartók and Csányi 2015) or the Spectral Neighbor Analysis Potential (SNAP) (Thompson et al. 2015) can now be built, by constituting a very large DFT database and the use of machine learning tools. Fitting empirical potentials to functional forms based on the knowledge of the chemical interactions responsible for the material cohesion has limitations and the development of methods that uses very generic functional forms, not based on physical considerations, is well under way (Handley and Behler 2014). This is where machine learning algorithms become even more necessary. A recent review of these methods that discusses the central ideas behind machine learning potentials as well as their current applicability and limitations can be found in Behler (2016). Among the latter, the size of the database required to fit multicompound systems remains, nevertheless, a major hurdle that has not yet been solved. It is, however, only a matter of time before more complex systems become treatable, especially in the context of AKMC, where only local minima and transition require accuracy.

An accurate description of the energetics is not always sufficient, however. In many cases, variations in the entropy associated with diffusion mechanisms can completely change the kinetics. Yet, evaluating the contribution of entropy on the migration barriers is very computational demanding and will depend significantly,

again, on the cohesive model used. Theoretical methods exist to do so, see a review in Van der Ven et al. (2010); however, there require a considerable amount of additional calculations as one should calculate the configurational, vibrational, electronic, and magnetic entropic contributions as it has been done for defect and defect clusters formation energies (Marinica and Willaime 2007; Murali et al. 2015; Tucker et al. 2010; Posselt et al. 2017). This becomes especially important for inhomogeneous conditions such as grain boundaries, high entropy alloys, and surfaces. For example, the tetrahedral vacancy cluster, formed by a three-vacancy cluster with a displaced atom in the center (Aidhy et al. 2016) is very unstable at low temperature in Ni, with an energy 0.4 eV above ground state, separated by a barrier of only 0.08 eV, but is found to be stable above 400 K, due to entropic effects (Mahmoud et al. 2018).

Incorporating these effects in lattice-based AKMC will require a better approach to evaluate barriers, including energy and entropy, without exploding the event catalog and the number of local environments increases with solutes. This could be done by expending on cluster expansion methods. One promising improvement in this approach towards modeling more realistic microstructures is the methods derived by Yuge and co-worker (Yuge and Okawa 2014) to take into account strain effects which can be non negligible during alloys phase transitions, and handle multiple lattices (Yuge 2012). The performance of three CE fitting algorithms have been investigated in Herder et al. (2015) who find that performance depends on system details and complexity and becomes a trade-off between accuracy and computational cost. They find that quality of a CE depends on the data that it is fit to and the algorithm used to identify terms to introduce in the CE.

Clearly, CE methods will have to consider more complex and larger objects containing 10 or 20 atoms. To do that requires a better description and classification of local environments. Topological analysis tools such as NAUTY (McKay and Piperno 2014) or the graph approach proposed in Yuge (2017), for example, while first used with off-lattice KMC approaches, provide a very efficient way to differentiate between local environments, even with a large number of solutes, while automatically taking symmetry operations into account.

Even if this is not the purpose of this chapter, one important issue is the speeding up of the simulations as the calculation speed has to be taken into account in the choice of the cohesive models. In particular, when both low and high migration barriers can be encountered during the point defect motion, the defect can be trapped and many KMC steps are necessary to change configuration which can drastically slow down the evolution of the microstructure. Different methods are being developed to boost the simulation, see for instance Athènes and Bulatov (2014) or Danielson et al. (2017).

Abstract

Materials for nuclear applications are subjected to extremely stringent conditions. The incoming energetic particles create different types of defects in the material that modify the system microstructure. These defects diffuse and interact with each other and pre-existing features in the material, leading to alterations of the material properties, and even to failure. To deploy reliable materials for such extreme applications, a deep understanding of the microstructural changes and their relation to material properties is critically required. Synergistic experimental and theoretical studies are paramount to gain such crucial knowledge. In this work we review one theoretical venue developed over the years to first understand and then predict the material response upon irradiation: an object kinetic Monte Carlo (OKMC) approach parameterized to first-principles data. We review the theory behind the kinetic Monte Carlo (KMC) algorithm and the specifics of the OKMC as a mesoscale methodology. We describe density functional theory (DFT) as an ab initio approach that can accurately calculate parameters required by the OKMC as input data to be able to analyze the microstructure evolution of the system. Finally, we show two applications lengthily studied in the literature: the microstructural evolution of both ferritic steels and tungsten under diverse irradiation conditions.

1   Introduction

Irradiation has the potential to significantly alter the atomic structure of the material being irradiated. As energetic particles collide with the underlying atomic structure, extra energy is deposited in the material generating a sequence of structural modifications that are commonly denoted as defects. It is the evolution of these defects and their coupling with the material that dictate the resilience of the material to such irradiation conditions. Defects at the electronic level are known to vary the cohesive properties of the material (Correa et al. 2012; Draeger et al. 2017) and are usually characterized by short existence time on the order of femtoseconds. Defects at the atomic level, such as vacancies and interstitials, may also be created during the irradiation process. These structural defects are characterized by much longer lifetimes compared to electronic defects, during which these defects can migrate and interact with one another, generating new microstructural features that modify the material properties, and may eventually lead to failure. The time and length scales required to study the evolution of the irradiation-created defects exceed that attainable by molecular dynamics (MD) calculations. This is because MD solves Newton's equations of motion for an ensemble of atoms using an integration time step on the order of femtoseconds. This implies that the total number of steps

needed to reach simulated times of hours is around 3.6×10^{18}, far beyond the
current computational capabilities. Accelerated MD (AMD) algorithms (Voter 1997,
1998; Sørensen and Voter 2000) extend the physical time that can be studied using
MD approaches and provide good insights into complex mechanisms, but, because
they also rely on a full description of the interatomic forces, their application is
still limited in the system size as well as the simulated time. The kinetic Monte
Carlo (KMC) algorithm (Elcock and McCombie 1958; Elcock 1959; Young and
Elcock 1966; Bortz et al. 1975; Gillespie 1976, 1977; Voter 2007) also called the
Stochastic Simulation Algorithm provides a methodology to overcome the MD time
limitation. The scope of applications for KMC is extraordinarily wide, ranging
from epidemiology and population kinetics to surface growth or radiation damage.
This chapter reviews the time evolution of this last type of defects generated under
irradiation as analyzed theoretically with a computational tool called object kinetic
Monte Carlo (OKMC).

   The specific type of defects generated under irradiation and the spatial cor-
relations between them depend on the irradiation conditions and the material
subjected to irradiation. Under electronic irradiation, usually Frenkel pairs, i.e.,
a vacancy and a self-interstitial, are formed (Was 2007). On the other hand, if
irradiation is performed with neutrons, protons, or heavier ions with high enough
energies, a thermal spike occurs in the material leading to a displacement cascade.
Displacement cascades are commonly characterized by a low density core and a
denser outer shell, i.e., the core is vacancy rich while the periphery is self-interstitial
rich (Was 2007). The main goal of the OKMC is to study how these long-standing
defects diffuse, react, and couple with pre-existing material's features to be able
to first understand and then predict the microstructural changes taking place upon
specific irradiation conditions. For such end, the OKMC needs the probabilities per
unit time of all the possible events in the system. These probabilities are usually
calculated in the context of transition state theory (TST) (Eyring et al. 1944; Voter
and Doll 1984, 1985). According to TST, the rate for an event to happen follows an
Arrhenius expression

$$\Gamma_{\alpha \to \beta}^{TST} = \nu^* \exp\left(-\frac{\Delta G_{\alpha \to \beta}}{k_B T}\right) \tag{1}$$

where ν^* is a pre-exponential factor, $\Delta G_{\alpha \to \beta}$ the activation free energy for the
event that takes the system from state α to state β, k_B the Boltzmann constant,
and T the temperature. This model relies on several assumptions: (i) the adiabatic
approximation (Born-Oppenheimer) holds; (ii) the dynamics of the nuclei can be
described with the classical equations of motion; (iii) the configuration at the initial
minimum is at equilibrium, i.e., the system follows a Boltzmann distribution; and
(iv) recrossing events at the transition state are negligible. The TST rate represents
an upper bound to the true rate, $\Gamma_{\alpha \to \beta}^{TST} > \Gamma_{\alpha \to \beta}$, and can be adjusted considering
dynamical corrections (Voter and Doll 1984, 1985). In the crystalline systems of
most interest, at intermediate-to-low homologous temperatures, TST is commonly

approximated considering that the potential energy landscape is mostly harmonic (Vineyard 1957). In this approach, termed as harmonic TST (HTST), the rate is obtained through the expression

$$\Gamma_{\alpha \to \beta}^{HTST} = \frac{\prod_k^{3N} \omega_k^{\alpha}}{\prod_k^{3N-1} \omega_k^{ts}} \exp\left(-\frac{\Delta E_{\alpha \to \beta}}{k_B T}\right) \qquad (2)$$

where ω_k^{α} are the normal mode frequencies in the initial minimum configuration (α), ω_k^{ts} are the normal mode frequencies when the system is at the transition state (ts), and $\Delta E_{\alpha \to \beta}$ is the activation potential energy for the particular event. Assuming that HTST holds, the big question is then how to obtain the activation energies and the vibrational frequencies to calculate the rate for the specific event. As we shall see in the following, for small defects and defect clusters containing less than around six individual defects, the most accurate tool that is commonly used is density functional theory (DFT) (Sholl and Steckel 2009), which considers electronic degrees of freedom and relies on fewer assumptions than classical empirical potentials. It is worth noting that free energies can also be computed within the DFT approach, which sometimes allows for the harmonicity constrain to be relaxed. Although more accurate, the computational cost constrains the calculations to fairly small samples and thus the size of the defects to be studied. The activation energy might depend on both the migration energy and a binding energy of the defect to a microstructural feature. For larger defects, the calculation of the rates usually relies on empirical potential approaches, such that interactions between defects are minimized and accurate parameters are obtained.

In this chapter we first review the theory behind the kinetic Monte Carlo algorithm to then particularize into the object-like KMC methods. Subsequently, we review the density functional theory approach and the calculations that can be done to obtain the mechanisms and the rates for such events to finally give some examples of OKMC simulations of microstructure evolution under irradiation.

2 Formulation and Mathematical Aspects of the Kinetic Monte Carlo Algorithm

The KMC algorithm gives one realization of the *Markovian master equation*. In this section we will review the definition and derivation of the master equation and its relation to the KMC method.

2.1 The Master Equation

2.1.1 Markov Processes

A Markov process (Kampen 1992) is a stochastic process with the property that the outcome of one step depends only on the outcome of the previous step. Formally, this can be written for n successive measurements as

$$P(x_n, t_n | x_1, t_1; \cdots ; x_{n-1}, t_{n-1}) = P(x_n, t_n | x_{n-1}, t_{n-1}) \tag{3}$$

That is, the conditional probability density P to find the system in a state defined by x_n at time t_n, given by the value x_{n-1} at t_{n-1}, is uniquely determined and is not affected by any knowledge of the values at earlier times. P is called the transition probability, and x_n and t_n are two stochastic variables representing the measure and the time of the process.

A Markov process is fully determined by the two functions $P(x_1, t_1)$ and $P(x_2, t_2 | x_1, t_1)$; the whole process can be constructed from them. For instance, taking $t_1 < t_2 < t_3$

$$
\begin{aligned}
P(x_1, t_1; x_2, t_2; x_3, t_3) &= P(x_1, t_1; x_2, t_2) P(x_3, t_3 | x_1, t_1; x_2, t_2) \\
&= P(x_1, t_1) P(x_2, t_2 | x_1, t_1) P(x_3, t_3 | x_2, t_2) \tag{4}
\end{aligned}
$$

Continuing with this logic, one finds successively all P_n. This property makes Markov processes manageable, which is the reason why they are so useful in applications.

Integrating Eq. 4 over x_2 and dividing by $P(x_1, t_1)$, one obtains for $t_1 < t_2 < t_3$

$$P(x_3, t_3 | x_1, t_1) = \int P(x_3, t_3 | x_2, t_2) P(x_2, t_2 | x_1, t_1) dx_2 \tag{5}$$

This is the Chapman-Kolmogorov equation. It is an identity which must be obeyed by the transition probability of any Markov process. The time ordering is essential: t_2 lies between t_1 and t_3. Two important remarks are as follows:

1. Two different Markov processes can describe the same physical system, depending on the level of coarseness of the description.
2. A Markov process is not restricted to one-component processes. For any r-component stochastic process, one may ignore a number of components, and the remaining s components again constitute a stochastic process. But, if the r-component process is Markovian, the process formed by the $s < r$ components in general is not. Vice versa, if a certain physically given process is not Markovian, it is sometimes possible by introducing additional components, to embed it in a Markov process. These additional components serve to describe explicitly information that otherwise would be contained implicitly in the past values of the variables.

As a matter of fact, in general, any closed isolated physical system can be described as a Markov process introducing all microscopic variables as components of the process. The key problem is to find a small set of variables which evolution can be described as a multicomponent Markov process. This reduction to a smaller number of variables is called "contraction" or "projection" (Kampen 1992).

2.1.2 Derivation of the Master Equation

Consider a Markov process in which the transition probabilities only depend on the time difference $\tau = t_2 - t_1$ such that $P(x_2, t_2 | x_1, t_1) = T_\tau(x_2 | x_1)$. The Chapman-Kolmogorov Eq. 5 for T_τ is a functional relation, which is not easy to handle in actual applications. The master equation is a more convenient version of the same equation: it is a differential equation obtained by going to the limit of vanishing time difference τ. It can be shown (Kampen 1992) that $T_\tau(x_2 | x_1)$ for small τ has the form

$$T_\tau(x_2 | x_1) = (1 - a_0 \tau)\delta(x_2 - x_1) + \tau W(x_2 | x_1) + \mathcal{O}(\tau) \tag{6}$$

Here $W(x_2 | x_1)$ is the transition probability per unit time from x_1 to x_2, and hence

$$W(x_2 | x_1) \geq 0 \tag{7}$$

The coefficient $(1 - a_0 \tau)$ in front of the delta function is the probability that no transition takes place during τ; hence

$$a_0(x_1) = \int W(x_2 | x_1) dx_2 \tag{8}$$

The Chapman-Kolmogorov Eq. 5 can be written as

$$T_{\tau + \tau'}(x_3 | x_1) = [1 - a_0(x_3)\tau']T_\tau(x_3 | x_1) + \tau' \int W(x_3 | x_2)T_\tau(x_2 | x_1) dx_2 \tag{9}$$

Dividing by τ', go to the limit $\tau' \to 0$, and use Eq. 8

$$\frac{\partial}{\partial \tau} T_\tau(x_3 | x_1) = \int \{W(x_3 | x_2)T_\tau(x_2 | x_1) - W(x_2 | x_3)T_\tau(x_3 | x_1)\} dx_2 \tag{10}$$

which is a differential form of the Chapman-Kolmogorov equation, known as the master equation. For a discrete Markov chain with index n, this equation reduces to

$$\frac{\partial P(x, t)}{\partial t} = \int \{W(x | x')P(x', t) - W(x' | x)P(x, t)\} dx' \tag{11}$$

If the range of $X = (x_1; x_2; \cdots; x_n)$ is a discrete set of states, the equation reduces to

$$\frac{\partial p_n(t)}{\partial t} = \sum_n \{W_{nn'} p_{n'}(t) - W_{n'n} p_n(t)\} \tag{12}$$

which represents a rate equation (gain-loss equation) for the probabilities of the separate states n. The first term is the gain of state n due to transitions from other

states n', and the second term is the loss due to transitions from n into other states. Remember that $W_{nn'} \geq 0$ when $n \neq n'$ and that the term with $n = n'$ does not contribute to the sum (Kampen 1992).

Equation 12 can be written in a more compact form when the following matrix $\mathbb{W}$ is defined

$$\mathbb{W}_{nn'} = W_{nn'} - \delta_{nn'} \left(\sum_{n''} W_{n''n} \right) \tag{13}$$

Then Eq. 12 can be written

$$\dot{p}_n(t) = \sum_{n'} \mathbb{W}_{nn'} p_{n'}(t) \tag{14}$$

Formally the solution of Eq. 14 with given initial $p_n(0)$ may be written

$$p_n(t) = \exp\{t \cdot \mathbb{W}_{nn'}\} p_n(0) \tag{15}$$

$\mathbb{W}_{nn'}$ needs to follow

$$\mathbb{W}_{nn'} \geq 0 \quad \text{for n} \neq \text{n'}; \tag{16}$$

$$\sum_n \mathbb{W}_{nn'} = 0 \quad \text{for each n'.} \tag{17}$$

Equation 16 shows the fact that the probability of staying in state n' is simply 1 minus the probability of escaping. For a complete reference on the properties of these matrices, see, e.g., Kampen (1992).

A fundamental property of the master equation is that as $t \rightarrow \infty$, all solutions tend to the stationary solution. This statement is strictly true only for a finite number of discrete states. For an infinite number of states, there are exceptions, such as the random walk.

3   The Kinetic Monte Carlo Algorithm

In any particular case, the master equation is fairly easy to write; however, solving it is quite another matter. The number of problems for which the master equation can be solved analytically is very limited. In addition, the master equation does not readily lend itself to numerical solutions due to the number and nature of its independent variables.

In 1976 Daniel T. Gillespie published his seminal paper *A General Method for Numerically Simulating Stochastic Time Evolution of Coupled Chemical Reactions* (Gillespie 1976). In this work, Gillespie developed the main theory behind what is nowadays known as the kinetic Monte Carlo algorithm. We will follow his

derivation here since it is concise and very clear. In Gillespie's words: "The method is a systematic, computer-oriented procedure in which rigorously derived Monte Carlo techniques are employed to *numerically simulate* the very Markov process that the Master Equation describes analytically." That is, the method circumvents the need to solve analytically or numerically the master equation and gives what is usually called "one realization of the master equation" since one dynamic trajectory in phase space is obtained from it. If many trajectories are simulated, the obtained probability distribution complies with the master equation, and thus, in essence, the algorithm is a method to numerically solve the master equation that we have described in previous sections.

Gillespie developed this method to study chemical reactions. In general, the method is applicable to every process that can be modeled with the master equation, and hence, the constraints imposed to its derivation apply to the problems that can be solved with this algorithm; mainly, the process has to be Markovian (remember that every deterministic process is Markovian) and first order in time.

We want to solve the dynamic evolution of a system characterized by a set of states in phase space α, β, γ, etc. As mentioned above, it is the researcher's task to define phase space so to comply with the necessary constraints and, therefore, to be able to solve the problem at hand using the kinetic Monte Carlo methodology. The fundamental hypothesis of the stochastic formulation, and the only assumption to be made by the computational method, is that the probability that a particular transition occurs in the next time interval δt is equal to $c_{\mu\nu}\delta t + o(\delta t)$, where $o(\delta t)$ denotes unspecified terms which satisfy $o(\delta t)/\delta t \to 0$ as $\delta t \to 0$. Therefore

$$c_{\mu\nu}\delta t \equiv \text{average probability, to first order in } \delta t,$$

$$\text{that a particular transition } (\mu \to \nu) \text{ occurs.} \tag{18}$$

We want to solve the probability for the system to be in state μ at time t, $\forall t$, and $P(\mu; t)$, knowing the initial probability distribution and the transition probabilities per unit time $c_{\mu\nu}$. It is worth mentioning that the master equation can be derived from Eq. 18 by using the addition and multiplication laws of probability theory to write $P(\mu; t+dt)$ as the sum of the probabilities of the different ways for the system to arrive at state μ at time $t + dt$:

$$P(\mu, t + dt) = P(\mu, t)\left[1 - \sum_{\mu}^{M} c_{\mu\nu}dt\right] + \sum_{\nu}^{M} c_{\nu\mu}P(\nu; t)dt \tag{19}$$

and therefore

$$\frac{\partial P(\mu, t)}{\partial t} = \sum_{\nu}^{M} c_{\nu\mu}P(\nu; t) - \sum_{\mu}^{M} c_{\mu\nu}P(\mu, t) \tag{20}$$

which is the master equation, with M as the total number of states.

The principal theoretical construct upon which the procedure is based is not the grand probability function $P(\mu, t)$, nor any of its derived quantities, but rather an entity which is called the *reaction probability density function*, $P(\tau, \mu\nu)$, which is defined as

$$P(\tau, \mu\nu)d\tau \equiv \text{probability at time t that the next transition}$$

$$\text{in volume V will occur in the differential}$$

$$\text{time interval } (t + \tau, t + \tau + d\tau)$$

$$\text{and will be transition } \mu \rightarrow \nu. \tag{21}$$

$P(\tau, \mu\nu)$ is a joint probability density function on the space of the continuous variable $\tau (0 \leq \tau < \infty)$ and the discrete variable $\mu\nu(\mu\nu = \alpha \rightarrow \beta, \alpha \rightarrow \gamma, \ldots, \beta \rightarrow \alpha, \ldots)$. This joint probability is the product of $P_0(\tau)$, the probability at time t that no transition will occur in the time interval $(t, t + \tau)$, times $c_{\mu\nu}d\tau$, and the subsequent probability that transition $\mu \rightarrow \nu$ will occur in the next differential time interval $(t + \tau, t + \tau + d\tau)$:

$$P(\tau, \mu\nu)d\tau = P_0(\tau) \cdot c_{\mu\nu}d\tau \tag{22}$$

Note that we need not worry about more than one reaction occurring in $(t + \tau, t + \tau + d\tau)$, since the probability for this to happen is $o(d\tau)$. $P_0(\tau)$ can be obtained if the interval $(t, t + \tau)$ is divided into K subintervals of equal length $\epsilon = \tau/K$. The probability if nothing happened in the first subinterval ϵ is

$$\prod_{\mu\nu}^{M} \left[1 - c_{\mu\nu}\epsilon + o(\epsilon) \right] = 1 - \sum_{\mu\nu}^{M} c_{\mu\nu}\epsilon + o(\epsilon) \tag{23}$$

For the whole interval, we can then write

$$P_0(\tau) = \left[1 - \sum_{\mu\nu}^{M} c_{\mu\nu}\epsilon + o(\epsilon) \right]^K = \left[1 - \sum_{\mu\nu}^{M} c_{\mu\nu}\tau/K + o(K^{-1}) \right]^K \tag{24}$$

In the limit of infinitely large K

$$P_0(\tau) = \exp\left[-\sum_{\mu\nu}^{M} c_{\mu\nu}\tau \right] \tag{25}$$

Substituting in Eq. 22, we obtain

$$P(\tau, \mu\nu) = c_{\mu\nu} \exp\left[-\sum_{\mu\nu}^{M} c_{\mu\nu}\tau \right] \tag{26}$$

The main goal of the KMC algorithm is to generate random points in phase space according to such probability density function. Three main methods have been developed to do so: (i) the direct method, (ii) the first reaction method (also called the first passage method), and (iii) the null event method.

3.1   The Direct Method

This method is based on the fact that any two-variable probability density function can be written as the product of two one-variable probability density functions. As such we can write $P(\tau, \mu\nu)$ as

$$P(\tau, \mu\nu) = P_1(\tau) \cdot P_2(\mu\nu|\tau) \tag{27}$$

where $P_1(\tau)d\tau$ is the probability that the next reaction takes place within the interval $[t + \tau, t + \tau + d\tau]$, independent of which reaction it might be. $P_2(\mu\nu|\tau)$ is the conditional probability that next event is $\mu\nu$ given that it occurs at time $t + \tau$. $P_1(\tau)d\tau$ is obtained summing $P(\tau, \mu\nu)d\tau$ over all possible events $\mu\nu$:

$$P_1(\tau) = \sum_{\mu\nu}^{M} P(\tau, \mu\nu) \tag{28}$$

Substituting this expression into Eq. 27 and solving for $P_2(\mu\nu|\tau)$

$$P_2(\mu\nu|\tau) = \frac{P(\tau, \mu\nu)}{\sum_{\mu\nu}^{M} P(\tau, \mu\nu)} \tag{29}$$

Substituting now the expression for $P(\tau, \mu\nu)$ given in Eq. 26 and defining $R = \sum_{\mu\nu}^{M} c_{\mu\nu}$, we obtain

$$P_1(\tau) = R \exp(-R\tau) \qquad (0 \leq \tau < \infty), \tag{30}$$

$$P_2(\mu\nu|\tau) = \frac{c_{\mu\nu}}{R} \qquad (\mu\nu = 1, 2, \ldots, M), \tag{31}$$

and we can now generate a random τ according to $P_1(\tau)$ and a random $c_{\mu\nu}$ from $P_2(\mu\nu|\tau)$ with the resulting pair $(\tau, c_{\mu\nu})$ distributed according to $P(\tau, \mu\nu)$. τ can be obtained drawing a uniformly distributed random number (ξ_1) in the interval $[0, 1)$ from the expression

$$\tau = \frac{1}{R} \ln \frac{1}{\xi_1} \tag{32}$$

while $c_{\mu\nu}$ can be obtained drawing a second random number (ξ_1) again uniformly distributed in [0, 1) and taking the event that satisfies

$$\sum_{\mu\nu}^{m-1} c_{\mu\nu} < \xi_2 \leq \sum_{\mu\nu}^{m} c_{\mu\nu} \tag{33}$$

3.2   The First Reaction Method

This method is based on the fact that the probability that at time t the event $\mu\nu$ occurs in the interval $(t + \tau, t + \tau + d\tau)$ irrespectively of all other possible events is given by

$$P_{\mu\nu}(\tau)d\tau = \exp\left(-c_{\mu\nu}\tau\right) \cdot c_{\mu\nu}d\tau \tag{34}$$

Therefore, independent times for each event might be drawn from such probability distribution using the same expression as before:

$$\tau_{\mu\nu} = \frac{1}{c_{\mu\nu}} \ln \frac{1}{\xi_{\mu\nu}} \tag{35}$$

where $\xi_{\mu\nu}$ is a random number to be drawn uniformly for each possible event. The actual next event is the one with the shortest time. This scheme generates a pair $(\mu\nu, \tau)$ that complies with the $P(\tau, \mu\nu)$ probability density function. Because the amount of random number needed is much larger than in the previous method, this algorithm is usually less efficient. However, recent implementations take advantage of spatial decompositions to accelerate the wall time for the system to evolve in time (Opplestrup et al. 2006).

3.3   The Null Event Method

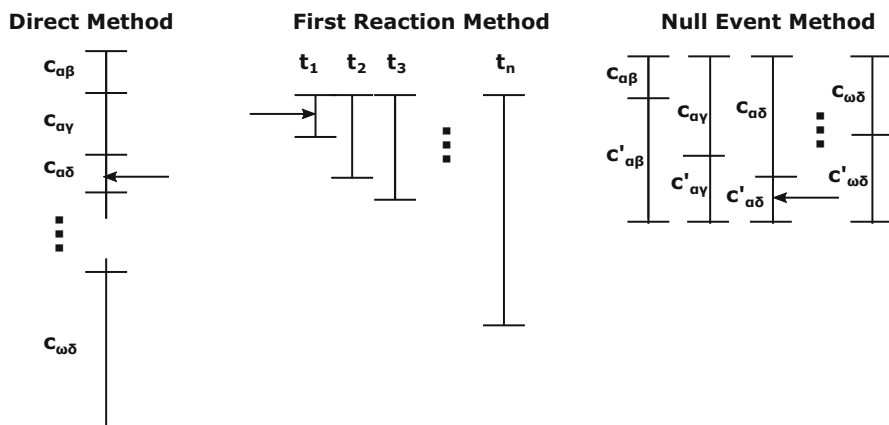
algorithm is based on the introduction of a new type of event, usually denoted as a null event, which if chosen keeps the microstructure in its original state. This extra event can be added to each individual event such that all events have the same total rate (Gilmer and Bennema 1972) or can be added to a cumulative rate of a set of events (Hanusse and Blanche 1981). It can be shown that this algorithm solves the same master equation as the previous two methods and therefore can be used to study the microstructural evolution, that is, the algorithm follows the right dynamics. The advantage of this method is that the searching wall time to find the event is reduced considerably, even to zero, i.e., the CPU time scales as $O(1)$. However, the simulated time step decreases, since it is sampled from the same probability distribution with the extra rates due to the null events, $\tau = \frac{1}{R_{\text{null}}} \ln \frac{1}{\xi_1}$, with R_{null} the aggregate of all rates. This implies that the best computational efficiency will occur


Fig. 1 Sampling approaches

for a minimum in the total null event rate (Chatterjee and Vlachos 2007). If the searching step in the direct method represents a large bottleneck in computational speed and the system is not significantly stiff (i.e., the total null event rate is not daunting), this algorithm can outperform the direct method.

Figure 1 shows schematics of the three sampling methods described above.

4 Searching and Updating Algorithms

Provided the rates are trivially calculated or are tabulated in advance, sampling Eq. 33 can represent the main computational bottleneck in KMC simulations. In general, the calculation of the rates is far from trivial, and several algorithms have been recently developed to calculate more accurately rates *on-the-fly* within a KMC scheme. This set of methods are usually denoted as adaptive KMC algorithms (Henkelman and Jonsson 2001; El-Mellouhi et al. 2008; Xu and Henkelman 2008). However, these methods are computationally demanding, and the total simulated time and the sample size remain limited. On the other hand, they are usually able (like MD or AMD) of obtaining the reaction mechanism without extra assumptions. In the context of irradiation to analyze the long-term microstructural evolution of the system under irradiation, the rates for the different events are usually pre-computed, and under these conditions, it is important to identify the possible different searching and updating algorithms that reduce the wall time in sampling Eq. 33 and updating the rates and its aggregate.

4.1 Linear Search

The linear search is the simplest algorithm to implement. It uses an array or list of possible events with an assigned rate that visits linearly, i.e., one by one in the list,

to calculate the cumulative rate, until Eq. 33 is satisfied. This method scales linearly with the number of events, i.e., $O(N)$ with N the total number of events. Grouping can be used to improve the efficiency in what has been denoted as n-level linear algorithms. In this case a set of events are grouped together and the cumulative rate computed in as many levels as wanted. Each search goes in general through a number of events that is $N_n \approx N^{1/n}$, with n the level of grouping. The wall time of this algorithms scales then as $nO(N_n)$, which can be considerably faster than the brute force linear search.

4.2   Binary Search

Binary searches rely on the generation of a tree data structure containing information about the rates (Gibson et al. 2000; Schulze 2002) to reduce the CPU time required to sample Eq. 33. In this structure, each node represents a cumulative propensity of the branches below it, such that the bottom nodes represent individual propensities for specific events. The number of levels in a tree will be at least $N_{level} = floor(\log_2(N))$. If this is the case, the tree is considered equilibrated, and the computational efficiency is maximum. The algorithm starts at the head node that contains the cumulative rate of the left branch. If the target rate is lower, the next search is performed in the children to the left of the head node, to the right otherwise. This process is repeated until the bottom of the tree is reached and the event identified. In this algorithm the CPU time scales as $O(\log_2(N))$; however, the pre-factor to keep the tree equilibrated might be significant, and, not in every situation, this algorithm is faster than the linear searches.

4.3   Constant Time Search

The main idea of this method is based on the null event (or rejection) algorithm, in which the need for searching is reduced to drawing an integer random number from a uniform distribution between $[1, N]$, with N the total number of possible events, which will directly point at the event to be performed, including a null event. A second random number must be generated to pick between the actual or the null events. The search does not depend on the number of events, N, and therefore scales as $O(1)$. In a stiff problem with significantly different rates, a grouping algorithm can be developed to minimize the amount of null events. This will resemble a combination between the n-level search with the extra addition of the null events. In this case the search would be $O(N_n)$, with N_n the number of groups. This null event (or padding) method could also be combined with a binary search to keep the tree balanced. A review of this method can be found in Slepoy et al. (2008).

Figure 2 shows a summary of the searching algorithms discussed above.
Fig. 2 Searching algorithms

5   Object Kinetic Monte Carlo Methods

The object kinetic Monte Carlo (OKMC) method uses a coarse-grained representation of the system to accelerate the wall time required to analyze its time evolution. In the context of materials under irradiation, the method averages out the underlying atomic structure to consider as possible event processes involving defects. Therefore, the algorithm follows the irradiation-created defects in time, solving for their migration and the interaction with one another and other kinds of features in the microstructure, such as grain boundaries, dislocations, alloying elements, or such. As it was mentioned in Sect. 1, TST is usually assumed to calculate the rates for each possible event, although, in general, experimental results or MD simulations can be also used to obtain such propensities, including dynamical corrections. The method results in a defect distribution evolving in time for a given initial microstructure (may be containing defect sinks such as interfaces or dislocations) under a given set of irradiation conditions, such as dose rate, temperature, pressure, and information about the nature of the defects created in the collision processes.

6   Density Functional Theory to Calculate Propensities

Density functional theory (DFT) is a mean field approach to solve the many-body Schrodinger equation (Hohenberg and Kohn 1964). It is based on the fact that the ground-state properties of a many-electron system are uniquely determined by an electron density that depends on only three spatial coordinates. As such, the many-body problem of M electrons with $3M$ spatial degrees of freedom is reduced to three spatial coordinates through the use of functionals of the electron density. DFT assumes that the electron dynamics are much faster than the nuclei and solves the ground-state electronic structure for a fixed positions of the nuclei, i.e., the

Born-Oppenheimer approximation is assumed to hold. Hohenberg and Kohn (1964) developed an energy functional for the system and demonstrated that the true ground state of such energy functional minimizes the functional. Subsequently, Kohn and Sham (1965) were able to reduce the many-body problem of interacting electrons in a static external potential to a solvable problem of noninteracting electrons evolving in an effective potential. The correctness of these methods mainly relies on the accuracy of this effective potential. This effective potential includes the external potential and the Coulomb interactions between electrons, with contributions from the exchange and correlation interactions. The simplest approach is the local-density approximation (LDA) that relies on the exact exchange energy for a uniform electron gas as given by the Thomas-Fermi model (Ceperley et al. 1980). More complex functionals for exchange and correlation have been developed and still are a very active field of research. One widely used example is the generalized gradient approximation (GGA) that incorporates information about the gradient of the electron density in the functionals to account for the non-homogeneity of the real electron density (Langreth and Mehl 1983; Becke 1988; Perdew et al. 1992). Hybrid functionals incorporating a portion of the exact exchange energy calculated from Hartree-Fock theory with the rest of exchange correlation from other sources are also extensively used. The problem of finding the ground-state electron density is variational and has to be solved iteratively in a self-consistent manner such that the effective potential and the wave functions are also obtained for such electron density.

DFT is widely used in chemistry and materials science to understand and predict the properties of complex systems under specific conditions. Although computationally more efficient than all-electron approaches, the solution of the DFT equations presents a computational bottleneck, which translates into limited system sizes and simulated times. In general, the computational scaling of this method is $O(n^3)$ with n the number of electrons since usually the diagonalization of the system Hamiltonian scales as n^3. The development of $O(n)$ methods is also a remarkably active research area (Niklasson et al. 2006; Witt et al. 2018).

In the context of materials under irradiation, this approach has been broadly used to estimate the properties of defects. Although usually calculated at 0 K, there have been some studies using ab initio MD to compute the required properties (Grabowski et al. 2007; Körmann et al. 2008; Grabowski et al. 2011; Glensk et al. 2015) at higher temperature. One of such properties is the defect formation energy. This is usually calculated as

$$E_{\text{for}}(D) = E[N_{\text{at}} + D] - (N_{\text{at}} + D)\mu \qquad (36)$$

where D represents the defect, N_{at} is the number of atoms in the bulk system, and μ is the cohesive energy of the material. This formation energy might be used to estimate the equilibrium defect populations.

Another important quantity is the migration energy ($E_m(D)$), which is defined as the difference of the energy of the system at the saddle point and the initial state

for a defect hopping. To compute this migration energy, the system is forced to converge to the minimum energy path (MEP) between the initial and final states. If the initial and final states are known, methods like the drag method (Trushin 2005) or the nudged elastic band (NEB) (Henkelman and Jonsson 2000; Henkelman et al. 2000) are commonly used. If the final state is unknown a priori, the dimer method (Henkelman and Jonsson 1999) or the Lanczos method (El-Mellouhi et al. 2008) are usually preferred. Recently, advanced methods have been developed to improve the predictions obtained with the traditional methods, such as free-end NEB (Zhu et al. 2007) or free-end adaptive NEB (Zhang et al. 2016). This $E_m(D)$ will be used in the HTST expression (Eq. 2) to compute the migration rate. The pre-factor is usually assumed constant and close to the Debye frequency of the material. However, under certain conditions, it has been shown that the explicit calculation of the pre-factor might significantly change the event rate. One of such conditions arises when the system is under nonuniform strain, in which case the pre-factor can change by orders of magnitude (Uberuaga et al. 2007). Vineyard pre-exponential factors can also be calculated within DFT, although the computational expense is high.

Binding energies are also crucial for the method to be predictive. The binding energy characterizes the interaction between two or more species in the system. It is defined as the energy gain in a given reactions that can be exothermic or endothermic:

$$E^b_{X-Y}(A) = E[S + X + Y] + E[S] - (E[S + X] + E[S + Y]) \tag{37}$$

where $E^b_{X-Y}(A)$ denotes the binding energy of species X and Y in system S, $E[S + X + Y]$ is the energy of the system with the interacting species, $E[S]$ is the reference system, and $E[S + X]$ and $E[S + Y]$ are the reference systems with specie X and Y, respectively. Important binding energies are, for example, from single defects to clusters, between defects and impurities or alloying elements, and between defects and sinks (such as grain boundaries or dislocations). This binding energy enters in the activation energy for a dissociation process, altering the propensity for such reaction to occur. Expressions derived from elasticity theory are commonly used to fit the values obtained from DFT and extrapolate for larger cluster sizes (Perini et al. 1984).

The interaction radius is also an important parameter needed in the OKMC method. In general, it depends on the species and its size. Usually, empirical relations based on DFT data are used. For defect clusters, a common expression is $r_n = Z \cdot \left(\frac{3n\Omega}{4\pi}\right)^{1/3} + r_0$, where Z is a bias factor depending on the nature of the defect, n is the number of single defects in the cluster, Ω is the atomic volume, and r_0 is a constant usually obtained with DFT.

DFT has also been used to obtain threshold displacement energies in materials of interest, i.e., the minimum energy that needs to be given to an atom such that a stable Frenkel pair is formed. This approach has been employed to study the energetic threshold depending on the orientation in materials such as α-Fe (Olsson et al. 2016) and W (De Backer et al. 2016).

7   Examples

In this section we will show a couple of examples in which this method has been applied to analyze the evolution of the microstructure under irradiation. The first one is for ferritic/martensitic steels, which is of great importance in nuclear applications. The second example studies the defect evolution in tungsten (W) and the interaction of the irradiation-created defects with He created from (n, α) nuclear reactions and the incoming flux from the plasma ashes.

7.1   Microstructural Evolution in α-Fe Under Irradiation

Irradiation of a metal and subsequent annealing while measuring electrical resistivity can provide important information about basic processes related to defect migration and defect stability, data that can be calculated with DFT or other atomic-scale models as mentioned in the previous section. C. C. Fu et al. (2005) using event kinetic Monte Carlo with parameters from DFT simulated the resistivity recovery curve of Fe after electron irradiation and correlated these results to the different peaks observed in experiments performed by Takaki et al. (1983). Figure 3 shows the derivative of the number of defects (N) as a function of temperature obtained in this case with OKMC and the same parameters as in Fu et al. (2005) for a dose of $2 \times 10^{-6} dpa$ (dpa = displacements per atom). The locations of the peaks found experimentally in Takaki et al. (1983) are marked in the same figure with arrows. These simulations show that the first peak (named stage ID2) appears because of the recombination of correlated Frenkel pairs. In this case the vacancy and self-interstitial belong to the same Frenkel pair in such a way that with one single self-interstitial jump, these defects recombine. Recombination of defects gives rise to a decrease in the resistivity of the material and therefore a peak in the derivative of the curve. The second stage, named IE, also corresponds to the recombination between vacancies and self-interstitials but for pairs of defects that are far away from each other, so more than one jump of the self-interstitial must occur for the defects to recombine. This peak appears at a temperature that corresponds to that of self-interstitial migration. The next stage, stage II, is due to the migration of self-interstitial clusters, while stage III is due to vacancy migration.

In the case of an alloy, if the concentration is low, the alloying element can be treated explicitly in the OKMC approach by treating every alloy atom as a defect. As mentioned above, in the OKMC approach, there is no underlying lattice, so, in principle, these atoms will be distributed randomly within the simulation cell. All the possible events that these atoms can perform, interaction with vacancies or self-interstitials, formation of clusters, or migration must be specified with their appropriate rates. For the case of FeCr alloys, there is information obtained from DFT on small clusters (Olsson et al. 2007; Olsson 2009). One important defect formed in FeCr alloys is the mixed interstitial dumbbell, which has a lower migration energy than the self-interstitial cluster, but also a low binding energy
Fig. 3 Derivative of the number of defects as a function of temperature for electron irradiation of Fe at a dose of $2 \times 10^{-6} dpa$ from OKMC calculations and parameters from Fu et al. (2005)

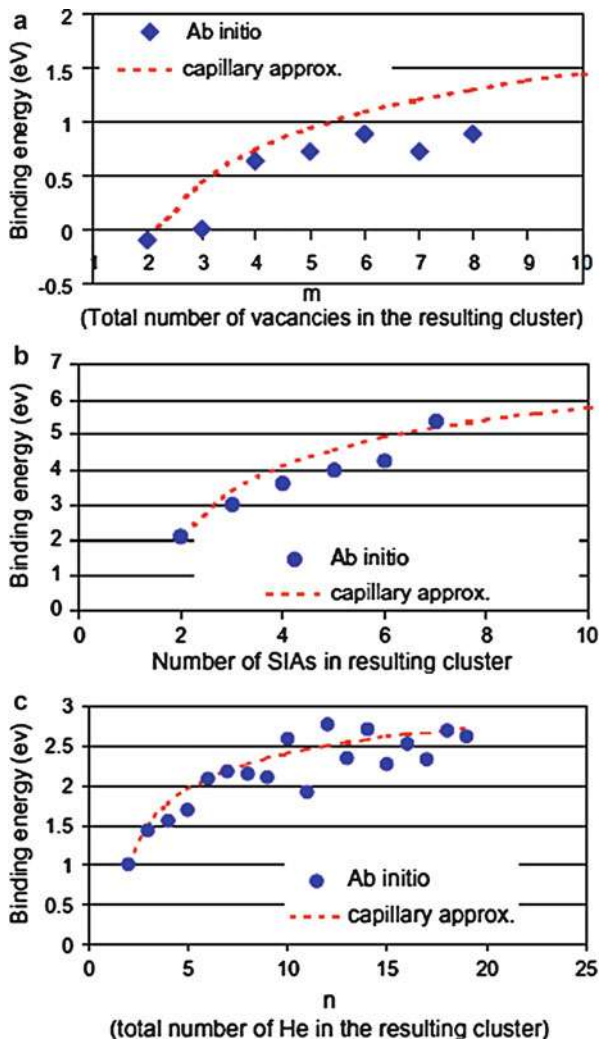
(Domain et al. 2004). Experimentally, it is observed that in low-concentration alloys (between 0.01 and 0.1% Cr), the IE peak in the resistivity recovery measurements shifts toward lower temperatures and the shift increases with Cr concentration (Abe and Kuramoto 1999; Maury et al. 1987). Using an OKMC model with parameters from DFT as described in Gámez et al. (2011) that include the formation of mixed dumbbells (ICr) as well as other Cr clusters (I2Cr, ICr2, and I2Cr2), the shift was reproduced as it can be seen in Fig. 4. This figure shows the results for pure Fe and for FeCr at the three concentrations measured experimentally in Abe and Kuramoto (1999), 0.019 at%, 0.047 at%, and 0.095 at%), and how the IE peak moves toward lower temperatures with increasing Cr concentration in agreement with the experiments. The reason behind this shift is in fact the formation of the ICr mixed dumbbell.

One of the advantages of the OKMC approach is that system sizes larger than those in lattice KMC (LKMC) models can be simulated, typically cubes of hundreds of nanometers on each direction. This allows for calculations of damage accumulation as a function of irradiation to doses that can be achieved experimentally and to model the formation of clusters large enough to be visible under transmission electron microscopy (TEM). An example of these types of simulations that have been performed by several groups for different conditions, starting with the work of Heinisch (1990) (see, e.g., Domain et al. 2004; Malerba et al. 2008; Becquart and Domain 2010), is presented here. In this case, the accumulation of damage during continuous irradiation of Fe and Cu is simulated. Details of these calculations are
in Caturla et al. (2000). In brief, a database of collision cascades in Cu and Fe for 30 keV recoils obtained from molecular dynamics simulations is used as initial damage distribution. This picosecond time damage is very different in Fe and in Cu. Cu presents mostly clustered vacancies with surrounding self-interstitial clusters, while in Fe most of the vacancies are isolated or forming very small clusters. The values of migration energies and binding energies of defects used in the calculations were obtained from empirical potentials. Figure 5 shows the total concentration of visible clusters as a function of dose for the case of the two materials studied, Cu and Fe. Here, the visibility conditions were considered as follows: 20 defects for vacancies in Cu, equivalent to a stacking fault tetrahedra of 1.5 nm, 350 vacancies for a 1 nm void in Fe, and 50 self-interstitials for a 1 nm loop in Fe. This figure shows that there is an important difference in the damage accumulated in Fe vs. Cu, phenomenon also observed experimentally (Dai et al. 1997). The reason for this difference is related both to the initial damage distribution and the effect of impurities in these two materials. In Cu, where no impurities are considered in the simulation, most self-interstitials and self-interstitial clusters disappear through recombination with vacancies or at grain boundaries, and most of the damage is vacancy clusters, with an average size of about 28 vacancies which corresponds with a 2 nm stacking fault, in agreement with experimental observations (Zinkle and Farrell 1989). In Fe, self-interstitials are trapped by impurities, which result in visible clusters, while vacancies are too small to be observed under TEM (with less than 15 defects). In Fe most of the evolution of the clusters and growth to sizes that can be observed experimentally is going to occur through defect diffusion and defect coalescence. And the description of these interactions depends on the set of reactions that the user of the OKMC model has decided to consider as the important ones.
Fig. 5 Visible defect clusters as a function of irradiation dose for the case of Fe and Cu (see Caturla et al. 2000 for details)

7.2   Microstructural Evolution in W Under Fusion Conditions

Critical components in magnetic fusion reactors are required to have stringent properties including low neutron activation, high melting point, good thermomechanical properties, low sputter erosion, and low tritium retention/co-deposition. Tungsten (W) is the leading plasma-facing material (PFM) candidate due to its high melting temperature, low erosion rates, and small tritium retention. These advantages are unfortunately coupled with very low fracture toughness characterized by brittle transgranular and intergranular failure regimes, which severely restrict the useful operating temperature window and also create a range of fabrication difficulties. Exposure to He and H plasma leads to the formation of diverse microstructures (pits, holes, bubbles, nanostructured surface morphology termed as fuzz) (Baldwin and Doerner 2008) that severely limit its utilization. Therefore, understanding the mechanisms leading to the W failure is crucial to develop materials to be able to withstand the extreme environments posed by fusion energy generation.

DFT has been broadly used to obtain the data mentioned above and needed by the OKMC to evolve the microstructure. Using different DFT approaches, the formation energies of intrinsic defects have been calculated. The single vacancy (V) values in the literature range from ~3.1 to ~3.7 eV (Söderlind et al. 2000; Becquart and Domain 2007; Suzudo et al. 2014), while for self-interstitial atoms (SIA), the values depend on the configuration. Some discrepancy arises in the literature about the most stable configuration, with similar values for the $\langle 111 \rangle$ dumbbell, $\langle 111 \rangle$ crowdion, and a slightly rotated configuration, with values around ~9.6–9.7 eV (Nguyen-Manh and Dudarev 2006; Suzudo et al. 2014) and ~10.41 (Becquart and Domain 2007) depending on the approach. Binding energies of individual defects

Fig. 6 Binding energies of individual defects to their clusters for (**a**) vacancies, (**b**) self-interstitial atoms, and (**c**) He atoms (Becquart and Domain 2010)


to defect clusters are also required. Becquart et al. calculated the ones for vacancies and interstitials using their DFT approach and use a capillary law for large defect clusters (>8 V for vacancy clusters and >7 SIA for interstitial clusters). Figure 6a and 6b shows the results for vacancies and self-interstitials, respectively. We observe that the capillary approximation fits well the ab initio data. One of the puzzling results in W is that the binding energy of two individual vacancies is repulsive, i.e., vacancies do not want to aggregate.

The migration energies for the intrinsic defects and their clusters are also needed. For individual defects, several sources are available in the literature (Becquart and Domain 2010; Suzudo et al. 2014; Huang et al. 2016), all describing single

vacancies with a large migration energy ($\sim$1.7 eV), while SIAs show a remarkably small migration barrier ($\sim$0.005–0.056) eV. Becquart et al. (2010) proposed an expression for the diffusion constant of defect clusters. In the case of vacancy clusters, the attempt frequency is given by $\nu = \nu_0(q^{-1})^{n-1}$, with $\nu_0 = 6 \times 10^{12}$ s^{-1} constant and equal for V and SIA, $q = 1000$, and n the number of individual defects in the cluster. Based on this model, Castin et al. (2017) have recently proposed an extension to account for the effect of grain boundaries and carbon impurities. The authors presented a sensitivity analysis of the parameters that mostly influence the onset of void swelling using their in-house OKMC code called MATEO concluding that the presence of carbon impurities in the W matrix strongly influences the kinetics of void formation due to the strong binding interaction between carbon and vacancies. They also showed the importance of correlated recombination after cascade events in the microstructure evolution. Mason et al. (2014) used a different parametrization of formation and migration of clusters to study loop accumulation and their interactions in a W thin film. In this case, they explicitly added elastic interactions between defects to analyze the evolution of collision cascades and compare the effect of impurity trapping and elastic trapping concluding that elastic loop trapping within a cascade can stabilize large loops at high temperatures, while they shrink at low temperatures. On the other hand, small loops glide to the surface at high temperature, hence accounting for the experimentally observed reduction in total loop density and the change in the loop size distribution (Fig. 7).

As mentioned above, the study of the effect of He and H is paramount to understand the response of W to plasma exposures and neutron irradiations. OKMC has also been used to study the evolution of W in the presence of these two light elements. For this end, parameterizations of the behavior of these elements and their interactions among them and with V and SIA have been developed. Becquart et al. (2010) used their parametrization to study the isochronal annealing of He desorption in W and compared the results to experimental observations, employing the LAKIMOKA OKMC code (Domain et al. 2004). Subsequently, they studied the microstructural evolution of W under irradiation accounting for He production. They observe that the OKMC model reproduces satisfactorily the microstructure formed in the track region by 800 ^{3}He implantation for different fluence conditions (see Fig. 8).

The influence of grain boundaries on the microstructure evolution accounting for He has also been studied within an OKMC model. Extending the parametrization of Becquart et al. (Becquart and Domain 2009; Becquart et al. 2010), Valles et al. (2015a, b) studied the retention of He in the sample depending on the density of grain boundaries under pulsed He irradiation. They observe that around 50% of the incoming ions were retained at the interfaces in nanocrystalline W, while in the case of larger grains, that number dropped to around 30%, which indicates a strong dependence of He retention with grain boundary configurations. They also conclude that in the nanocrystalline W, mixed He$_n$V$_m$ clusters contain more vacancies with a lower He/V ratio.

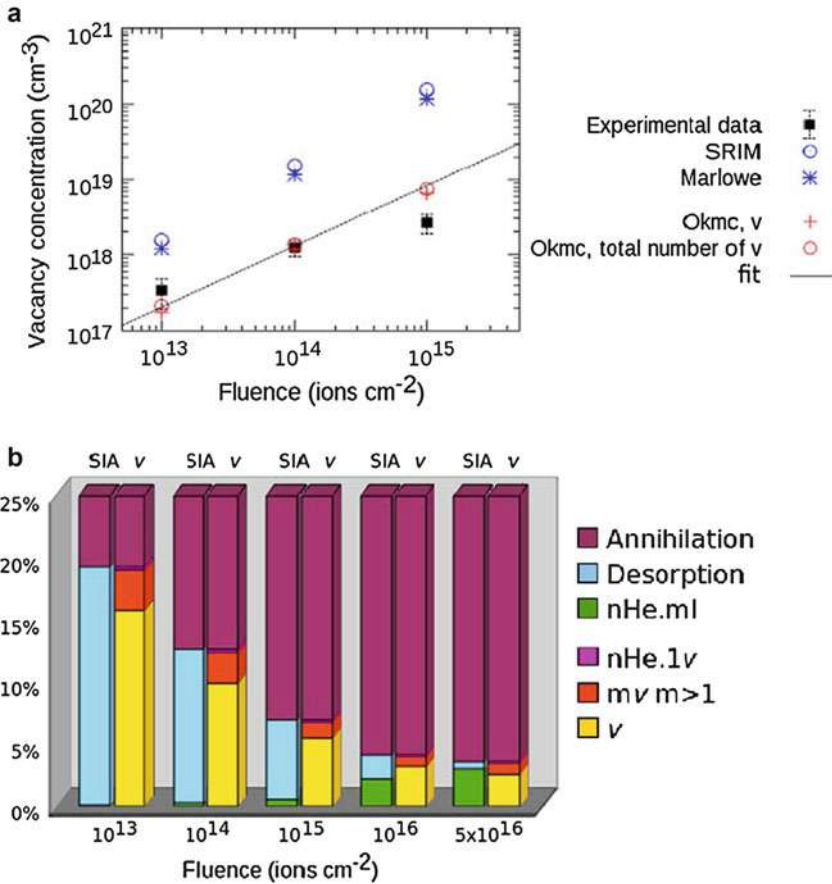
Valles et al. (2017a) have also studied the influence of H atoms in the defect evolution under irradiation and the effect of grain boundaries in the sample. They
Fig. 7 Evolution with the accumulated dose of the void density and average void diameter found in OKMC simulations, as compared to experimental evidence (red dots) (Castin et al. 2017)


Fig. 8 (**a**) Vacancy concentration at the end of the implantation sequence for different fluences: a comparison of the experimental data with the SRIM, MARLOWE, or OKMC models. The black line is a linear fit (in the logarithmic scale) of the OKMC results. (**b**) The amount of desorption, annihilation, and clustering versus fluence at the end of the implantation stage as calculated by OKMC (Becquart et al. 2011)

extended the energetics for small clusters available in the literature (Henriksson et al. 2005; Fernandez et al. 2015; Lu et al. 2014; Ohsawa et al. 2010) to parametrize the H-V interactions using DFT calculations and considered H-SIA clusters as immobile. It is important to note that the H-H interaction is repulsive and, therefore, pure H clusters will not occur. However, in the presence of defects, the situation is different, with a strong binding between vacancies and H atoms. The authors conducted OKMC simulations using the MMonCa code (Martin-Bragado et al. 2013) and concluded that grain boundaries have a clear influence on the number density and distribution of vacancies, observing a larger concentration

in the nanocrystalline sample compared to a single-crystal sample. Also, they observed that H retention is highly influenced by both grain boundaries and vacancy concentration, the size of H_nV_m clusters varies slightly with the presence of grain boundaries, and grain boundaries act as fast diffusion pathways for H. Other KMC models on the same system reached similar conclusions (Oda et al. 2015).

Impurities, such as carbon and oxygen, or alloying elements or transmutation products will also influence the long-term damage evolution in W. DFT calculations have shown that both vacancies and He atoms strongly interact with solute atoms. Carbon and oxygen have also been found to be able to trap He atoms, increasing its retention in the material and the probability of forming bubbles. Self-interstitial atoms also interact with solute atoms and impurities (Suzudo et al. 2014; Gharaee et al. 2016; Huang et al. 2017, 2018). Some of these extra atoms modify the relative stability of SIA configurations, which in turn modifies the transport properties and the flux coupling between the defects and the solute elements. Very recently, Castin et al. (2018) have developed an OKMC model based on DFT calculations to study the role of carbon impurities in defect evolutions and also the presence of rhenium upon neutron irradiation, which also impacts the diffusivity of defects and therefore the microstructure evolution. Their model compares well with experiments in terms of both density of loops and voids.

Another material problem where the OKMC has been extensively applied was the analysis of the formation of a nanostructured surface morphology termed as fuzz appearing in W exposed to He plasma under conditions relevant for energy generation. The increased surface area and fragility of these nanostructured surfaces raise new concerns for the use of W as a fusion reactor PFM, particularly as a source of high-Z dust that will contaminate the plasma. Lasa et al. (2014) developed a model considering the He atoms and the bubbles as the objects in the system. He atoms are mobile but bubbles are not. Bubbles are considered to blast at a threshold distance from the surface that depends on the bubble radius. They concluded that the square root of time dependence of the growth rate is due to the He bubble growth and not to He diffusivity. The surface above the bubbles grows as interstitial loops are emitted from the bubbles with a preferential direction toward the surface. Bubble rupture near the surface will create roughness as seen in the experiments. Even though the model does not consider elastic interactions, nor surface diffusion or W knockout adatom formation, it reproduces the experimentally found growth dependence on time, which suggests that those mechanisms might not be crucial to explain fuzz formation. Building on this model, refining the parametrization, Valles et al. (2017b) studied the effect of temperature on fuzz growth. The authors identified the reason for fuzz formation as the formation of large He_nV_m clusters, which are only stable at intermediate temperatures (900–1900 K). At low temperatures (700 K), fuzz growth is prevented by the stability of small He_9V_1 clusters, hindering He emission. In contrast, at high temperatures (2500 K), fuzz does not grow due to the high He emission from He_nV_m clusters, leading to their dissolution and, thus, preventing He retention.

8   Limitations of the Method

The main limitation of the method is the fact that all possible mechanisms characterizing viable events have to be identified a priori and taken as input for the OKMC simulations. However, it is oftentimes the case that unforeseen mechanisms occur as the system evolves in time. One simple example often given in the literature is the adatom diffusion on a {100} free surface in fcc metals, which was long misunderstood until Feibelman showed that the exchange mechanism could be energetically favorable compared to direct migration (Feibelman 1990). Recent examples include the computational observation using MD that stacking fault tetrahedra (characteristic irradiation-created defects in fcc metals) might indeed migrate with diffusivities depending on their atomic structure, contrary to the commonly accepted assumption that described these defects as immobile (Martinez and Uberuaga 2015). It was shown that their mobility can significantly impact the long-term behavior of the system, precisely relying on an OKMC model as implemented in the code MMonCa (Martin-Bragado et al. 2013). Another interesting example is the understanding that small He clusters might indeed diffuse in a W matrix as Frenkel pairs are created and the self-interstitial annihilates with a different vacancy to the originally created, leading to net translation of the cluster. Using a cluster dynamics model as implemented in the code Xolotl (Xu et al. 2012), it was shown that the incorporation of this mechanism in the viable events significantly modifies the amount of He retained in the W wall and the bubble distribution. As the microstructure becomes more complex, the probability of finding new mechanisms increases, which might significantly modify the long-term evolution of the system (Uberuaga et al. 2018). Therefore, much attention needs to be given to understanding the atomistic processes occurring in the systems of interest under irradiation and their characterization with accurate rates for the OKMC calculations to be predictive.

It is also commonly assumed that the rates for the possible events are independent of the current configuration, i.e., there is no long-range interaction between defects that might modify their diffusivities. There are studies in the literature mitigating this limitation (Hudson et al. 2005; Wen et al. 2009; Subramanian et al. 2013; Mason et al. 2014). A common approach is to use a linear approximation in which the dipolar tensor of the defect is used to compute a variation of the energy at the saddle point and at the initial state due to elastic interactions (among defects and also between irradiation-created defects and pre-existing dislocations/grain boundaries (Vattré et al. 2016)). These modifications in the rates due to elastic interactions have been shown to modify the microstructural evolution of the system. A similar situation is encountered in the case of charged defects, in which long-range Coulomb interactions might be considered to bias defect diffusivities (Martin-Bragado et al. 2006). Although these long-range effects might be significant, they are not commonly considered based on computational arguments. Usually this problem scales as $O(N^2)$, with N the number of species, which reduces the efficiency of the algorithm and the attainable simulated time. This bottleneck could

be in part mitigated relying on fast multipole methods, which reduce the algorithmic complexity to $O(N)$ (Arsenlis et al. 2007), albeit with a large pre-factor, or Fourier transform methods ($n \log(n)$), with n the number of grid points (Hunter et al. 2011; Bertin et al. 2015), to accelerate the computation of the interactions.

In principle the method should be able to handle alloying elements and impurities provided that the whole parametrization is known. In practice this represents another challenge in terms of computation since the number of events can increase considerably. Also, the definition of local concentration and its relation with a certain cluster is unclear for non-dilute alloys. In this scenario, it is also important to consider the possibility of defect trapping, i.e., the presence of superbasins in which defects might flicker between nearby positions without much addition to the simulated time, reducing considerably the efficiency of the algorithm. Several methods have been proposed to alleviate this drawback that can indeed significantly increase the efficiency in such situations (Novotny 1995; Fichthorn and Lin 2013; Athènes and Bulatov 2014).

In common conditions in nuclear environments, the amount of irradiation-created defects per unit time and volume is considerable and increases with time until it reaches steady state (if attainable). Tracking all these defects in an efficient manner is a challenge. Parallel algorithms to take advantage of parallel architectures have been recently developed with the goal of improving both simulated time and system size (Shim and Amar 2005a, b; Martínez et al. 2008, 2011). Implementation on GPU architectures has also been considered with the same goal and showed promising results (Jiménez and Ortiz 2016).

9   Conclusions

We have reviewed in this chapter the kinetic Monte Carlo (KMC) methodology describing in detail the theory behind this powerful and flexible approach and how it can be used to study the microstructure evolution of systems under irradiation. The KMC approach described here is called object KMC (OKMC), which coarsegrains out the atomic structure to focus on elements (or objects) of interest, such as irradiation-created defects, impurities, transmutation or alloying elements, etc. These objects evolve in time according to prescribed rules characterized by probabilities per unit time (or rates), which enter in the OKMC algorithm to follow the system evolution. It is commonly assumed that the rates follow transition state theory, which relates activation free energies and attempt frequencies with such rates. We have seen how these parameters can be accurately calculated using density functional theory, which explicitly accounts for the electronic degrees of freedom. Although computationally expensive, which limits system size and total simulated time if dynamics are required, its accuracy, superior to that of empirical interatomic potentials makes it the method of choice to obtain the required values for single defects and small defect clusters, along with their interactions with impurities and alloying elements. We have shown two examples in which the evolution of the

system under irradiation has been studied using this methodology: ferritic steels and tungsten. In both systems we show that the results in terms of defect distributions can be satisfactorily compared to experimental observations. Finally, we have reviewed the limitations of the methodology and how current research approaches are tackling those limitations.

Rate Theory: Cluster Dynamics, Grouping Methods, and Best Practices

101

Thomas Jourdan

Contents

Abstract

Cluster dynamics is a mean field method which is used to simulate the evolution of defect clusters in materials under aging and irradiation conditions. Its popularity is due to the simplicity of the underlying "cluster gas" model, which is able to simulate accurately and efficiently dilute cases, provided it is carefully parametrized. In this chapter cluster dynamics formalism is reviewed. Parametrization of cluster dynamics models and numerical schemes to efficiently solve cluster dynamics equations are discussed.

1   Introduction

Microstructure evolution under irradiation is driven by phenomena occurring over very different time and length scales. For example, displacement cascades are produced in a few picoseconds and span over a few tens of nanometers, whereas subsequent defect diffusion over micrometers requires a few seconds or more.

e-mail: thomas.jourdan@cea.fr

Quantitative simulation of the impact of radiation damage over experimental time scales requires the modeling of all these processes. Although no single tool is capable of performing such a task, cluster dynamics has emerged as a versatile tool to explore various consequences of irradiation. In particular, when it is informed with atomistic calculations, it has proven capable of simulating precipitation in dilute alloys (Clouet et al. 2005; Jourdan et al. 2010), void and loop nucleation, growth, and coarsening (Ortiz et al. 2007; Xu et al. 2012b; Moll et al. 2013), without suffering the limitations of fully atomistic calculations.

A distinctive feature of cluster dynamics is its mean field character, which solves the length scale problem. Microstructure evolution is obtained by solving a set of ordinary differential equations (ODEs) on cluster concentrations. However, for some phenomena which are highly localized in space, such as displacement cascades, mean field formalism can be a drawback, and special care must be taken. Concerning the time scale problem, high-frequency events, which limit the efficiency of stochastic methods such as object kinetic Monte Carlo (OKMC), may also hinder the solving of cluster dynamics equations. More precisely, the large scatter in reaction rates leads to very stiff equations, for which dedicated methods must be used. In addition, to simulate large clusters, it can be essential to reduce the number of equations by approximating the initial ODE set. Grouping methods (Golubov et al. 2001a) and Fokker-Planck-based methods (Ghoniem and Sharafat 1980) are useful ways to achieve such reduction.

In this article we first present the cluster dynamics formalism. Then, parametrization of cluster dynamics models is discussed. In the last section, technical aspects for the efficient solving of cluster dynamics equations are presented.

2   Cluster Dynamics Formalism

Cluster dynamics is a mean field approach which considers the microstructure as a collection of clusters. These clusters can diffuse in the matrix and absorb and emit other clusters (Martin 2006; Clouet 2009). For this reason, this model is sometimes called a "cluster gas model." As such, cluster dynamics is essentially appropriate for dilute cases, where clusters can be distinguished unambiguously. Such cases include the precipitation of secondary phases in dilute alloys and the formation of point defect clusters. It bears much resemblance to OKMC and mostly requires the same input parameters.

Let us consider, for example, the formation of vacancy and self-interstitial clusters under irradiation in a pure metal. Assuming that only one type of cluster exists for each self-defect, point defect clusters can be conveniently identified by a single index n. We use $n < 0$ for a vacancy cluster containing $|n|$ vacancies and $n > 0$ for an interstitial cluster containing n self-interstitials. The evolution equation, for the concentration C_n of mobile clusters in class (n), reads (Hardouin-Duparc et al. 2002; Xu et al. 2012a; Jourdan et al. 2014):

$$\frac{dC_n}{dt} = G_n + \sum_{\substack{m \in \mathcal{M} \\ n-m \neq 0}} J_{n-m,n} - \sum_{m \in \mathcal{M}} J_{n,n+m} - \sum_{m \in \mathbb{Z} \setminus \{0\}} J_{m,m+n}$$

$$- \sum_j k_{j,n}^2 D_n \left(C_n - C_{n,j}^{\mathrm{e}} \right). \tag{1}$$

In this equation, G_n and D_n are the production rate and the diffusion coefficient of cluster (n), respectively, and $\mathcal{M}$ is the set of mobile species. The factor $k_{j,n}^2$ represents the sink strength of sink type j which is not explicitly treated with cluster dynamics variables, in analogy with classical rate theory approach (Nichols 1978). In the present case, network dislocations and grain boundaries, for example, are taken into account with sink strengths, whereas vacancy and interstitial clusters are explicitly treated with the dedicated equations on C_n. Equilibrium concentration of (n) near sink j is noted $C_{n,j}^{\mathrm{e}}$.

The flux $J_{n,n+m}$ is a net flux between classes (n) and ($n+m$), due to the mobility of (m) only. It is defined by:

$$J_{n,n+m} = \beta_{n,m} C_n C_m - \alpha_{n+m,m} C_{n+m}, \tag{2}$$

where $\beta_{n,m}$ and $\alpha_{n+m,m}$ are the absorption and dissociation rates, respectively. The effect of mobility of (n) is taken into account with the term $J_{m,m+n}$ in Eq. (1). Absorption rates are closely related to the sink strengths used in rate theory (Nichols 1978). They take different forms, depending on the cluster type, the presence of long-range interactions (elastic, but also electrostatic interactions for materials with charged defects Kotomin and Kuzovkov 1992), and the presence of an energy barrier for the association of clusters (Waite 1958). For example, if (n) is a cavity in an infinitely dilute system and if elastic interactions between (n) and (m) are neglected, we obtain, for a three-dimensional diffusion of (m) (Waite 1957):

$$\beta_{n,m} = 4\pi (r_n + r_m) D_m, \tag{3}$$

which corresponds to the classical sink strength $k_{n,m}^2 = 4\pi (r_n + r_m) C_n$. In Eq. (3) r_n is the radius of cluster (n). The emission rate of (m) by ($n + m$) is obtained by imposing that $J_{n,n+m}$ is zero at equilibrium, so

$$\alpha_{n+m,m} = \frac{\beta_{n,m}}{V_{\mathrm{at}}} \exp\left(-\frac{F_{n+m,m}^{\mathrm{b}}}{k_{\mathrm{B}} T} \right), \tag{4}$$

where $F_{n+m,m}^{\mathrm{b}} = F_n^{\mathrm{f}} + F_m^{\mathrm{f}} - F_{n+m}^{\mathrm{f}}$ is the binding free energy of cluster (m) to cluster (n) and F_n^{f} is the formation free energy of cluster (n). This free energy notably contains a configurational entropy term. It is important to note that the thermodynamic part of a cluster dynamics model is only given by the

emission coefficients. In particular, contrary to the classical nucleation theory (Feder et al. 1966), the chemical potential of the monomer in the matrix is not present. This is due to the fact that in cluster dynamics there is no distinction between the matrix, where heterophase fluctuations occur, and the secondary phase. All clusters, whatever their size, evolve due to the absorption and emission processes. This seamless description of the nucleation, growth, and coarsening processes is one of the strengths of the method.

If the hypothesis of infinite dilution is not well justified, corrections can be performed on the absorption (Nichols 1978; Brailsford and Bullough 1981) and on the emission (Lépinoux 2009; Berthier et al. 2010) rates.

Under irradiation, dislocation loops quickly reach sizes which are comparable to the mean distance between clusters. Loops interact with each other or with preexisting dislocations. Loop size and density saturate, while the network dislocation density reaches a steady state, as a result of incorporation of loops and dislocation recovery (Brager et al. 1977). Cluster dynamics, as described above, is unable to simulate such phenomena. Although the validity of cluster dynamics at high doses is questionable, it may be desirable to include loop interactions and dislocation recovery into cluster dynamics formalism to perform qualitative modeling in support of experiments. This has been done recently (Zouari et al. 2011; Michaut et al. 2017), based on evolution equations proposed for rate theory (Stoller and Odette 1987) and then adapted for cluster dynamics (Jourdan 2015).

Up to now, cluster dynamics has been described for a pure metal containing self-defects or a dilute binary alloy under thermal aging. For more complex materials, a natural extension of Eq. (1) is to describe clusters through tuples $(n_1, n_2, \ldots, n_p)$, where p is the number of components in clusters. This has been done mostly in the case of self-defect clusters in the presence of gas atoms, such as helium and hydrogen (Ghoniem et al. 1983; Golubov et al. 2007; Ortiz et al. 2007; Marian and Bulatov 2011; Moll et al. 2013). For multicomponent alloys, one of the difficulties is to parametrize the model. In addition, negative flux couplings can arise, which cannot be taken into account in cluster dynamics due to its mean field character. Even if a reliable parametrization is available, the number of equations to solve becomes too large as soon as three components or more are present. For all these reasons, approximations to the initial problem can be necessary. Some recent attempts have aimed at simulating either precipitation or self-defect cluster evolution in multicomponent alloys (Ke et al. 2017; Mamivand et al. 2017), using equations similar to Eq. (1) coupled with CALPHAD approach.

Although surfaces can be taken into account in an effective way through sink strengths, it is sometimes necessary to describe them explicitly. For this purpose, a spatial dependency of rate equations on depth is introduced. The system is however assumed to be locally homogeneous, so that the mean field hypothesis of cluster dynamics remains valid. In practice, a diffusion term is added to Eq. (1) (Ortiz et al. 2004; Xu et al. 2012a; Jourdan et al. 2014), and the system is discretized along the depth. This approach is well adapted to simulate, for example, nonuniform damage creation by ion irradiation or irradiation of thin foils. Spatially resolved cluster dynamics in three dimensions has also been developed (Dunn and Capolungo 2015).

3 Parametrization of Cluster Dynamics

Among the parameters of cluster dynamics models, diffusion coefficients and binding energies at low temperature for small clusters can be estimated by atomistic calculations (Domain and Becquart 2001; Fu et al. 2004; Fu and Willaime 2008). Analytical laws for binding energies can be used to extrapolate values for larger clusters (Soneda and Diaz de la Rubia 2001; Varvenne et al. 2014; Alexander et al. 2016). A more difficult task is to calculate the binding *free* energies, so very often entropic contributions are neglected. However, it should be noted that to lead to quantitative results, such contributions should be included. In particular, it has been shown that cluster dynamics can reproduce atomistic kinetic Monte Carlo (AKMC) results on precipitation under thermal aging, provided that cluster free energies, taking into account configurational entropies, are calculated with the same energy model (Clouet et al. 2005; Jourdan et al. 2010) (Fig. 1). Another example is the annealing of loops in iron after helium implantation (Moll et al. 2013). Using an atomistically-informed model for the thermodynamics of helium bubbles (Jourdan and Crocombette 2011) appeared crucial to properly model the annealing kinetics of interstitial dislocation loops, which evolve due to Ostwald ripening by vacancy emission. Modeling the kinetics permitted, in turn, to *deduce* the vacancy free
Fig. 1 Density of copper precipitates, mean radius, and monomer concentration in AKMC and cluster dynamics (CD) in a Fe-1.34at.%Cu alloy during thermal aging at 500 °C. Two different models for interface free energies in cluster dynamics are used, a Cahn-Hilliard approach (σ_{CH}) or a size-dependent interface energy (σ_n), obtained by the method of overlapping distributions, using the same energy model as for AKMC simulations (Jourdan et al. 2010)

activation energy from experiments. In general, under thermal aging, results are more sensitive to the precise values of emission coefficients than to the absorption coefficients.

For complex alloys, setting up a physically based thermodynamic parametrization is much more difficult than for model materials, if not impossible. A common approach is to use the so-called gray alloy approach. Only self-defect clusters are considered, and their properties reflect the chemical composition of the materials. Such an approach must somehow be calibrated on experiments and has a limited predictive character. However, it can be useful to perform sensitivity studies or to investigate the relevance of some mechanisms (Zouari et al. 2011; Michaut et al. 2017).

Under irradiation, microstructures of self-defect clusters are also very sensitive to coefficients $\beta_{n,m}$. Indeed, the growth rate of these clusters depends on the net flux of interstitials and vacancy to them. Since in general interstitials and vacancies are created in equal numbers, the growth of self-defect clusters results from tiny differences between interstitial and vacancy fluxes. These differences, which are crucial to explain phenomena such as void swelling and irradiation creep, are essentially explained by elastic effects which favor the absorption of interstitials by dislocations. In this "dislocation bias" model (Greenwood et al. 1959; Bullough and Perrin 1970), the preferential absorption of interstitials by dislocations leads, by conservation of matter, to a net flux of vacancies to voids. Therefore simulating quantitatively the growth of voids and dislocation loops requires precise knowledge of absorption coefficients. Obtaining sink strengths from experiments requires some assumptions (Kiritani et al. 1975; Golubov et al. 2001b), such as the fraction of freely migrating species. Alternatively, sink strengths can be evaluated numerically (Dubinko et al. 2005; Rouchette et al. 2014; Heinisch et al. 2000). It has been shown, however, that sink strengths greatly depend on the precise properties of point defects, such as point defect anisotropy at saddle point (Dederichs and Schroeder 1978; Skinner and Woo 1984; Carpentier et al. 2017), so up to now general laws to be implemented in cluster dynamics are still lacking.

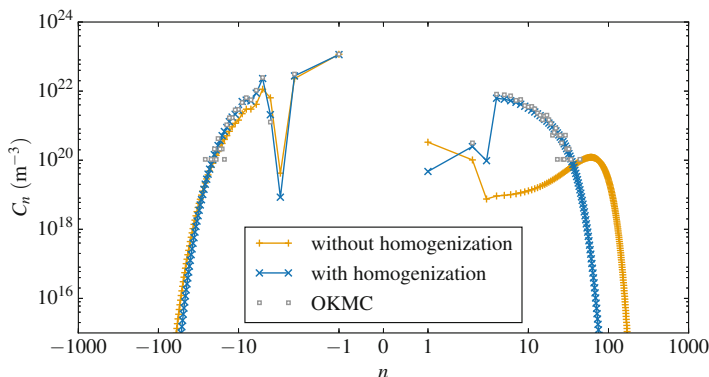
Besides bias values, cluster dynamics results under irradiation are known to be very sensitive to production rates G_n. To define them, it is tempting to perform molecular dynamics (MD) simulations of displacement cascades, count the remaining clusters at the end of the simulations, and average the cluster populations over several runs. However, this method overestimates cluster densities in general. Indeed, at the end of MD simulations, clusters are still spatially correlated, whereas cluster dynamics can only describe a homogenous distribution of clusters. To circumvent this problem, an idea is to let self-defects and self-defect clusters diffuse over longer times, with OKMC, for example (Adjanor et al. 2010; Becquart and Domain 2011). It can be expected that if the temperature is high enough, the damage will be less correlated at the end of the simulation, so a transfer to cluster dynamics is more valid. However, it is not always easy to define a proper annealing time, since fast diffusers (typically interstitials) will homogenize more rapidly than slow diffusers (typically vacancies). For this reason it seems more legitimate to work on homogenization distance instead of homogenization time. This homogenization distance is given by cluster dynamics itself: for example, two clusters a few nanometers apart can be considered either as spatially correlated if the


Fig. 2 Cluster distributions obtained with full OKMC simulations or cluster dynamics with two different source terms. Cascades are produced with the primary damage code MAR-LOWE (Robinson 1989), so only mono-interstitials and mono-vacancies are generated. For the non-homogenization case, a zero-time homogenization process was actually imposed to trigger close pair recombinations and clustering, but no thermally activated diffusion. Such small times are typical of MD simulations. Homogenization was performed using the procedure published in Jourdan and Crocombette (2012). Calculations were performed at 300 K up to 10^{-3} dpa, for an irradiation of iron with 20 keV iron ions and a damage rate of 10^{-4} dpa.s^{-1} (see Jourdan and Crocombette 2012 for more details)

density of clusters in cluster dynamics is low (e.g., at the beginning of irradiation) or uncorrelated if the average distance between defects in cluster dynamics is also a few nanometers. On this basis, a procedure has been proposed to provide a homogenized source term which is time dependent, even under constant irradiation (Jourdan and Crocombette 2012). A comparison between cluster dynamics with homogenized source term and full OKMC simulations, for an irradiation with 20 keV iron ions, is shown in Fig. 2. It should be noted that if only isolated Frenkel pairs are created by irradiation, this method is equivalent to reducing the production rate of self-interstitials and vacancies, due to recombinations which occur during homogenization. For ion and neutron irradiations, the source terms also contain self-defect clusters, either because they are created during the MD simulations or because they result from the diffusion and agglomeration of defects during the homogenization process. Therefore, this procedure naturally includes some aspects of "production bias" rate theory model (Golubov et al. 2012). One-dimensional migration of interstitial clusters, which is another cornerstone of this model, can be implemented by appropriate absorption coefficients (Singh et al. 1997).

4   Solving Cluster Dynamics Equations

Cluster concentrations at a given time are obtained by solving an ODE set containing equations similar to Eq. (1). This ODE set is known to be very stiff, which means that the use of explicit schemes requires very small time steps, so it may not be possible to run the problem until the desired physical time. It was soon recognized

that implicit methods based on multistep methods, such as the GEAR package (Hindmarsh and Gelinas 1971) or the more recent CVODES solver (Hindmarsh et al. 2005), are more appropriate for such problems (Ghoniem and Sharafat 1980). These methods require the solving of linear systems based on the Jacobian matrix of the ODE set. Without optimization of this step, the calculation may be intractable for memory and computation time problems. For systems containing more than a few thousands of equations, it is clearly advantageous to provide the analytical form of the Jacobian matrix, instead of letting the solver evaluate it by finite differences. In addition, if only a small proportion of cluster classes are mobile, the Jacobian matrix is sparse, and dedicated solvers can be used. Examples of the use of sparse direct solvers are given in Xu et al. (2012a) and Jourdan et al. (2014). A final improvement consists in resizing the cluster size space on the fly, in order to avoid useless consideration of zero concentration clusters (Jourdan et al. 2014).

Even when the sparsity of the Jacobian matrix is taken into account, the computation time and memory use can become too large as the maximum cluster size increases. For example, to simulate the formation of a 10 nm cavity in iron filled with helium atoms over a spatial discretization of 100 slices, it is necessary to consider more than 10^{11} equations, which is well beyond the current capabilities of computation resources. In this case, approximating the master equation (1) becomes necessary. Two different kinds of methods can be distinguished:

- Grouping methods, first developed by Kiritani (1973), consist in solving equations for the moments of the cluster distribution over groups of equations. It was shown by Golubov et al. (2001a) and Ovcharenko et al. (2003) that accurate results can be obtained by taking into account the zeroth and first moments of the distribution. One of the advantages of this method is to be able to handle the mobility of large clusters (Golubov et al. 2007). However, it does not guarantee that cluster concentrations remain positive.
- Fokker-Planck-based methods. Although they can also be viewed as grouping methods since the final number of equations is reduced, the mathematical justification is completely different. For large values of n, the master equation for immobile species can be written as a Fokker-Planck equation (Goodrich 1964; Wolfer et al. 1977):

$$\frac{\partial}{\partial t} C(x, t) = -\frac{\partial}{\partial x} [F(x, t) C(x, t)] + \frac{\partial^2}{\partial x^2} [D(x, t) C(x, t)], \quad (5)$$

with $x_n = n$, $C(x_n, t) \approx C_n(t)$ and

$$F(x, t) = \sum_{m \in \mathcal{M}} m [\beta_m(x) C_m(t) - \alpha_m(x)], \quad (6)$$

$$D(x, t) = \frac{1}{2} \sum_{m \in \mathcal{M}} m^2 [\beta_m(x) C_m(t) + \alpha_m(x)]. \quad (7)$$

This equation can then be discretized on a coarse mesh to reduce the number of equations to solve. Special care must be taken to connect the master equation used for small clusters to the discretized Fokker-Planck equation used for large clusters (Jourdan et al. 2014). Formulating the problem with a conservative form and using a finite volume approach is particularly convenient to ensure that matter is exactly conserved (Jourdan et al. 2014). The last important point is to choose an appropriate discretization scheme for the advection term. Recently, it has been shown that high-resolution, monotonicity-preserving schemes permit to accurately reproduce reference cluster distributions obtained by solving all equations, without introducing negative concentrations nor spurious oscillations (Jourdan et al. 2016) (Fig. 3). Although they are more computationally expensive than simple upwind schemes, high-resolution schemes do not introduce numerical diffusion and should therefore be preferred when high precision is needed on cluster
Fig. 3 Long-time limit cluster distributions for the clustering of quenched-in vacancies (Koiwa 1974) using different approximations (circles): (**a, b, c**) Fokker-Planck (FP) with upwind, centered, and high-resolution schemes for the advection term and (**d**) grouping method. Grouping and Fokker-Planck with high-resolution discretization scheme give very similar results, except in the distribution tail where negative concentrations occur with the grouping method (Jourdan et al. 2016)

distributions. The Fokker-Planck method can be generalized to multidimensional cases and permits to drastically reduce the number of equations. An example is given in Moll et al. (2013), where a spatialized simulation of helium implantation in iron could be performed. One drawback of this method, however, is that it is not really appropriate to treat the mobility of large clusters.

Alternatively, stochastic methods can be used to solve cluster dynamics equations. Among them, the simplest one is the so-called stochastic simulation algorithm (SSA) proposed by Gillespie (1976) and recently used for cluster dynamics (Marian and Bulatov 2011; Hoang et al. 2015). A finite volume V is envisaged, and equations on the number of clusters $N_n = C_n V$, derived from Eq. (1), are solved by a kinetic Monte Carlo method, using the appropriate rates for all possible events. An advantage of this method is that it does not require the solving of linear systems, so the memory requirements are lower than for deterministic solving, especially if large cluster spaces are considered. However, time steps are in general very low due to high-frequency events, so it is less efficient than deterministic solving for systems with one- or two-dimensional cluster spaces. Coupling stochastic approaches for large cluster sizes to deterministic solving for small clusters has been proposed, in order to avoid the stochastic treatment of high-frequency events (Surh et al. 2004; Gherardi et al. 2012; Terrier et al. 2017).

5   Conclusions and Perspectives

Over the last two decades, cluster dynamics has proven an interesting method to simulate irradiation processes over long time scales. Two aspects must be considered with care to obtain reliable results within the domain of validity of cluster dynamics: the numerical schemes to solve cluster dynamics equations and the parametrization of models. Efficient and accurate numerical schemes exist for time integration and for grouping methods. Additional efficiency improvements could be obtained by using hybrid methods, which couple deterministic to stochastic solving. Concerning the parametrization of cluster dynamics models, atomistic calculations now provide a large amount of data that can be used either directly in cluster dynamics or to parametrize scaling laws. Although no complete parametrization, from cluster free energies to sink strengths, exists even in pure metals, all tools are available to fill this gap. A remaining issue is to be able to treat heterogeneities in materials, which is not possible with current cluster dynamics models.

Experimental Validation of Models: *In Situ* TEM for Radiation Damage

102

Kazuto Arakawa and Michael P. Short

Contents

Abstract

In situ transmission electron microscopy (TEM) is a powerful technique for validating dynamic models of radiation-produced defects in metals. In this chapter, we examine key advances from the last ten years in *in situ* TEM

K. Arakawa (✉)

which have enabled the validation of models and theories of radiation-induced defects, including TEM at the atomic scale and techniques for extracting defect information from nanoscale TEM. We conclude with an outlook and perspective on advances to come in the next ten years, expected to further aid in radiation damage model validation.

1 Introduction

Nuclear fission and fusion materials are primarily degraded by the accumulation of lattice defects produced upon knock-on displacement of host atoms under irradiation – point defects (vacancies and self-interstitial atoms (SIAs)) and their clusters (dislocation loops and cavities (voids and bubbles), etc.) (Was 2007). In understanding radiation damage, precise knowledge of its component processes – the production of defects and their movement and interaction with others – is crucial. Therefore, dynamics of radiation-produced defects in comparatively simple pure metals and model alloys have been extensively studied by modeling methods such as density functional theory (DFT), molecular dynamics (MD), kinetic Monte Carlo (kMC), and rate equations (RE) (Dudarev 2013; Marian et al. 2017). Needless to say, these modeling studies require experimental validation. Nowadays, *in situ* transmission electron microscopy (TEM) is recognized as a powerful technique for model validation. This chapter focuses on the use of *in situ* TEM for radiation-produced defects in "pure" metals and model alloys as a model validation technique. Following the description of the capabilities and limitations of the *in situ* TEM in Sect. 2, the key advances in the last ten years are provided in Sect. 3. Finally, a perspective of the outlook for the next ten years is given in Sect. 4.

2 Capabilities and Limitations of the *In Situ* TEM for Visualizing Radiation-Produced Defects

TEM is the most powerful technique for the observation of local structures such as defects and precipitates within solids with atomic to nanoscale spatial resolution. In *in situ* TEM (Fig. 1), the dynamic behavior of such local structures is probed in response to applied stimuli, such as heating, cooling, deformation, and irradiation with high-energy electrons, ions, and photons. Here, the typical imaging mechanisms of TEM and its capabilities and limitations are briefly provided to give context.

TEM enables both reciprocal-space (diffraction) and real-space imaging for the same region. It functions by passing an incident electron wave through a specimen, whereby the wave function of the transmitted electron wave at the exit surface of the specimen (exit wave) is Fourier transformed at the back focal plane of a magnetic objective lens. It is again Fourier transformed at the image plane of the objective lens. The distributions of the absolute square of the wave functions (intensities) at these planes correspond to the diffraction and real-space magnified image, respectively.

Fig. 1 Example of a transmission electron microscope (TEM) combined with a low-energy ion accelerator at Shimane University in Japan (Arakawa et al. 1999). Using this instrument, the dynamic behavior of local structures such as defects within solids can be monitored with nanoscale spatial resolution and recorded with 30 frames per second, in response to ion irradiation under heating, cooling, or deformation

Among various imaging methods, the most typical ones adopted for defect imaging are atomic high-resolution TEM (HRTEM) (De Graef 2003; Kirkland 2010) and nanoscale "low-resolution" bright-field and dark-field TEM (De Graef 2003; Hirsch et al. 1965; Jenkins and Kirk 2001). Normally, the specimens are illuminated by an almost ideal plane wave for conventional TEM. Instead, they are illuminated by a convergent electron beam for scanning TEM (STEM) (Pennycook and Nellist 2011). Even "low-resolution" bright-field and dark-field TEM and STEM are very useful and often utilized, because they are superior in terms of applicability to thicker specimens, wider areas, and temporal resolution. Principally, conventional

TEM is superior to STEM in terms of temporal resolution, although STEM also has remarkable advantages. Therefore, conventional TEM is generally utilized for *in situ* TEM probing dynamical behavior of defects. Hereafter, only conventional TEM is described.

2.1 Atomic High-Resolution TEM (HRTEM)

HRTEM can be adopted only for comparatively thin specimens less than a few 10's of nanometers in thickness. Multiple reflections in the diffraction signal are selected for imaging using a comparatively large objective aperture at the back focal plane of the objective lens. The transmitted plane wave at the exit surface of a specimen is modulated by the electrostatic potentials around individual atoms within the specimen. For very thin specimens with only a few to several atomic layers in thickness, only the phase of the electron wave is shifted by $\sigma V_p (x, y)$, where σ is the interaction constant being a function of the electron acceleration voltage and $V_p (x, y)$ is the projected potential onto the observation plane (x–y plane). This phase modulation is converted to an amplitude modulation by the objective lens. HRTEM is therefore called phase-contrast imaging. For a specific condition with a specific objective lens defocus (Scherzer defocus) and objective aperture radius (Scherzer frequency), the final image corresponds to the distribution of $1-2\sigma V_p (x, y)$, i.e., the projection of the atomic arrangement onto the observation plane. This image is called the structure image. However, for thicker specimens, both the phase and amplitude of the electron wave are modulated in a complex manner. Then, the image reflects only the spatial frequencies corresponding to the atomic arrangement. This image is called the lattice image. Therefore, interpretation of the HRTEM images often requires image simulations for model structures (Kirkland 2010). To the author's knowledge, the best spatial resolution recorded to date in HRTEM is 43 pm, which corresponded to the (633) lattice fringe of tungsten (Akashi et al. 2015). The HRTEM, therefore, can be applied to observation of the core structure of defects. In contrast, the direct detection of moving atomic-scale defects such as point defects has been performed only for very limited systems with only a few atomic layers of thickness (e.g., carbon nanotube) (Suenaga et al. 2007), and it has not been achieved for metals, to the author's knowledge.

2.2 Nanoscale "Low-Resolution" Bright-Field and Dark-Field TEM

Bright-field and dark-field TEM can be adopted for comparatively thick specimens from tens to hundreds of nanometers in thickness. Only a transmitted or excited diffracted reflection in the diffraction signal is selected for bright-field or dark-field TEM, respectively, using a comparatively small objective aperture at its back-focal plane. In normal bright-field and dark-field TEM, the electron incident direction deviates from precise low-index directions, and only systematic reflections (reciprocal lattice vectors, 0**g**, 1**g**, 2**g**, 3**g**, etc.) are highly excited. In the process

of electron waves transmitted through a specimen, only those corresponding to these reflections (ϕ_0, $\phi_{\mathbf{g}}$, $\phi_{2\mathbf{g}}$, $\phi_{3\mathbf{g}}$, etc.) interfere with one another, which is called dynamical diffraction. In the two-beam approximation, where only the transmitted wave ϕ_0 and a diffracted wave $\phi_{\mathbf{g}}$ are considered, the following Howie–Whelan equations on dynamical diffraction are established (inelastic scattering is neglected here, for simplicity):

$$\begin{cases} \frac{d\phi_0(x,y,z)}{dz} = \frac{i\pi}{\xi_0}\phi_0\left(x, y, z\right) + \frac{i\pi}{\xi_{\mathbf{g}}} \exp\left(-2\pi i\left(-sz - \mathbf{g}\cdot \mathbf{R}\left(x, y, z\right)\right)\right) \phi_{\mathbf{g}}\left(x, y, z\right) \\ \frac{d\phi_{\mathbf{g}}(x,y,z)}{dz} = \frac{i\pi}{\xi_{\mathbf{g}}} \exp\left(-2\pi i\left(sz + \mathbf{g}\cdot \mathbf{R}\left(x, y, z\right)\right)\right) \phi_0\left(x, y, z\right) + \frac{i\pi}{\xi_0}\phi_{\mathbf{g}}\left(x, y, z\right) \end{cases},$$

(1)

where $\mathbf{R}(x, y, z)$ is the displacement around a defect (z-coordinate along the depth in a specimen), ξ_0 and $\xi_{\mathbf{g}}$ are parameters called extinction distances being functions of the corresponding structure factor, and s corresponds to the deviation of the diffraction vector for $\phi_{\mathbf{g}}$ from $\mathbf{g}$ and means the deviation from the exact Bragg condition (Hirsch et al. 1965). These equations clearly show that defect contrast arises from the factor $\mathbf{g} \cdot \mathbf{R}(x, y, z)$ and only the component of $\mathbf{R}(x, y, z)$ being parallel to $\mathbf{g}$ contributes to defect contrast. The contrast in the image due to this mechanism is called diffraction contrast. The bright-field or dark-field images correspond to the distribution of $|\phi_0(x, y)|^2$ or $|\phi_{\mathbf{g}}(x, y)|^2$ at the exit surface of the specimen, respectively. For example, in imaging dislocations, what is imaged is spatially extended $\mathbf{R}(x, y, z)$ around a dislocation (Hirth and Lothe 1982). Even so, in weak-beam dark-field TEM, where intensity of the adopted reflection is weak under considerable deviation of the s value from zero, the spatial resolution can reach approximately 2 nm (Jenkins and Kirk 2001). In ordinary bright-field TEM, the spatial resolution is worse. The displacement field $\mathbf{R}(x, y, z)$ around a dislocation is primarily parallel to its Burgers vector, $\mathbf{b}$. The dislocation contrast, therefore, almost vanishes when $\mathbf{g} \cdot \mathbf{b} = 0$ is satisfied. Using this relationship, the direction of $\mathbf{b}$ can be determined. In imaging stacking faults, defect contrast also arises from $\mathbf{R}(x, y, z)$ of the stacking faults. In contrast, in imaging cavities, the local structure-factor reduction due to the presence of a cavity is imaged. It is therefore called structure-factor contrast (Jenkins and Kirk 2001).

2.3   Capabilities and Limitations of *In Situ* TEM

The dynamic behavior of defects can be monitored and recorded through a camera, in response to various stimuli. Temporal resolution normally ranges from 10 to 30 frames per second (fps) for ordinary cameras. Nowadays, even 400 fps can be achieved for high-speed and high-sensitivity cameras. As basic stimuli, heating and cooling are applicable. For commercially available specimen holders, the maximum temperature is approximately 1573 K, and the minimum temperature is approximately 10 K. For irradiation sources, electrons and ions are available (Hinks 2015). For *in situ* high-energy electron irradiation, high-voltage electron microscopes with

acceleration voltages higher than 1000 kV are applicable. For *in situ* ion irradiation, microscopes combined with ion accelerators are applicable (Fig. 1).

The most remarkable limitation for *in situ* TEM is the necessity of the use of thin-foil specimens, ranging from a few nanometers to a few hundred nanometers in thickness, as described above. In considerably thin specimens, the specimen surface can significantly influence the behavior of defects. For example, mobile defects can escape to the free surface. This is one of the major reasons why "low-resolution" bright-field and dark-field TEM suitable to comparatively thick specimens are very useful. The second limitation is that directly tracking considerably fast-moving defects is impossible, because of the limitation in temporal resolution. The third limitation is that directly probing moving atomic-scale defects is still practically impossible, as described above. Another limitation for the *in situ* TEM is the energy of electrons for observation, with 200 keV in kinetic energy for ordinary 200-kV microscopes. For example, even 200 keV electron irradiation of aluminum specimens causes knock-on displacements to produce additional point defects, thereby changing the image by measuring it. In *in situ* TEM experiments, these limitations should be considered.

3   Key Advances in the Last Ten Years in the *In Situ* TEM for Radiation-Produced Defects

Here, the key advances in the last ten years in the *in situ* TEM for radiation-produced defects in metals are briefly provided. For this purpose, typical successful examples are shown, for direct evaluation of the dynamic properties of slow-moving nanoscale defects and indirect evaluation of the dynamic properties of invisible atomic-scale defects.

3.1   Direct Evaluation of Dynamic Properties of Nanoscale Defects

As described above, in *in situ* TEM, temporal resolution is limited to a few tens of milliseconds at best. Also, practically, only nanoscale defects can be directly tracked. However, in some cases, motion of nanoscale defects is considerably slow, which can be directly tracked by normal *in situ* TEM. There, the most remarkable key advance in the last ten years is that dynamic behaviors of *individual* nanoscale defects have been observed to evaluate their dynamic properties, which can be compared with modeling results.

3.1.1   Motion of Nanoscale Defects and Their Interaction with Other Defects

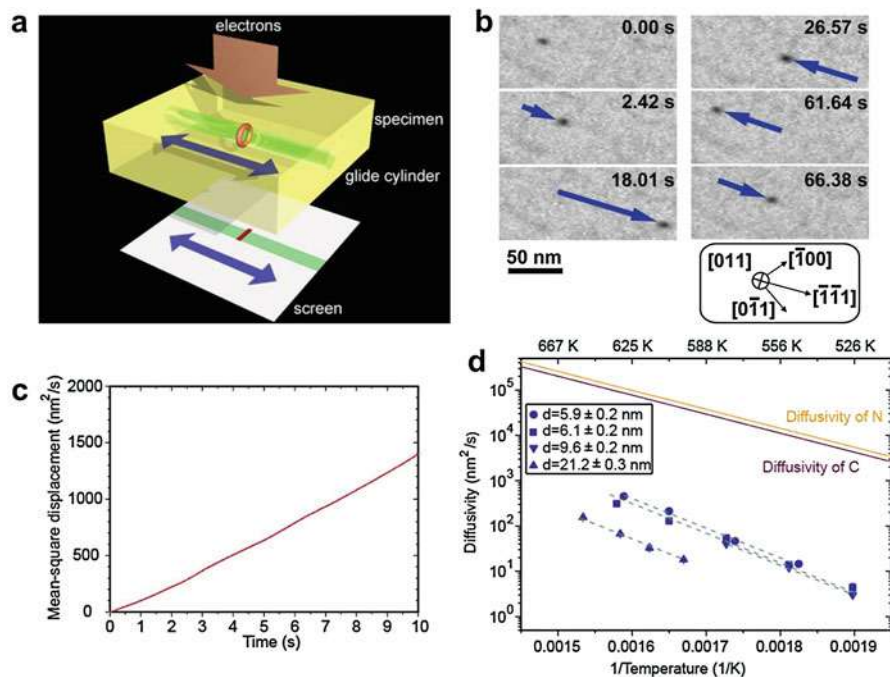
One of the most successful examples is an experiment for 1D glide diffusion of SIA dislocation loops (Arakawa et al. 2007). This phenomenon is critical in the accumulation process of defects in metals upon irradiation. There had previously


Fig. 2 TEM visualization of 1D glide diffusion of 1/2<111> SIA dislocation loops in high-purity iron (Arakawa et al. 2007). (**a**) Experimental setup of the TEM observation of a 1D-diffusing loop. (**b**) Bright-field TEM observation of an almost isolated 1D-diffusing 1/2[11$\bar{1}$] loop 5.9 nm in diameter at 575 K. (**c**) Mean squared displacement as a function of time for the loop shown in (**b**). (**d**) Arrhenius plot of the diffusivity of almost isolated 1/2<111> loops. Matching symbols correspond to the same loop with diameter *d*. The diffusivities of carbon and nitrogen in the matrix (Lord and Beshers 1966) are also drawn

been extensive MD (Marian et al. 2002; Osetsky et al. 2003; Soneda and Diaz de La Rubia 2001; Terentyev et al. 2007; Wirth et al. 2000) and theoretical studies (Barashev et al. 2000; Dudarev 2002) of this effect. Here, the diffusivity or activation energy for diffusion was directly compared between the TEM experiment and the MD calculations.

Figure 2 shows the TEM experiment on 1D diffusion of loops with **b** = 1/2<111> in high-purity iron (purity, 99.998 wt.%) (Arakawa et al. 2007). Figure 2a shows the experimental setup. In this experiment, the thin-foil effect on 1D diffusion was eliminated even for thin-foil specimens by setting the specimen surface to be parallel to the loop glide direction (**b** direction). Here, the effect of the electron irradiation for the observation was negligible, because its energy was only 200 keV, and therefore its associated PKAs were below the displacement threshold energy. Figure 2b shows an example of a bright-field TEM observation of an almost isolated 1/2[11$\bar{1}$] loop 5.9 nm in diameter at 575 K, which undergoes 1D diffusion along its **b** direction. By directly tracking the loop position with a time step of the frame

interval (1/30 s), the loop motion was analyzed. Figure 2c shows the mean squared displacement as a function of time for the loop, as shown in Fig. 2b. From the slope of the line in Fig. 2c, the diffusivity for this loop at this temperature can be directly evaluated. Figure 2d shows the Arrhenius plot of the evaluated diffusivity for various loops with diameter d. It clearly shows that the temperature dependence of the diffusivity satisfies Arrhenius' law. From the slope of the lines, the activation energy, E, for the diffusion can be evaluated. As a result, the E value was 1.3 eV, found to be independent of the loop size. These experimental results can be compared with corresponding MD results (Marian et al. 2002; Osetsky et al. 2003; Soneda and Diaz de La Rubia 2001; Terentyev et al. 2007; Wirth et al. 2000). The size independence of the diffusivity matches the MD results. The experimental E value (1.3 eV) is, however, considerably greater than the E value obtained by MD for perfectly pure metals (0.1 eV). The considerably high E value in the experiment was attributed to the effect of impurity atoms with high diffusivity such as carbon and nitrogen forming a Cottrell atmosphere around loops and following the loop motion (Fig. 2d), although it is still controversial.

This experimental technique has been also successfully applied to other cases, such as 2D climb diffusion of loops (Swinburne et al. 2016), elastic interaction among loops (Dudarev et al. 2010), collision processes between two loops (Arakawa et al. 2011; Arakawa et al. 2017), and the dynamical interaction of bubbles with grain boundaries (Ono et al. 2007) and collision cascades (Ono et al. 2009). Thus, it has become possible to make direct experimental validation of modeling results for dynamic properties of nanoscale defects under certain conditions.

3.1.2 Growth or Shrinkage of Nanoscale Defects

Ordinarily, bright-field and dark-field *in situ* TEM with a wide field of view is applied to visualize dynamic defects. In contrast, even *in situ* HRTEM with a narrow field of view can be applied to the evaluation of the growth or shrinkage processes of static defects.

Figure 3 is an example, which shows the atomistic growth process of a void in magnesium by absorption of vacancies produced under electron irradiation (Xu et al. 2013). This process was interpreted in terms of the vacancy diffusion process as calculated by MD (Xu et al. 2013).

This experimental technique is principally applicable to other defects. Actually, even using weak-beam dark-field TEM, the nucleation and propagation of unit jog at the periphery of SIA dislocation loops have been detected in the past (Arakawa et al. 2000). This could be extended to HRTEM.

3.2 Indirect Evaluation of Dynamic Properties of Invisible Atomic-Scale Defects

Directly tracking moving atomic-scale volumetric defects in metals is practically impossible, unless the specimen is so thin that defects can too easily reach free surfaces. Understanding dynamic behaviors of these invisible defects behind visible-

(**b**) A vacancy layer nucleated as indicated by the *yellow arrow*. (**c**) The vacancy layer extended on the facet. (**d**) The growth of the facet. Scale bar, 2 nm

defect accumulation is, however, considerably important and feasible. To extract the dynamic properties of these invisible defects, the formation and growth processes of visible nanoscale point defect clusters under irradiation have been compared between TEM experimental results and corresponding modeling results. In the past, the primary modeling technique for such comparison has been rate theory based on mean-field theory (Kiritani 1994). However, in the last ten years, even kMC has been often adopted to such comparisons. kMC takes into account even spatial correlations among defects (Amino et al. 2011), and it is more suitable to quantitative comparisons. Here, examplary studies in which *in situ* TEM is used to monitor or infer defect evolution or migration are shown.

3.2.1 Fast-Moving Point Defects

In high-energy electron irradiation, only point defects (vacancies and SIAs) are principally produced as primary damage, and the production of point defects is almost spatially homogeneous (Was 2007). Therefore, high-energy electron irradiation is suitable to extract dynamic properties of point defects.

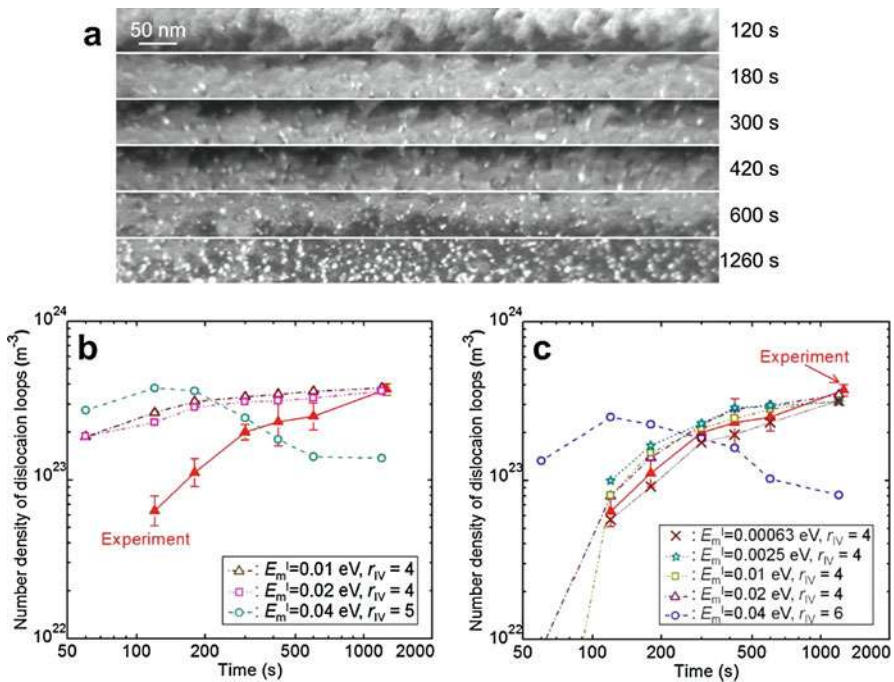
Figure 4 shows the comparison between a TEM experiment and corresponding kMC for the formation and growth process of SIA dislocation loops in high-purity (purity, 99.9999 wt.%) tungsten at 16 K under 2000 keV electron irradiation (Amino et al. 2016). At this temperature, vacancy thermal migration is frozen, and the moving defects are only SIAs. Figure 4a shows weak-beam dark-field TEM images of the loops for different irradiation times for a beam flux of 3.0×10^{22} m^{-2}s^{-1}. From these TEM photographs, both average size and number density of loops were measured as a function of irradiation time. These experimental data were compared with kMC. In the kMC simulation, almost all the parameters for the dynamic properties of SIAs were regarded as fitting parameters, such as the migration dimension (3D or 1D), migration activation energy (E_m^I), and reaction radius values


Fig. 4 Comparison between TEM and kMC for the formation and growth of SIA dislocation loops in high-purity tungsten under 2000-keV electron irradiation (Amino et al. 2016). (**a**) Weak-beam dark-field TEM images of loops for different irradiation times. (**b**) Comparison between the experiment and kMC for temporal variation in loop number density. In the kMC, the SIA migration dimension is 3D. (**c**) Comparison between the experiment and kMC for temporal variation in loop number density. In the kMC, the SIA migration dimension is 1D

with an impurity atom (r_{IX}), a vacancy (r_{IV}), and another SIA (r_{II}). Figures 4b, and 4c show examples for the comparison. The 3D migrating SIA never reproduces the experimental result (Fig. 4b). In, contrast, simulating 1D migrating SIAs reproduces the experimental result for the other parameters within a limited range (Fig. 4c). This result matches a DFT result showing that the most stable SIA structure is a crowdion undergoing 1D migration (Nguyen-Manh et al. 2006). The range within the parameter space reproducing the experimental results was considerably narrow. Thus, the parameters for the SIA dynamics can be fixed, through the comparison between TEM and kMC.

3.2.2   Collision Cascade Defects

In the primary damage process of ion and neutron irradiation, point defect clusters are also generated as well as point defects, which is called the collision cascade (Was 2007). The collision cascade has never been directly observed by any experiment. Its structure calculated by MD depends on the interatomic potentials chosen (Terentyev et al. 2006), the correct choice and quality of which are often unresolved matters of great debate. Therefore, modeling the defect accumulation processes under collision cascade is less straightforward. Even so, some efforts for the comparison between TEM and kMC (and cluster dynamics) for ion irradiation have been performed. For example, validation of the dynamic properties of invisible small defects has been attempted (Xu et al. 2012). Also, the trapping centers of intrinsically fast-moving defects were examined (Mason et al. 2014). These types of studies are growing in number, and represent an area of considerable growth for using *in situ* TEM to validate primary radiation damage. Ultimately a carefully planned suite of *in situ* TEM experiments could even help inform the choice of the best MD interatomic potentials to use, further boosting the efficacy of more complex simulations not as easily validated by experiments.

4   Outlook of the Next Ten Years of the *In Situ* TEM for Radiation-Produced Defects

Efforts for reducing the limitations of the TEM are expected, as increasing especially the time resolution of *in situ* TEM represents a way to both acquire more data for existing experiments and temporally resolve new regimes of radiation defect accumulation. For example, temporal resolution will be significantly improved using microscopes with pulsed electron sources. The ideal spatial resolution for a 15-ns pulse is approximately 1 nm (LaGrange et al. 2012). This type of high-speed technique will be applied to fast-moving nanoscale defects (Arakawa et al. 2014). Efforts for directly observing dynamic behaviors of atomic-scale defects are expected, by improving the signal-to-noise ratio in the image. For example, this new technique will be applied to the nucleation process of point defect clusters.

In addition to simply improving the resolution in both time and space of the *in situ* TEM, carefully coordinated sets of experiments can be used to rapidly resolve current scientific questions and matters of debate. For example, a set of

TEM observations on the self-ion irradiation of pure tungsten after one second of irradiation (Yi 2015) has garnered two competing explanations for the observed cluster size distribution (Sand 2017, Jin 2018). The former explains the defect size distribution using primary radiation damage and sub-cascade splitting, while the latter uses cluster dynamics and rate theory to explain the deviation from the power law size distribution. Neither study can be confirmed right or wrong without more data. An *in situ* study, acquiring sufficiently resolved TEM images with tens of millisecond resolution over a period of minutes, could help to determine whether dynamical effects are responsible for the cluster size distribution or not.

The example above may have other ramifications for the choice of MD inter-atomic potentials, constantly a matter of debate. The sheer data throughput rate of *in situ* TEM can generate enough information to apply techniques of machine learning, first to decide which available potential is most suitable to reproduce an experiment, then as a training database to iteratively design better potentials for even better experimental reproduction.

Finally, the combination of direct visualization of radiation-induced defects in the *in situ* TEM with complimentary *in situ* measurements of material property evolution can yield ultra-high throughput structure-property relationships in irradiated materials. For example, studies such as those of Xu et al (Xu 2013) which directly visualize void growth could be combined with new techniques such as *in situ* transient grating spectroscopy (TGS) of the thermo-elastic properties of irradiated metals (Dennett 2019). Theories relating changes in elasticity due to defect structures can be combined with the directly visualized structures themselves, helping to reconcile theory, simulation, and experiment at once. As these capabilities are further developed and enhanced, it will always fall to the *in situ* TEM to provide the direct structural visualization to map new structure-property relationships at unprecedented resolution.

Modeling Radiation-Induced Segregation and Precipitation: Contributions and Future Perspectives from Artificial Neural Networks

103

Nicolas Castin and Lorenzo Malerba

Contents

Abstract

Radiation-induced segregation and precipitation is one of the main factors for the changes in macroscopic properties taking place in steels under irradiation. For instance, reactor pressure vessel steels and ferritic-martensitic steels are known to harden and embrittle within the lifetime of the reactors. The development

of quantitative predictive models for these changes is a very challenging task, because of the highly multiscale nature of the mechanisms taking place at the microstructural level and the chemical complexities involved. Complete physical-based approaches such as object kinetic Monte Carlo models are promising tools to take this challenge, but their parametrization must be accurately and adequately elaborated. In this chapter, we revise how highly powerful and flexible numerical tools offered by machine learning systems, specifically artificial neural networks, have contributed to these models. Perspectives for future developments are also discussed, in light of the state-of-the art modeling activities in the community.

1   Introduction

Irradiation with bombarding particles results in a continuous creation of point defects in the bulk of the studied material, i.e., vacancies and self-interstitial atoms (SIA). The increased concentration of vacancies thus enhances the kinetics of diffusion-driven process (such as precipitation of insoluble species) but might also alter the thermodynamic equilibrium. Moreover, SIA exhibit a profoundly different behavior from vacancies, potentially giving rise to processes not normally observed in materials. For instance, reactor pressure vessel steels and ferritic-martensitic steels are well known to harden and embrittle under neutron irradiation (Petrequin 1995), potentially limiting the lifetime of the power plants. Today, experimental evidence (Bergner et al. 2014) demonstrated that the main responsible for this degradation are nano-sized diffuse solute clusters, invisible to the transmission electronic microscope (TEM) but observable with the atom probe tomography (APT) (Kuksenko et al. 2013; Meslin et al. 2010), which are fully radiation-induced features.

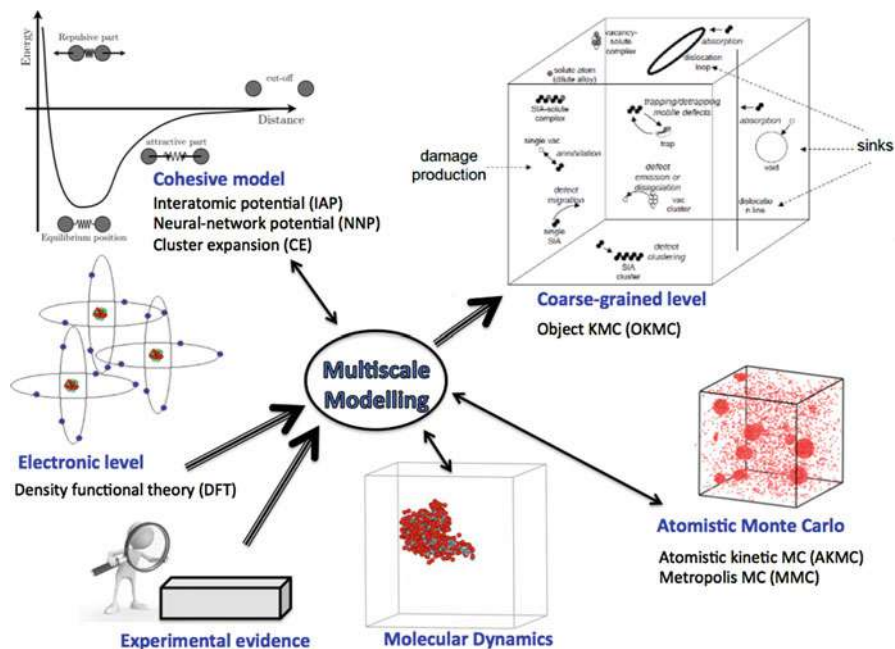
Because it all starts at the atomic level, only a multiscale strategy can derive thorough and nonempirical physical models capable of describing the mechanisms leading to the formation of these nano-sized embrittling solute clusters. Figure 1 depicts an overview of a modeling approach based on kinetic Monte Carlo (KMC) methods, which is one of the possible choices to bridge the gap from the electronic to coarse-grained level. Interested readers are directed to general overviews for alternative approaches (Becquart et al. 2010; Becquart and Domain 2011). In the lowest left corner, two fundamental sources of input data are (a) calculations based on first-principle physics to address the electronic structure, most often using the density functional theory (DFT), and (b) any kind of experimental evidence, e.g., formation energies, diffusion coefficients, phase diagrams, etc. Unquestionably, these remain the only true final judge on any model prediction. The story ends at the coarse-grained level, which is in this work implemented by the object kinetic Monte Carlo (OKMC) method. There, the processes undergone by the defects injected during irradiation are described as thermally activated events that correspond, for the objects involved, generally clusters of point defects, to specifically designed laws


Fig. 1 Multiscale modeling approach for describing the effects of irradiation in structural materials

for mutual interactions, mobility, and stability. A substantial number of reactions must be carefully parametrized in OKMC models, which are achieved summoning a variety of methods and models at lower scales, ranging from DFT, molecular dynamics, and atomistic kinetic Monte Carlo (AKMC).

OKMC models have been widely used to describe the microstructural evolution in materials under irradiation, in terms of radiation defects, i.e., vacancies, SIA, and their clusters. For example, a model of this type was successfully developed (Jansson and Malerba 2013) to simulate irradiation processes in Fe-C systems, as reference system for models addressing steels, i.e., with a more complex composition. However, the only objects explicitly treated were point defects and their clusters. The parameters describing their migration and dissociation were specific for Fe, and the effect of C was effectively introduced in terms of traps for mobile clusters, without explicitly introducing C atoms. Likewise, models of this type have been extended to model chemically more complex systems, e.g., Fe-Mn-Ni as representative of RPV steels (Chiapetto et al. 2015a) or FeCr as representative of ferritic-martensitic steels (Chiapetto et al. 2015b). The effect of the presence of solutes was implicitly introduced in terms of changes of parameters due to the presence of solutes, without explicitly introducing them in the simulation box. This was achieved in a simplified way, assuming that the solute atoms are always uniformly and randomly distributed in the simulation volume, so that their effect

is inherently independent of local fluctuations of composition. Clearly, the solutes must be explicitly included in future models for describing the formation of their clusters.

Playing the role of reference metrics for the physical description of the studied material, vital inputs in multiscale modeling approaches are, undoubtedly, cohesive models. Given a set of atoms described by their coordinates in space and their chemical species, their task is to provide a numerical value for the total energy of the system in any configuration. They thus determine the driving forces, e.g., solute transports by point defects, and eventually the formation of solute-rich clusters. In a quantum mechanism framework, ab initio methods, e.g., DFT, are, for many good reasons, regarded as the most reliable choice to explore the energy landscape of the system. There are, however, limitations. Firstly, some degree of empiricism remains. Unfortunately, a blind use of DFT may, in some cases, provide imperfect predictions (Olsson et al. 2010). Secondly, even with state-of-the-art computing facilities, using DFT still implies a huge cost in CPU resources which is often unaffordable and, sometimes, unwarranted. For these reasons, alternative cohesive models are still extensively used, empirical interatomic potentials (IAP) being a very popular example. On the one hand, in addition to the largely reduced computing cost, the main advantage of these potentials is the possibility to achieve a tunable compromise between various target properties. It can thus mix DFT-originated with experimental-originated data, as conveniently as required. For example, an FeCu potential (Pasianot and Malerba 2007) was fitted to faithfully reproduce the experimentally observed Cu solubility limit in Fe, whereas DFT is known to underestimate it (Messina et al. 2017). The affordable computing time allows large and complex systems, containing up to several million atoms, to be studied. On the other hand, the simplicity proper to IAP also implies an intrinsic limitation in their capacities of making accurate prediction of various sets of properties at the same time.

Suitable low-computing-cost cohesive models allow the gap between the basic atomic level and the realm of longer timescale Monte Carlo (MC) models to be bridged. Many more gaps remain to bridge, however. Even using IAP, the precise calculation of the energy barriers the system has to overcome through thermal activation, which are at the core of MC methods, poses severe computing time limitations. Repetitive and heavy routine calculations are indeed required at key steps of a MC simulation, significantly limiting the range of applicability of the method. Similar limitations arise in connection with storage and integration of data/knowledge moving from one scale to a higher one. An illustrative example is the calculation of migration energies of single point defects in a chemically changing environment. These need to be routinely calculated using a dedicated method in order to let a Monte Carlo simulation that describes diffusion-driven processes to progress, but they entail a prohibitive computational cost if the calculation is performed in a precise way each time. Bridging the gap between models thus here means finding a numerical solution for either speeding up the calculation of the migration energies or, from another standpoint, extrapolating knowledge in the MC model from a limited amount of examples.

Machine learning techniques, specifically artificial neural networks (ANN), are very promising tools for taking this challenge. These tools have been progressively coupled to atomistic Monte Carlo models to improve their physical reliability, within affordable computing loads (Castin and Malerba 2010; Castin et al. 2014). ANN are flexible and powerful regression techniques, capable to assimilate complex and inexpressible laws of interactions from a limited number of explicit examples. Once the ANN are properly designed, they provide the values required for the model at a very limited computing cost, thanks to their mathematical simplicity. The remaining of this chapter is organized as follows. In Sect. 2, we start by providing a basic description of ANN techniques and the underlying mathematical framework. Next, in Sect. 3, we describe how ANN were used to create enhanced AKMC tools, providing novel and accurate models for solute transport and segregation. Both rigid-lattice and lattice-free concepts are presented. Similar mathematical concepts to the latter are then further exploited in Sect. 4 to define ANN-based cohesive models, directly fitted from DFT. Finally, we provide visions and recommendations for future perspectives in Sect. 5.

2   Artificial Neural Networks: A Practical Form of Artificial Intelligence

Artificial neural networks (ANN) are a concept of *weak artificial intelligence*, in a group of paradigms often denoted to as *machine learning*, or *computational intelligence*. They can be seen as self-learning systems aimed at extracting hidden knowledge from their environment, in order to take relevant actions when entirely new situations are encountered. For the particular application to the design of numerical predicting tools, for instance, they are *surrogate models* sparing the user the (otherwise fastidious) need to explicitly formulate knowledge about the problem at hand.

A complete description of the theoretical and mathematical frameworks of ANN goes beyond the scope of this paper. For a complete and detailed reference textbook, interested readers are directed to Bishop (1995) or to a more concise overview in Bishop (1994).

2.1   The Multilayer Perceptron: A Universal Approximation Machine

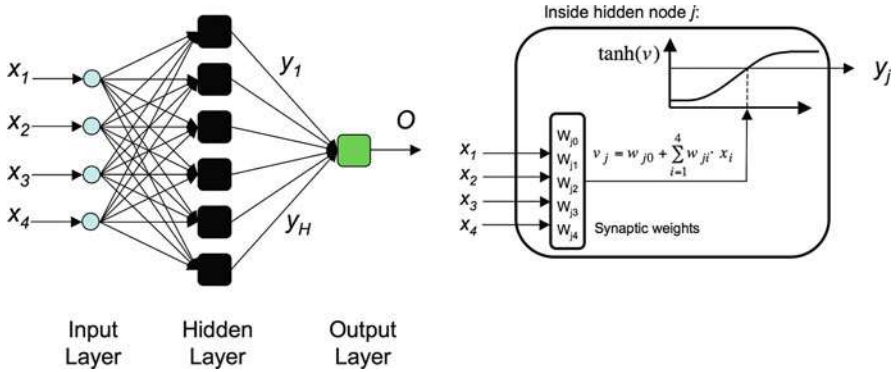
The so-called *multilayer perceptron* depicted in Fig. 2 provides appropriate solutions for the design of general numerical regressions. Inspired from biological neural networks such as the human brain, the fundamental idea is to create a network of simple processing units (either called neurons or nodes in the literature), thus constructing a sophisticated and complex response out of a set of simple individual rules. For the sake of simplicity, at least from the mathematical point of view, ANN are typically constituted of organized layers of nodes. On the left-hand side in Fig. 2,


Fig. 2 Example of feed-forward multilayer perceptron with four input variables (x_1, x_2, x_3, and x_4), one hidden layer with $H = 6$ nodes, and one output (O). The right part of the figure shows the detail inside a node of the hidden layer. The signal is propagated from the left to the right of the network, in a layer-by-layer fashion

the input layer is the collection of the raw input signals for the whole network. On the right-hand side, the last layer is called the output layer, providing the answer of the network. In between, several intermediate layers may be introduced (there is only one in the figure). They are called *hidden layers*, for the reason that they are, in practice, invisible to the user. There is in theory no restriction about how nodes of different layers can be connected to each other. For simplicity, many networks do not allow backward connections: a given node never receives as input-output signals coming from nodes of either the same layer or from the next layers. Such a network is qualified as *feed-forward*. Lastly, the network shown in the figure is said to be *fully connected*, because all nodes in a given layer receive as input all output signals coming from the immediately preceding layer, and no *layer bypass* is allowed. The inputs for the first (and only) hidden layer are the raw input signals of the network.

The interest of the feed-forward multilayer perceptron, in its simplest form as depicted in Fig. 2, is that it fulfills the *universal approximation theorem* (Hornik et al. 1989): for any continuous function $F(x_1, \ldots, x_n)$, there exists an ANN with a finite number of hidden nodes that fulfill the following condition, for all sets of inputs x_i and all ε:

$$|F(x_1, \ldots, x_n) - O(x_1, \ldots, x_n)| < \varepsilon \tag{1}$$

Here, $O(x_1, \ldots, x_n)$ is the output of the ANN. The multilayer perceptron can therefore, in theory, be regarded as a universal approximation machine capable of perfectly assimilating any problem with a numerical character. It is safe and reasonable to assume that such degree of idealness cannot be dreamed of in practice, unless perhaps for some academical examples. Concretely, it is the authors' opinion that the flexibility and generality of the ANN internal structure, avoiding the user to explicitly formulate knowledge about the problem at hand, come at

an unavoidable cost. Indeed, ANN might be very successful in understanding a given problem from a limited amount of examples, but expecting it to perform a truly general understanding is hazardous. In other words, it is safe to assume that ANN is inherently devoted (not to say limited) to interpolation problems, whereas the extrapolation outside the domain of the input space covered during training is uncertain. Therefore, during any application of ANN, it is important to make sure that the domain of applicability can be determined. This can in fact be delicate in some cases, as discussed later.

2.2   Supervised Training

In this work, ANN are designed to implement numerical regression tools. This is therefore a *supervised training problem*, and training can be regarded as an optimization problem that consists in the minimization of the following objective function:

$$f(N_H, \bar{w}) = \sum_{i=1}^{N_T} (o_i(N_H, \bar{w}) - d_i)^2 \qquad (2)$$

Here N_T is the number of available examples of I/O for training, d_i is the desired output for the example i, and o_i is the corresponding prediction by the network. The latter is a function of the ANN architecture, i.e., the number N_H of nodes in the hidden layer and, finally, the vector $\bar{w}$ of synaptic weights. Assuming that N_H is fixed, the minimization of function f is thus the problem of determining the optimal numerical value of the synaptic weights $\bar{w}$: it can be undertaken by any classical method for nonlinear optimization. In this work, we used the method proposed by Levenberg (1994) and Marquardt (1963) (LM).

A major concern while training ANN is to guarantee that the predictions for new sets of inputs are equally accurate, compared to predictions on the available set of examples used for training. Indeed, without control, there is a risk that the ANN does not develop a general logic but in reality rather memorizes the complete set of available examples, as illustrated in Fig. 3. We see that reasonable interpolation is achieved by the ANN if the latter is not too complex, i.e., if N_H is small. Predictions are however not equally accurate for all training examples. If the number of hidden nodes is increased, the ANN manages more accurate predictions for all known points but clearly loses generality. This pathology cannot be easily identified only on the basis of a limited amount of examples of I/O, especially if the dimensionality of the problem at hand is large. ANN training must therefore be *regularized*. A common regularization approach is called *early stopping* and is based on the idea that memorization of the provided examples, or more generally can we say *network overspecialization*, develops only at a certain moment of training, i.e., after a certain number of training iterations, called *epochs* in ANN jargon. The most natural way to prevent it is therefore to divide the available table of examples of I/O into two
Fig. 3 (Left) Schematic illustration of ANN overspecialization for a simple problem with one variable x and one output y. Blue points represent data in the training set. The dashed line shows predictions by an ANN with a small number N_H of hidden nodes, whereas the plain line shows predictions of another ANN where too many hidden nodes were introduced. (Right) Typical evolution of the average error committed on the training set (TSet) and reference set (RSet) with increasing number of training epochs (N_H being fixed) or with increasing N_H (at the end of training)

different and nonoverlapping sets: (a) The training set is used to minimize function f in Eq. (2). Only these examples are thus used to calculate the gradients with the LM algorithm, and the synapses are updated during each epoch taking only them into account. (b) The reference set is used to measure, after every epoch, the average error of prediction on new cases. Figure 3 shows the typical evolution of the average error of prediction on both sets during the training epochs. The error committed on the training set always decreases. The error on the reference set, however, ceases to decrease from a certain epoch and then starts to increase, as a clear sign of the onset of overspecialization. Training is therefore interrupted at that moment.

At this stage, the determination of the optimal network architecture is still an open question. In our applications, we invariably found optimal architectures using no more than one hidden layer in the ANN. Determining the optimal architecture is thus a mono-parametric study: networks with increasing N_H are trained separately, and the one committing the lowest error on the reference set is finally retained, as depicted in Fig. 3. Too small a N_H understandably leads to higher errors of prediction, because not enough degrees of freedom are available in the network. Oppositely, too high a N_H increases the risk of overspecialization, and the error on the reference set increases as well.

3 Enhanced Atomistic Kinetic Monte Carlo Models

Atomistic kinetic Monte Carlo (KMC) methods are widespread simulation tools dedicated to describe diffusion-controlled phenomena at the atomic level. Generally based on a rigid-lattice approach, they feature an explicit spatial characterization of the diffusion of lattice defects and atoms, enabling a detailed investigation of the kinetics of formation of fine microstructural features. The evolution of the alloy proceeds through migration events of single defects (vacancies and/or interstitials)

(Young and Elcock 1966; Bortz et al. 1975; Fichthorn and Weinberg 1991), which are stochastically selected at each step based on their transition rates:

$$\Gamma = \Gamma_0 \cdot \exp\left(\frac{-E_m}{k_B T}\right) \tag{3}$$

Here, k_B is Boltzmann's constant, T the absolute temperature, Γ_0 the attempt frequency, and E_m the migration energy, generally evaluated in static atomic-level calculations. The accuracy of the latter parameter is thus crucial to ensure the physical reliability of the model, as it embodies both thermodynamic and kinetic properties of the system being studied.

Migration rates associated with single point defects are traditionally computed with several approaches; see, e.g., Chatterjee and Vlachos (2007) and Becquart and Domain (2010) for extensive reviews. Here, we use the nudged elastic band (NEB) method (Henkelman and Jónsson 2000), which provides the migration energy given both initial and final states of the desired transition. The direct on-the-fly use of any cohesive models (e.g., IAP or DFT) to calculate energy barriers is impractical, because the exact saddle-point configurations in each transition event are unknown and must be sought with time-consuming procedures. A concrete solution based on ANN to overcome this technical limitation is depicted in Fig. 4. The AKMC module is found on the left-hand part of the figure, where an example of migration event for a single vacancy is indicated by the black arrow. The local atomic configuration (LAC) is defined by the species located in the closest neighbor lattice nodes to both initial and final vacancy sites, denoted as A to M and encircled by a blue line in the figure. This LAC is described by a vector of numerical signals, aimed at communicating with other modules of the simulation code. The migration energies are obtained in the NEB module, using a suitable cohesive model to evaluate total energy and atomic forces. This may be directly returned to the AKMC module (on-the-fly mode), but most importantly it is also stored in a database aimed at designing an ANN in replacement of the NEB module. The ANN is obviously expected to accurately return the migration energies corresponding to the same configurations as previously added in the database, but most importantly it is aimed at making faithful predictions for new (never previously calculated) configurations, i.e., for any atomic configuration that may be encountered during the AKMC simulation. This prediction is very fast produced by any computer, thereby gaining orders of magnitude in terms of computing time.

3.1   Assuming a Rigid-Lattice Description of the Studied System

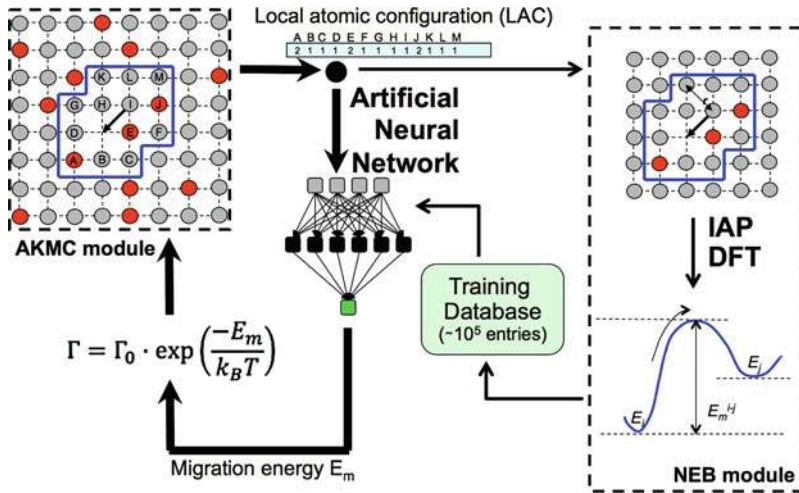
In rigid-lattice models, the atoms in the studied system are assumed to occupy always the nodes of a perfect lattice, e.g., bcc. This hypothesis is reasonable if single vacancies are the only defect present in the system, but it can also include more complex defects, such as vacancy-solute clusters (Castin et al. 2012), single SIA (Terentyev et al. 2012), or even small SIA clusters (Castin 2011). In these cases,


Fig. 4 AKMC model aided with ANN for fast and accurate on-the-fly estimations of the activation energies associated to the migration of single point defects
Fig. 5 Snapshots from an AKMC simulation of a thermal annealing experiment in a Fe-1.34% Cu at 500°C

the LAC vector in Fig. 4 may remain limited to a minimal amount of information: since the atomic coordinates are deducible from the crystallographic structure, only the chemical nature of each lattice site needs to be specified. The LAC is thus unequivocally defined with a vector of integers: each of them takes a predefined value that varies with the chemistry (e.g., value 1 stands for Fe, 2 for Cu, 3 for Ni, etc.) for the atoms sitting at sites A to M in the figure.

This methodology was applied to simulate thermal annealing experiments in Fe-based model alloys. Primarily using IAP as cohesive models, the FeCr system was first considered (Castin and Malerba 2010), and also the FeCu system (Castin et al. 2011), modeling the kinetics of precipitation. The physical accuracy of these models was later on significantly enhanced (Messina et al. 2017; Castin et al. 2017), using DFT directly as cohesive model. In a cubic simulation box with periodic boundary conditions, the prescribed content in solutes is initially introduced in random positions, as illustrated on the left-hand side in Fig. 5, together with a single vacancy. The simulation proceeds by computing its possible migration events toward each 1 nn position (eight in bcc structures). The individual migration energies are evaluated by the procedure illustrated in Fig. 4, which entirely pilots the evolution of the

system. Homogeneous precipitation of solutes eventually takes place, as depicted in Fig. 5, if so dictates the thermodynamics embedded in the underlying cohesive model, reflected by the ANN if the error of prediction is low enough.

In the absence of a formal feedback on the ANN predictions, their reliability for new atomic configurations must be maximized with a proper choice of the examples in both the training and the reference sets. Mathematically speaking, a new configuration is a new combination of integers in the LAC vector. Since each of these integers is seen at all positions many times in the training database (in other words, many cases are included with either an Fe or an X atom sitting in a given lattice site), new configurations are actually never in an extrapolative area in the input space. However, a new configuration can be considered as extrapolative from a physical point of view, if it describes a case governed by the kinds of interactions that were never, at least qualitatively, included in the training set. One can show (Castin and Malerba 2010) that the ANN predictive capabilities are maximized if the training data encompasses all expected stages of the thermal annealing process, as depicted in Fig. 5: Configurations where the solute atoms are randomly diluted in the matrix, or found under the form of small and big clusters, should be equally represented in the ANN training database.

The accuracy of prediction performed by the ANN trained to predict the vacancy migration energies, and the results of the AKMC simulations, is summarized in Fig. 6. In the FeCr case, the DFT-based model leads to predictions in better agreement with experimental evidence than the one based on IAP. Both densities and average sizes of the formed solute clusters coincide. In the FeCu case, the mechanism for the coherent stages of Cu precipitation in Fe was revealed (Castin et al. 2011), further stressing the importance of Cu cluster mobility (Soisson and Fu 2007): classical Ostwald ripening is not sufficient to explain the rapid kinetics of Cu precipitation. This was rendered possible, thanks to the model hybridization, and the accurate parametrization enhanced by the ANN. Even if the predictions obtained from an IAP resulted very satisfactory, the DFT-based parametrization maximized the agreement with experimental evidence. The solubility limit as predicted by DFT did not match the experimental one (Messina et al. 2017), with a consequent overestimation of the cluster density. Nevertheless, the model significantly improved from the point of view of time rescaling, necessary to convert the time in the MC simulation into a physical time comparable to the experiment, which resulted more consistent.

3.2 Applications Beyond the Rigid-Lattice Limit

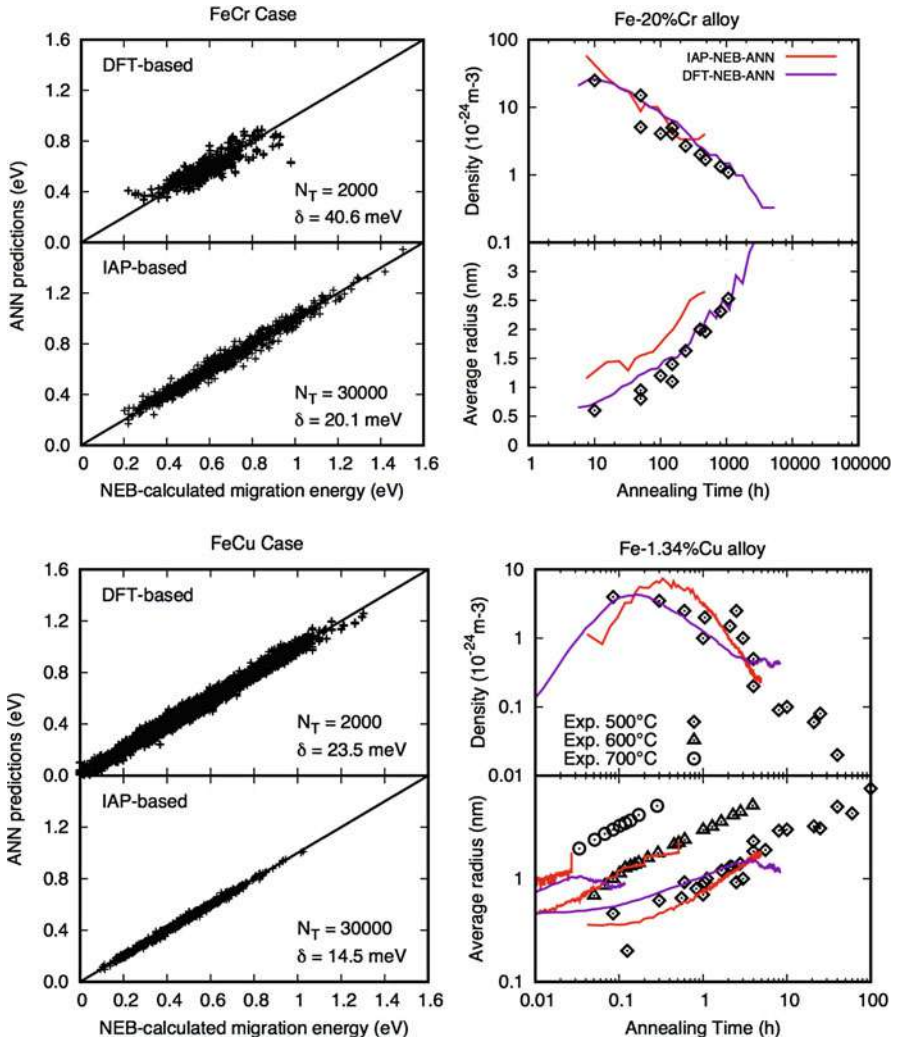
The ANN-based AKMC algorithm as described in the previous section is not directly applicable to systems where the rigid-lattice assumption is no longer valid, e.g., near free surfaces, grain boundaries, in the presence of dislocations, or in the presence of nanostructural features such as dislocation loops. By removing the rigid-lattice assumption, the definition of the transitions and especially of the LAC becomes much more complex. Therefore, a different formulation is needed.


Fig. 6 Application of the ANN-based AKMC model to thermal annealing experiments. The ANN accuracy of prediction for the vacancy migration energies is shown on the left panels. N_T is the number of examples in the training database, and δ is the residual average error of prediction, after training. On the right panels, the series "IAP-NEB-ANN" refers to the ANN trained from NEB calculations using an IAP, whereas "DFT-NEB-ANN" is based on DFT, (top) in Fe-20%Cr at 500°C. Experimental data is taken from Novy et al. (2009), Novy (2009), and Bley (1992), (bottom) in Fe-1.34%Cu at 500, 600, and 700 °C. Experimental data is taken from Goodman et al. (1973), Kampmann and Wagner (1986), Mathon et al. (1997), and Perez et al. (2005)

Fully lattice-free AKMC models do exist. They constantly explore the local curvature of the potential energy surface and find transitions to nearby basins looking for saddle points, as specified by the transition state theory (Fichthorn and Weinberg 1991). For example, in 2001, Henkelman and Jonsson used the

dimer method (Henkelman and Jónsson 1999), which in theory searches for all possible transitions without the need to make assumptions. Other authors developed different schemes, though accomplishing the same finality, e.g., the ART method (Barkema and Mousseau 2001; Béland et al. 2011). In these, the definition of the migration events, and the calculation of their corresponding migration barriers, is made on the fly. Clearly, the advantage is the flexibility with respect to the simulated system. However, the required computing time is prohibitive for performing long simulations, inherently limiting the practical application of the method to no more than a few thousands of events. This is undoubtedly insufficient to study long-term and slow processes such as precipitation or depletion of solutes at interfaces.

Similar ideas to the ANN-based model described in the previous sections may be developed in a lattice-free framework (Castin et al. 2014), for proposing a compromise between the afore-discussed extremes. The search for any possible transition events with a fully general method is equivalent to test migration vectors in the $3N$ space, starting from the present state of the system. This allows the definition of a large number of migration events, which can become unmanageable. Additionally, many events found are likely to be minor (e.g., slight displacement of a single atom to a very nearby stable position), thus not letting the system advance significantly in time. Instead, we define a generic procedure for defining transitions, assuming the most likely events. Let's consider the example of a grain boundary in FeCr alloys. Making legitimate assumptions, migration events may be defined looking for sites with enough open volume (thus playing the role of a pseudo-vacancy) (Castin et al. 2014), using a geometrical criterion based on Voronoi vertexes, as shown in Fig. 7a. In the figure, seven atoms are found within a prescribed maximal distance from an eligible site, thus leading to the definition of seven transition events (the migration of any of them toward the site). A vector of migration is thus naturally defined for each transition, as illustrated in Fig. 7b. The direction of evolution for the system is thus reduced to a vector in three dimensions (indicated as $\bar{d}^{(e)}$ in Fig. 7b), expressing the relative translation for the migrating atom.

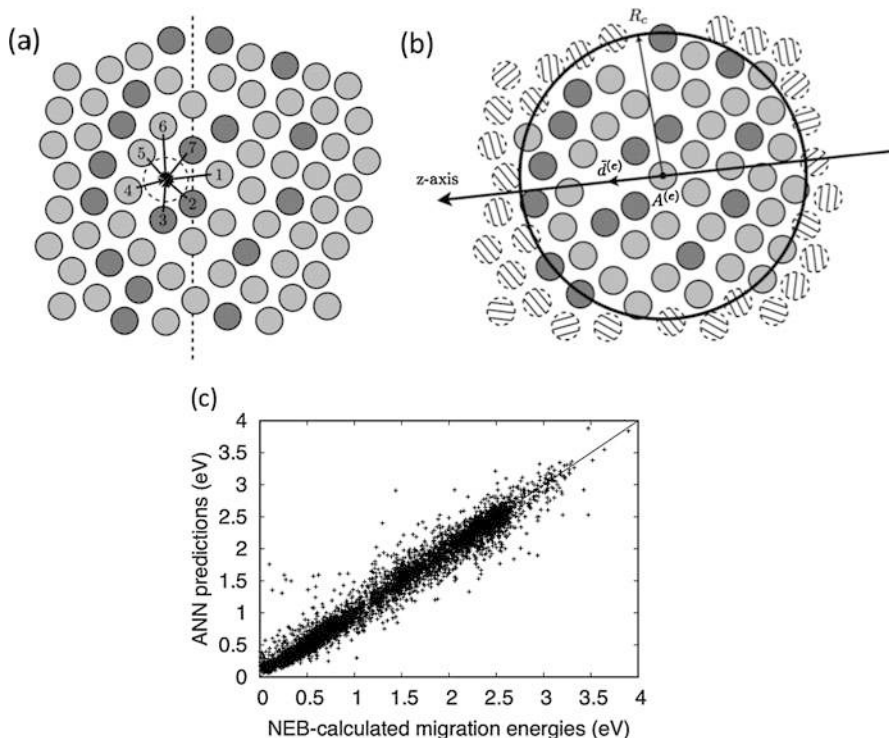
The activation energy associated with each event may be defined using a semirigid-lattice procedure: the migrating atom is first rigidly translated to the destination site, and later on full static relaxation using conjugate gradients is applied. The obtained configuration is defined as the final state assigned to the event, and NEB is applied to evaluate the migration energy. Similar to the idea illustrated in Fig. 4, many examples of transition events are gathered in a database, until enough data are available for designing an ANN, aimed at fully replacing the NEB calculations. Similar to the rigid-lattice AKMC, its purpose is strictly to provide a numerical estimate of the migration energy. The required inputs are, again, a description of the initial state (calculated from the relaxed atomic coordinates in the $3N$ space). The direction of migration is, also, implicitly provided, because the z-axis of the attached referential system of spherical coordinates is, by convention, aligned with the migration vector $\bar{d}^{(e)}$. It is worth noting that the final state of the system, i.e., after a given migration event is applied, is not known. Different from the rigid-lattice case, it cannot be fully deduced without the application of static relaxation.


Fig. 7 Application of the ANN-based AKMC model to a lattice-free problem. (**a**) Definition of possible transition events with a generic procedure. (**b**) Definition of a migration vector (denoted as $\bar{d}^{(e)}$) and a LAC (atom within a given cutoff radius R_c) for a given event. (**c**) Accuracy of the prediction of the event migration energy, achieved by the ANN after training

Following a basic Monte Carlo algorithm, a list of events is established at every step of the simulation using the generic procedure, and the ANN is used to estimate the associated migration energies. One event is thus stochastically selected among the others. From this point, only static relaxation is necessary, after the migration atom is rigidly placed at its destination. The application of NEB is then optional and may be reserved for occasional feedback on the ANN predictions.

The major advantage of the here proposed lattice-free AKMC model is that the CPU cost is reduced to the minimum necessary. Instead of applying a general transition search method many times at each step of the simulation (for which it is in principle necessary to define a list of events), this operation is performed only once, i.e., for the selected event only. Once again, this algorithm entirely relies on the capacity of an ANN to make faithful predictions of the event migration energies, given as input a description of the initial state, and of the migration vector $\bar{d}^{(e)}$. We demonstrate the feasibility, successfully training an ANN for the case of a single vacancy migrating near a grain boundary in FeCr alloys, as shown in Fig. 7c. Taking advantage of the symmetry of the system, the ANN input variables were taken to be

the moduli of the following C_{nlm} coefficients. These are, by construction, invariant with respect to rigid rotations around the migration vector $\bar{d}^{(e)}$ in Fig. 7.

$$C_{nlm} = \frac{1}{N_{\text{RC}}} \sum_{i=1}^{N_{\text{RC}}} S_i R_n(r_i) Y_{lm}(\theta_i, \varphi_i) \tag{4}$$

Here, n, m, and l are integers defining the complexity for an expansion in series, with $0 \leq m \leq l$. The summation in Eq. (4) is performed over all neighboring atoms i found within the prescribed cutoff R_C from the migrating atom, located in space using their relative $(r_i, \theta_i, \varphi_i)$ spherical coordinates. Functions $R_n(r_i)$ are series of orthogonal radial functions, and Y_{lm} is the Laplace spherical harmonics. Finally, S_i is an integer describing the chemical species of the atom i, e.g., 1 for Fe, 2 for Cr, etc. The vector of ANN input variables is defined as:

$$\bar{C} \triangleq [|C_{nlm}|] \tag{5}$$

with $1 \leq n \leq N_{\text{Max}}$ and $0 \leq l \leq L_{\text{Max}}$. The number N_C of ANN input variables is thus given by:

$$N_C = N_{\text{Max}} \left(L_{\text{Max}} + \frac{L_{\text{Max}}(L_{\text{Max}} + 1)}{2} \right) \tag{6}$$

The ANN shown in Fig. 7c was defined taking $N_{\text{Max}} = 8$ and $L_{\text{Max}} = 36$, thus with $N_C = 5616$. It was trained on the basis of a database collecting a total of 31000 NEB calculation. The average residual error of prediction is 123 meV.

4   Neural-Network Potentials Fitted from DFT

As previously evoked, cohesive models are a central element in a multiscale modeling strategy. Density functional theory (DFT) is, in this respect, often an ideal and thus preferred choice. Cluster expansion models, e.g., the FeCrW by Bonny et al. (2016), were originally proposed to extrapolate DFT data for rigid-lattice configurations (van de Walle and Ceder 2002). In this case, the total energy is decomposed in contributions from clusters of atoms, according to predefined patterns: these are, e.g., pairs of atoms found in first nearest-neighbor position, triangles, quadruplets, etc. While this approach has been especially taken for addressing simulations in bulk materials driven by vacancy defects (der Ven and Ceder 2005), it has also been used to consider configurations with self-interstitials (Ngayam-Happy et al. 2012). It is worth noting that the deployment of a CE in the latter case is far more delicate, mainly because of the increasing complexity in the geometry of the explored configurations and the ensuing reduction of exploitable symmetries. As a consequence, the required numbers of clusters in the expansion for a proper general description rapidly explodes.

Given these limitations, neural-network potentials (NNP) are a very promising alternative method. They naturally benefit from the generality and portability proper of ANN, therefore not making any assumption regarding the kind of interactions between the chemical species in the target alloy. Such qualities are predicated to surpass the abilities of EAM-like potentials or any CE, provided that enough data are available for training. As in the case of the CE, NNP are meant to learn from DFT directly, and no experimental data can be directly incorporated. Different from CE, however, NNP are not limited to a rigid-lattice formalism nor by the geometrical complexity of the configurations described.

A method for designing NNP specifically aimed for KMC models in binary Fe-based alloys was proposed (Castin et al. 2017). Consistent with the prerequisites for high-dimensional potentials, the total energy of a given atomic configuration is decomposed as:

$$E_{\text{ANN}}^{(\text{Tot})} = \sum_{a=1}^{N} E_{\text{ANN}}^{(X(a))}(\rho^{(a)}) \tag{7}$$

Here, ρ is the local atomic density. Superscript (a) refers to a particular atom within the N constituting the studied configuration, and $X(a)$ denotes the chemical species for atom (a), i.e., $X(a)$ = Fe, Cu, Cr, …. Functions $E_{\text{ANN}}^{(X(a))}$ are atomic energy functions (AEF), providing an estimation of the energy assigned to every atom of the corresponding chemical species; subscript ANN refers to the fact that each AEF is implemented by an individual ANN. Their input variables are a description of the local atomic density, using symmetry functions defined as follows:

$$Q_{nl}^{(a)} \triangleq \sum_{m=-l}^{l} |C_{nlm}^{(a)}|^2 \tag{8}$$

with $C_{nlm}^{(a)}$ defined above in Eq. (4) but the S_i coefficients for determining the chemical species are not included. Instead, this information is included by expanding the vector of ANN input variables in distinct components. Considering the example of a binary FeX alloy, three distinct $\bar{Q}$ vectors are combined, each including the contribution from chemical sub-ensembles in the neighboring atoms, i.e.:

$$\bar{Q}^{(a)} \triangleq \left[Q_{\text{FeFe}}^{(a)} Q_{\text{FeX}}^{(a)} Q_{\text{XX}}^{(a)} \right] \tag{9}$$

Here, $Q_{\text{Fe}}^{(a)}$, $Q_{\text{X}}^{(a)}$, and $Q_{\text{FeX}}^{(a)}$ are identical as defined in Eq. (5) but only consider either Fe atoms, X atoms, or both, respectively. Given N_{Max} and L_{Max}, the number N_Q of symmetry functions (corresponding to the ANN input variables) is thus given by:

$$N_{\text{Q}} = 3N_{\text{Max}}(L_{\text{Max}} + 1) \tag{10}$$

NNP were fitted for both the bcc FeCu and the FeCr systems (Castin et al. 2017) and also for the FeNi case. Primarily aiming to incorporate DFT-based energies

in rigid-lattice Monte Carlo models, training configurations were extracted from NEB calculations of single point defects migration energies (both single vacancy and single self-interstitial). To fix the ideas, each NNP was fitted from 2000 to 5000 NEB calculation (requiring 10–30 million CPU hours), providing a total number of 20,000–50,000 atomic configurations. The vector of input variables was defined using $N_{Max} = 5$ and $L_{Max} = 10$, thus leading to $N_Q = 165$. The accuracy of prediction, after training, is summarized in Fig. 8. Similar results were later on obtained for the FeNi system, as also shown in the figure.

In addition to refine the models for thermal annealing experiments (previously shown in Fig. 6), the potentials were used to evaluate the phase diagram, using a Metropolis Monte Carlo method. As shown in Fig. 9, we see that DFT predicts a Cr solubility limit that is very consistent with an extensive review of experimental data (Bonny et al. 2008, 2010); alloying Cr atoms should remain fully solute in the ferritic matrix at all temperatures, up to a concentration near 9at%Cr from which α' phases form.
Fig. 8 Accuracy of prediction achieved by the ANN potential for the FeNi, FeCu, and FeCr systems. δ is the mean absolute error of prediction

5   Future Perspectives: Proper Modeling of Radiation-Induced Hardening in Ferritic Steels

Artificial neural networks and machine learning schemes in general may find manifold applications in a multiscale modeling framework. The examples provided here are essentially all based on the idea of predicting how chemically complex local atomic configurations and/or specific strain fields influence the activation energy of selected thermally activated events, shortcutting computationally heavy calculation methods. Appropriately trained ANN are then used to inform more or less standard atomistic KMC models. Similar schemes can be used to calculate other quantities than activation energies and to transfer atomistic details to non-atomistic models, thereby helping in the effort of bridging between scales. Here a few examples are discussed.

As previously mentioned in Sect. 1, OKMC models were proposed for describing the microstructural evolution in RPV and F/M steels, assuming a gray matrix approximation as far as solute atoms are concerned. A future development of these models would consist in making the parameters of migration and dissociation of point-defect clusters sensitive to the local composition. As a matter of fact, phenomena of radiation-enhanced or radiation-induced heterogeneous precipitation are expected to create significant fluctuations in the local composition. Thus, vacancies will form complexes with solute atoms, mobile SIA clusters and dislocation loops will be repelled or attracted by regions rich in a given solute, while immobilized defects of the same type will become decorated by solutes, especially when these are dragged by point defects. In order to describe these processes, it becomes necessary to know, for example, how the formation, trapping, and migration energy of point-defect clusters change as a function of the local composition. Such a type of information cannot be calculated on the fly. First of all, such calculation would offset the advantage of non-atomistic modeling tools, i.e., the fact of simulating relatively long timescale. Secondly, concentration-dependent quantities are inherently averages or else randomly selected values for different configurations with the same local solute concentrations. ANN trained to calculate these quantities as functions of the local atomic configurations would allow the introduction of the chemical and atomistic detail in models that in fact do not include atoms but handle only, in the best case, local concentrations.

Therefore, a more realistic description of solute dragging by single point defects could be provided, beyond the assumption of infinite dilution limit, incorporating the effect of local chemical configurations. For instance, the dragging of a solute by a point defect may be reduced by the presence of other solutes, or the carrying defect may more favorably bind to a different solute encountered along the way. Given an adequate cohesive model as input, the ANN-based technique described in Sect. 3 could be integrated in the OKMC model to provide on-the-fly appropriate parameters at negligible computational cost.

Another example concerns the behavior of SIA loops decorated by solutes. By DFT some data on the relevant binding energy can be obtained in the presence of a

limited number of solutes at a time, and it is impossible to explore all possible ways in which solutes will aggregate around a loop. A valuable improvement in the model would be to train ANN to accurately predict the binding energy between SIA loops and decorating solutes, ideally on DFT data. Given as input a loop size in number of SIA and a content in solutes (either as an explicit set of spatial coordinates or as a composition in regions of space), ANN could assimilate how the effective binding energy changes.

Similarly, and without mutual exclusion, ANN could be used to predict how the migration energy of mobile defects is influenced by the presence, in non-atomistic models such as those of OKMC type, of strain fields, such as those created by dislocation loops and lines, grain boundaries, etc. It is of course possible to describe this effect by associating with each extended defect the strain field that it generates, as calculated in an elasticity theory framework, treating, for example, single point defect as elastic dipoles and parametrizing their migration energy on DFT as function of the dipole/strain field interaction. However, this is an approximation that slows down significantly the calculation and is limited to relatively simple strain fields, the description of which becomes complicated when, for example, the materials are anisotropic, or when strain-field superposition occurs. In contrast, ANN could be trained in this sense directly on atomistic models, to provide, say, the migration energy of a single point defect as function of the local strain field. Moving to different scales and processes, when applying dislocation dynamic models to describe plastic deformation in irradiated materials, it becomes necessary to define local rules of interactions between specific types of dislocations and obstacles. These obstacles can be solute clusters or precipitates of different types and compositions, loops orientated in different ways, decorated or not by solutes, etc. By molecular dynamics, it is possible to explore only a limited number of configurations, temperature being also a key variable to define the result of the dislocation/obstacle reaction. Once again, ANN trained to predict the key parameters that govern the interaction between dislocations and defect, depending on the specific features of both, would enable dislocation dynamic models to become more local and take into account variables, such as chemical composition of obstacles, which are currently very difficult or impossible to include in these models.

All the examples given concern quite strictly machine learning applied to varying atomistic configurations. In a more general and futuristic way, machine learning may one day shortcut and replace numerical simulation models that require long computing times to provide an answer. These models, e.g., suite of codes that, through different scales, provide the increase of yield strength as a consequence of irradiation for a given temperature, flux, fluence, materials composition, etc., may be used to provide examples of results for given initial and operating conditions, on which suitable machine learning schemes could be trained, possibly also completed by experimental examples. These machine learning schemes would then eventually be able to provide equivalent results, at negligible computational cost.

6   Conclusive Remarks

In this chapter, we have surveyed our work aimed at achieving a more physically accurate parametrization of atomic-scale modeling, more specifically kinetic Monte Carlo models devoted to the description of irradiation-induced microstructure changes in metals and alloys. However, the value of the concepts and examples here presented goes beyond the field of materials modeling, as there exist many more research fields where ANN, and machine learning techniques in general, can provide substantial contributions and help building more advanced and accurate models. It is in fact common in many modeling activities to face the need for more powerful and flexible regression techniques, which may appreciatively enhance the quality and applicability of the model.

Multiscale Modeling of Diseases

Multiscale Modeling of Diseases: Overview

104

George E. Karniadakis and Ming Dao

Contents

Abstract

Some of the most recent advances in multiscale modeling of human diseases are briefly summarized. These progresses benefited from the rapid development of advanced multiscale modeling techniques as well as the development and availability of new mechanobiology experimental techniques and diverse imaging modalities. The close interdisciplinary collaborations between modeling scientists, experimentalists, and medical doctors enabled unprecedented quantitative understanding of human pathologies. Two specific examples are given on the recent advances in multiscale modeling of malaria – an infectious disease and sickle cell disease – a genetic disease. Future outlook is presented, followed by a brief introduction of the chapters included in this section.

1   Overview of Recent Advances

All biological systems in a human, e.g., from a big organ such as the heart to a simple cell such as the red blood cell (RBC), are multiscale and multi-rate in nature with characteristic spatiotemporal scales disparate by several orders of magnitude. Diseases often affect the cellular structure of diverse cells, the tissues, the signaling mechanisms, but also one or multiple organs. For example, parasitic infectious diseases or other hereditary hematologic disorders, such as sickle cell disease, are often associated with major morphological changes and affect the viscoelastic properties of RBCs, that is, they are becoming stiffer. Protein or hemoglobin changes in RBCs, in turn, can disrupt blood flow and possibly lead to vaso-occlusion affecting significantly brain perfusion, as in the case of cerebral malaria. Modeling of these hematologic disorders requires a seamless multiscale approach, where blood cells and their components as well as blood flow in arteries, arterioles, and capillaries are all represented accurately using physiologically consistent parameters. However, not all these parameters can be obtained from first-principles nor from in vivo experiments, but with careful ex vivo or in vitro experiments they can be estimated with adequate accuracy in many cases.

In the past decade or so, there have been many exciting developments in the field of blood rheology, cell mechanics, and tissue mechanics for human diseases, and multiscale modeling has played a critical role in the process. These advances were made possible due to the following three key factors, among others:

1. The development of advanced multiscale modeling techniques (Lin et al. 2013, 2017a) that interface heterogeneous descriptions and corresponding computational solvers across scales. Also, the development of coarse grained versions of molecular dynamics that can simulate much bigger domains and for longer time scales. Finally, large-scale simulations are now being performed almost routinely on most of the labs on inexpensive CPU and GPU clusters providing unprecedented computational power

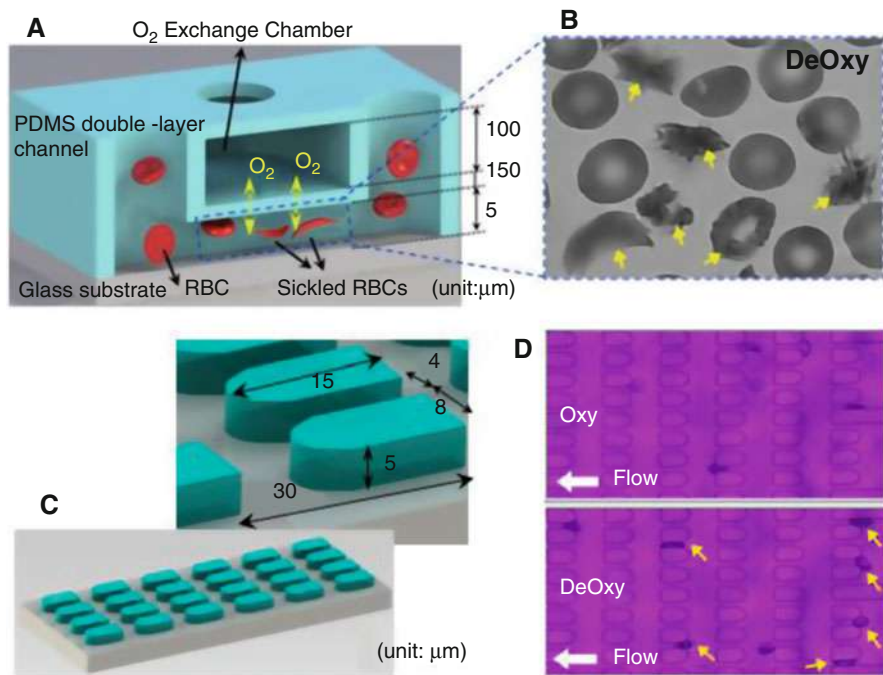
2. The development of new mechanobiology experimental techniques (Bao and Suresh 2003; Suresh 2007a; Suresh et al. 2005; Diez-Silva et al. 2010) and diverse imaging modalities (Choi et al. 2007; Park et al. 2008, 2010; Hosseini et al. 2016). These tools were made widely available within the past 10–15 years, while not available or hardly accessible to the previous generation of researchers, including optical tweezers (OT) (Dao et al. 2003; Diez-Silva et al. 2010), atomic force microscope (AFM) (Bao and Suresh 2003; Suresh 2007a, b; Carvalho et al. 2013), microfluidics (Bow et al. 2011; Quinn et al. 2011; Du et al. 2013, 2015), diffraction phase microscope (DPM) (Park et al. 2008, 2010), tomography phase microscope (TPM) (Choi et al. 2007) etc. The recent advances have provided diverse and accurate multiscale measurements for static and dynamic experiments that help to obtain input parameters and validate the simulation outputs of the multiscale models. Figure 1 shows a microfluidic platform developed recently at MIT for investigating biophysical/biomechanical


Fig. 1 A microfluidic platform developed recently for investigating biophysical/biomechanical alterations in sickle RBCs under transient hypoxia conditions (Du et al. 2015). (**a**) shows an oxygen-controlled chamber while (**b**) shows the result of hypoxic conditions and the heterogeneity of shapes of sickle RBCs. (**c**) shows a flow cytometer with obstacles designed so that deformable RBCs can easily flow through while stiffer sickled RBCs can get stuck. (**d**) shows some typical results of flowing RBCs under oxygenated (20% O_2) and deoxygenated (2% O_2) conditions, where the yellow arrows indicate sickled RBCs being trapped by the microgates. More details can be found in Du et al. (2015).

alterations in sickle RBCs under transient hypoxia conditions (Du et al. 2015), enabling patient-specific multiscale models as demonstrated in Li et al. (2016, 2017b).

3. The close interdisciplinary collaborations between modeling scientists, experimentalists, and medical doctors in pursuing deep, quantitative understanding of human pathologies (Peng 2011). These interdisciplinary research efforts have been strongly promoted by specific funding initiatives such as the Interagency Modeling and Analysis Group (IMAG) Multiscale Modeling (MSM) Consortium at National Institutes of Health (NIH) in USA, the European Research Council (ERC) supported projects such as "MATHCARD" and "iHEART," as well as international collaborative programs such as Singapore-MIT Alliance for Research and Technology (SMART).

Here we would like to discuss two specific examples where we employed multiscale modeling with microfluidic platforms, advanced phase microscopy, AFM, and optical tweezers synergistically. The first example is about the recent advances in multiscale modeling of an infectious disease – malaria, and the second example is about the latest progresses in a genetic disease – sickle cell disease. More details and other diseases/disorders will be covered in the following chapters included in this section, including modeling of blood clots and lung pathologies.

Malaria: Malaria is still a major infectious disease threatening global public health, with high mortality in young children (Desai et al. 2007; Greenwood et al. 2008; O'Meara et al. 2010; Wells et al. 2015). The disease is transmitted between mosquito hosts and human hosts by *plasmodium* parasites, which infect RBCs. There were a number of key advances recently on the mechanical property changes versus disease states, including the confirmation of RESA protein being the key molecule almost single-handedly responsible for the stiffening of the infected RBCs within the first 24 h (Mills et al. 2007), the precise measurement of up to 10 times progressive stiffening of the infected RBCs within 48 h using multiple independent experimental techniques (OT, microfluidics, DPM) (Suresh et al. 2005; Park et al. 2008; Bow et al. 2011; Mills et al. 2007; Diez-Silva et al. 2012), the quantitative measurement of cytoskeleton damages through the disease states (Shi et al. 2013; Sinha et al. 2015), and protein specific adhesion characteristics (Carvalho et al. 2013; Xu et al. 2013). In parallel, accompanying these new understandings and new experimental data, the multiscale modeling of the healthy and malaria infected RBCs made significant advances as well (Dao et al. 2003, 2006; Quinn et al. 2011; Bow et al. 2011; Li et al. 2005, 2007; Fedosov et al. 2011a, b; Peng et al. 2013; Li et al. 2014; Fedosov et al. 2014; Zhang et al. 2015; Pivkin et al. 2016; Tang et al. 2017), including the RBC membrane model capable of incorporating spectrin tetramer and junction complex connections with lipid membrane (Peng et al. 2013; Tang et al. 2017), the detailed model that can incorporate cytoskeleton and/or membrane defects (Li et al. 2005, 2014; Peng et al. 2013; Zhang et al. 2015; Tang et al. 2017), and the latest OpenRBC whole cell model that includes currently all the cytoskeleton proteins and in future versions the metabolic pathways (Tang et al. 2017). These models were able to accurately reproduce experimental results using OT, microfluidics, DPM, etc., and provided quantitative tools for exploring many mechanistic insights not directly extractable through experiments only (Dao et al. 2003, 2006; Quinn et al. 2011; Bow et al. 2011; Li et al. 2005, 2007, 2014; Fedosov et al. 2011a, b, 2014; Peng et al. 2013; Zhang et al. 2015; Pivkin et al. 2016; Tang et al. 2017).

Sickle Cell Disease: Sickle cell disease is a genetic disease caused by a single amino acid defect in producing hemoglobin (Hb). It was named by Linus Pauling the first *molecular disease* in an early paper (Pauling et al. 1949). The defective hemoglobin, or sickle hemoglobin (HbS), will polymerize and form stiff HbS bundles under low oxygen conditions, resulting in sickle-shaped and stiff RBCs as well as enhanced adhesion. These severely compromised RBC mechanical properties are responsible for the related clinical complications in sickle cell disease, including vaso-occlusive painful crisis, acute chest syndrome, and various

organ/tissue damages in spleen, lung, bone, etc. (Piel et al. 2017; Ware et al. 2017). Some recent new progresses and fundamental understanding in sickle cell disease include the establishment of single-cell based microfluidics platform for dynamic sickling kinetics and capillary obstruction measurements under transient-hypoxia (Du et al. 2015; Li et al. 2017a, b), the detailed characterization of the transient-hypoxia sickling characteristics for different sickle RBC density populations (Du et al. 2015; Li et al. 2016, 2017a), the AFM characterization of sickle RBCs (Maciaszek and Lykotrafitis 2011; Li et al. 2017a), the normoxia shape and mechanical property characterization at single-cell level for different sickle RBC density populations (Xu et al. 2017). With these new experimental techniques and newly available experimental data, the multiscale modeling of sickle RBCs made many significant advances as well (Li et al. 2017a; Lu et al. 2017), including the detailed polymerization model capable of predicting the homogenous and heterogeneous nucleation and growth of the polymerized HbS fibers and fiber bundles (Lu et al. 2016, 2017), the whole cell model capable of incorporating HbS polymerization and resulted shape changes (Lu et al. 2017; Lei and Karniadakis 2012; Li et al. 2012, 2013), and the vaso-occlusion model that incorporate both cell stiffening and cell adhesion (Lei and Karniadakis 2013). These models were able to correctly simulate some critical in vivo vaso-occlusive observations in mice (Kaul and Fabry 2004) and in vitro experiments using the latest microfluidics platform (Du et al. 2015; Li et al. 2017b), and again helped providing many mechanistic insights not directly extractable through experiments only (Li et al. 2017a).

2   Outlook

Multiscale modeling techniques are not unique to biological systems, and advances across other disciplines will find their way to multiscale modeling of human diseases. Bottom-up approaches are still computationally expensive and more *aggressive* coarsening techniques will help to alleviate the cost without sacrificing greatly the accuracy. A particularly useful coarse-graining aspect is the dynamic refinement or de-refinement as shown in Fig. 2 that could target the fine-graining in regions that molecular details matter while representing the rest of the system with sufficient accuracy but at much coarser fidelity. Domain decomposition methods, like the one presented in the next chapter, will enable scaling up from the microscale and mesoscale to the macroscale, hence integrating molecular details with organ-level biomechanics. Precision medicine implies individualized diagnosis and predicting the evolution of a disease, e.g., a possible rupture of a brain aneurysm, but this, in turn, requires a lot of personal data from a patient gathered at routine medical exams and at the time of crises. Therefore, *data-driven multiscale modeling* will play a central role in future modeling of diseases and the great challenge is how to incorporate such data at different scales of multiscale models. Machine and deep learning will play a big role in this data-model interaction for classification, as in the work of Xu et al. (2017), but also for inference and prediction of the evolution of the diseases, even for short term, e.g., in trying to predict glucose
Fig. 2 Multiscale simulation of polymerization inside the RBC: The stiff HbS fiber interacts with the RBC membrane and distorts the RBC to the sickle shape. The HbS fiber is simulated by a hybrid HbS fiber model where two HbS fiber models at different length scales are coupled by applying a mesoscopic adaptive resolution scheme (MARS). In the HbS fiber, one small yellow particle represents one HbS molecule, and 56 HbS molecules are coarse-grained as one large yellow particle. In the RBC membrane, green particles represent actin junctions, blue particles represent spectrin proteins, black particles represent glycophorin proteins, white particles represent the band-3 complex, and red particles represent the lipid particles. (For more details see Lu et al. (2017); Courtesy of Lu Lu and He Li, Brown University)

levels in diabetic patients by monitoring glucose histories and train properly a deep neural network using personalized data, e.g., multi-omics approach and data. In fact, the proper integration of multi-omics with existing multiscale models at the molecular level may be one of the greatest challenges in future generations of multiscale modeling but such a significant advance will make precision medicine at last realizable. At the higher scale levels, several observed quantities from blood pressure, to oxygen concentration, to even monitoring the stiffness of human arteries are becoming possible through the use of wearable biosensors for generation of big data that could eventually help multiscale models to be truly predictive.

3 Brief Introduction of the Chapters

In ▶ Chap. 105, "Domain Decomposition Methods for Multiscale Modeling," Bian and Praprotnik introduce domain decomposition methods that facilitate a smooth transition from one modeling method to another one in adjacent domains. For example, they demonstrate how a continuum formulation, e.g., the Navier-Stokes

equations can be interfaced with the molecular dynamics method applied to a region where the continuum hypothesis breaks down. For more complex fluids that contain molecular structures, they couple molecular dynamics methods with coarse-grain molecular dynamics in the far field. The matching interface conditions can be applied directly to the state variables or indirectly by interpolating the forces across the domains.

In ▶ Chap. 106, "Particle-Based Methods for Mesoscopic Transport Processes," Li Z et al. introduce particle-based methods for mesoscopic transport processes. Biological processes at cellular and subcellular levels involve the transport of many reacting biochemical species, such as enzymes, proteins, and nutrients. The particle-based stochastic models for mesoscopic transport processes, including thermal transport, reactive chemical transport, and ionic transport in mesoscopic systems, are reviewed and discussed.

In ▶ Chap. 107, "Continuum- and Particle-Based Modeling of Human Red Blood Cells," Li XJ et al. address modeling of RBCs by both continuum and particle-based methods. The continuum method is more efficient and can simulate larger domains but the dissipative particle dynamics method used in the particle-based approach can represent molecular details down to the level of transmembrane proteins.

In ▶ Chap. 108, "Computational Models of Eukaryotic Cells in Health and Disease," Lykov K and Pivkin IV present computational models for eukaryotic cells suspended in flow or adherent to a substrate. These models represent a phenomenological top-down approach. The mechanical properties of the cell model components are obtained based on general principles and macroscopic properties of the cell. A future bottom-up approach will allow construction of eukaryotic cell models by relating the mechanical behavior of the whole cell with the bio-chemical properties of its molecular constituents.

In ▶ Chap. 109, "Multiscale Modeling of Malaria-Infected Red Blood Cells," Dasanna AK et al. review malaria disease modeling on the level of single infected RBC, thus quantifying its stiffer mechanics and cytoadherence – the two hallmarks of malaria disease. They discuss recent advances in multiscale models and show how such models are validated and subsequently used to put forward new hypotheses and even to be used for developing new treatment strategies.

In ▶ Chap. 110, "Multiscale Modeling of Sickle Cell Anemia," Li XJ and Lei H review multiscale modeling methods of sickle cell anemia with similar characteristics as malaria but with markedly larger variation of RBC shapes. Unlike its name, roughly 20% of deformed RBCs have the sickle shape whereas the rest can be elongated, granular, maple-leaf and several other shapes. This shape heterogeneity produced by the hemoglobin polymerization process inside sickle RBCs under hypoxic conditions, e.g., in post-capillary venules, affects the rheology of sickle blood and can also lead to different cell-cell and cell-wall interactions that can, in turn, cause total vaso-occlusion, which is responsible for most of the patient crises.

In ▶ Chap. 111, "Multiscale Modeling of Blood Flow-Mediated Platelet Thrombosis," Yazdani A et al. focus on blood flow mediated platelet thrombosis that is common in coronary or carotid arteries but also in prosthetic cardiovascular

devices. The authors describe a bottom-up particle approach starting with molecular dynamics for platelets as well as coarse-grained versions of it and scale up to RBCs and plasma using dissipative particle dynamics. The coagulation cascade that involves multiple advection-diffusion-reaction processes can also be modeled by a new version of dissipative particle dynamics that can deal with transport of species at the mesoscale.

▶ Chapter 112, "Cluster-Guided Multiscale Lung Modeling via Machine Learning," by Lin CL et al. focuses on multiscale modeling of airflow distribution and aerosol transport in the human lung. The scale separation from the trachea to alveoli spans over two orders of magnitude so this is a particularly challenging multiscale problem. The authors discuss methods for modeling lungs both for a specific patient as well as for a group of patients. The entire framework is presented consisting of an imaging-based lung model and a high-fidelity computational fluid dynamics model. For "between patients" modeling, the authors use machine learning to identify homogeneous sub-populations among healthy and diseased populations, in order to bridge individual and population scales.

Abstract

Domain decomposition methods (DDM), which originate from the Schwarz alternating method to solve elliptic partial different equations, are largely extended and prove to have increasing influences on multiscale modeling of materials. We discuss some of the important extensions of the DDM in the fields

of multiscale modeling for soft materials such as simple and complex fluids. To this end, we typically model the fluids in two or more levels of detail, which exploits the computational efficiency of the coarse model and physical accuracy of the fine description. For simple fluids, we take a continuum perspective to couple the molecular dynamics (MD) and Navier-Stokes equations by matching the state variables and/or fluxes across the hybrid interface. For complex fluids, we take a discrete perspective to encompass the complex structure of the molecules and couple the MD with coarse-grained MD by interpolating the forces between the two levels of descriptions.

1   Introduction

Domain decomposition methods (DDM) may represent a generic concept of solving a problem defined on a global domain by first dividing the domain into a set of overlapping/non-overlapping subdomains. Given that the set of the subdomains covers the original domain and a local problem is solved in each subdomain, the solution for the original global problem is available. Therefore, in a nutshell, it is a methodology of "divide and conquer." However, such a generic concept may be interpreted quite differently in various disciplines.

The name of DDM is mostly referred in applied mathematics, where it represents the decomposition of partial differential equation (PDE) or its approximation on the whole domain into a set of coupled problems on interconnecting subdomains. This dates back to the classical Schwarz alternating method proposed in 1870 (Smith et al. 1996), where the solution of an elliptic boundary value problem is obtained by alternatively solving two same elliptic boundary value problems defined in the two overlapping subdomains. For a general classification of DDM, the decomposition of domain may enter (Toselli and Widlund 2005):

1. At the continuum level, where different PDE models are appropriate for different regions. For example, in the applications of fluid-structure interactions, the fluid and solid regions are described by PDEs of fluid and solid mechanics, respectively. Another example is the aerodynamic boundary layer proposed by Ludwig Prandtl in 1904 (Landau and Lifshitz 1987); in the vicinity of bounding surface, viscous effects of the fluid are significant, while far away from the surface, a description of inviscid flow is sufficient.
2. At the discretization level, where different approximation schemes are employed in different regions. For example, a finite difference method is adopted in one region, while a finite element method is preferred in the other region.
3. At the algebraic level, where a large linear (sparse) system of equations results from the discretization of the PDE. A global iterative method may be inefficient so that a strategy from DDM may choose to solve each block of the linear system individually by employing a direct or iterative method. In this context, the DDM is considered as a preconditioner in combination with other acceleration

techniques such as Krylov space methods. The numerical analysis of DDM as a preconditioner is very developed, which may be found in excellent monographs (Smith et al. 1996; Quarteroni and Valli 1999; Toselli and Widlund 2005).

In practice of numerical modeling, the decomposition at these three levels mentioned above may be interconnected.

Utilizing the idea of DDM for multiscale modeling with heterogeneous mathematical/physical descriptions is also not a new concept. In computational chemistry, one of the earliest examples is the QM/MM (quantum mechanics/molecular mechanics) (Warshel and Karplus 1972; Warshel and Levitt 1976), where chemical reactions involving large molecules are handled by quantum mechanics and regions at elsewhere by classical models. Typically, the degrees of freedom for the two descriptions are fixed during the course of the simulation.

A sudden increase of attention in applying DDM for multiscale modeling of fluids started with the paper of O'Connell and Thompson (1995), where one subdomain is simulated by molecular dynamics (MD) with Lennard-Jones potential, while the other subdomain is solved by a finite difference method discretization of the Navier-Stokes (NS) equations. The overlapping region of the two subdomains implements the "handshaking" of the physical models at two scales. Since the inception of this work, many further important contributions emerge, especially on the constraint dynamics of MD's artificial boundary such as the Maxwell buffer (Hadjiconstantinou and Patera 1997; Hadjiconstantinou 1999), flux-exchange method (Flekkøy et al. 2000; Delgado-Buscalioni and Coveney 2003a; Flekkøy et al. 2005; De Fabritiis et al. 2006), least constraint dynamics (Nie et al. 2004; Werder et al. 2005), adaptive forcing (Pivkin and Karniadakis 2006; Fedosov and Karniadakis 2009), and so on. These methodologies are from a continuum perspective of fluid mechanics, and the coupling of two distinct scales is mainly for modeling simple liquids. There exist a few excellent review articles on this topic (Wijesinghe and Hadjiconstantinou 2004; Mohamed and Mohamad 2010; Delgado-Buscalioni 2012).

Another important research line on DDM for multiscale modeling of structured or complex fluids is represented by the adaptive resolution scheme or AdResS from computational physics/chemistry. In one subdomain, a detailed MD model with atomic details is employed, while in the other subdomain, a coarse-grained (CG) model is adopted. The CG model is usually constructed off-line and, if required, is able to reproduce quantities of interest from MD faithfully. A complex molecule may diffuse across the interface between the two subdomains and change degrees of freedom gradually. In the overlapping region of the two subdomains, either force or energy is interpolated smoothly between the two distinct descriptions. Previous excellent technical reviews on this research line are also available (Praprotnik et al. 2008; Delle Site and Praprotnik 2017). Another interesting hybrid approach has been proposed recently in Scukins et al. (2015), where the hybrid MD/continuum hydrodynamics system of liquid water is considered as two completely miscible liquids using two-phase modeling, where one phase corresponding to the MD and the other to fluctuating continuum hydrodynamics.

For modeling biological functions and diseases, especially those being localized such as the endothelial glycocalyx layer (Weinbaum et al. 2007; Deng et al. 2012) and blood clot formation (Fogelson and Neeves 2015), the DDM appear to be very promising because one can treat different subdomains of the system using different models and methods. In this chapter, we discuss some of the important extensions of the DDM in the fields of multiscale modeling for simple and complex fluids. In the following, we shall first describe the DDM for simple fluids, which include some introduction materials on MD and NS equations. Furthermore, in the same section, we illustrate a few effective algorithms to couple the MD and NS descriptions, with a focus on constraining the artificial boundary of MD. Subsequently, we revisit the concepts of DDM for complex fluids or AdResS. Along the discussions of fundamental algorithms, we illustrate a few selected applications. We summarize this chapter in the end with some perspectives.

2 Domain Decomposition Methods for Simple Fluids

2.1 Molecular Dynamics

We consider a system of N identical, spherical, and structureless particles; they have the same mass m and are enclosed in a volume $\mathscr{V}$. The Hamiltonian $\mathscr{H}$ of the system is defined as

$$\mathscr{H}(\mathbf{r}^N, \mathbf{p}^N) = \sum_{i=1}^{N} \left[\frac{|\mathbf{p}_i|^2}{2m} + u_i(\mathbf{r}^N) \right], \tag{1}$$

where the first and second terms on the right-hand side are the kinetic and potential energies, respectively. The value of $(\mathbf{r}^N, \mathbf{p}^N)$ defines a phase point, where $\mathbf{r}^N = (\mathbf{r}_1, \mathbf{r}_2, \ldots, \mathbf{r}_N)$ are $3N$-dimensional coordinates and $\mathbf{p}^N = (\mathbf{p}_1, \mathbf{p}_2, \ldots, \mathbf{p}_N)$ are $3N$-dimensional momenta. In addition, velocity is defined as $\mathbf{v}_i = \mathbf{p}_i/m$. The trajectory of a phase point is determined by Hamilton's equations:

$$\dot{\mathbf{r}}_i = \frac{\partial \mathscr{H}}{\partial \mathbf{p}_i}, \quad \dot{\mathbf{p}}_i = -\frac{\partial \mathscr{H}}{\partial \mathbf{r}_i}. \tag{2}$$

More specifically, we consider an argon-like liquid described by a shifted Lennard-Jones (LJ) potential truncated at $r_{ij} = r_c$

$$u(r) = \begin{cases} 4\varepsilon \left[\left(\frac{\sigma}{r}\right)^{12} - \left(\frac{\sigma}{r}\right)^6 - \left(\frac{\sigma}{r_c}\right)^{12} + \left(\frac{\sigma}{r_c}\right)^6 \right], & r \leq r_c \\ 0, & r > r_c \end{cases} \tag{3}$$

where ε and σ set the characteristic energy and length scales, respectively. Relative distance between particles is $r_{ij} = |\mathbf{r}_{ij}|$ and $\mathbf{e}_{ij} = \mathbf{r}_{ij}/r_{ij}$. The potential is pairwise,

and therefore, the potential energy of particle i is $u_i(\mathbf{r}^N) = 1/2 \sum_j^{N_{\text{neigh}}} u(r_{ij})$, where N_{neigh} is the number of neighboring particles within a spherical region of radius r_c around particle i. Hence, a pairwise force between particles i and j reads

$$\mathbf{F}_{ij} = -\frac{\partial u(r_{ij})}{\partial r_{ij}} \mathbf{e}_{ij}. \tag{4}$$

The MD trajectories evolve by a time integrator, such as the Verlet velocity algorithm (Allen and Tildesley 1989; Tuckerman 2010) with time step δt.

2.2   Navier-Stokes Equations

We consider an isothermal description of the fluids, where the energy or entropy change of the fluids is ignored. We have the conservations of mass and momentum densities as (Landau and Lifshitz 1987)

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{V}) = 0, \tag{5}$$

$$\frac{\partial \rho \mathbf{V}}{\partial t} + \nabla \cdot \Pi = 0, \tag{6}$$

where ρ, $\mathbf{V}$, and Π are density, velocity, and stress fields, respectively. Here velocity is capitalized to differentiate with the MD particle's velocity $\mathbf{v}$. For a compressible Newtonian fluid, the stress reads

$$\Pi = \rho \mathbf{V}\mathbf{V} - p\mathbf{I} - \eta \left(\nabla \mathbf{V} + \nabla \mathbf{V}^T \right) + \mathbf{I} \left(\frac{2}{3}\eta - \zeta \right) \nabla \cdot \mathbf{V}, \tag{7}$$

with $\mathbf{I}$ being the identity tensor and η and ζ the dynamic and bulk viscosities, respectively. The equation of state $p = p(\rho)$ and viscosities are usually obtained from MD simulations in the context of DDM for multiscale modeling. For an incompressible fluid, the term $\nabla \cdot \mathbf{V} = 0$ is dropped.

The Navier-Stokes equations are typically solved by mesh-based methods, such as finite difference, finite volume, and finite element, or other Lagrangian mesh-free particle methods.

2.3   Concurrent Coupling Between Particle Dynamics and Continuum Description

For illustrative purpose, we consider a specific hybrid simulation between MD and NS equations solved by a finite difference method (FDM). To demonstrate the concept, we take an example of unidirectional flow such as the Couette flow and
Fig. 1 (Color online) Sketch of a domain decomposition method and time stepping for coupling discrete particle dynamics with finite difference scheme. Subdomain Ω_1 is described by a molecular dynamics (MD) simulation, while subdomain Ω_2 is described by a finite difference method (FDM). The whole domain is bounded by two walls $\partial\Omega_1$ and $\partial\Omega_2$, at $y = y_0$ and y_1, respectively. An artificial boundary $\Gamma_1 : [y_b, y_a]$ applies to the MD, and an artificial boundary $\Gamma_2 : y = y_e$ applies to the FDM. A hybrid reference line is defined at $y = y_r$, at which the global solution is pieced together by combining results from MD below y_r and results from FDM above y_r. FDM runs with time step Δt, and DPD runs with time step δt, where $\Delta t = N_s \delta t$ and $N_s \gg 1$ is a positive integer. Time integrations of FDM and MD are staggered to synchronize. The communication time step between the two simulations is $\Delta t_{\text{comm}} = \Delta t$. The arrows between two time axes indicate information passing. (Modified from Bian et al. (2016))

couple the two descriptions along the y direction. This is best sketched in Fig. 1. The hybrid reference line is defined at y_r, and the global solution combines the solution of the MD below y_r and the solution of the FDM above y_r. The subdomain of MD is a three-dimensional box spanning $[0, L_{MD}] \times [0, L_{MD}]$ in x and z direction. In y direction, it ranges from $y_0 = 0$ to y_a. In the case of a wall-bounded domain, there are solid particles below y_0, and specific molecular interactions at fluid-solid interfaces that are different from fluid-fluid interactions must be taken into account. The FDM domain ranges from y_e to y_1 in y direction. No-slip or partial slip condition may apply at y_1 for the continuum description.

The time integrations of the two simulations are staggered to synchronize the average time progression. To minimize the lag time of information exchange (Bian et al. 2015b), we take communication time step $\Delta t_{\text{comm}} = \Delta t = N_s \delta t$. A typical

choice of N_s is an integer number so large ($N_s \gg 1$) that individual particle's velocity decorrelates after $N_s \delta t$ MD steps. This signifies the timescale separation of the two distinct descriptions of fluids; over each Δt the FDM follows a description of continuum mechanics, meanwhile the relevant molecular process reaches a quasi-stationary state. Therefore, given the intrinsic δt of MD and stability constraint on Δt, scale separation parameter N_s demands a low threshold for the grid size of FDM.

To couple the two scale descriptions, we have to pay more attention to the two artificial boundary regions Γ_1: $C \rightarrow P$ (continuum to particles) and Γ_2: $P \rightarrow C$ (particles to continuum). More specifically, on the communication between the two solvers, the particle simulation integrates with time step δt from $t = t - 3\Delta t/2$ to $t = t - \Delta t/2$. To impose the artificial boundary Γ_2 for the continuum ($P \rightarrow C$) at $t - \Delta t$, it is straightforward to perform simple spatial averaging on particle velocities between $y_d \leq y < y_c$ and thereafter temporal averaging over $t - 3\Delta t/2 < t \leq t - \Delta t/2$ as, for example, for the velocity state variable,

$$\mathbf{V}_e = \frac{1}{N_s} \sum_{j=1}^{N_s} \frac{1}{N_{cd}} \sum_{i=1}^{N_{cd}} \mathbf{v}_i. \tag{8}$$

Here, N_{cd} is the instantaneous number of particles located in cell $P \rightarrow C$. Furthermore, the region $P \rightarrow C$ is centered at $y = y_e$ with a thickness of r_c. Similarly, we may alternatively come up easily with the averaging procedures to impose mass and momentum fluxes at interface y_e of the FDM for compressible fluids as (Flekkøy et al. 2000)

$$\rho \mathbf{V} \cdot \mathbf{e}_y = \frac{1}{v_c} \sum_i m \mathbf{v}_i \cdot \mathbf{e}_y, \tag{9}$$

$$\Pi \cdot \mathbf{e}_y = \frac{1}{v_c} \sum_i \left(m \mathbf{v}_i \mathbf{v}_i + \frac{1}{2} \sum_{j \neq i} \mathbf{F}_{ij} \mathbf{r}_{ij} \right), \tag{10}$$

where $\mathbf{e}_y$ is the unit vector pointing outward at $y = y_e$ from FDM and v_c is the local cell volume centered at $y = y_e$ for spatial averaging. Furthermore, Eqs. (9) and (10) need temporal averaging over $t - 3\Delta t/2 < t \leq t - \Delta t/2$ as is done for Eq. (8). For non-isothermal case, energy flux can be imposed as well at the continuum interface (Delgado-Buscalioni and Coveney 2003a).

For more complex flow scenarios, a simple local-time-and-space averaging of particle quantities may not provide sufficiently smooth boundary conditions for the continuum description and may result in instability of the continuum solutions. Therefore, novel algorithms for noise reduction (Li et al. 1998; Grinberg 2012) are called for. Another alternative is to couple one continuum solver with multi-instance MD simulations, so the concept of ensemble averaging may be exploited (Neumann and Bian 2017).

Once $\mathbf{V}_e$ or the fluxes are updated at $t - \Delta t$, the FDM integrates one step from $t - \Delta t$ to t. Its new state variable solutions $\mathbf{V}_a$ and $\mathbf{V}_b$ at y_a and y_b or fluxes at y_a are passed to the particle simulation and are further utilized in various constraint dynamics (as explained in the next four subsections) to set the artificial boundary $\Gamma_1 : y_b \leq y < y_a$ of the particle simulation from $t - \Delta t/2$ to $t + \Delta t/2$. Meanwhile, the MD simulation integrates with time step δt from $t - \Delta t/2$ to $t + \Delta t/2$. Afterward, again Eq. (8) or Eqs. (9) and (10) are applied to impose state or flux boundary conditions of Γ_2 at t. The alternation of imposing artificial boundaries and the staggered integrations of the two simulations repeat until the end of the hybrid simulation.

Due to the truncation of the subdomain for the MD simulation, an average pressure force $\mathbf{F}^P(y)$ must be imposed at the truncation line $y = y_a$ inward. The best way to devise $\mathbf{F}^P(y)$ so far is to make use of the radial distribution function of particles and MD interacting forces to reflect the average effects outside y_a in the continuum limit. $\mathbf{F}^P$ is position-dependent and applies to each particle i within $y_a - y_i < r_c$ distance from y_a in the interior, that is, particles in Γ_1. This approach proves to induce negligible density oscillations near the artificial boundary (Werder et al. 2005; Lei et al. 2011). However, the imposed averaged force does not completely prevent particles from leaving outside. Therefore, a specular reflection or particle deletion is implemented at y_a. The former approach is more suitable to deal with an incompressible fluid, while the latter approach together with a particle insertion procedure (Delgado-Buscalioni and Coveney 2003b) is more physical to describe a compressible fluid by a grand-canonical ensemble so that the total number of particle in the MD subdomain fluctuates (Flekkøy et al. 2005).

The tricky part is to impose the artificial boundary in $\Gamma_1(C \rightarrow P)$ for MD particles from $t - \Delta t/2$ to $t + \Delta t/2$. There is *no unique way* to achieve this, as many extra degrees of freedom on particles are under-determined. For coupling state variable, the usual strategy is to perform a constraint dynamics on each particle i in Γ_1 in such a way that

$$\frac{1}{N_{\Gamma_1}} \sum_{i=1}^{N_{\Gamma_1}} \mathbf{v}_i = \overline{\mathbf{V}}_{\Gamma_1}, \tag{11}$$

is satisfied at every δt or on average over $N_s \delta t$ and thermal fluctuations are affected as little as possible. Here, N_{Γ_1} is the instantaneous number of particles in Γ_1, and $\overline{\mathbf{V}}_{\Gamma_1}$ is the average velocity of the continuum solutions in the same region. In this case, $\overline{\mathbf{V}}_{\Gamma_1} = (\mathbf{V}_a + \mathbf{V}_b)/2$ at time t. For coupling the fluxes, it is similar that we need to spread fluxes (few degrees of freedom) obtained from the continuum solution to the particles within the artificial boundary Γ_1.

In the following, we shall focus on four popular algorithms of constraint dynamics in Γ_1. Since we deal primarily with a unidirectional flow for illustrative purpose, we use scalar variables instead of vector ones. The constraint of the particle dynamics is always performed in x direction of the flow, and therefore the index for x is omitted. Velocities in y and z directions are not altered by the constraint dynamics.

2.4   Relaxation Dynamics

A relaxation dynamics method was proposed in the first paper of hybrid simulations on liquid flow (O'Connell and Thompson 1995). Effectively it reads as

$$\dot{v}_i = \frac{F_i}{m} + \frac{\varepsilon}{\delta t}\left(\overline{V}_{\Gamma_1} - \frac{1}{N_{\Gamma_1}}\sum_{j=1}^{N_{\Gamma_1}} v_j\right),\tag{12}$$

where F_i is the usual total particle force on particle i. The rest of the terms on the right-hand side act as a relaxing force, which drives each particle i in Γ_1 toward the average velocity $\overline{V}_{\Gamma_1}$ over $\delta t/\varepsilon$ time period. In O'Connell and Thompson (1995), the continuum has the same time step as that of the particle simulation, that is, $\Delta t = \delta t$. Moreover, the relaxation parameter is chosen as $\varepsilon = 0.01$ for the particular properties of the fluid simulated, where the authors argue that a smaller value of ε provides inadequate coupling, while a larger value may lead to excessive damping of thermal fluctuations.

2.5   Maxwell Buffer

The Maxwell buffer was first proposed in Hadjiconstantinou and Patera (1997) as

$$v_i = V_i + \delta v_i,\tag{13}$$

$$V_i = V_b + (V_a - V_b)(y_i - y_b)/\Delta y,\tag{14}$$

where a deterministic component V_i is obtained by a linear interpolation between the values on the two nearest grid points V_a and V_b. Under the assumption of a local equilibrium for MD, the stochastic component δv_i is drawn from the Maxwell-Boltzmann distribution at a given temperature $k_B T$,

$$p(\delta v_i) = \sqrt{\frac{m}{2\pi k_B T}}\exp\left[\frac{-m(\delta v_i)^2}{2k_B T}\right].\tag{15}$$

It is simple to see that Eqs. (13) and (14) satisfy directly the constraint posed in Eq. (11).

2.6   Least Constraint Dynamics

By taking the extremum of the time integral of the Lagrangian for the particles in Γ_1, which is subject to the non-holonomic constraint in Eq. (11), the equation of motion (EoM) for each particle i in Γ_1 is according to (Nie et al. 2004)

$$\dot{v}_i = \frac{F_i}{m} - \frac{1}{N_{\Gamma_1}} \sum_{j=1}^{N_{\Gamma_1}} \frac{F_j}{m} + \frac{1}{\delta t} \left(\overline{V}_{\Gamma_1} - \frac{1}{N_{\Gamma_1}} \sum_{j=1}^{N_{\Gamma_1}} v_j \right). \tag{16}$$

Instead of repeating the derivation for Eq. (16) as in Nie et al. (2004), we may arrive at the same expression from another perspective. To satisfy the constraint in Eq. (11), an extra body force $F_{\Gamma_1}^b$ is introduced *dynamically* at every time step δt such that (Werder et al. 2005)

$$\overline{v}'_{\Gamma_1} = \overline{v}_{\Gamma_1} + \frac{\delta t}{N_{\Gamma_1} m} (F_{\Gamma_1} + F_{\Gamma_1}^b), \tag{17}$$

where $\overline{v}_{\Gamma_1}$ is the average velocity and F_{Γ_1} is the total force in Γ_1 due to particle interactions,

$$\overline{v}_{\Gamma_1} = \frac{1}{N_{\Gamma_1}} \sum_{j=1}^{N_{\Gamma_1}} v_j, \quad F_{\Gamma_1} = \sum_{i=1}^{N_{\Gamma_1}} F_j. \tag{18}$$

To satisfy Eq. (11), we set $\overline{v}'_{\Gamma_1} = \overline{V}_{\Gamma_1}$, and therefore, we obtain an expression for the body force $F_{\Gamma_1}^b$ as

$$F_{\Gamma_1}^b = \frac{N_{\Gamma_1} m}{\delta t} (\overline{V}_{\Gamma_1} - \overline{v}_{\Gamma_1}) - F_{\Gamma_1} = \frac{N_{\Gamma_1} m}{\delta t} \left(\overline{V}_{\Gamma_1} - \frac{1}{N_{\Gamma_1}} \sum_{j=1}^{N_{\Gamma_1}} v_j \right) - \sum_{j=1}^{N_{\Gamma_1}} F_j. \tag{19}$$

The value of $F_{\Gamma_1}^b$ is dynamic and may vary at every δt. If we spread the body force $F_{\Gamma_1}^b$ from Eq. (19) *evenly* on N_{Γ_1} particles in Γ_1, it gives exactly the same EoM as in Eq. (16) for each particle i.

2.7   Flux-Exchange Coupling

The exchange of flux for dense fluids was first proposed in Flekkøy et al. (2000) and extended in Delgado-Buscalioni and Coveney (2003a). Rather than constraining the state variables directly, as done in the previous three methods, this method imposes flux at the truncation line y_a of the subdomain of particle simulation. Therefore, the EoM of particles in Γ_1 reads

$$\dot{v}_i = \frac{F_i}{m} + F^x(y_i), \quad F^x(y_i) = \tau_a^{xy} A\lambda(y_i), \tag{20}$$

where $A = L_x \times L_z$ is the surface area of the truncation and τ_a^{xy} is the shear stress at y_a from the continuum. The distribution function $\lambda(y_i)$ of the shear force on each particle must be normalized

$$\lambda(y_i) = g(y_i)/\sum_{j=1}^{N_{\Gamma_1}} g(y_j), \tag{21}$$

where $g(y)$ is an arbitrary function so that $\lambda(y)$ diverges at $y = y_a$ and decays to zero as y approaches y_b from y_a.

If we assume that there is a locally linear shear flow within Γ_1, which is a reasonable assumption for many flow problems, then the distribution function $\lambda(y)$ may be defined better than an arbitrary one (Ren 2007). By assuming a locally linear shear flow, we can work out the continuum limit of the shear forces on line y_a from particles within Γ_1. By setting the shear force on y_a from particles equal to the continuum solution of FDM at y_a, we have an identity as follows:

$$A\tau_a^{xy} = \int_0^{r_c} A d\gamma^D(h) h\dot{\gamma} dh, \tag{22}$$

where h is the distance of particle i from y_a ($h = y_a - y_i$) and $\dot{\gamma}$ is an arbitrary shear rate, while given the particle interaction potential, $\gamma^D(h)$ can be numerically evaluated (Bian et al. 2016). Equation (22) holds for an arbitrary shear rate $\dot{\gamma}$. Therefore, given a shear stress τ^{xy} from the continuum solution of FDM, the distribution of shear force on each particle i is independent of $\dot{\gamma}$ as

$$F^x(y_i) = B_0 \tau_a^{xy} \gamma^D(h) h, \tag{23}$$

where B_0 is a normalization constant for the particular particle simulation parameters.

2.8   Some Comments on Different Coupling Strategies

In order to bridge the concepts of state and flux coupling, Walther et al. (2012) applied the gradient of velocities averaged from MD simulations to impose the flux boundary condition on the lattice Boltzmann continuum solver. For conservation and stability purposes, we may have also a mixture of coupling state variables and fluxes; we refer to Flekkøy et al. (2005), Ren (2007), Bian et al. (2015b, 2016) and references therein for further discussions.

On the accuracy of the coupling schemes, the quantity of interest has been often the *mean field* variables, such as velocity, density, and stresses, which are sufficient from the continuum perspective. There has not been a consensus as to which of the four methods is most effective, as all the methods introduce above are actually capable of generating accurate mean profiles. For practical convenience, the relaxation dynamics involves an empirical parameter ε, which requires more trial-and-tune simulations. Therefore, the least constraint dynamics is preferred over the relaxation dynamics. The Maxwell buffer and flux exchange have the same easiness as the least constraint dynamics.

However, if we take a microscopic perspective and take the continuum description as a bath to supplement the truncated particle simulation, we may evaluate more closely certain quantities of interest in the particle region. For example, by calculating the fluctuation correlations between field variables of MD, we may compare the performance of the coupling schemes mentioned above (Bian et al. 2015a, 2016, 2018). It turns out that we have two sources of errors in the particle region; one is due to the truncation of the particle domain, and the other is due to the constraint dynamics performed on the particles in the artificial boundary. The first source of error is universal for different coupling strategies, and it may be almost completely removed by implementing an appropriate particle removal and insertion algorithm to mimic the grand-canonical ensemble of the an open particle system (Delgado-Buscalioni and Coveney 2003b; Delle Site and Praprotnik 2017). On the second source of error, the Maxwell buffer completely ignores any intrinsic thermal velocity correlations between particles and simply constrains individual particle's velocity as identical independent Gaussian distribution in the artificial boundary, therefore introducing the most artifacts, whereas the other constraint algorithms are relatively mild and commit much smaller error on this aspect (Bian et al. 2016).

Furthermore, if the overlapping region between particle and continuum subdomain increases, that is, if we can afford to perform extra volume of particle simulation, the contaminations of all the constraint dynamics on the thermal fluctuation correlations have very similar behavior, and the negative effects decrease linearly as the size of the overlap increases (Bian et al. 2016).

Thus far, there has been quite a few applications which were enabled by the DDM for multiscale modeling, bridging the atomistic and continuum descriptions. One of the most apparent classes of application is to model local or singular effects accurately with MD and capture bulk macroscopic flow behavior elsewhere with NS equations. This type of problem includes the fluid-solid boundary conditions with flow slip or epitaxial growth taking place (Thompson and Robbins 1990; O'Connell and Thompson 1995), contact line problem with contact angle as a dynamic variable (Hadjiconstantinou 1999), lid-driven cavity flow with singular stress at the corner (Nie et al. 2006), sound propagation through lipid monolayer (De Fabritiis et al. 2006), platelet deposition on the wall of a brain aneurysm (Grinberg et al. 2013), and so on. In the next section, however, we will describe a triple-scale approach that couples atomistic and continuum hydrodynamics through an intermediate CG description.

3   Domain Decomposition Methods for Complex Fluids: Adaptive Resolution Scheme

Another branch of DDM is related to coupling fine and CG descriptions of soft matter and molecular liquids within a particle-based framework. Similarly to other domain decomposition approaches, the aim of such adaptive resolution simulations is to model the interesting part of the system with the detailed atomistic (AT)

resolution, which is coupled with a CG representation of the remaining part of the system. Among the most advanced multiscale methods for conducting this kind of molecular simulations is the adaptive resolution scheme (AdResS) (Praprotnik et al. 2005, 2008, 2011). The method can successfully couple two or more levels of resolution concurrently present in the system. AdResS enables the particles to change their resolution on the fly, during the course of an MD simulation. The method is suitable for molecular systems where the AT resolution is required only in a spatially localized region, whereas a lower CG level of detail is sufficient for the rest of the system. Such cases are typically found in simulations of biological macromolecules, e.g., DNA. There, the AT resolution is required only for the macromolecule and the solvent in its vicinity, whereas the solvent farther away is adequately treated on a simplified CG level.

AdResS allows molecules to freely move across different regions and change their resolution on the fly according to their position in the system. When a CG molecule leaves the CG domain, it is remapped into the atomistically resolved molecule with a random orientation. To avoid any overlaps of its atoms with the atoms of the neighboring molecules, it is required that introduction of the atomistic degrees of freedom is continuous and not instantaneous. To this end, an interface layer between the AT and CG regions is introduced that allows an atomistic molecule to gradually find an energetically permissible orientation with respect to its neighboring molecules. This transition region, also called a hybrid (HY) region, contains hybrid molecules where both representations are superimposed.

Two levels of resolution are coupled via a force interpolation scheme. The intermolecular force between given molecules α and β is defined as

$$\mathbf{F}_{\alpha\beta}^{\text{AdResS}} = w(X_\alpha)w(X_\beta)\mathbf{F}_{\alpha\beta}^{AT} + [1 - w(X_\alpha)w(X_\beta)]\mathbf{F}_{\alpha\beta}^{CG}, \tag{24}$$

where X_α and X_β are the centers-of-mass positions of the molecules α and β, respectively, and w is a weighting function that governs the transition between different resolution regions and therefore needs to be smooth. This function depends on the position of the mapping point of the molecule and is defined in the following way: $w = 1$ corresponds to the AT region and $w = 0$ to the CG region, whereas the values $0 < w < 1$ correspond to the HY region.

Original variant of the AdResS based on the force coupling above does not allow for a definition of a Hamiltonian and consequently has to be employed in conjunction with a thermostat. A recent Hamiltonian version of the method, i.e., H-AdResS (Potestio et al. 2013b; Everaers, R. 2016; Español et al. 2015), on the other hand, allows for the definition of a global Hamiltonian. This enables one to perform adaptive resolution Monte Carlo simulations (Potestio et al. 2013a). However, as the translation invariance is broken due to the resolution change, this implies that the total linear momentum cannot be conserved by H-AdResS. Since the linear momentum conservation is crucial for hydrodynamics, the original AdResS, which is not Hamiltonian, can therefore preserve linear momentum despite broken translational symmetry and is thus more convenient for coupling with the continuum hydrodynamics, as described below. Recent extensions of AdResS

also involve coupling to a quantum level of description (Poma and Delle Site 2010, 2011; Agarwal and Delle Site 2015, 2016; Delle Site 2018) as well as to open systems that exchange mass, momentum, and energy with their surroundings (Delgado-Buscalioni et al. 2015; Sablić et al. 2016; Wang et al. 2013; Agarwal et al. 2014, 2015; Delle Site 2016; Mukherji and Kremer 2013; Kreis et al. 2015). This allows for conducting MD simulations either in the grand-canonical statistical ensemble or under non-equilibrium conditions (Delgado-Buscalioni et al. 2015; Sablić et al. 2016, 2017b; Delle Site 2018). AdResS has been successfully applied to biomolecular systems (Zavadlav et al. 2017) such as proteins (Zavadlav et al. 2014; Fogarty et al. 2015) and DNA molecules (Zavadlav et al. 2015a, b, 2016b) solvated in multiscale solvents (Bevc et al. 2013; Nagarajan et al. 2013; Zavadlav et al. 2014, 2015b). In connection to hydrodynamics phenomena, AdResS has also been used to couple MD to the dissipative particle dynamics (DPD) method (Hoogerbrugge and Koelman 1992; Español and Warren 1995, 2017; Groot and Warren 1997; Español 1995), the multiparticle collision dynamics (MPC) (Malevanets and Kapral 1999), and smoothed dissipative particle dynamics (SDPD) (Español and Revenga 2003; Vázquez-Quesada et al. 2009). In the DPD, groups of atoms/molecules are lumped to form soft beads that interact via explicit soft conservative, random, and dissipative forces to simulate fluids on a mesoscopic scale with correct hydrodynamics interactions. In the SDPD, the Navier-Stokes equations are numerically solved with a formalism that is reminiscent of MD, whereas in the MPC the system is modeled by particles with continuous positions and velocities and stochastic interparticle interactions. Thus, using AdResS Petsev et al. (2015, 2017) coupled the MD to SDPD, whereas Alekseeva et al. (2016) linked the MD with MPC. The robustness of both hybrid approaches was demonstrated on a Lennard-Jones fluid. AdResS has been also applied to couple MD with DPD water (Zavadlav and Praprotnik 2017). In this chapter, however, we will focus on coupling with the continuum hydrodynamics (Delgado-Buscalioni et al. 2008, 2009, 2015).

One can combine AdResS with the flux-exchange coupling (Flekkøy et al. 2000; Delgado-Buscalioni and Coveney 2003a, 2004; Delgado-Buscalioni et al. 2005; Flekkøy et al. 2005; De Fabritiis et al. 2006; Delgado-Buscalioni and De Fabritiis 2007), described in Sect. 2.7, to link an MD with a continuum hydrodynamic domain, resulting in a triple-scale setup (Delgado-Buscalioni et al. 2008, 2009), as depicted in Fig. 2. In this triple-scale approach, the particle-based domain is simulated by MD simulation. The dynamics of molecules is thus governed by Newton's equations of motion, as explained in Sect. 2.1. On the other hand, continuum description enables the study of macroscopic fluid flows. The fluid is described by Navier-Stokes equations (see Sect. 2.2). The Navier-Stokes equations can be numerically solved in different ways (Koumoutsakos 2005), e.g., the finite volume method, where the continuum region is divided into small cells of volume (De Fabritiis et al. 2006; Delgado-Buscalioni et al. 2008). In such a way, discretized Navier-Stokes equations are then integrated in time using an explicit Euler scheme (Delgado-Buscalioni and De Fabritiis 2007).

The MD and continuum domains share an interface, as shown in Fig. 2. The otherwise independent MD and continuum domains exchange information after
Fig. 2 Domain decomposition of triple-scale liquid water system: coupling of atomistic and continuum hydrodynamics. The MD domain contains atomistic and coarse-grained water molecules, whereas the continuum domain is solved by computational fluid dynamics approach. (Reprinted from Delgado-Buscalioni et al. 2015)

every fixed time interval Δt (Delgado-Buscalioni et al. 2008). Flux balance implies the conservation of mass and momentum across the interface, i.e., both domains should receive equally large but oppositely signed mass and momentum transfer across the interface over each Δt. The momentum flux across the interface is then used to update the flow variables at the continuum boundary cells. In turn, the same (but oppositely signed) flux needs to be imposed into the particle system across the interface (see Sect. 2.3).

The triple-scale method has been applied to simple liquids, i.e., liquid of tetrahedral molecules and water (Delgado-Buscalioni et al. 2008, 2009). Equilibrium structural properties, i.e., the radial distribution function and density profile, in MD domain of the triple-scale system have been validated against reference all-atom MD simulations. Furthermore, the mass fluctuations of the open MD domain were demonstrated to agree with the theoretical grand-canonical predictions (Delgado-Buscalioni et al. 2009). The fluids were also exposed to the Couette and Stokes flows (Delgado-Buscalioni et al. 2008, 2009), and the resulting velocity profiles agreed with continuum hydrodynamics.

Of course, the underlying idea of this triple-scale scheme is that AdResS plays the role of the inserting facility for complex molecules such as star polymers (Delgado-Buscalioni et al. 2015; Sablić et al. 2016, 2017a, b). In the CG domain, a given star polymer, consisting of several tens of monomers, is represented with only one very soft CG bead. We face the problem of inserting new molecules into a dense liquid. Thus, the idea behind the resolution change is that AdResS allows the insertion of molecules of arbitrary size into the system. The CG domains act as

a mass reservoir where large molecules can be easily inserted due to soft effective interactions among CG beads (Delgado-Buscalioni and Coveney 2003a; De Fabritiis et al. 2004; Borg et al. 2014). Then, as the molecules move toward the AT domain, they gain the fine-grained details employing AdResS.

4 Summary and Perspectives

We have presented the DDM for multiscale modeling of simple and complex fluids. For simple fluids we employ a perspective of continuum mechanics, where state field variables and fluxes are fundamental quantities. Therefore, it is natural to couple state variables and/or fluxes between a particle simulation (e.g., MD) simulation with a NS solver. Within this perspective, the MD resolves local effects and provides macroscopic averages as a closure for the NS equations. Other physical quantities in MD that are not needed for NS are considered as unwanted, ignored, or filtered out. Consequently, various constraint dynamics on state variable or fluxes of MD are all effective and do not have apparent difference on the hybrid coupled simulations. If we are interested not only in the macroscopic behavior but also in certain mesoscopic or microscopic physics of the particle simulation in the course of hybrid simulation, the conclusion is different. For example, thermal fluctuations are hallmarks, and one of the driving mechanisms for physical processes at micro-/mesoscopic scales. If we evaluate the correlations of the thermal fluctuations in the particle simulations in the context of a hybrid simulation, we find that the constraint algorithm of Maxwell buffer ignores the local correlations completely, while other three constraint dynamics are relatively better at preserving the natural properties of the particle simulations.

We have also briefly presented the particle-based multiscale linear-momentum-preserving AdResS for coupling fine and CG molecular representations. AdResS is suitable to simulate fluids on the micro-/mesoscopic scale, where hydrodynamics plays an important role. In this spirit, AdResS has been recently applied to link MD and DPD methods for simulation of water at ambient conditions (Zavadlav and Praprotnik 2017). As the DPD water model corresponds to several water molecules, the supramolecular coupling is enabled by a recently developed clustering algorithm SWINGER that assembles, disassembles, and reassembles clusters as needed during the course of the simulation (Zavadlav et al. 2016a). This allows for a seamless coupling between standard atomistic MD and DPD models. In the future, this framework could be applied to important problems such as abnormal rheological and biomechanical properties of red blood cells encountered in disease states (Chang et al. 2016; Altenhoff et al. 2007; Rossinelli et al. 2015; Fedosov et al. 2010, 2011).

In this chapter, we focus on the DDM for fluids, and for readers interested in DDM for solid materials, there are quite a few excellent technical reviews, e.g., Miller and Tadmor (2009). There are other multiscale modeling methods tightly related to DDM, such as *CONFFESSIT* (Laso and Öttinger 1993) and *heterogeneous multiscale method* (Ren and Weinan 2005; Weinan et al. 2007; Borg et al. 2013; Yasuda and Yamamoto 2010), where a macroscopic model is selected for

the whole domain and a microscopic solver is utilized to provide fine details such as boundary conditions or constitutive relations wherever needed. Along the research line of adaptive mesh refinement, Garcia et al. also develop the algorithm refinement technique at the finest scale of the mesh to switch on microscopic description such as the direction simulation of Monte Carlo (Garcia et al. 1999). Kevrekidis and colleagues propose space-selective microscopic descriptions without a macroscopic equation (therefore, named as *equation-free*) (Kevrekidis and Samaey 2009). By employing novel gap-tooth interpolation in space and projection in time, the equation-free framework is able to perform system-level tasks and predictions.

There are also a few high-performance software packages free for usage (Tang et al. 2015; Neumann and Bian 2017; Halverson et al. 2013). Together with the algorithm developments, they will foster further applications of DDM for multiscale modeling.

Particle-Based Methods for Mesoscopic Transport Processes

Contents

Abstract

Biological phenomena at cellular and subcellular levels involve transport of reacting biochemical species, including proteins, enzymes, and nutrients. At the mesoscopic scale, stochastic effects can play an important role and dominate the biological processes. Therefore, the continuum deterministic description, which ignores fluctuations, becomes no longer accurate. To this end, mesoscopic methods with stochastic terms are attracting more attention as a promising approach for tackling challenging problems in cellular biology and bioengineering. This chapter describes particle-based stochastic models for mesoscopic transport processes, including thermal transport, reactive chemical transport, and ionic transport in mesoscopic systems.

1 Introduction

At the mesoscopic scale, thermal fluctuations and discrete features play important roles in biological processes, and the classical approaches based on deterministic transport equations are inadequate to predict the time evolution of the mesoscale biological system (Hellander 2008). Deterministic equations are formulated as a system of (generally, nonlinear) ordinary differential equations (ODEs) and partial differential equations (PDEs) for the dynamics of mean-field concentrations of the biochemical species. However, at cellular and subcellular levels, the biological processes present considerable variations from cell to cell (Chen et al. 2017). The variations arise from the fact that the cells are so small that the discrete features and stochastic effects become crucial and may play a significant role in the relevant dynamics. Therefore, to accurately model biological processes at the mesoscopic scale, a better approach involves developing discrete particle-based methods suitable for stochastic processes, where the discreteness of the biochemical species and the randomness of transports and reactions are explicitly accounted for. From a modeling point of view, stochastic dynamics is considerably harder to simulate and analyze than the mean-field behavior (Schnoerr et al. 2017).

For mesoscopic processes driven by thermal noises, a popular approach that accounts for the effects of thermal fluctuations is the Markovian stochastic process, where stochastic terms induced by equilibrium or non-equilibrium fluctuations can be modeled in terms of Gaussian white noise (Ortiz de Zárate and Sengers 2006). A Markovian approximation is valid when the correlation time of fluctuations is much shorter than the characteristic timescale of the dynamics of fluid particles/voxels. This is true as long as the size of fluid particles/voxels is much larger than the biochemical molecule size. As the size of fluid particle/voxel becomes comparable with the molecule size, it is anticipated that the macroscopic or mesoscopic modeling framework based on equilibrium/non-equilibrium statistics will fail to describe the underlying system dynamics accurately. In this regard, microscale methods with much higher computational cost, such as the reaction-diffusion master equation (RDME) (Drawert et al. 2016; Schnoerr et al. 2017), must be employed to attain insight into the discrete features of biochemical reactive transport.

This chapter focuses on recent advances in particle-based methods, including dissipative particle dynamics (DPD), smoothed particle hydrodynamics (SPH), and smoothed dissipative particle dynamics (SDPD), for mesoscale transport processes. In these methods, the stochastic terms induced by thermal fluctuations are modeled as Markov processes. Developing these methods has provided not only a deeper understanding of the transport processes in the presence of fluctuations but also a framework for modeling non-equilibrium processes of mesoscopic systems using a local equilibrium approximation and investigating the energetic fluctuations of mesoscopic transport in biological systems and beyond. Methods for thermal transport at the mesoscopic scale are introduced in Sect. 2. The methods for modeling mesoscopic reactive transport are discussed in Sect. 3. Section 4 presents the methods for modeling mesoscopic ionic transport, and Sect. 5 concludes with a brief summary and discussion.

2   Mesoscopic Thermal Transport

Compared to healthy tissues, unhealthy tissues (especially tumors and cancers) usually have lower pH values and higher temperatures stemming from microenvironment abnormalities (Taghizadeh et al. 2015). The differences between unhealthy and healthy tissues can be used to design targeted therapies. For example, based on the fact that tumor microenvironments are slightly hyperthermic, thermosensitive polymers and liposomes can be used as targeted drug carriers to effectively deliver drugs to tumor cells without harming healthy cells (Perez-Herrero and Fernandez-Medarde 2015). However, developing thermosensitive drug delivery techniques with controllable drug release in non-isothermal processes requires a fundamental understanding of the mesoscopic thermal transport and knowledge of the role thermal fluctuations play in biological processes. This section introduces two mesoscopic modeling methods that can provide such fundamental understanding and knowledge.

First, Avalos and Mackie (1997) and Español (1997) developed an energy-conserving DPD (eDPD) model that augments the classical DPD model with the internal energy as an additional property of each DPD particle. The classical DPD model was developed based on equilibrium thermodynamics (Español and Warren 1995), where the dissipative and random forces satisfying the fluctuation-dissipation theorem act as a thermostat to maintain the system at a constant temperature. Thus, the classical DPD method is limited to modeling isothermal systems and can neither sustain temperature gradients nor model thermal transport in non-isothermal processes (Li et al. 2017). In contrast, in the eDPD method, each eDPD particle is considered as a coarse-grained particle associated with an internal energy in addition to other quantities, such as position and momentum. The stochastic differential equations governing the dynamics of eDPD particles include the conservations of momentum and energy in the form of (Li et al. 2014):

$$
\begin{aligned}
m_i \frac{\mathrm{d}^2 \mathbf{r}_i}{\mathrm{d}t^2} &= m_i \frac{\mathrm{d}\mathbf{v}_i}{\mathrm{d}t} = \mathbf{F}_i = \sum_{i \neq j} (\mathbf{F}_{ij}^C + \mathbf{F}_{ij}^D + \mathbf{F}_{ij}^R) \,, \\
C_v \frac{\mathrm{d}T_i}{\mathrm{d}t} &= q_i = \sum_{i \neq j} (q_{ij}^C + q_{ij}^V + q_{ij}^R) \,,
\end{aligned}
\tag{1}
$$

where m, t, $\mathbf{r}_i$, $\mathbf{v}_i$, and $\mathbf{F}_i$ denote mass, time, position, velocity, and force vectors, respectively. T_i represents the temperature, C_v the thermal capacity, and q_i the net heat flux of particle i. The summations of force and heat flux are carried out over all particles within a cutoff radius r_{cf} from particle i for forces and a cutoff radius r_{ct} for heat fluxes.

The three components of $\mathbf{F}_i$, including conservative, dissipative, and random forces, are given by $\mathbf{F}_{ij}^C = a_{ij} w_C(r_{ij}) \mathbf{e}_{ij}$, $\mathbf{F}_{ij}^D = -\gamma_{ij} w_D(r_{ij}) (\mathbf{e}_{ij} \cdot \mathbf{v}_{ij}) \mathbf{e}_{ij}$, and $\mathbf{F}_{ij}^R \mathrm{d}t = \sigma_{ij} w_R(r_{ij}) \mathrm{d}W_{ij} \mathbf{e}_{ij}$, respectively (Groot and Warren 1997). The coefficients a, γ, and σ determine the strength of each force. The weight functions $w_C(r)$,

$w_D(r)$, and $w_R(r)$ are defined with a cutoff radius r_{cf} beyond which these weight functions vanish. $dW_{ij} = dW_{ji}$ are independent increments of the Wiener process. Using the assumption of local thermodynamic equilibrium, Español (1997) derived a Fokker-Planck equation (FPE) for the stochastic equation (1). The FPE solution gives the relationship between the dissipative force and the random force, which requires $\sigma_{ij}^2 = 4\gamma_{ij}k_B T_i T_j/(T_i + T_j)$ and $w_D(r) = w_R^2(r)$. It indicates that the fluctuation-dissipation theorem is applied locally based on the particle temperature T_i instead of the system's thermodynamic temperature, stressing the local nature of the eDPD model (Avalos and Mackie 1997). The heat fluxes between two particles i and j, accounting for the thermal conduction q_{ij}^C, viscous heating q_{ij}^V, and random heat flux q_{ij}^R, are given by (Li et al. 2014)

$$q_{ij}^C = k_{ij} w_{CT}(r_{ij}) \left(T_i^{-1} - T_j^{-1} \right) , \tag{2a}$$

$$q_{ij}^V = \frac{1}{2C_v} \left\{ w_D(r_{ij}) \left[\gamma_{ij} \left(\mathbf{e}_{ij} \cdot \mathbf{v}_{ij} \right)^2 - m_i^{-1}\sigma_{ij}^2 \right] - \sigma_{ij} w_R(r_{ij}) \left(\mathbf{e}_{ij} \cdot \mathbf{v}_{ij} \right) \xi_{ij} \right\} , \tag{2b}$$

$$q_{ij}^R = \beta_{ij} w_{RT}(r_{ij}) \xi_{ij}^e , \tag{2c}$$

where the thermal conduction q_{ij}^C contains T^{-1} rather than T because the thermodynamic quantity conjugated to the internal energy is the inverse of the temperature instead of the temperature itself (Español 1997). The parameters k_{ij} and β_{ij} determine the strength of the thermal conduction and the random heat flux, respectively. In particular, k_{ij} plays the role of a thermal conductivity given as $k_{ij} = C_v^2 \kappa (T_i + T_j)^2/4k_B$, where κ is interpreted as a mesoscale heat friction coefficient. The relationships $\beta_{ij}^2 = 2k_B k_{ij}$ and $w_{CT}(r) = w_{RT}^2(r)$ are required to satisfy the fluctuation-dissipation theorem. A common choice of the weight functions is $w_{CT}(r) = w_{RT}^2(r) = (1 - r/r_{ct})^{s_T}$ with a cutoff radius r_{ct}, where the case of $s_T = 2.0$ corresponds to the typical quadratic weighting function (Groot and Warren 1997).

For an eDPD particle, the characteristic scale of the kinetic energy related to its momentum is $k_B T$, while the characteristic scale of the internal energy related to its temperature is $C_v T$. A scaling factor $k_B T/C_v T$ is required to convert kinetic energy into internal energy. Therefore, the heat flux q_{ij}^V due to viscous heating given by Eq. (2b) has a factor $1/C_v$ when the kinetic energy $k_B T$ is taken as the energy unit. Also, the factor 2 in the denominator guarantees that the heat generated by nonconservative interactions is distributed evenly to both particles of a pair. Through numerical experimentation, Li et al. (2014) demonstrated that Eqs. (1) and (2) conserve energy.

The transport properties, such as diffusivity and viscosity, do not need to be prescribed in eDPD. Groot and Warren (1997) and Marsh et al. (1997) have derived the expressions of diffusivity and kinematic viscosity in terms of DPD parameters, which are given as

$$D = \frac{3k_B T}{4\pi\gamma\rho} \left(\int_0^\infty r^2 g(r) w_D(r) dr \right)^{-1}, \quad \nu = \frac{D}{2} + \frac{2\pi\gamma\rho}{15} \int_0^\infty r^4 g(r) w_D(r) dr, \tag{3}$$

where $g(r)$ is the radial distribution function. A rough analytical prediction of D and ν can be obtained by substituting $w_D(r) = w_R^2(r) = (1 - r/r_{cf})^s$ and $g(r) = 1.0$ into Eq. (3), which leads to $D = 3k_B T \prod_{i=1}^3 (s + i)/8\pi\gamma\rho r_{cf}^3$ and $\nu = D/2 + 16\pi\gamma\rho r_{cf}^5/5 \prod_{i=1}^5 (s + i)$.

The DPD fluid's thermal conductivity also can be calculated in terms of the model parameters. When the energy transport is dominated by thermal conduction, the macroscopic thermal conductivity λ can be calculated as (Mackie et al. 1999)

$$\lambda = \frac{2\pi}{3} \frac{\rho^2}{T^2} \int_0^\infty r^4 k w_{CT}(r) g(r) dr , \tag{4}$$

where $k = C_v^2 \kappa T^2/k_B$ and $w_{CT}(r)$ is the weight function. Given $w_{CT}(r) = (1 - r/r_{ct})^{s_T}$ and $g(r) = 1.0$, an analytical estimate for the thermal conductivity λ can be obtained as $\lambda = 16\pi\rho^2\kappa C_v^2 r_{ct}^5/k_B \prod_{i=1}^5 (s_T + i)$. In particular, when the typical quadratic weight function $(1 - r/r_{ct})^2$ is adopted for $w_{CT}(r)$, $\lambda = 2\pi\rho^2\kappa C_v^2 r_{ct}^5/315 k_B$. Let $\mathrm{Pr} = \rho\nu C_v/\lambda$ be the Prandtl number, which is a dimensionless number whose value can be obtained from experiments. By replacing λ with Pr, the result is a formula for determining the mesoscale heat friction κ given by $\kappa = 315 k_B \nu/2\pi\rho \mathrm{Pr} C_v r_{ct}^5$. Notably, this formula is obtained from the typical quadratic weight function. When a different weight function is employed, a similar formula could be derived from Eq. (4).

The expression of Eq. (3) indicates that both the diffusivity D and kinematic viscosity ν of the eDPD fluid increase linearly with the temperature if other variables in Eq. (3) remain constant. However, for most of the liquids, including water, ethanol, and glycerin, the diffusivity increases, but the kinematic viscosity decreases with increasing temperature. To correct the temperature-dependent properties (diffusivity, viscosity, and thermal conductivity) of these liquids, Li et al. (2014) analyzed the sensitivity of D, ν, and λ with respect to the model parameters and defined the exponent of the weighting function s as a function of temperature. They took liquid water as an example and demonstrated that the eDPD model can produce the correct temperature-dependent diffusivity and viscosity, as well as Prandtl numbers, for various temperatures, which is consistent with available experimental data. For details on the eDPD model parameterization, refer to Li et al. (2014) and Lei et al. (2017).

Alternatively to the bottom-up eDPD model, a top-down particle-based model for mesoscopic thermal transport can be derived from macroscopic PDEs governing the conservations of continuity, momentum, and energy. By introducing thermal fluctuations into an SPH discretization of the (deterministic) Navier-Stokes equations, Español and Revenga (2003) developed the SDPD model. The following SPH discretization was used:

$$m_i \frac{\mathrm{d}^2 \mathbf{r}_i}{\mathrm{d}t^2} = m_i \frac{\mathrm{d}\mathbf{v}_i}{\mathrm{d}t} = \sum_j \left[\frac{P_i}{d_i^2} + \frac{P_j}{d_j^2} \right] F_{ij} \mathbf{r}_{ij} - \frac{5\eta}{3} \sum_j \frac{F_{ij}}{d_i d_j} \left[\mathbf{v}_{ij} + (\mathbf{v}_{ij} \cdot \mathbf{e}_{ij})\mathbf{e}_{ij} \right] ,$$

$$T_i \frac{\mathrm{d}S_i}{\mathrm{d}t} = \frac{5\eta}{6} \sum_j \frac{F_{ij}}{d_i d_j} \left[\mathbf{v}_{ij}^2 + (\mathbf{v}_{ij} \cdot \mathbf{e}_{ij})^2 \right] - 2\kappa \sum_j \frac{F_{ij}}{d_i d_j} (T_i - T_j) ,$$

$$(5)$$

where P and T are the pressure and temperature given by the local equilibrium assumption. The number density d of the fluid particles is computed as $d_i = \sum_j W(|\mathbf{r}_i - \mathbf{r}_j|)$, where $W(r)$ is a compact bell-shaped smoothing kernel (Monaghan 2005). The geometrical factor F_{ij} is given by $F_{ij} = -\nabla W(r_{ij})/r_{ij}$. The transport coefficients are the shear viscosity η and the thermal conductivity κ. The relationship between pressure and density should be specified via an equation of state. The popular choices in SDPD simulations are $p = c^2 \rho$ and $p = p_0(\rho/\rho_0)^\gamma + b$ (Vázquez-Quesada et al. 2009). The first term in the entropy equation is the viscous heating term that captures the physical mechanism by which the energy dissipated by viscous forces transforms into the internal energy. The last term is the heat conduction term induced by the temperature difference between particles.

Using the GENERIC (General Equation for Non-Equilibrium Reversible-Irreversible Coupling) formalism (Grmela and Öttinger 1997; Öttinger and Grmela 1997), thermal fluctuations are then systematically introduced to satisfy the first and second laws of thermodynamics. The velocity and entropy random terms are given by (Español and Revenga 2003)

$$m_i \mathrm{d}\tilde{\mathbf{v}}_i = \sum_j A_{ij} \mathrm{d}\hat{\mathbf{W}}_{ij} \cdot \mathbf{e}_{ij} ,$$

$$T_i \mathrm{d}\tilde{S}_i = -\frac{1}{2} \sum_j A_{ij} \mathrm{d}\hat{\mathbf{W}}_{ij} : \mathbf{e}_{ij} \mathbf{v}_{ij} + \sum_j C_{ij} \mathrm{d}W_{ij}^H ,$$

$$(6)$$

respectively, where $\mathrm{d}\hat{\mathbf{W}}_{ij} = (\mathrm{d}\mathbf{W}_{ij} + \mathrm{d}\mathbf{W}_{ij}^T)/2$ is the symmetric part of a matrix of independent increments of the Wiener process $\mathrm{d}\mathbf{W}_{ij}$. $\mathrm{d}W_{ij}^H$ is an independent increment of the Wiener process for each pair of particles, giving rise to the heat conduction terms. Using the fluctuation-dissipation theorem, the parameters A_{ij} and C_{ij} are related to viscosity η and thermal conductivity κ as

$$A_{ij} = \left[\frac{40}{3} \eta k_B \frac{T_i T_j}{T_i + T_j} \frac{F_{ij}}{d_i d_j} \right]^{1/2} , \quad C_{ij} = \left[4\kappa k_B T_i T_j \frac{F_{ij}}{d_i d_j} \right]^{1/2} . \quad (7)$$

Thus, the equations of an SDPD model are obtained by adding the stochastic terms in Eq. (6) to the SPH equations in Eq. (5). Kordilla et al. (2014) derived similar stochastic equations by directly discretizing the fluctuating hydrodynamics equations (Ortiz de Zárate and Sengers 2006) with the SPH method.

Although derived using different approaches, the "bottom-up" eDPD and "top-down" SDPD methods have many similarities. Both SDPD and eDPD momentum equations have a conservative force that comes from the gradient of potential energy, a dissipative force induced by viscous friction, and a stochastic term representing thermal fluctuations. SDPD and eDPD energy equations include a heat conduction term to reduce temperature differences between neighboring fluid particles, a viscous heating term to account for the internal energy generated by the viscous dissipation, and a stochastic term induced by thermal fluctuations. In each method, the stochastic contributions in velocities and energies directly relate to the dissipative terms via the fluctuation-dissipation theorem.

Because eDPD was derived from coarse-graining microscopic dynamics (Español et al. 2016), phenomenological expressions for the particle interactions in Eq. (1) can be easily derived to account for complex physics. In the last decade, the bottom-up eDPD approach has been successfully applied to diverse problems involving non-isothermal processes. For example, Cao et al. (2013) used eDPD to simulate natural convection in an eccentric annulus and investigated the effects of various factors on the streamlines and temperature distributions (shown in Fig. 1a). Tang et al. (2016) applied the eDPD method to modeling thermosensitive polymers and simulated the thermally induced self-assembly process of thermoresponsive micelles and vesicles (Fig. 1b). Other examples include heat-stiffening polymer nanocomposites (Cudjoe et al. 2017), thermophoretic microswimmers (Fedosov et al. 2015), natural convection in microchannels (Abu-Nada 2010), and thermoresponsive microgels (Li et al. 2015a).

Due to the similar form of the equations, it should be possible to include complex physics in SDPD using the eDPD coarse-graining procedure. To date, most SDPD applications are concerned with complex fluids and colloidal suspensions (Litvinov et al. 2008; Bian et al. 2012; Lei et al. 2016). The advantage of SDPD for such applications is that the properties of each fluid component, including density, viscosity, and speed of sound, are prescribed directly as model parameters and do not need to be estimated from other model parameters as with eDPD.

3   Mesoscopic Diffusive and Reactive Transport

Many biological processes depend on the concentrations of specific proteins, ions, or other biochemical factors (Anand et al. 2003). For example, proteins in an aqueous solution diffuse in a living cell due to Brownian motion and some collisions of appropriate proteins may lead to chemical reactions. Thus, diffusion and reaction are two fundamental transport processes in biological systems.

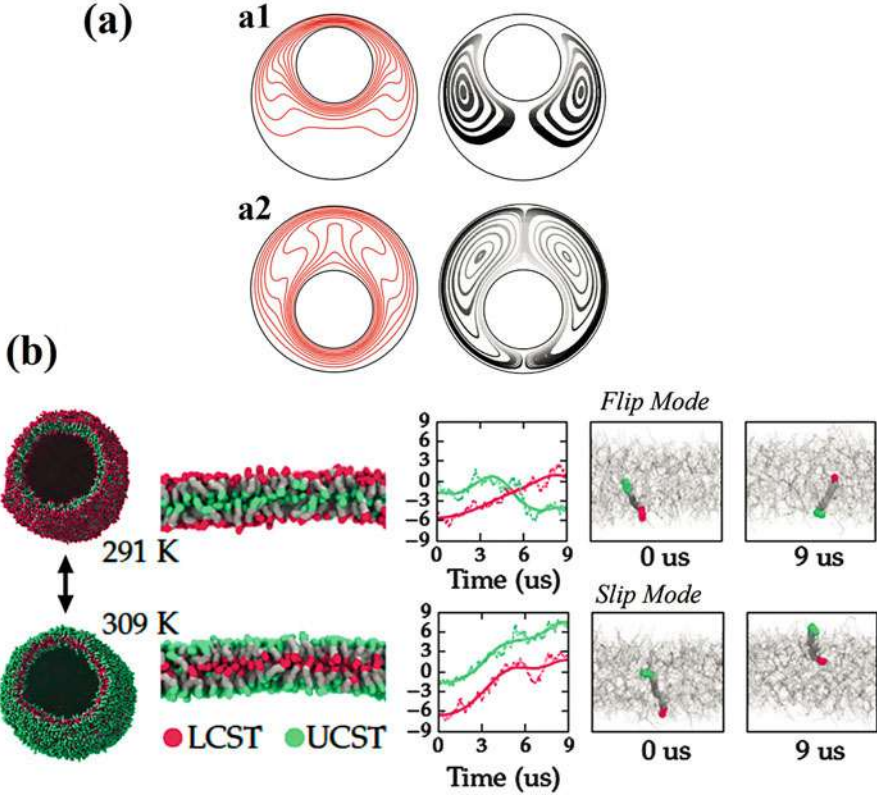
For modeling mesoscopic diffusive and reactive transport, Li et al. (2015b) developed a transport dissipative particle dynamics (tDPD) model by defining concentration carried by each DPD particle in addition to other quantities, such as position and momentum. The time evolution of the position and solute concentration of a tDPD particle i with unit mass $m_i \equiv 1$ is governed by the mass and momentum conservation laws, which can be described by the following set of equations:


Fig. 1 (**a**) Thermal (left) and flow (right) fields of the natural convection in an eccentric annulus with two different eccentricities. (Adapted from Cao et al. 2013). (**b**) Thermally induced inversion of a unilamellar vesicle formed by triblock copolymers and a proper orthogonal decomposition (POD) analysis showing two dominant molecular movement modes, i.e., flip and slip, during membrane inversion. (Adapted from Tang et al. 2016)

$$\frac{\mathrm{d}^2\mathbf{r}_i}{\mathrm{d}t^2} = \frac{\mathrm{d}\mathbf{v}_i}{\mathrm{d}t} = \mathbf{F}_i = \sum_{i \neq j}(\mathbf{F}_{ij}^C + \mathbf{F}_{ij}^D + \mathbf{F}_{ij}^R) + \mathbf{F}_i^{\mathrm{ext}},$$

$$\frac{\mathrm{d}C_i}{\mathrm{d}t} = Q_i = \sum_{i \neq j}(Q_{ij}^D + Q_{ij}^R) + Q_i^S,$$

(8)

where t, $\mathbf{r}_i$, $\mathbf{v}_i$, and $\mathbf{F}_i$ denote time and position, velocity, and force vectors, respectively. $\mathbf{F}_i^{\mathrm{ext}}$ is the force on particle i from an external force field. Just as in the classical DPD model, the pairwise interaction between tDPD particles i and j consists of the conservative force $\mathbf{F}_{ij}^C = a_{ij}w_C(r_{ij})\mathbf{e}_{ij}$, dissipative force $\mathbf{F}_{ij}^D = -\gamma_{ij}w_D(r_{ij})(\mathbf{e}_{ij} \cdot \mathbf{v}_{ij})\mathbf{e}_{ij}$, and random force $\mathbf{F}_{ij}^R\mathrm{d}t = \sigma_{ij}w_R(r_{ij})\mathrm{d}W_{ij}\mathbf{e}_{ij}$. C_i represents the concentration of one species defined as the number of a chemical

species carried by a tDPD particle i and Q_i, the corresponding concentration flux. The net concentration flux on a particle i accounts for the Fickian flux Q_{ij}^D, the random flux Q_{ij}^R, and a source term Q_{ij}^S generated by local chemical reactions. Because tDPD particles have unit mass, this definition of concentration is equivalent to the concentration in terms of chemical species per unit mass. Then, the volume concentration, i.e., chemical species per unit volume, is ρC_i, where ρ is the number density of tDPD particles. Of note, C_i can be a vector $\mathbf{C}_i$ containing N components, i.e., $\{C_1, C_2, \ldots, C_N\}_i$, when N chemical species are considered.

The driving force for diffusion of each species is the gradient of chemical potential $Q = -DC\nabla\mu/RT$, where D is the diffusion coefficient, R the universal gas constant, T the absolute temperature, and μ the chemical potential given by $\mu = \mu_0 + RT\ln C$ for dilute solutions (Ortiz de Zárate and Sengers 2006). By substituting the chemical potential μ into the expression for Q, the diffusion driving force is found to be proportional to the concentration gradient ∇C, which corresponds to a concentration difference between two neighboring tDPD particles. It follows that the Fickian and random fluxes in the tDPD model are given by

$$Q_{ij}^D = -\kappa_{ij} w_{DC}(r_{ij})\left(C_i - C_j\right), \quad Q_{ij}^R \mathrm{d}t = \varepsilon_{ij} w_{RC}(r_{ij})\mathrm{d}W_{ij}^{cc}, \tag{9}$$

where κ_{ij} and ε_{ij} determine the strength of the Fickian and random fluxes. $\mathrm{d}W_{ij}^{cc} = \mathrm{d}W_{ji}^{cc}$ are independent increments of the Wiener process. $w_{DC}(r)$ and $w_{RC}(r)$ are weight functions with a cutoff radius r_{cc}. The Fickian friction parameter κ plays the analogous role for concentration differences between tDPD particles, as γ does for momentum. In general, the concentration friction κ is a $N \times N$ matrix when the interdiffusivities of N different chemical species are involved. However, considering N chemical species in dilute solution and neglecting the interdiffusivities of different species, the system is then reduced to a set of uncoupled diffusion equations with independent diffusivities between species. Hence, κ becomes a diagonal matrix (Balluffi et al. 2005).

By applying the local-equilibrium assumption to the tDPD system, the random term Q_{ij}^R is related to the dissipative term Q_{ij}^D by satisfying the fluctuation-dissipation theorem (Li et al. 2015b)

$$\varepsilon_{ij}^2 = m_s^2 \kappa_{ij} \rho (C_i + C_j), \quad w_{DC}(r_{ij}) = w_{RC}^2(r_{ij}), \tag{10}$$

where m_s is the mass of a single solute molecule, while C_i and C_j are the respective concentrations on particles i and j. For detailed derivations for obtaining Eq. (10), refer to Li et al. (2015b). In general, the mass of a single solute molecule m_s is much smaller than that of a tDPD particle m, which is often chosen as the mass unit. Consequently, the magnitude of ε is small for $m_s \ll m$, which indicates that the contribution of the random flux Q_{ij}^R to the total diffusion coefficient D is negligible unless m_s becomes comparable to m in nanoscale systems.

The macroscopic properties, including viscosity and diffusivity of a tDPD system, are output properties rather than input parameters. Due to the random movements of tDPD particles generated by stochastic forces, the effective dif-

fusion coefficient D consists of both the random diffusion D^{ξ} and the Fickian diffusion D^F. In general, the random contribution D^{ξ} is a combined result of the random movements of tDPD particles and random flux Q_{ij}^R in Eq. (9). However, the variance of random flux Q_{ij}^R has a small prefactor m_s^2 as given by Eq. (10). Thus, the contribution of the random flux Q_{ij}^R to D^{ξ} is negligible in practical applications. In the derivations, it is assumed that D^{ξ} is induced by the random movements of tDPD particles. In particular, for a tDPD system in thermal equilibrium, the diffusion coefficient D^{ξ} induced by the random movements of tDPD particles and the macroscopic diffusion coefficient D^F due to the Fickian flux can be calculated by Li et al. (2015b)

$$D^{\xi} = \frac{3k_B T}{4\pi\gamma\rho \cdot \int_0^{r_c} r^2 w_D(r)g(r)dr} \ , \quad D^F = \frac{2\pi\kappa\rho}{3} \int_0^{r_{cc}} r^4 w_{DC}(r)g(r)dr \ , \tag{11}$$

where r_c is the cutoff radius for forces and r_{cc} is the cutoff radius for concentration flux. Let $w_D(r) = (1-r/r_c)^{s_1}$ and $w_{DC}(r) = (1-r/r_{cc})^{s_2}$ be the weight functions of the dissipative force $\mathbf{F}_{ij}^D$ and the Fickian flux Q_{ij}^D, respectively. When the radial distribution function of ideal gas $g(r) = 1.0$ is employed, both D^{ξ} and D^F can be evaluated analytically as $D = D^{\xi} + D^F = 3k_B T \prod_{i=1}^{3}(s_1+i)/8\pi\gamma\rho r_c^3 + 16\pi\kappa\rho r_{cc}^5 / \prod_{i=1}^{5}(s_2+i)$, where s_1 and s_2 are the exponents of $w_D(r)$ and $w_{DC}(r)$.

Because the particle-based tDPD method satisfies the conservation of concentration automatically, it provides an economical way to solve advection-diffusion-reaction (ADR) equations with a large number of species. Xu et al. (2011) used a two-dimensional model to investigate biofilm growth in a narrow channel and demonstrated the effects of flow velocity, growth parameter, and hydrodynamic interaction on the biofilm growth regime and morphology. Li et al. (2015b) employed tDPD to study the dynamic process of blood coagulation, modeled by a set of 23 coupled ADR equations for the evolution of 25 biological reactants involved in a combined model of intrinsic and extrinsic pathways of blood coagulation process and fibrinolysis. They reported the tDPD simulation correctly produced the thrombin burst followed by a drop and provided qualitatively correct evolution of fibrin concentration initialized by an injured vessel wall in flowing blood (shown in Fig. 2a).

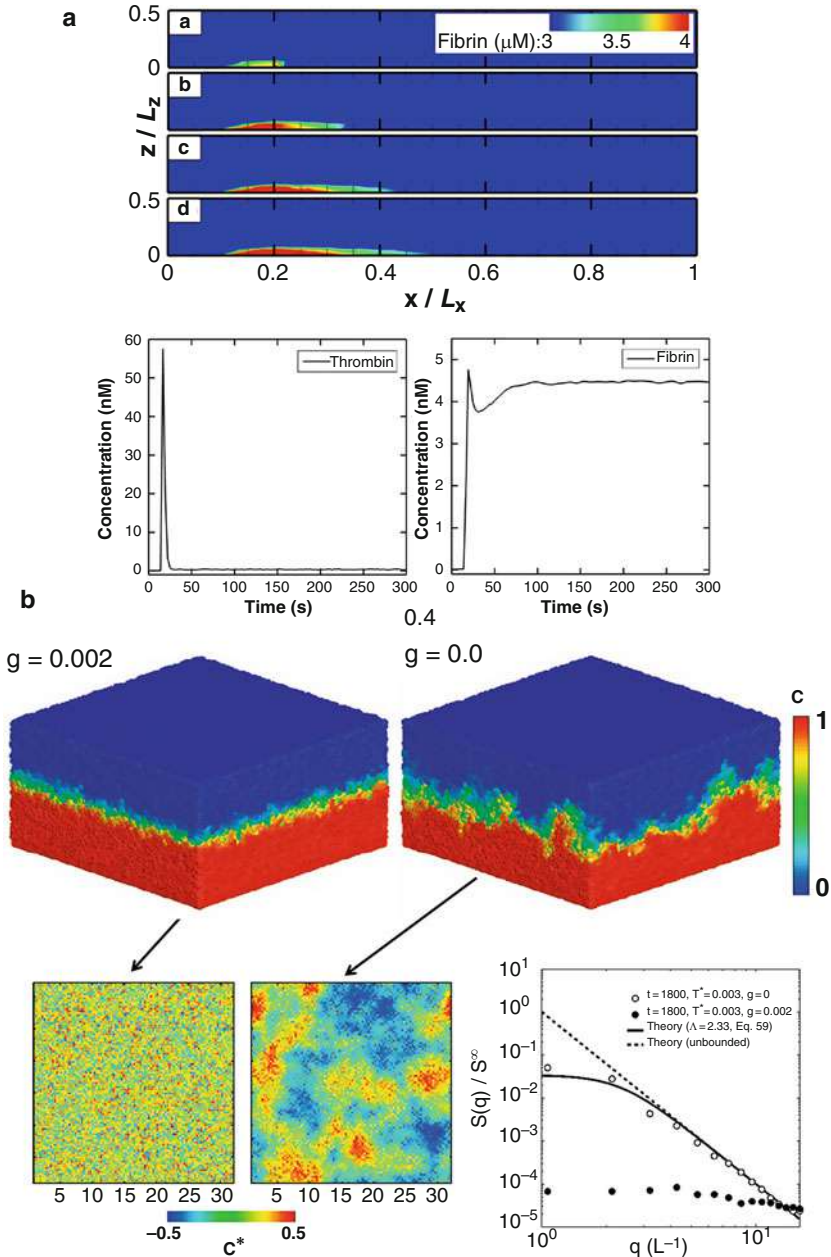
Alternatively, mesoscopic mass transport can be modeled by a top-down approach: numerically solving the fluctuating hydrodynamics equations, including the continuity equation $d\rho/dt = -\rho(\nabla \cdot \mathbf{v})$ and momentum conservation equation $\rho d\mathbf{v}/dt = -\nabla P + \nabla \cdot \tau + \nabla \cdot \mathbf{s}$ with a random stress tensor $\mathbf{s}$ and the stochastic advection-diffusion equation $\rho dC/dt = \nabla\cdot(D\nabla C)+\nabla\cdot\mathbf{J}$ with a random flux vector $\mathbf{J}$ (Ortiz de Zárate and Sengers 2006). Using the fluctuation-dissipation theorem, the random stress in the momentum equation is related to the viscous stress, while the random concentration flux in the advection-diffusion equation relates to the Fickian diffusion. Kordilla et al. (2014) used SPH discretization to solve these equations. Similar to the tDPD model, the effective diffusion coefficient D in the SPH-based model (Kordilla et al. 2014) consists of a deterministic Fickian coefficient D^F and stochastic contribution D^{ξ}.


Fig. 2 (**a**) Time evolution of the fibrin concentration field during the dynamic process of blood coagulation in flowing blood and the concentrations of thrombin and fibrin at the center of the injured wall region. (Adapted from Li et al. 2015b). (**b**) Formation of "giant fluctuations" of the front between light and heavy fluids with and without gravity, where the light fluid is on the top of the heavy fluid. The map shows the concentration field, and the plot shows corresponding power spectra of the concentration field. (Adapted from Kordilla et al. 2014)

Kordilla et al. ([2014](#)) applied this SPH-based model for studying the formation of "giant fluctuations" of the front between light and heavy fluids with and without gravity, where the light fluid is on top of the heavy fluid (shown in Fig. [2b](#)). Their results indicate that the presence of gravity significantly reduces front perturbations for all considered values of Fickian diffusion D_F, but the effect of gravity becomes less pronounced as D^F increases. When the Fickian diffusion D_F becomes significantly larger than D_ξ, the stochastic diffusion reduces to a deterministic diffusion, and fluctuations completely disappear. Kordilla et al. ([2014](#)) also demonstrated that in the absence of gravity, the SPH-based model recovers the characteristic q^{-4} divergence of the interface power spectrum and its scale-invariant nature, which are in good agreement with the experiments and analytical solutions.

4   Mesoscopic Ionic Transport

Ionic transport is ubiquitous in biological processes and is extremely important in the vital activity of all organisms. The concentration gradient of potassium ion K^+, sodium ion Na^+, and calcium ion Ca^{2+} across the cell membrane is the basis for the transmission of excitation in organisms. It is not surprising that ionic transport is implicated in numerous diseases. For example, cystic fibrosis is an autosomal recessive disease, which is induced by defective ion transport and characterized by hyperabsorption of Na^+ in the airway epithelia (Kunzelmann and Mall [2003](#)). Transport of Ca^{2+} from muscle cells leads to relaxation of muscles, while the entry of these ions into the cytoplasm upon excitation produces muscle contraction (Rüegg [1992](#)). An inherited skeletal muscle disorder, named Brody disease, is clinically characterized by exercise-induced muscle stiffness, rooted from abnormal Ca^{2+} transport (Guglielmi et al. [2013](#)). Also, the flux of ions across the membranes of neurons changes the electrochemical gradient and results in the production of an electrical signal sent between neurons in the brain (Purves et al. [2004](#)). Disruption of ionic homeostasis significantly affects the neuron activities. Alzheimer's disease is associated with increased intracellular Na^+ and K^+ levels in brain regions, which is induced by imbalanced ionic transport contributed to the pathophysiology of Alzheimer's disease (Vitvitsky et al. [2012](#)). Understanding the functional role and mechanism of ionic transport at cellular/subcellular levels is of crucial physiological importance to develop new diagnostic tests for diseases and to discover novel drug molecules (Modi et al. [2012](#)).

However, simulating fluctuating electrohydrodynamic phenomena with fully coupled hydrodynamics and electrostatics with long-range Coulomb interactions is challenging. Here, a variant of DPD method is used to tackle this challenge. It extends the classical DPD method that has proven accurate and effective in modeling mesoscopic fluctuating hydrodynamics (Groot and Warren [1997](#)) and introduces ions represented by explicit charged particles in a DPD system. The electrostatic interactions between these ions can be computed by two approaches: (1) all interactions between the charged particles are summed in real space, and (2)

all charged particles are projected onto a local electrostatic field that is governed by the Poisson's equation $\nabla(\varepsilon \nabla \varphi) = -\beta e^2 \rho$ and solved separately.

As a consequence of the soft interactions in the DPD model, charged particles may overlap and form infinitely strongly bound ion pairs through electrostatic interactions. To avoid overlapping of charged DPD particles, Groot (2003) distributed the charge within an electrostatic smearing radius R_e using a charge distribution $f(r) = 3(1 - r/R_e)/\pi R_e^3$, while González-Melchor et al. (2006) used a Slater-type charge distribution $f(r) = \exp(-2r/\lambda)/\pi \lambda^3$ with a decay length λ. With explicit ions, the Ewald summation method (Ewald 1921) is a widely used route to calculate electrostatic interactions in particle systems. Because point charges interact according to Coulomb's law, the total electrostatic energy for a periodic cubic system of side L is given by

$$U(\mathbf{r}) = \frac{1}{4\pi \varepsilon_0 \varepsilon_r} \sum_i \sum_{j>i} \sum_{\mathbf{r}} \frac{q_i q_j}{|\mathbf{r}_{ij} + \mathbf{n}L|}, \tag{12}$$

where $\mathbf{n} = (n_x, n_y, n_z)$ with n_x, n_y, and n_z being integer numbers. The sum over $\mathbf{n}$ takes into account the periodic images. The Ewald treatment decomposes the long-range electrostatic energy in a real space and the reciprocal space contributions, so both the real and reciprocal parts can be computed by short-ranged sums as an approach to $1/r$, capturing the full long-range nature of electrostatic interactions (González-Melchor et al. 2006).

Different from a direct calculation of the electrostatic forces, Groot (2003) introduced a lattice to the DPD system and spread out the charges over the lattice nodes. Then, the long-range portion of the interaction potential was calculated by solving the Poisson equation on the grid based on a particle-particle particle-mesh (PPPM) algorithm by transferring quantities (charges and forces) from the particles to the mesh and vice versa. It has been noted that the PPPM method works efficiently in DPD if the grid size equals the particle size. Because the mesh defines a coarse-graining length for electrostatic interactions, correlation effects on length scales shorter than the mesh size cannot be properly accounted for. Explicit treatment of the ions is computationally expensive, especially for systems with high ionic concentrations. To this end, Medina et al. (2015) developed a Condiff-DPD model with ions represented by the concentration of the ionic species. They used DPD equations for fluid particles and Brownian pseudo particles to describe the evolution of the ionic concentrations. Instead of direct interactions, the pseudo-ions and DPD particles are coupled through a lattice, where the Poisson equation is solved using the PPPM algorithm. Compared to "explicit-ion" simulations whose computational costs depend on the number of ions, the cost for electrostatic calculations in a simulation with "implicit ions" is dominated by the cost for solving the Poisson equation. Using the PPPM method, the cost primarily depends on the number of mesh points.

Although, the particle-to-mesh and then mesh-to-particle mapping/redistribution can solve the Poisson equation for particle-based systems (Groot 2003), its depen-

dence on a grid may contradict the original motivation for using a Lagrangian method, and additional computational complexity and inefficiencies are introduced. To abandon grids and use a unifying Lagrangian description for mesoscopic electrokinetic phenomena, Deng et al. (2016) developed a charged DPD, or cDPD, model, where the Poisson equation is solved on moving cDPD particles rather than grids. Specifically, cDPD describes the solvent explicitly in a coarse-graining sense as DPD particles, while the ion species are described semi-implicitly, i.e., using a Lagrangian description of ionic concentration fields, associated with each moving cDPD particle, which provides a natural coupling between fluctuating electrostatics and hydrodynamics.

The state vector of a cDPD particle can be written as $(\mathbf{r}, \mathbf{v}, c_\alpha, \phi)$, which is not only characterized by its position $\mathbf{r}$ and velocity $\mathbf{v}$ as in the classical DPD model but also by ionic species concentration c_α (with α representing the αth ion type) and electrostatic potential ϕ on the particle. A cDPD particle is then viewed as a coarse-grained fluid volume, which contains the solvent and other charged species. Exchange of the concentration flux of charged species occurs between neighboring cDPD particles, much like the momentum exchange in the classical DPD model. The time evolution of the state vector of a cDPD particle i with unit mass $m_i \equiv 1$ is governed by the following set of stochastic differential equations:

$$
\begin{aligned}
\frac{d^2\mathbf{r}_i}{dt^2} = \frac{d\mathbf{v}_i}{dt} = \mathbf{F}_i &= \sum_{i \neq j}(\mathbf{F}_{ij}^C + \mathbf{F}_{ij}^D + \mathbf{F}_{ij}^R + \mathbf{F}_{ij}^E), \\
\frac{dc_{\alpha i}}{dt} = q_{\alpha i} &= \sum_{i \neq j}(q_{\alpha ij}^D + q_{\alpha ij}^E + q_{\alpha ij}^R),
\end{aligned}
\tag{13}
$$

where the total force $\mathbf{F}_i$ consists of three pairwise forces as in classical DPD method, i.e., the conservative force $\mathbf{F}_{ij}^C = a_{ij}w_C(r_{ij})\mathbf{e}_{ij}$, dissipative force $\mathbf{F}_{ij}^D = -\gamma_{ij}w_D(r_{ij})(\mathbf{e}_{ij} \cdot \mathbf{v}_{ij})\mathbf{e}_{ij}$, and random force $\mathbf{F}_{ij}^R = \sigma_{ij}w_R(r_{ij})\xi_{ij}\mathbf{e}_{ij}$, as well as an electrostatic force $\mathbf{F}^E$ coupling hydrodynamics and electrokinetics, given by

$$
\mathbf{F}_{ij}^E = \lambda_{ij}\rho_{ei}\mathbf{E}_{ij}, \quad \mathbf{E}_{ij} = (\phi_i - \phi_j)\omega_E(r_{ij})\hat{\mathbf{r}}_{ij},
\tag{14}
$$

where the coupling parameter λ_{ij} is linearly related to the macroscopic dimensionless coupling parameter $\Lambda = c_0 k_B T \tau^2/(\rho_0 r_0^2)$ with c_0 and ρ_0 as the reference concentration and reference mass density, which are chosen as the respective salt concentration and mass density of bulk solution. r_0 and τ are the unit length and time in DPD. $\rho_{ei} = \sum_\alpha z_\alpha c_{\alpha i}$ is the total charge density within the ith particle, and $\mathbf{E}_{ij}$ is the relative electric field determined by the difference of electrostatic potential field between particles i and j and a weighting function $\omega_E(r)$. Although the electrostatic forces are essentially not pairwise, i.e., $\mathbf{F}_{ij}^E \neq \mathbf{F}_{ji}^E$, a zero total force condition $\sum_{i,j}\mathbf{F}_{ij}^E = 0$ is always satisfied because of the charge neutrality condition $\sum_i \sum_\alpha z_\alpha c_{\alpha i} = 0$, which guarantees the global momentum conservation if there is no external electrostatic field.

Transport equations of ionic species are implemented in the cDPD model by introducing extra degrees of freedom and corresponding evolution equations associated with each cDPD particle. Diffusion of ionic species is driven by three flux terms, i.e., the Fickian flux q_{ij}^D induced by the concentration gradient, electrostatic flux q_{ij}^E induced by electrostatic potential gradient, and random flux q_{ij}^R due to thermal fluctuations, which can be written as

$$
\begin{aligned}
q_{\alpha ij}^D &= -\kappa_{\alpha ij}\,(c_{\alpha i} - c_{\alpha j})\,\omega_{qD}(r_{ij}), \\
q_{\alpha ij}^E &= -\kappa_{\alpha ij}\,z_\alpha\,\bar{c}_{\alpha ij}\,(\phi_i - \phi_j)\,\omega_{qD}(r_{ij}), \\
q_{\alpha ij}^R &= \xi_{\alpha ij}\,\omega_{qR}(r_{ij})\,\theta_{ij}\,\delta t^{-1/2},
\end{aligned}
\tag{15}
$$

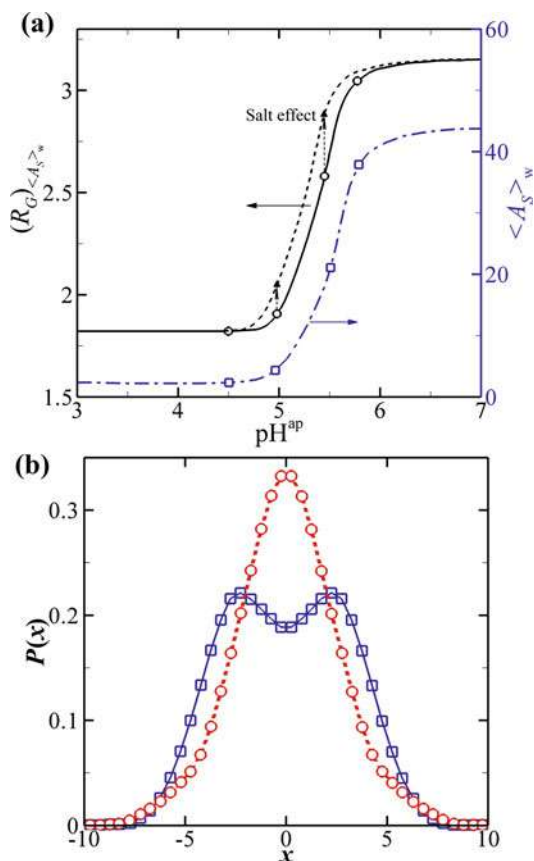
where $\bar{c}_{\alpha ij} = (c_{\alpha i} + c_{\alpha j})/2$ is the average ionic concentration, $\kappa_{\alpha ij}$ is the diffusion coefficients of the αth species, and $\omega_{qD}(r_{ij})$ is a weighting function. The parameters in q_{ij}^D and q_{ij}^R are related via the generalized fluctuation-dissipation theorem, i.e., $\omega_{qD}(r) = \omega_{qR}^2(r)$ and $\xi_{\alpha ij}^2 = \kappa_{\alpha ij}(c_{\alpha i} + c_{\alpha j})/c_0 r_0^3$, which suggests that the variance of random flux is proportional to r_0^{-3}. Thus, the random flux cannot be neglected in micro-/nanoscales where $r_0 \ll 10^{-6} m$.

The electrostatic potential ϕ on each cDPD particle is determined by solving the Poisson equation at every time step. Consider the dimensionless Poisson equation rescaled by the DPD units $\nabla(\varepsilon(\mathbf{r})\nabla\phi(\mathbf{r})) = -\Gamma\rho_e(\mathbf{r})$, where $\varepsilon(\mathbf{r})$ is the local relative permittivity and $\Gamma = e^2 c_0 r_0^2/\varepsilon_0 k_B T$. The Poisson equation should be solved at every time step using, for example, a successive over-relaxation iteration scheme. Then, the electrostatic potential ϕ_i on the ith cDPD particle is obtained iteratively as

$$
\phi_i^k = \phi_i^{k-1} + \vartheta\left[\chi\rho_{ei} - \sum_{j\neq i}\bar{\varepsilon}_{ij}\phi_{ij}^k\omega_\phi(r_{ij})\right],
\tag{16}
$$

where χ is linearly related to the macroscopic parameter Γ that characterizes the strength of the electrostatic interactions, $\bar{\varepsilon}_{ij} = (\varepsilon_i + \varepsilon_j)/2$ is the average permittivity, $\omega_\phi(r)$ is a weight function, and ϑ is a relaxation factor. The value of ϑ can be adaptively changed during the iteration process, and the value of ϕ_i at the previous time step can be taken as an initial estimate of ϕ_i^{k-1} to achieve faster convergence. Then, the iteration of Eq. (16) is performed until the absolute differences $|\phi_i^k - \phi_i^{k-1}|$ are below a predefined tolerance.

Both the DPD model based on explicit ions (Groot 2003) and the cDPD model based on semi-implicit ions (Deng et al. 2016) have been applied to fluctuating electrohydrodynamic phenomena investigations. Posel et al. (2014) applied Groot's DPD model with explicit ions (Groot 2003) to study pH-dependent self-assembly of poly(2-vinylpyridine)-block-poly(ethylene oxide) diblock copolymers in aqueous media. They quantified the dependences of the apparent radius of gyration and

Fig. 3 (**a**) Apparent radius of gyration $(R_G)_{\langle A_S \rangle_w}$ and weight-averaged association number $\langle A_S \rangle_w$ as functions of the pH^{ap}, where the effect of the salt is depicted by the shift in the radius of gyration. (Adapted from Posel et al. 2014). (**b**) Mass density distribution for both positive (blue squares)- and negative (red circles)-charged polyelectrolytes drifting in electroosmotic flow between two positively charged surfaces. (Adapted from Deng et al. 2016)


weight-averaged association number on pH, shown in Fig. 3a, and simulated the micellization process that coincides credibly with experimental observations. Deng et al. (2016) used the cDPD model to simulate the dilute polyelectrolyte solution drifting by electroosmotic flow in a microchannel. Unlike the migration of an uncharged polymer in the channel flow, they reported that negative-charged polyelectrolytes are likely to remain at the channel center because of the electrostatic repulsion from the charged surface, while the positive-charged polyelectrolytes drift away from the center with double peaks (Fig. 3b). Moreover, Zhou et al. (2013) investigated the response of a charged colloid and its surrounding microion cloud to an alternating electric field. Moshfegh and Jabbarzadeh (2016) simulated the electroosmotic flow in narrow nanochannels via explicit electrostatic interactions computed using the Ewald summation method. The authors acknowledge they currently are not aware of any top-down mesoscopic particle-based methods for ionic transport that consistently incorporate thermal fluctuations.

5   Summary

This chapter has considered different particle-based methods for mesoscopic transport processes, including thermal transport, reactive biochemical transport, and ionic transport in mesoscopic systems. These mesoscopic methods consistently incorporate thermal fluctuations based on non-equilibrium thermodynamics and are capable of describing certain mesoscopic features that deterministic macroscopic methods cannot model. The equations of a particle-based mesoscopic model can be derived from either bottom-up coarse-graining of microscopic dynamics or top-down discretization of macroscopic PDEs. Regardless of how mesoscopic models are obtained, they have similar structures, representing relevant physical mechanisms that dominate mesoscopic processes. Because mesoscopic methods are grounded in both macroscale and micro-/nanoscale models, they can play an important role in multiscale modeling of diseases and relevant bioengineering applications by seamlessly bridging the gap between microscopic molecular biology and macroscopic bulk behavior.

Despite considerable developments in recent years, particle-based mesoscopic methods are still evolving. New variations in models, novel theoretical interpretations, and innovative numerical algorithms often appear in literature. These methods have been applied to a large number of problems, including polymer and colloidal suspensions, multiphase fluids, biological materials, cell dynamics, and blood rheology, and new applications in different areas are still emerging. In the near future, these methods likely will be used even more widely for tackling challenging problems in biorheology, cellular biology, and bioengineering.

Additional research is needed in several areas, including the parameterization of mesoscopic models. Tuning model parameters manually by trial and error only works for simple systems. For problems with high-dimensional parameter spaces, Bayesian and/or machine-learning methods hold significant promise for inferring the model parameters (Lei et al. 2017). Coupling mesoscopic methods with other micro-/macroscopic methods to handle multiscale problems is another emerging research area. With concurrent coupling algorithms, i.e., domain decomposition (Tang et al. 2015) or adaptive resolution scheme (Praprotnik et al. 2006), in the lower limits, the mesoscopic methods can be coupled with microscale techniques, while in the upper bounds, the mesoscopic methods can be coupled with discretized PDEs. However, in concurrently coupled system, preserving correct fluctuations across the interface of heterogeneous solvers remains a challenging problem. Moreover, there is a need to decrease the computational cost of mesoscale methods, which could be achieved, for example, by improving the integration algorithms (Leimkuhler and Shang 2015) and efficient parallel implementations with graphics processing units (Blumers et al. 2017). Domain decomposition is routinely used to improve the scalability of particle codes. Parallel-in-time algorithms should be also investigated to further increase mesoscale method performance.

Contents

Abstract

Computational modeling and simulations can tackle a broad range of morphological, mechanical, and rheological problems relevant to blood and blood cells. Here, we review some continuum-based and particle-based computational approaches toward the modeling of healthy and diseased red blood cells (RBCs) with focus on the most recent contributions, including the three-level multiscale RBC model coupled with the boundary integral method of surrounding flows and two-component RBC models with explicit descriptions of lipid bilayer, cytoskeleton, and transmembrane proteins.

1   Introduction

Blood is a bodily fluid that delivers oxygen and nutrients to living cells and takes away metabolic waste products from those same cells. It is composed of blood cells suspended in blood plasma, which makes up about 55% of the volume of whole blood. Blood plasma is the liquid component of blood, which contains mostly water and other substances like dissolved proteins, glucose, and clotting factors. Blood cells are mainly red blood cells (also called erythrocytes or RBCs), white blood cells (also called leukocytes or WBCs), and plasma (also called thrombocytes). Taking together, these three kinds of blood cells add up to a total 45% of the volume of whole blood. In particular, RBCs are the most common type of blood cells, with each cubic millimeter (1 mm^3) of blood containing about 4–6 million RBCs.

A normal RBC is a nucleus-free cell; it is essentially a cell membrane encapsulating a hemoglobin solution. Upon maturation, it adopts a unique biconcave shape of approximately $8.0\,\mu m$ in diameter and $2.0\,\mu m$ in thickness (Fig. 1a). The RBC membrane consists of three basic components: a lipid bilayer, a cytoskeletal network, and transmembrane proteins such as glycophorins, band 3, and some substoichiometric glycoproteins (e.g., CD44, CD47) (Fig. 1b). The deformability of an RBC is determined by the elasticity, geometry, and viscosity of the RBC membrane. A normal RBC is highly deformable allowing it to squeeze through capillaries as small as 3 microns in diameter without any damage. Several pathological conditions, including malaria, sickle cell disease, hereditary spherocytosis, and elliptocytosis, can alter the shape and deformability of circulating RBCs, leading to possible vascular obstruction. Over the past few decades, computational models, such as continuum-based and particle-based RBC models, have been proven to be an important tool in accurately resolving a broad range of biological problems associated with RBCs (Abkarian and Viallat 2008; Vlahovska et al. 2011; Li et al. 2013, 2017b). Actually, there is a great variety of modeling approaches since no universal solution for all blood flow related problems. In this chapter, we overview the computational approaches toward the modeling of RBCs focusing on the most recent contributions.
Fig. 1 Schematic representation of the morphology of (**a**) a normal RBC and (**b**) its two-component membrane structure (Li et al. 2017a)

For the most problems, the surrounding blood plasma plays a significant role in the RBC dynamics. The accurate modeling of the fluid-structure interaction between the RBCs and the surrounding flow is crucial to predict the physics. There are three major groups of numerical methods in the existing literature to study motion and deformation of RBCs in flow (Pozrikidis 2010; Barthès-Biesel 2016; Freund 2014). In the first group of methods, boundary integral equations are used to represent the Stokes flow and coupled to the membrane (Walter et al. 2010; Pozrikidis 1992), which is usually modeled as meshes or spectral elements (Zhao et al. 2010) either by enforcing the membrane equilibrium equation directly (Pozrikidis 1992) or by the finite element method based on the virtual work principle (Walter et al. 2010; Peng et al. 2011). This type of methods has been known to be very precise in various studies of simple shear flow and plane hyperbolic flow (Barthès-Biesel 2016; Freund 2014). In the second group of the immerse-boundary type methods, the fluid domain is solved using either the finite difference method (Yazdani et al. 2011) or the lattice Boltzmann method (LBM) (Sui et al. 2008), and the capsule membrane is solved using continuum methods such as finite element method (FEM). The force from capsule membrane nodes is distributed to the fluid domain as Dirac delta functions, which are approximated by smooth functions sharply varying over a few fixed grid meshes. The precision of these methods may be reduced as the methods do not treat the membrane as physical boundaries but as approximated Dirac functions. In the third group, particle methods such as dissipative particle dynamics (DPD) (Pivkin and Karniadakis 2008; Peng et al. 2013), multiparticle collision dynamics (MPCD) (Noguchi and Gompper 2005; McWhirter et al. 2009), and smoothed particle hydrodynamic (SPH) method (Hosseini and Feng 2012) are used, and the capsule and RBC membranes are modeled as triangular networks of particles with bond, angle, and dihedral interactions (Discher et al. 1998). In addition to these three groups, phase-field methods (Du et al. 2004) and arbitrary Lagrangian Eulerian (ALE) method using FEM (Barber et al. 2011; Ni et al. 2015) are used as well to study capsules and vesicles.

2   Continuum-Based Models

Continuum-based models provided useful insights in many aspects of RBC mechanics by adopting the robust and accurate numerical methods developed in the well-established continuum mechanics community (Barthès-Biesel 2016). The cell membrane is typically 7.5–10 nm in thickness; hence it is usually treated as a two-dimensional viscoelastic material embedded in a three-dimensional space. Traditionally, continuum-based RBC models treat RBC membrane and intracellular hemoglobin solution as homogeneous materials, using boundary integral method (BIM) (Ramanujan and Pozrikidis 1998; Lac et al. 2004; Zhao et al. 2010; Veerapaneni et al. 2011), immersed boundary method (IBM) (Peskin 2002; Doddi and Bagchi 2009; Yazdani and Bagchi 2011; Fai et al. 2013), and fictitious domain method (FDM) (Shi et al. 2014; Hao et al. 2015). These continuum-based models describe the modeling system using locally averaged variables, such as density, stress, and velocity, with ordinary and partial differential equations governing flow

dynamics and fluid mechanics. Blood flow in microcirculation normally falls in the Stokes regime where inertial effects are negligible, hence making BIM a popular technique for addressing multiphase flow problems. The BIM method exploits the fact that the equations of fluid motion are linear and can be recast into an integral equation for the evolution of the interface (Ramanujan and Pozrikidis 1998; Lac et al. 2004; Zhao et al. 2010; Veerapaneni et al. 2011). Among other continuum solvers, the IBM has become very effective in addressing fluid-structure problems (Peskin 2002; Fai et al. 2013). There are several numerical extensions of IBM depending on the choice of the structural and fluid formulations. For example, the front-tracking method (Doddi and Bagchi 2009; Yazdani and Bagchi 2011) used a first-order finite element triangulation of cell membrane, while the full Navier-Stokes equation has been solved using projection splitting scheme. More recently, FDM for solving coupled fluid-structure systems by introducing a Lagrange multiplier over the solid domain has been used (Shi et al. 2014; Hao et al. 2015). This multiplier acts as a penalty term that imposes the kinematic constraint in the solid domain. Another computational challenge is to include the membrane thermal undulations; progress in this direction has been made by introducing a stochastic formulation for IBM (Atzberger et al. 2007).

These continuum-based RBC models allow the study of blood flow dynamics on macroscopic length and time scales. However, the RBC membrane is considered as a uniform continuum media in these continuum models, and the detailed molecular structure was not considered. Recently, multiscale RBC models that include sufficient molecular details have been developed. For example, Peng et al. have developed a three-level multiscale model of RBCs and coupled it with a boundary element model to study the dynamic response of RBCs in tube and shear flows (Peng et al. 2010). For the RBC membrane, we built a three-level multiscale model to simulate its viscoelastic behaviors at different length scales, including single protein scale, protein complex scale, and cell scale. For the fluids surrounding the RBC, we used a boundary element approach to study the fluid dynamics based on the Stokes equation of viscous flow (Peng et al. 2011).

The dynamics of RBCs involves physics at different length scales. For example, in the whole-cell level, RBCs may undergo tank-treading motions in shear flow in the micro meter scale (Fischer et al. 1978; Tran-Son-Tay et al. 1984). In the protein complex scale, junctional complexes of RBCs may experience fluctuations due to mode switching (Lee and Discher 2001; Zhu et al. 2007). In the protein level, tension may induce spectrin unfolding in the nanoscale (Rief et al. 1999; Zhu et al. 2007). We developed a multiscale framework to investigate the physics in different length scales, including three models at three different length scales, and coupled them together using a hierarchical multiscale approach, as shown in Fig. 2.

At Level I, Zhu and Asaro developed a model of spectrin using Monte-Carlo simulation (Zhu and Asaro 2008). Spectrin is the major RBC cytoskeleton protein that forms a triangular network. Rief et al. applied AFM to stretch a single spectrin and found that it can be modeled accurately using a nonlinear constitutive model called worm-like chain (WLC) (Rief et al. 1999; Discher et al. 1998; Li et al. 2005). Besides that, it was found that if the spectrin is stretched beyond its contour
Fig. 2 Two-component RBC model using three-level hierarchical multiscale method (Peng et al. 2010)

length, multiple protein domains may unfold to increase the contour length. In order to capture the full mechanical behavior of the spectrin, Zhu and Asaro took into account its domain unfolding feature by employing a Monte-Carlo method, as the probability of the unfolding is a function of the loading (Zhu and Asaro 2008). By simulating the unfolding of the spectrin, Zhu and Asaro got consistent force-displacement curves as in the AFM experiment (Rief et al. 1999). In addition, the effect of stretching rate is also quantified. After these force-displacement curves are obtained, the information is passed as a database to the next level model (Level II).

At Level II, Zhu et al. developed a 3D junctional complex model with molecular details using Brownian dynamics (BD), which is a basic protein complex unit in the RBC cytoskeleton (Zhu et al. 2007). In the junctional complex, an actin protofilament is associated with six or five spectrins. Zhu et al. built an exact geometry model based on the state-of-the-art understanding of the molecular structure of a junctional complex, including the binding sites between spectrins and actins (Sung and Vera 2003). They simulated thermal fluctuations of the RBC membrane using this model (Zhu et al. 2007), and predicted the area and shear moduli of the cytoskeleton, as functions of membrane deformation (Zhu et al. 2007; Peng et al. 2010), which can be passed to the next cell level model (Level III).

At Level III, Peng et al. developed a whole-cell model of RBCs using finite element method (FEM) and considered the normal and tangential interactions between the lipid bilayer and the cytoskeleton (Peng et al. 2010, 2011). The cytoskeleton may slide against the lipid bilayer (Fischer 1992; Dodson and Dim-itrakopoulos 2010), since the cytoskeleton is connected to the lipid bilayer through transmembrane proteins such as band 3 and glycophorin C, which can move freely

within the lipid bilayer. In order to describe the bilayer-cytoskeletal interaction accurately, we modeled the RBC membrane as two distinct layers. We employed an inner layer to present the cytoskeleton with finite area and shear stiffnesses, and negligible bending stiffness, and an outer layer to represent the lipid bilayer with zero shear stiffness, huge area stiffness, and significant bending stiffness. Vertical elastic interaction and tangential viscous friction between the lipid bilayer and the cytoskeleton are simulated using a contact algorithm based on the penalty method (Malone and Johnson 1994). The bilayer-cytoskeletal friction coefficient is estimated based on the Stokes-Einstein relation and experimentally measured diffusivities of band 3 and glycophorin C in the lipid bilayer (Kapitza et al. 1984; Kodippili et al. 2009; Tomishige 1998). Reduced integration shell elements based on Mindlin theory were used to simulate both the outer and the inner layers (Peng et al. 2010).

Besides the elasticity, we also considered the viscosities of the lipid bilayer and the cytoskeleton, which play significant roles in dynamics processes such as tank-treading. For example, it has been demonstrated that without considering the membrane viscosity, the predicted tank-treading frequency cannot match the experimental measurement (Fedosov et al. 2011a; Peng et al. 2011). Different from the existing study (Fedosov et al. 2011a), we consider the viscosities of the lipid bilayer and the cytoskeleton separately using a generalized Voigt-Kelvin stress-strain relation (Evans and Skalak 1980). Furthermore, we modeled the sliding between the bilayer and the skeleton as a viscous friction force. The viscous fluids surrounding the cell are incorporated in the following boundary element model of Stokes flow.

We applied a boundary element method to simulate the Stokes flows inside and outside of the RBC and coupled it with FEM to study the fluid-structure interaction. We used a staggered algorithm with explicit time integration (Peng et al. 2011). For the interface dynamics in the Stokes flow with zero Reynolds number, we applied the boundary integral equation (Pozrikidis 1992) so that the velocity $\mathbf{v}^f$ is given as

$$
\begin{aligned}
\mathbf{v}^f(\mathbf{x}_0) \;=\; & \frac{2}{1+\Lambda}\bar{\mathbf{v}}^f(\mathbf{x}_0) \\
& -\frac{1}{4\pi\eta_1(\Lambda+1)}\int_{\Gamma^{fb}}\mathbf{G}(\mathbf{x},\mathbf{x}_0)\cdot\Delta\mathbf{t}^f(\mathbf{x})d\Gamma(\mathbf{x}) \\
& +\frac{1-\Lambda}{4\pi(1+\Lambda)}\!\!\iint_{\Gamma^{fb}}\mathbf{v}^f(\mathbf{x})\cdot\mathbf{T}(\mathbf{x},\mathbf{x}_0)\cdot\mathbf{n}(\mathbf{x})d\Gamma(\mathbf{x}),
\end{aligned}
\tag{1}
$$

where Γ^{fb} is the membrane surface and $\bar{\mathbf{v}}^f$ is the prescribed undisturbed velocity field of the shear flow. The vector $\Delta\mathbf{t}^f = \mathbf{t}^{f,1} - \mathbf{t}^{f,2}$ is the discontinuity in the interfacial surface traction, where $\mathbf{t}^{f,1}$ is the traction in the outside surface $\Gamma^{fb,1}$ of the interface and $\mathbf{t}^{f,2}$ is the traction in the inside surface $\Gamma^{fb,2}$ of the interface. The surface traction is related to the nodal force through the principle of virtual work (Walter et al. 2010). $\iint$ denotes the principal value integration.

G is the Green's function for velocity. Its components are

$$G_{ij}(\mathbf{x}, \mathbf{x}_0) = \frac{\delta_{ij}}{|\mathbf{x} - \mathbf{x}_0|} + \frac{(x_i - x_{0_i})(x_j - x_{0_j})}{|\mathbf{x} - \mathbf{x}_0|^3}, \qquad (2)$$

where δ_{ij} is Kronecker's delta. **T** is the Green's function for stress. It can be written as

$$T_{ijk}(\mathbf{x}, \mathbf{x}_0) = -6\frac{(x_i - x_{0_i})(x_j - x_{0_j})(x_k - x_{0_k})}{|\mathbf{x} - \mathbf{x}_0|^5}. \qquad (3)$$

Extensive validations have been conducted in each level to verify the models, such as optical tweezers stretching (Peng et al. 2010), micropipette aspiration (Peng et al. 2010), tank-treading, and tumbling of RBCs in shear flow (Peng et al. 2011). More importantly, the effect of stress-free cytoskeleton state on the tank-treading behavior has been compared with the available experiments in details (Dupire et al. 2012; Peng et al. 2014, 2015). Besides validations, we predicted correlation between the occurrence of spectrin unfolding and increase in the mechanical load upon individual skeleton-bilayer pinning points and related it to the vesiculation process (Knowles et al. 1997). The simulation results also show that during tank-treading, the protein density variation is insignificant for healthy RBCs, but significant for cells with a smaller bilayer–cytoskeletal friction coefficient, which may be the case in hereditary spherocytosis (Walensky et al. 2003). We also predicted two different modes of motions for RBCs in shear flow (Peng and Zhu 2013) and studied the effect of stress-free state on the tank-treading motion (Peng et al. 2014, 2015; Dupire et al. 2012). We showed that the cell maintains its biconcave shape during tank-treading motions under low shear rate flows, by employing a spheroidal stress-free state in the cytoskeleton (Peng et al. 2014). Furthermore, we numerically confirmed the hypothesis that, as the stress-free state approaches a sphere, the threshold shear rates corresponding to the establishment of tank treading decrease. By comparing with the experimental measurements (Dupire et al. 2012), our study suggests that the stress-free state of RBCs is a spheroid that is close to a sphere, rather than the biconcave shape applied in existing models (Peng et al. 2014). In addition, we also quantified the stability phase diagram of different motion modes in high shear rate flows and explored the effect of stress-free state on the phase diagram (Peng et al. 2015).

3   Particle-Based Models

Particle-based models treat both the fluid and the cell membrane as particulate materials, and they can model critical biophysical processes involving the RBCs at cellular and subcellular scales, such as membrane fluctuations and the defective membrane structure. Several particle-based RBC models, including molecular-detailed composite RBC models (Li and Lykotrafitis 2012, 2014; Tang et al. 2017)
Fig. 3 Two-component RBC model at protein resolution (Tang et al. 2017; Li and Lykotrafitis 2014) and coarse-grained level (Peng et al. 2013)

and coarse-grained RBC models (Discher et al. 1998; Li et al. 2005; Noguchi and Gompper 2005; Pivkin and Karniadakis 2008; Pan et al. 2010; Fedosov et al. 2010; Peng et al. 2013), have been developed and employed to quantify the structural, mechanical, and rheological properties of RBCs in health and disease.

Generally, the molecular-detailed composite RBC models describe explicitly lipid bilayer, cytoskeleton, and transmembrane proteins using coarse-grained molecular dynamics (CGMD) (Li and Lykotrafitis 2012, 2014). They are able to capture the membrane-related structural problems in RBCs. Specifically, the spectrin tetramer in the composite membrane model is represented by a chain of 39 beads (gray particles in Fig. 3a) connected by spring bonds (Li et al. 2007). The corresponding potential has the form,

$$V_{cy}^{s-s} = \frac{1}{2}k_0(r - r_{eq}^{s-s})^2 \tag{4}$$

where k_0 and r_{eq}^{s-s} are the spring constant and equilibrium distance between two spectrin particles, respectively. Spectrin particles that are not connected by the spring potential interact with each other via the repulsive term of Lennard-Jones potential, given by

$$V_{\text{rep}}(r_{ij}) = \begin{cases} 4\epsilon \left[\left(\frac{\sigma_{ij}}{r_{ij}} \right)^{12} - \left(\frac{\sigma_{ij}}{r_{ij}} \right)^{6} \right] + \epsilon & r_{ij} < r_{\text{eq}}^{s-s}, \\ 0 & r_{ij} \geq r_{\text{eq}}^{s-s} \end{cases} \tag{5}$$

where ϵ is the energy unit and σ_{ij} is the length unit, and r_{ij} is the distance between spectrin particles. To couple the lipid bilayer and spectrin network, actin junctional complexes are connected to the glycophorin C, and the middle beads of the spectrin network are bonded to the band-3 complexes which are specifically rendered in yellow particles. These bonds are modeled as harmonic springs, given by

$$V_{\text{cy}}^{a-s} = \frac{1}{2} k_0 (r - r_{\text{eq}}^{a-s})^2, \tag{6}$$

where $r_{\text{eq}}^{a-s} = 10\,\text{nm}$ is the equilibrium distance between an actin and a spectrin particle.

These molecular-detailed composite membrane models have been successfully to study some issues associated with RBC membrane defects, such as the multiple stiffening effects of nanoknobs on malaria-infected RBCs (Zhang et al. 2015; Chang et al. 2016), the vesiculation of mature RBCs in hereditary elliptocytosis and spherocytosis (Li and Lykotrafitis 2015), and the diffusion of transmembrane proteins in normal and defective RBC membrane (Li et al. 2016). However, modeling only a portion of the RBC membrane does not efficiently depict the whole-cell characteristics strongly related to RBC mechanics and rheology.

More recent efforts have focused on this approach, leading to a two-component whole-cell model (OpenRBC) at protein resolution with explicit descriptions of lipid bilayer, cytoskeleton, and transmembrane proteins (Fig. 3a) (Tang et al. 2017). In the OpenRBC, the modeled RBC is generated from a triangular mesh of cytoskeleton that resembles the biconcave disc shape of a normal RBC, where the lipid molecules and mobile band-3 particles are randomly placed on triangular faces. The modeled RBC system is also optimized by a velocity quenching algorithm to avoid the overlap of particles. It can simulate an entire RBC with a resolution down to single protein level, which offers unique tools for the qualitative and quantitative predictions of dynamic and mechanical properties of healthy and pathological RBCs beyond available experimental measurements, such as the vesiculation of RBCs in hereditary spherocytosis and elliptocytosis (Tang et al. 2017), and rupture of RBCs in splenic passage (Li et al. 2018). However, at present, they are computationally very expensive for large-scale applications such as modeling whole blood involving a large number of RBCs. On the other hand, coarse-grained whole-cell model provides the opportunity to significantly reduce the computational complexity. For example, a three-dimensional multiscale RBC (MS-RBC) model has been developed and successfully applied to RBC simulations at different length scales (Pivkin and Karniadakis 2008; Fedosov et al. 2010).

In the MS-RBC model, the cell membrane is modeled by a 2D triangulated network with N_v vertices connected by springs, where each vertex is represented by a DPD particle. The RBC membrane model takes into account the elastic energy,

bending energy, and constraints of fixed surface area and enclosed volume, which is defined as

$$V = V_s + V_b + V_a + V_v, \tag{7}$$

where V_s is the elastic energy that mimics the elastic spectrin network, given by

$$V_s = \sum_{i \in \text{springs}} \left[\frac{k_B T l_m}{4p} \frac{3x_i^2 - 2x_i^3}{1 - x_i} \right] + \sum_{\alpha \in \text{triangles}} \frac{1}{A_\alpha} \left[\frac{3\sqrt{3}k_B T l_m^3 x_0^4}{64p} \frac{4x_0^2 - 9x_0 + 6}{(1 - x_0^2)} \right], \tag{8}$$

where $k_B T$ is the energy unit and A_α is the area of triangle α formed by three vertices. Also, $x_i = l_i/l_m$, $x_0 = l_0/l_m$, where l_i is the length of spring i, l_0 and l_m are the equilibrium spring length and maximum spring extension, and p is the persistence length.

The cell membrane viscoelasticity is imposed by introducing a viscous force on each spring, which has the form,

$$\mathbf{F}_{ij}^D = -\gamma^T \mathbf{v}_{ij} - \gamma^C (\mathbf{v}_{ij} \cdot \mathbf{e}_{ij}) \mathbf{e}_{ij}, \tag{9}$$

$$\mathbf{F}_{ij}^R dt = \sqrt{2k_B T} \left(\sqrt{2\gamma^T} d\overline{\mathbf{W}}_{ij}^S + \sqrt{3\gamma^C - \gamma^T} \frac{tr[d\mathbf{W}_{ij}]}{3} \mathbf{1} \right) \cdot \mathbf{e}_{ij}, \tag{10}$$

where γ^T and γ^C are dissipative parameters, $\mathbf{v}_{ij}$ is the relative velocity of spring ends, and $d\overline{\mathbf{W}}_{ij}^S = d\mathbf{W}_{ij}^S - tr[d\mathbf{W}_{ij}^S]\mathbf{1}/3$ is the traceless symmetric part of a random matrix representing the Wiener increment.

The bending resistance of the RBC membrane is modeled by

$$V_b = \sum_{\alpha, \beta \text{ pair}} k_b \left[1 - \cos(\theta_{\alpha\beta} - \theta_0) \right], \tag{11}$$

where k_b is the bending modulus constant, $\theta_{\alpha\beta}$ is the instantaneous angle between two adjacent triangles having common edge, and θ_0 is the spontaneous angle. In addition, the RBC model includes the area and volume conservation constraints, which mimic the area-incompressibility of the lipid bilayer and the incompressibility of the interior fluid, respectively. The corresponding energy terms are given by

$$V_a = \frac{k_a k_B T (A - A_0)^2}{2l_0^2 A_0}, \quad V_v = \frac{k_v k_B T (V - V_0)^2}{2l_0^3 V_0}, \tag{12}$$

where k_a and k_v are the area and volume constraint coefficients. Here A_0 and V_0 are the equilibrium area and volume of a cell, respectively.

The MS-RBC model is multiscale, as the RBC can be represented on the spectrin level, where each spring in the network corresponds to a single spectrin tetramer with the equilibrium distance between two neighboring actin connections of ~75 nm. On the other hand, for more efficient computations, the RBC network can also be highly coarse-grained with the equilibrium spring lengths of up to 500~600 nm. In addition, being constructed from a coarse-grained molecular dynamics (CGMD) approach, the MS-RBC model can naturally include membrane thermal fluctuations (Fedosov et al. 2011b; Chang et al. 2017). Such formulations are compatible with coarse-grained mechanical descriptions of the RBC membrane with the advantage of including the viscosity of the RBC membrane without additional cost. Thus, the particle-based whole-cell models can resolve subcellular and cellular scales.

A two-component particle-based whole-cell model, which separately accounts for the lipid bilayer and cytoskeleton but implicitly includes the transmembrane proteins, has been developed and implemented using DPD (Fig. 3b) (Peng et al. 2013). In this two-component whole-cell model, the cell membrane is modeled by two distinct components, i.e., the lipid bilayer and the spectrin network. Specifically, through the DPD approach, each component is constructed by a two-dimensional triangulated network, which is analogous to the one-component whole-cell model; however, the lipid bilayer of the two-component whole-cell model has no shear stiffness at healthy state but only bending stiffness and a very large local area stiffness, whereas the cytoskeleton has no bending stiffness but possesses a finite shear stiffness. In addition, this unique two-component whole-cell model takes into account the bilayer-cytoskeleton interaction potential, which is expressed as a summation of harmonic potentials given by

$$V_{\text{int}} = \sum_{j,j' \in 1 \dots N_{bs}} \frac{k_{bs}(d_{jj'} - d_{jj',0})^2}{2},$$ (13)

where k_{bs} and N_{bs} are the spring constant and the number of bond connections between the lipid bilayer and the cytoskeleton, respectively. $d_{jj'}$ is the distance between the vertex j of the cytoskeleton and the corresponding projection point j' on the lipid bilayer, with the corresponding unit vector $\mathbf{n}_{jj'}$; $d_{jj',0}$ is the initial distance between the vertex j and the point j', which is set to zero in the current simulations. Physical view of the local bilayer-cytoskeleton interactions includes the major connections via band-3 complex and ankyrin, as well as the secondary connections via glycophorin C and actin junctions; here we consider them together as an effective bilayer-cytoskeleton interaction and model it as a normal elastic force, $\mathbf{f}_{jj'}^E$, and a tangential friction force, $\mathbf{f}_{jj'}^F$. The corresponding elastic force on the vertex j of the cytoskeleton is given by

$$\mathbf{f}_{jj'}^E = \begin{cases} k_{bs}(d_{jj'} - d_{jj',0})\mathbf{n}_{jj'} & d_{jj'} < d_c \\ 0 & d_{jj'} \geq d_c \end{cases}$$ (14)

where $d_c \approx 0.2\,\mu m$ is the cutoff distance. The tangential friction force between the two components is represented by

$$\mathbf{f}_{jj'}^{F} = -f_{bs}[\mathbf{v}_{jj'} - (\mathbf{v}_{jj'} \cdot \mathbf{n}_{jj'})\mathbf{n}_{jj'}], \tag{15}$$

where f_{bs} is the tangential friction coefficient and $\mathbf{v}_{jj'}$ is the difference between the two velocities.

The two-component whole-RBC model is capable of simulating the interactions between the lipid bilayer and the cytoskeletal network of human RBCs (Peng et al. 2013; Li et al. 2014; Chang et al. 2016). Furthermore, it is computationally more efficient than the two-component OpenRBC model for blood flow modeling. Herein, the two-component whole-cell RBC model has been used in simulations of blood flow and quantified the existence of bilayer-cytoskeletal slip for RBC membrane in pathological state (Peng et al. 2013; Li et al. 2014).

4   Summary

To summarize the continuum-based and particle-based models of RBCs, we list the main features and applications of some existing mesoscale RBC models in Table 1. The main differences are the molecular details considered and the length scales these models can reach. The two-component CG model focused on the detailed bilayer-cytoskeletal interaction and transmembrane protein diffusion, but it is too expensive to employ it to study a whole cell with current methodology. The two-component DPD model studied the whole-cell behavior and explored the bilayer-cytoskeletal interaction in a simplified way. The three-level multiscale approach is developed to bridge three models in different length scales, but due to the information passing, some information is lost, such as the thermal fluctuations in the whole-cell level.

There is still plenty of room to improve these models. For example, only one-way coupling has been done for the three-level multiscale RBC model, and two-way coupling can be added to study how the deformation in the macroscale can influence the dynamics of the proteins in the microscale. In addition, future effort will be put on how to improve the efficiency of the two-component CGMD RBC model in order to apply it in the whole-cell scale and couple it with fluid motion. Such simulations could shed light on the coupling of biology, chemistry, and mechanics (the "triple-point"). To make model predictions more reliable, it would require further mesoscopic validation and reliability testing of these models against experimental and clinical studies. Moreover, smoothed dissipative particle dynamics (SDPD) and smoothed particles hydrodynamics (SPH) have been also applied to study RBCs models (Hosseini and Feng 2012; Fedosov et al. 2014; Müller et al. 2015). Compared to conventional DPD, SDPD adopt advantages from smoothed particles hydrodynamics (SPH) (Van Liedekerke et al. 2013), such as thermal consistency and specification of viscosity.

Table 1 Comparison of different RBC models

RBC models	Main characteristics	Examples of application
Two-component CGMD composite model (Li and Lykotrafitis 2012, 2014; Zhang et al. 2015)	One-particle-thick bilayer model Small piece of membrane	Transmembrane protein diffusion RBC membrane defects RBC membrane vesiculation
Three-level multiscale model (Peng et al. 2010, 2011)	FLM, LD and MC Spanning from protein to cell	Micropipette vesiculation Dynamics junctional complexes Spectrin unfolding
OpenRBC model (Tang et al. 2017)	One-particle-thick bilayer model Bilayer-cytoskeletal interaction Whole-cell level	RBC vesiculation RBC lysis
One-component DPD model (Pivkin and Karniadakis 2008; Fedosov et al. 2010)	Coupled with fluids Systematic coarse-graining Whole-cell level	Membrane thermal fluctuations Tank-treading motion Microfluidics
Two-component DPD model (Peng et al. 2013; Li et al. 2014)	Bilayer-cytoskeletal interaction Whole-cell level	Bilayer-cytoskeletal slip Bilayer tethering Membrane thermal fluctuations
Two-component MPCD model (Noguchi and Gompper 2005; McWhirter et al. 2009)	Coarse-grained model Whole-cell level	Tube flow Tank-treading motion
LBM model (Zhang et al. 2008; Reasor et al. 2012)	Fluid-structure interaction Whole-cell level	Blood rheology Cell margination
Continuum model (Ramanujan and Pozrikidis 1998; Dao et al. 2003; Yazdani and Bagchi 2011; Freund 2013)	Uniform property No molecular details	Large-scale blood flow modeling Tank-treading Optical tweezers stretching

Since the RBC is a model system for cell mechanics and biological membranes, RBC models can be applied in other systems as well. For example, recently we extended the two-component RBC DPD model to study the blood vessel walls by considering the isotropic matrix and the anisotropic collagen fibers separately (Witthoft et al. 2016). Furthermore, we can also apply RBC models to study the lipid bilayer and the actin cortex network or the intermediate filament network in general eukaryotic cells, because some of them share similar structures as the spectrin network of RBCs, such as the auditory outer hair cells and the nucleus lamina (Alberts et al. 2002; Boal 2012).

Computational Models of Eukaryotic Cells in Health and Disease

108

Kirill Lykov and Igor V. Pivkin

Contents

Abstract

Eukaryotic cells play a crucial role in many processes in health and disease in the human body. The importance of an understanding of cell behavior from the mechanical point of view triggered the development of many computational models. In this chapter, we present recent progress in this field. We focus primarily on computational models of suspended in flow and adherent to substrate eukaryotic cells.

1 Introduction

Cells are building blocks of living beings, and there is a wide variety of cell types each tailored for a specific purpose in the body. Cells composed of the cell membrane, complex 3D cytoskeletal network, and various organelles, including the nucleus, are called eukaryotic cells. These cells play roles in many processes of a mechanical nature in health and disease, e.g., cell migration, wound healing, and

K. Lykov (✉) · I. V. Pivkin

e-mail: kirill.lykov@usi.ch; igor.pivkin@usi.ch

cancer metastasis. The mechanics of the eukaryotic cell as a whole is determined by the properties of its subcellular components.

The plasma membrane separates the body of the cell from the extracellular environment. It is composed of different lipids and cholesterol with the inclusion of various embedded proteins. The volume inside the cell membrane is filled with the protein-rich fluid, called cytosol. Although the plasma membrane has a mechanism for the fluid and solute exchange with the surrounding, it is mostly impermeable, which leads to volume conservation of a cell. Incompressibility of the lipid layers results in plasma membrane surface area conservation and bending resistance.

The space between the plasma membrane and cell organelles is occupied, besides of cytosol, by a complex filament network called cytoskeleton. It is a dynamic structure, which maintains the integrity of the cell. In addition, it plays an essential role in many cell processes: migration, adhesion, division, stress resistance, and mechanotransduction. The cytoskeleton is composed of interconnected filaments of three main types: actin filaments, microtubules, and intermediate filaments (Suresh 2007). Actin filaments are semiflexible biopolymers, which exhibit the highest resistance to deformations until some critical stress value. If the stress is higher than this value, they are fluidized. Intermediate filaments can resist moderate deformations, and they do not fluidized under high values of shear stress, hence, providing structural integrity to the cell. Microtubules do not contribute significantly to the cell stiffness. Being interconnected with filaments of other types, they stabilize the cytoskeleton. They also might contribute to the compression resistance under high pressure (Brangwynne et al. 2006).

The nucleus is the largest eukaryotic organelle, and it is stiffer than the cell itself (Guilak et al. 2000; Friedl et al. 2011). Mechanics-wise, the most important components of the nucleus are nucleus envelope and chromatin network. The nucleus envelope is composed of two phospholipid bilayers with attached lamin meshwork. These bilayers act as a barrier between cytoplasm and nucleus internal structure (Denais and Lammerding 2014). In comparison to the cell membrane, nucleus membrane exposes weaker area and volume constraints allowing fluid to get in and out (Rowat et al. 2006). The nuclear lamina, which is often considered to be the main contributor to the nucleus stiffness (Gerlitz and Bustin 2012), is 2D meshwork attached to the inner bilayer. According to a recent study, lamina levels control nuclear strain stiffening at large extensions (Stephens et al. 2017). Contrary, chromatin network, which occupies the nucleus volume, governs response to small deformations (Stephens et al. 2017).

Mechanical properties of eukaryotic cells depend on the cell type as well as the state of the cell. Cells can be in suspended state, when they are traveling in the blood stream, or in the adherent state, when they are attached to the extracellular matrix. Another source of alternations in cell structure and mechanics is various diseases (Nematbakhsh and Lim 2015), which might alter the properties of any of the cell components. One example is softening of the cell membrane by HIV before invasion into the cell by the insertion of fusion peptide (Agrawal et al. 2016). Due to the dominant role of cytoskeleton in the cell mechanics, it is not surprising that the progression of numerous diseases leads to the cytoskeleton properties alteration.

The most prominent example is the cytoskeleton structure degradation and density decrease of epithelial tumor cells (Suresh 2007). In several cancers, the higher is the metastatic potential of a cell, the lower is the stiffness of the cytoskeleton and, hence, the cell as a whole (Nematbakhsh et al. 2017; Cross et al. 2007; Liu et al. 2015b). Other diseases which change the cytoskeleton mechanics are neurodegeneration, liver cirrhosis, pulmonary fibrosis, and blistering skin diseases (Ramaekers and Bosman 2004). Some tissue-specific disorders are linked to the alteration of the mechanical properties of the nucleus due to the mutations in genes encoding lamins and associated nuclear envelope proteins: Emery-Dreifuss muscular dystrophy, dilated cardiomyopathy, familial partial lipodystrophy, as well as over 20 other diseases (Rowat et al. 2006; Rynearson and Sussman 2011).

The great variety of cell types as well as diseases altering cell mechanics led to the development of numerous experimental techniques for investigating cell mechanical properties. These techniques can be split into two groups. The methods in the first group, such as atomic force microscopy (AFM) and micropipette aspiration, operate with individual cells to estimate their viscoelastic properties. A classical review of methods of this type can be found elsewhere (Suresh 2007). The second group of experimental techniques with higher throughput includes microfluidic experiments. There is a great variety of microfluidic devices and principles they employ to operate. A good review of the current status of the microfluidics with application to cells can be found elsewhere (Chaudhuri et al. 2016).

2   Modeling Approaches

Despite a significant progress in the experimental techniques in cell biophysics, the computational modeling remains an irreplaceable complementing tool. Firstly, it improves our understanding of the subcellular component mechanics, which is valuable for many applications. In particular, it can influence the drug discovery by offering a rich target space for possible alteration of cell properties. Secondly, numerical simulations allow to predict cell behavior in a complex environment, and thus, their use may improve and accelerate the design of various microfluidic devices (Rossinelli et al. 2015). In particular, numerical simulations can help in the acquisition of information related to fluid microrheology, including often unexpected flow properties in complex domains resulting in various cell phenomena (merging, lysis, adhesion, damage, signaling) (Nan et al. 2014; Yung et al. 2009; Pinho et al. 2013).

Recent advances in computational methods, as well as hardware development, catalyzed the creation of a number of eukaryotic cell models in the last 5 years. The variety of models can be explained by the complexity of the problem. The first source of this complexity is the diversity of the cell types along with processes they are involved in. The second one is the lack of understanding of the role that each cell component plays during mechanical deformations. Finally, there is no full understanding of the active cell response. These factors explain the fact that the

current state-of-the-art models are phenomenological, and each one is tailored to describe a very particular cell line and related processes.

The computational methods employed in eukaryotic cell modeling can be split into three groups: mesh-based, particle-based, and combined. Among mesh-based methods, the most popular one is finite element method (FEM). Typically, models exploiting FEM describe only cell mechanics without considering surrounding fluid. Dissipative particle dynamics (DPD) is a particle-based method, which is also used in many models. DPD allows parametrizing the fluid and fluid-structure interactions, while the cell itself is modeled with the help of various many-body potentials. Among combined methods, a well-developed approach is to model the fluid with the Lattice-Boltzmann (LB) method, cells with finite element method (FE), and cell-fluid interactions using immersed boundary (IB) method. We will call this approach LB/IB.

The focus of this review is mechanical eukaryotic cell models. We do not consider cell models used for the tissue modeling; a review of these models can be found elsewhere (Fletcher et al. 2017). The models for cells without nucleus such as red blood cells (RBCs) are also beyond the scope of this review. Overview of recent developments in this field can be found in other chapters of this book. Further, we split the existing eukaryotic cell models into two groups. The first group contains models for the suspended cells which are usually employed to study fluid flow problems. The second group is dedicated to the modeling of the cells in the adherent state.

2.1   Suspended Cell Models

Suspended cells can be of different origin: most of them are blood cells (RBCs, platelets, white blood cells (WBCs)) and mesenchymal stem cells; others are cells of epithelial origin traveling with the blood stream such as circulating tumor cells (CTCs). CTCs are emitted by the primary cancer tumor and can travel long distances to create secondary tumors. Both WBCs and CTCs are bigger and stiffer than RBCs. This leads to the so-called margination, which is a process whereby these cells are displaced to the vessel wall (Nematbakhsh and Lim 2015). An important problem is the detection of CTCs in the blood sample, and numerous microfluidic devices have been developed for this purpose. Devices employing margination, cell rolling, hydrodynamics-induced cell sorting are all studied using models considered in this section.

Perhaps one of the simplest approaches to modeling of the eukaryotic cell is to ignore its internal structure and to apply one of the existing RBC models with altered parameters. The reasoning is that RBC and eukaryotic cell membranes are similar in many aspects and there are several well-established and validated RBC models (Ye et al. 2016). These models usually take into account volume and area conservation, bending resistance, and membrane viscoelastic forces. Such models, coupled with various fluid solvers, capture the effects of cell size and shape and, hence, are often used in simulations of microfluidic devices employing deterministic

lateral displacement principle or cell-free layer formation. The main strength of these models is low computational cost and resolved hydrodynamic interactions in a flow.

In a series of papers, Takeishi et al. modeled the margination of WBCs and CTCs and, in a later work, adhesion of CTCs to vessel walls (Takeishi et al. 2014, 2015) (see Fig. 1a). This development allowed the authors to numerically investigate the effect of the cell size on the flow mode and cell velocity, as well as to identify similarities and differences between WBCs and CTCs. Further, it was found that the bullet motion enables firm adhesion of a cell to the capillary wall (Takeishi et al. 2016). These results suggest that even under the interaction between proteins responsible for WBC rolling, a cell can show firm adhesion in a small capillary. Modeling-wise, Takeishi et al. employed LB/IB method and empty shell cell representation. For validation of the model, simulation results for the deformation of a spherical cell in shear flow were compared with previously published works.

Fedosov et al. also studied WBCs margination, but they, additionally, took into account the effect of RBCs (Fedosov and Gompper 2014) (see Fig. 1b). It was found that WBC margination occurs mainly within a region of intermediate hematocrits and for relatively low flow rates. Moreover, simulations showed that RBC aggregation slightly enhances WBC margination, particularly at the high hematocrit values. DPD method was used to describe fluid and cell particles.

Later, Rossinelli et al. employed a similar DPD-based empty shell model to describe both WBCs and CTCs in two microfluidic devices (Rossinelli et al. 2015). Snapshot of cells squeezing between obstacles mimicking the geometry of the microfluidic devices is shown in Fig. 1c. They demonstrated the applicability of this model for the predictive studies of the performance of microfluidic devices. In particular, the simulation results reproduced the experimentally observed effect of deterministic lateral displacement of bigger cells for the whole blood passing through the array of cylindrical obstacles.

The work by Xiao et al. is dedicated to the mutual effect of rolling CTC in the capillary on the blood flow dynamics (Xiao and Fu 2016a) (see Fig. 1d). By the help of computational modeling of suspended CTC and RBCs, it was demonstrated that, in the microvessel of $15\,\mu m$ diameter, the CTC has an increased probability of adhesion due to a growing wall-directed force. However, with the increase in microvessel size, an enhanced lift force at higher hematocrit detaches the adherent CTC quickly. An increased blood flow resistance in the presence of CTC was also found. Moreover, the significant deformation induced by high flow rate and the presence of aggregation promote the adhesion of CTC. In another work, the same group of authors applied a very similar cell model to investigate an individual cell passing through a narrow slit (Xiao and Fu 2016b). Specifically, they studied the effect of cell size, nucleus, and cell membrane shape on the transmigration through a slit. This model represents the cell and nucleus as an empty shell.

Zhang et al. studied CTC and WBC passing through micro-filtering channels of different shapes (Zhang et al. 2014). In particular, they considered channels with circular, rectangular, and triangular cross sections and inspected pressure signatures
Fig. 1 (**a**) Simulation of a cell adherent to the tube wall (Takeishi et al. 2016). (**b**) Simulation demonstrating WBC margination in the RBC flow (Fedosov and Gompper 2014). (**c**) Cell models squeezing between obstacles in microfluidic device (Rossinelli et al. 2015). (**d**) Snapshot from the simulation of the cell adherent to the wall (blue) together with RBCs (Xiao and Fu 2016a). (**e**) Sketch of a cell passing through a micro-filtering circular channel (Zhang et al. 2014). (**f**) Multicomponent model of eukaryotic cell passing between two constrictions of microfluidic device (Lykov et al. 2017). Nucleus shown in green, cytoskeleton filaments in orange

for CTCs and WBCs passing through this channel. They demonstrated that circular channels feature the highest critical pressure and, thus, are more suitable for cell-separation microfluidic devices (see Fig. 1e). The developed model exploits volume of fluid method, and no subcellular components were explicitly modeled.

Finally, in recent combined experimental and modeling work, Lykov et al. investigated cell mechanics in micropipette aspiration and microfluidic experiments (Lykov et al. 2017) (see Fig. 1f). The mesoscale particle-based model of the eukaryotic cell consisted of a membrane, cytoskeleton, and nucleus. The fluid was discretized using DPD method. The calibration of the model was done using micropipette aspiration experimental data. The model was validated using microfluidic experiments. Authors studied the role of subcellular components and observed that cell cytoskeleton filament density and cross-link concentration could both significantly affect cell resistance to stress. Other results include quantification of the nucleus components contribution and effect of cell viscosity during cell traversal in the microfluidic devices.

Although considered models of suspended cells use different discretization methods, most of them employ a simple empty shell cell representation. This approach can be applied to study flow phenomena in which cell size and shape play a key role. To study a broader class of phenomena, which include severe flow-induced cell deformations, internal structure disruption, and effect of changes in the cytoskeleton due to drug treatment, models that explicitly describe internal cell

components are necessary. The drawback of such models is that they require more complicated parametrization procedure. Increase in computational cost, however, is modest, since it is usually dominated by the cost of flow discretization.

2.2   Adherent Cell Models

The interest in studying processes, which imply significant deformation of the adherent cell and, thus, involve mechanical response of the internal cell components, led to the development of approaches which explicitly model the nucleus and cytoskeleton. Typically, these models use the same hollow sphere model for the cell membrane and, sometimes, the nucleus. The cytoskeleton is modeled by various approaches. These models opened the route to the numerical investigation of such processes as needle microinjection, AFM indentation, cell migration, and deformation in microfluidic devices.

Kardas et al. proposed a computational approach to model the structure of bone cells (Kardas et al. 2013). The model takes into account integrins, nucleus, centrosome, and cytoskeletal proteins (see Fig. 2a). It was shown that the load acting on the nucleus is rising with increasing deformation applied to the integrins. The numerical simulations demonstrated that the nucleus is more affected by stress if the distributions of intermediate filaments and microtubules are random than if they are regular. Computational-wise, FEM was employed to discretize governing equations.

Ujihara et al. presented a cell model to study tensile and compression tests (Ujihara et al. 2010, 2012). The model incorporates a cell membrane, a nuclear envelope, and actin filaments (see Fig. 2b). During the tensile test, it was observed that the total elastic energy of the model is dominated by actin fibers contribution. The compression test revealed that the alignment of bundles of actin filaments significantly affects cell stiffness. In addition, the passive reorientation of actin filament bundles perpendicular to the direction of compression induced an increase in the resistance to the elongation of a cell and, thereby, increased the cell stiffness. Particle-based model was used in simulations utilizing minimum energy concept. It was validated by comparing load-deformation curve with experimental data.

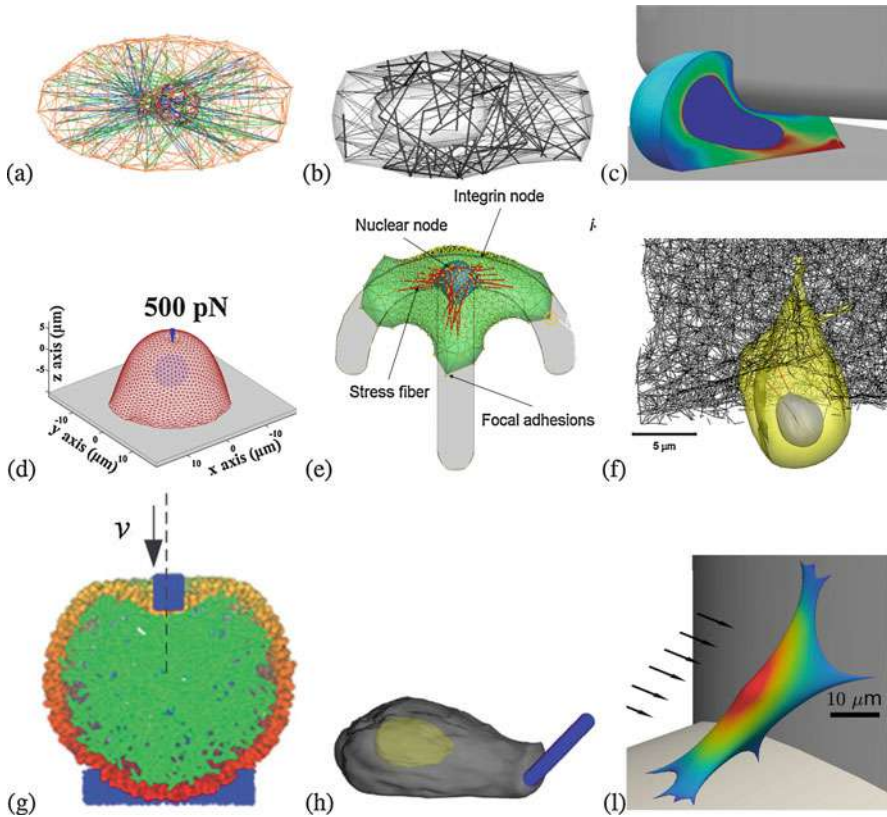
Dowling et al. presented a study of the role of the active remodeling and contractility of the actin cytoskeleton in the response of chondrocytes (cartilage cells) to shear (Dowling et al. 2012) (see Fig. 2c). The key feature of the model is that it incorporates both passive viscoelastic component and active, describing cytoskeleton remodeling. By the help of numerical simulations, the authors showed that a purely passive cell model is incapable of predicting the response of normal chondrocytes to the stress, while adding the cytoskeleton remodeling gives results close to the in vitro study. Interestingly, the passive model can predict drug-treated cells with the disrupted cytoskeleton, which might be considered as evidence that actin cytoskeletal network is the main contributor to the stress resistance during discussed processes. In another paper, where a similar model was used, authors predicted the increased compressive resistance of spread cells compared with round


Fig. 2 (**a**) Cell model taking into account integrins, nucleus, centrosome, and cytoskeletal protein (Kardas et al. 2013). (**b**) Snapshot from simulation of the tensile test (Ujihara et al. 2010). (**c**) Simulation of the probe indentation process; color map depicts average stress fiber activation levels (Dowling et al. 2012). (**g**) Simulated cell microinjection: green particles represent cytoskeleton, blue rectangular is needle tip, and yellow-orange particles represent cell membrane. (**h**) Deformation of the plasma and nuclear membranes induced by micropipette pulling (Zeng et al. 2012). (**d**) Snapshot from AFM experiment simulation for adherent cell (Fang and Lai 2016). (**i**) Snapshot from simulation of the cell attached to the walls of the bioreactor; the flow direction is shown with arrows; the shear stress distribution is depicted with color (Guyot et al. 2016)

cells (Ronan et al. 2012). The nucleus and membrane were represented in the model as a passive hyperelastic material, while ODE described the cytoskeleton remodeling. The equations were discretized with the help of FEM.

Fang and Lai studied changes in the cell mechanics as cell shifts from suspended to the adherent state (Fang and Lai 2016). The model consists of cell membrane, nucleus envelope, and three internal networks representing microtubules, F-actin, and intermediate filaments. In addition, it takes into account the movement of

adhesion molecules which allows simulating cell spreading. In order to estimate the cell model elastic modulus, simulation of AFM experiment was employed (see Fig. 2d). The force-indentation relationship was used to determine the mechanical changes in cells during state shift. The explicit modeling of the subcellular components allowed to investigate the impact of different cell components on the resistance to the external stress and to examine the effect of nucleus presence on the AFM results. The model was validated by comparing the AFM simulation results with the experimental data.

Kim et al. developed a model to predict cell migration behavior on 2D and 3D curved surfaces (Kim et al. 2012). The model takes into account focal adhesion dynamics, actin motor activity, as well as cytoskeleton remodeling and nucleus (see Fig. 2e). The simulations revealed that cell migration speed depends on the cross-sectional area of the microfluidic channel. The relationship between migration speed and the channel width agreed with the experimental data. This model was also applied to study cell migration on 2D micropatterned geometries (Kim et al. 2013). The further development of the model allowed prediction of cell invasion into a 3D extracellular matrix (ECM) in response to different extracellular biochemical cues (Kim et al. 2015) (see Fig. 2f). The new model takes into account filopodia penetration dynamics. The average filopodia speed was predicted, and cell membrane advance velocity agreed with experiments of 3D HUVEC migration for diverse ECMs with different pore sizes and stiffness.

By the help of numerical modeling, Liu et al. predicted the cell damage induced by the needle during the microinjection procedure (Liu et al. 2015a). In particular, authors quantified the effects of the size, shape of the microinjector tip, and injection velocity on cell damage. The proposed model is based on DPD method. It explicitly describes cell membrane as well as the cytoskeleton and motor activity. To validate the model, authors measured the mechanical properties of the model using the particle-tracking microrheology. The cell model showed power law behavior in terms of mean square displacement and lag time. The mechanical moduli obtained from the simulations were in agreement with the experimental data.

Zeng et al. applied cell model to study the role of the actin cytoskeleton network in mechanotransduction and nucleus deformation (Zeng et al. 2012). In the experiment simulated in this work, a micropipette is pushed into the cytoplasm of an endothelial cell and then pulled away at a constant rate. Authors showed that the stress propagation through the random cytoskeletal network could be a mechanism to effect nucleus deformation, without invoking any biochemical signaling activity. It was reported that nucleus strain varies in a sigmoidal manner with actin filament concentration, while there exists an optimal concentration of actin-binding proteins that maximize nucleus displacement. In addition, a theoretical analysis for these nonlinearities in terms of the connectivity of the random cytoskeletal network was provided. Particle-based model was employed, which explicitly describes cell membrane, nucleus envelope, and cytoskeletal actin network. The simulation results were validated using experimental data.

Guyot et al. modeled an adherent cell in the bioreactor subjected to the shear stress due to the fluid flow (Guyot et al. 2016). The simulations were used to estimate

shear stress experienced by cells as a function of the bioreactor inlet flow velocity. The authors showed that the shear stress values predicted by their model are different from shear stress obtained with the help of empty scaffolds model, which is often used as a reference. The proposed model can be applied to optimize the bioreactor geometry and flow conditions as well as to provide insight into the cell deformation during these processes. With the help of LB/IB method, the cell was simulated as an empty shell with the elastic nucleus inside. To estimate elastic properties of the cell, micropipette aspiration experiments were used.

The most important common feature of the models considered in this section is that they take into account, besides of nucleus envelope and cell membrane, mechanics of the cytoskeleton. Due to that, such models can describe more accurately changes in the cell during different mechanical tests as well as cytoskeleton-related processes. Additionally, these models give an insight into the impact of subcellular components during particular experiments.

3   Conclusion

The range of applications of eukaryotic cell models is expanding rapidly. Suspended cell models are now widely used in studies of behavior and deformations of cells in various microfluidic devices and blood circulation. In turn, adherent cell models provide an insight into cell mechanics when cells are subjected to mechanical stress or during migration in the extracellular matrix. Majority of suspended cell modeling approaches employ empty shell representation of the cell, which narrows the applicability of these models to problems with moderate cell deformations. The drawback of the existing adherent cell models is their specialization on a very particular phenomenon for a specific cell type.

All of the models considered in this review follow the top-down or phenomenological approach (Kollmannsberger and Fabry 2011). The mechanical properties of the cell model components are not obtained by considering the properties of the material at the microscopic or molecular level. Instead, the choice of model and parametrization for the subcellular components is based on general principles and macroscopic properties of the cell. An alternative bottom-up or reductionist method assumes gradual development of the model starting from the very accurate models of all constituents. At the very moment, there is a lack of experimental and theoretical knowledge to follow the latter approach. Future developments will allow construction of eukaryotic cell models by rigorously linking mechanical behavior of the entire cell with the properties of its molecular constituents, connecting cell chemistry and mechanobiology.

Abstract

Malaria is a parasitic disease which takes approximately half a million lives every year. The unicellular parasites are transmitted by mosquitoes and mainly affect vascular blood flow by invading red blood cells (RBCs). The pathogenicity of malaria primarily results from substantial changes in the stiffness of infected RBCs and their ability to adhere to endothelial cells and other circulating blood cells, leading to a substantial disruption of normal blood circulation and inflammation of the vascular endothelium. Multiscale modeling of malaria has proved to contribute significantly to the understanding of this devastating disease. In particular, modeling on the level of single infected RBCs allows quantification of their mechanics, cytoadherence, and individual as well as collective behavior in blood flow. Recent modeling advances in this direction are discussed. We show how computational models in malaria are validated and used for the interpretation of experimental observations or the establishment of new physical hypotheses. Such computational models have a strong potential to elucidate a number of physical mechanisms relevant for malaria and to aid in the development of novel diagnostic tools and treatment strategies.

1 Introduction

Malaria is a mosquito-borne disease caused by *Plasmodium* parasites (Miller et al. 2002). These are unicellular eukaryotic cells whose continuous battle with humans has left a larger imprint on our genome than any other infectious diseases. There exist several *Plasmodium* species, including *P. falciparum*, *P. vivax*, *P. ovale*, *P. malariae*, and *P. knowlesi*, which cause very different disease severity. *P. falciparum* (Pf) is considered to be the most dangerous form of the disease with several hundred thousand deaths per year worldwide. The life cycle of a parasite is schematically illustrated in Fig. 1. Motile sporozoites are injected into the human skin during a mosquito blood meal. After entering the bloodstream, the sporozoites travel to the liver and infect hepatocytes. Within about 2 weeks, tens of thousands of merozoites form and are then released into the bloodstream, where they invade red blood cells (RBCs). Following RBC invasion, merozoites multiply inside infected RBCs (iRBCs) for about 48 h and finally rupture the RBC membrane (Abkarian et al. 2011), releasing around 20 new merozoites into the bloodstream. At the same time, some merozoites develop into the sexual form called gametocytes, which can be taken up from the blood by mosquitoes. These gametocytes infect female mosquitoes, where they first develop in the gut and later move to the salivary glands. This completes the life cycle of malaria parasites.

Infection of RBCs by malaria parasites leads to significant stiffening of the iRBC membrane for the case of Pf parasites (Cranston et al. 1984; Diez-Silva et al. 2010). Membrane stiffening can be moderate for other malaria species. The intraerythrocytic development of Pf parasites includes three major stages, called ring
Fig. 1 The life cycle of malaria parasites. A mosquito infects a human host during a blood meal (stage 1). Then, malaria parasites in the form of sporozoites use blood vessels to reach the liver. They infect hepatocytes, develop into merozoites, and finally rupture the liver cells and enter the bloodstream again (stage 2). The merozoites invade RBCs, where they progress through the asexual intraerythrocytic stages, including ring, trophozoite, and schizont forms. Finally, RBCs are ruptured and new merozoites are released into the bloodstream, closing the asexual cycle in the blood (stage 3). Sexual forms are also produced in the blood (stage 4), which are taken up by a mosquito (stage 5), resulting in its infection and development in the gut (stage 6). They again become sporozoites and move to the salivary glands (stage 1), thus closing the malaria life cycle. From National Institute of Allergy and Infectious Diseases (NIAID)

(0–24 h), trophozoite (24–36 h), and schizont (40–48 h). During this development, the RBC membrane can stiffen by up to a factor of ten in comparison with healthy RBCs (Diez-Silva et al. 2010; Fedosov et al. 2011b). In addition, at the schizont stage iRBCs attain a near-spherical shape, since the parasites change the osmotic pressure inside the iRBC and also because they fill more and more of its volume.

The stiffening and shape change of iRBCs impair their ability to deform and may lead to capillary occlusions (Cranston et al. 1984; Shelby et al. 2003).

Inside iRBCs, merozoites remain virtually invisible to the immune system. However, the membrane stiffening can be detected in the spleen, where RBCs have to squeeze through narrow slits as a part of the RBC quality control system (Engwerda et al. 2005; Pivkin et al. 2016). In order to survive at the late stages (trophozoite and schizont), parasites position adhesive proteins at the RBC membrane surface, which mediate cell adhesion to the endothelium (Brown et al. 1999; Miller et al. 2002). This mechanism delays or even prevents the passage of iRBCs through the spleen, allowing enough time for parasites to develop and rupture the cell membrane. Interestingly, the adhesive system induced by the parasite is similar to the way white blood cells (WBCs) adhere in the vasculature as a prerequisite for extravasating into the surrounding tissue, e.g., in the context of an infection (Helms et al. 2016). While WBCs use hundreds of microvilli with adhesive tips, iRBCs use thousands of adhesive knobs. In both cases, the protrusion from the surface seems essential to make contact with the endothelium (Korn and Schwarz 2006). Cytoadhesion is also the main reason for the absence of the late stages of iRBCs in patient blood samples, because adhesive cells remain immobile in the microvasculature. While cytoadhesion facilitates further progression of malaria, it has a strong potential for severe disruption of normal blood flow. Infected cells at the late stages are able to adhere not only to the vascular endothelium but also to other infected and healthy RBCs. Adherence of iRBCs is likely to be the main cause of bleeding complications in cerebral malaria due to blockages of small vessels in the brain (Adams et al. 2002). Cytoadherence also leads to inflammation of the vascular endothelium, which is an important part of the symptoms of the disease (Miller et al. 2002).

In this chapter, we focus on modeling various aspects of the malaria disease, using a multiscale computational framework. At the current stage, the multiscale approach to malaria already spans all relevant levels: from molecular aspects of RBC remodeling by the parasite to cell-level changes in mechanics and cytoadherence of iRBCs, and to the flow of many RBCs in complex geometries. Computational models are validated by comparison with a growing range of single-cell experiments under healthy and diseased conditions. Here, we discuss all levels of the multiscale problem of the blood stage of malaria. In particular, we discuss how the RBC is remodeled by the parasite. We then address modeling of RBC mechanics and the changes it experiences over the course of intraerythrocytic parasite development. Simulations of parasite invasion of RBCs and the cytoadherence of iRBCs at the late stages are described. Finally, we also review numerical efforts to understand blood rheology and flow in malaria and illustrate several microfluidic examples which can be utilized as novel devices for malaria detection and diagnosis. The computational modeling has proved to be a valuable tool in elucidating involved physical and biological mechanisms in malaria, and we discuss possible future steps, which can bring realistic simulations closer toward medical applications.

2   Methods and Models

2.1   Structure of Healthy and Infected Red Blood Cells

Healthy human RBCs have a biconcave shape with approximately 7.5–8.7 μm in diameter and 1.7–2.2 μm in thickness (Fung 1993). The RBC envelope consists of a phospholipid bilayer and a network of spectrin proteins (cytoskeleton) attached at the inner side of the bilayer via transmembrane proteins; see Fig. 2a. The spectrin network supplies shear elasticity to a RBC membrane, while the lipid bilayer serves as a barrier for exchange of solutes and provides resistance to bending and viscous damping when sheared. Human RBCs neither have organelles nor bulk cytoskeleton and are filled with a highly concentrated hemoglobin solution. Viscosity of the cytosol is about 6×10^{-3} Pa·s, while the plasma viscosity is approximately 1.2×10^{-3} Pa·s at a physiological temperature of 37 °C (Wells and Schmid-Schönbein 1969). Thus, the cytosol viscosity is about five times larger than that of the plasma under physiological conditions.

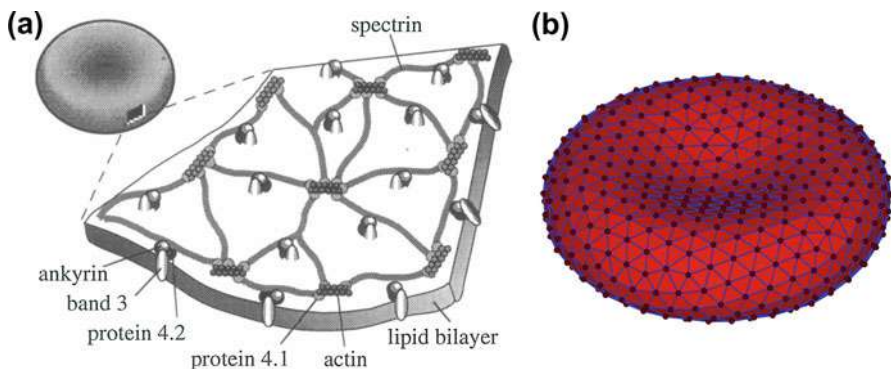
In comparison to healthy cells, iRBCs contain a growing parasitic body inside them. Furthermore, after the end of the ring stage or about halfway through the asexual cycle, the iRBC membrane starts developing adhesive protrusions on its surface, known as knobs, which are responsible for cytoadhesion. Knobs have been visualized using scanning electron microscopy (SEM) (Gruenberg et al. 1983) and atomic force microscopy (AFM) (Nagao et al. 2000; Quadt et al. 2012) during the different stages of the life cycle. These experiments have shown that the formation of knobs is strain-dependent and variable, with a density of about 10–30 knobs/μm² at the trophozoite stage and around 40–60 knobs/μm² at the schizont stage. The


Fig. 2 (**a**) A schematic of the RBC membrane structure, showing the spectrin cytoskeleton being anchored to the lipid bilayer by transmembrane proteins (Reproduced with permission from Hansen et al. 1997). (**b**) Mesoscopic representation of a RBC membrane by a triangular network of mechanical bonds. For iRBCs, adhesive bonds are anchored at the vertices of this network (Reproduced with permission from Fedosov et al. 2014)

height of knobs remains nearly constant around 10–20 nm, while the knob diameter decreases from 160 to 100 nm (Gruenberg et al. 1983), when iRBCs progress from the trophozoite to the schizont stage.

2.2   Overview of Hydrodynamic Methods

Modeling blood flow in malaria requires mathematical formulations for fluid flow on the one side and blood cell shape and mechanics on the other side. Both blood plasma and RBC cytosol can be considered to be viscous Newtonian fluids. For microcirculatory blood flow, we deal with hydrodynamics at low Reynolds numbers, and therefore the Stokes equation has to be solved to describe fluid flow. For WBCs and iRBCs in the schizont stage, a spherical cell shape can be assumed and analytical solutions are available for the Stokes equation (Cichocki and Jones 1998). For the standard case of non-spherical RBCs, however, numerical approaches have to be employed. Fluid flow can be simulated by a variety of methods including continuum approaches based on the Navier-Stokes equations (Wendt 2009) and particle-based simulation methods, such as smoothed particle hydrodynamics (Monaghan 2005), dissipative particle dynamics (Pivkin et al. 2011), and multi-particle collision dynamics (Gompper et al. 2009). Even though continuum techniques are often faster and more robust than particle-based methods, certain features such as thermal fluctuations and the inclusion of suspended complex structures (e.g., molecules and cells) are better suited for particle-based methods. Therefore, particle-based methods are very popular for the modeling of the dynamics of complex fluids such as blood.

2.3   Adhesive Dynamics of Spherical Cells

Modeling the motion of spherical cells, such as WBCs and iRBCs at the schizont stage (Helms et al. 2016; Dasanna et al. 2017), is mathematically much simpler than the motion of cells with a non-spherical shape. Adhesive dynamics of a spherical cell in shear flow can be described by the Langevin equation (Hammer and Apte 1992; Korn and Schwarz 2007) as

$$\partial_t X(t) = u^\infty + M\{\mathbf{F}_S + \mathbf{F}_D\} + k_B T \nabla M + \xi(t), \tag{1}$$

where $X(t)$ is a six-dimensional vector describing sphere translation and rotation, M is the mobility matrix, u^∞ is the imposed flow, and $\mathbf{F}_S$ and $\mathbf{F}_D$ denote shear (i.e., from fluid flow) and direct (e.g., gravity, adhesion) forces and torques, respectively. The term with ∇M is a non-zero spurious drift, since the mobility matrix depends on the sphere position. The last term $\xi(t)$ corresponds to a random force which represents thermal fluctuations and obeys the fluctuation-dissipation theorem with an equilibrium temperature T.

For cell adhesion, stochastic bond dynamics is modeled between receptors on the cell surface and ligands at the substrate. Bond association and dissociation are governed by on- and off-rates, k_{on} and k_{off}, respectively. Usually k_{on} is taken to be constant, and a bond with the rate k_{on} may form between a receptor and a ligand if the distance between them is less than a specified encounter distance r_0. For an existing bond, Bell's equation $k_{off} = k_{off}^0 \exp(F/F_d)$ (Bell 1978) is used to model that most bonds dissociate faster under force F, with an internal force scale F_d. Mechanically, a bond is assumed to be a harmonic spring with a spring constant k_s and equilibrium bond length ℓ_0. The probability for bond association and dissociation is calculated as $P = 1 - \exp(-k\Delta t)$, where Δt is the time step employed in simulations.

2.4   Modeling Cell Deformation

In the general case of a non-spherical cell shape, hydrodynamic flow has to be combined with a deformable cell model. RBCs are modeled by a flexible network of springs with triangular elements (Seung and Nelson 1988; Noguchi and Gompper 2005; Fedosov et al. 2010), as shown in Fig. 2b. The free energy of the membrane is defined as

$$U_{cell} = U_s + U_b + U_{a+v}, \tag{2}$$

where U_s is the spring's potential energy to impose membrane shear elasticity, U_b is the bending energy to represent bending rigidity of a membrane, and U_{a+v} stands for the area and volume conservation constraints, which mimic area incompressibility of the lipid bilayer and incompressibility of the cytosol, respectively. Linear properties of a regular hexagonal network can be derived analytically, providing a relation between the model parameters and the membrane macroscopic properties (Seung and Nelson 1988; Fedosov et al. 2010). Similar to the adhesive dynamics for spherical cells, receptors can be placed at the spring network and on- and off-rates can be used to model adhesive interactions with the substrate (Fedosov et al. 2011a, b). More details on blood cell and flow modeling can be found in recent reviews (Li et al. 2013; Fedosov et al. 2014; Freund 2014).

3   Results

3.1   RBC Shapes and Mechanics

The biconcave shape of RBCs is controlled by the relative ratio between their membrane area and cell volume and by the membrane elastic properties. The volume of a RBC is about 35–40% smaller than the volume of a sphere with the same surface area. Thus, the reduced volume of a RBC is normally in the range between 0.6 and 0.65. Lipid vesicles with this reduced volume attain a biconcave shape which

closely resembles that of RBCs (Seifert et al. 1991). In comparison to vesicles, RBC membrane also possesses shear elasticity supplied by the spectrin network. This mechanical component is important to prevent budding of vesicles from the RBC membrane and membrane rupture under very large deformations. Therefore, the equilibrium shape of RBCs in general is determined by a minimum energy of both bending and shear-elastic contributions (Lim et al. 2002).

For both contributions to the Hamiltonian, it is not clear what the appropriate reference state should be. In case of the bending energy, it is important to consider whether a membrane has spontaneous curvature, especially because the RBC membrane is known to have very different compositions in the inner and outer leaflets. Most existing RBC models (Noguchi and Gompper 2005; Fedosov et al. 2010) assume the spontaneous curvature to be zero. A large enough spontaneous curvature can lead to a variety of different shapes (e.g., stomatocyte, echinocyte) and change the importance of bending and shear-elastic contributions (Lim et al. 2002). However, questions whether a human RBC membrane possesses a non-zero spontaneous curvature and whether this curvature would be isotropically distributed on the RBC surface still remain unanswered.

The reference state for the shear-elastic energy is generally referred to as stress-free shape of a RBC (Peng et al. 2014). It appears plausible to assume the biconcave shape of RBCs as the stress-free shape, because transmembrane proteins, which connect the spectrin network and the lipid bilayer, are able to diffuse within the bilayer, leading to a potential relaxation of existing elastic stresses. However, recent simulations (Peng et al. 2014) show that the assumption of biconcave stress-free shape leads to an incorrect prediction of the transition from tumbling dynamics to tank-treading dynamics of a RBC in shear flow. On the other hand, the assumption of a spherical stress-free shape results in a stomatocytic shape of the membrane for physiological values of RBC bending rigidity and shear elasticity (Li et al. 2005). An assumption of a spheroidal stress-free shape close to a sphere seems to be able to resolve these issues (Peng et al. 2014).

The mechanical properties of RBC membranes have been measured by a number of single-cell experimental techniques, including micropipette aspiration (Waugh and Evans 1979; Discher et al. 1994), deformation by optical tweezers (Henon et al. 1999; Suresh et al. 2005), optical magnetic twisting cytometry (Puig-de-Morales-Marinkovic et al. 2007), and three-dimensional measurement of membrane thermal fluctuations (Popescu et al. 2007; Park et al. 2008). Optical tweezers and micropipette aspiration methods apply a strong global deformation to the RBC membrane, while optical magnetic twisting cytometry and measurements of membrane thermal fluctuations correspond to local measurements. The two former techniques allow a measurement of the macroscopic shear modulus of a RBC membrane. Figure 3 presents a comparison between the deformation of a healthy RBC by optical tweezers (Suresh et al. 2005) and the corresponding numerical simulations (Fedosov et al. 2010). The numerical simulations mimic experimental conditions and allow the quantification of observed RBC deformation. A best fit (black line) between simulations and experiments is achieved for the two-dimensional (2D) Young's modulus of $Y = 18.9\,\mu$N/m and 2D shear modulus
Fig. 3 Stretching response of a healthy RBC and iRBCs for different stages compared with the optical tweezers experiments (Suresh et al. 2005). D_A and D_T refer to the axial and transverse diameters (Reused with permission from Fedosov et al. 2011b)

of $\mu = 4.73\,\mu\text{N/m}$. Note that this value of the shear modulus is in 2D such that $\mu \approx Y/4$, while Fedosov et al. (2010) provide a 3D value with $\mu \approx Y/3$.

Optical magnetic twisting cytometry (Puig-de-Morales-Marinkovic et al. 2007) allows the measurement of local rheological properties (e.g., the complex modulus) of a RBC membrane. Complex modulus consists of storage and loss moduli, which are determined by elastic and viscous properties of the membrane, respectively. Therefore, both bending rigidity and shear elasticity affect the storage modulus, while the loss modulus is associated with the viscosity of a membrane, cytosol, and suspending medium (Fedosov et al. 2010). Simulations performed to quantify the experimental data (Puig-de-Morales-Marinkovic et al. 2007) have yielded a value of $\kappa = 3 \times 10^{-19}$ J for the bending rigidity (about $70 k_B T$) and $\eta_m = 2.2 \times 10^{-8}$ Pa·s·m for the membrane viscosity (Fedosov et al. 2010). Measurements of membrane thermal fluctuations (Popescu et al. 2007; Park et al. 2008) are directly associated with the membrane characteristics; however, their reliable interpretation for RBCs still remains difficult. There exist large discrepancies between different studies, which are likely to originate from the approximations used in analytical models derived for planar and near-spherical membranes (Strey et al. 1995; Betz and Sykes 2012). Hence, a quantitative interpretation of fluctuation measurements requires reliable and accurate simulation models of a RBC.

A number of experiments with RBCs provide sufficient evidence for a complex membrane mechanical response including its unique viscoelastic properties. In addition, it has been recognized that RBCs possess a metabolic activity through the consumption of adenosine triphosphate (ATP), which contributes to measured membrane flickering. The studies with ATP depletion (Betz et al. 2009; Park et al. 2010) have shown that membrane fluctuations decrease; however, during the ATP depletion process, there is no guarantee that RBCs are not subject to changes in membrane elasticity. In contrast, another investigation (Evans et al. 2008) has questioned the effect of ATP on measured flickering. A recent experimental and simulation study (Turlier et al. 2016) has provided compelling evidence for cell activity by testing directly the fluctuation-dissipation relation, which is valid for any system in equilibrium. A violation of the fluctuation-dissipation relation has been shown, and a contribution of active processes to the observed membrane flickering has been demonstrated (Turlier et al. 2016).

3.2   Mechanics of RBC Invasion by a Parasite

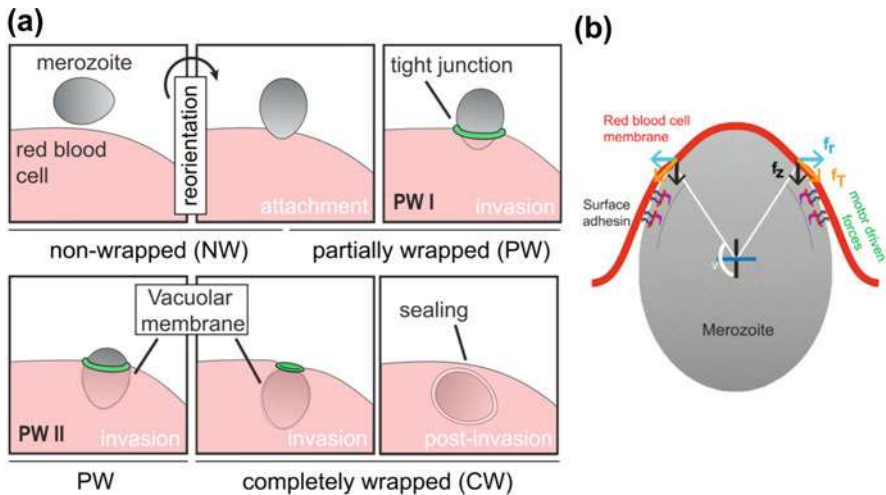
The first important step in the blood cycle of malaria is the invasion of RBCs by merozoites. Conceptually, this process can be divided into discrete steps, as shown schematically in Fig. 4a. Invasion commences with a low-affinity,


Fig. 4 (**a**) The stages of merozoite invasion. Schematic representation depicting different wrapping phases of the merozoite from reorientation and attachment through two partially wrapped states (with different wrapping fractions) to post-invasion. (**b**) Actomyosin force supports merozoite invasion. f_T is the force acting tangentially along the membrane surface as it wraps along the particle, whereas f_z is the component of this tangential force along the z axis whose role is to inject the particle into the membrane, while the component f_r is balanced by an equal force at the other side of the membrane (Reprinted with permission from Dasgupta et al. 2014b)

long-range (12–40 nm), and nondirectional binding of a RBC by the merozoite, which then reorients such that its apex directly contacts the RBC. Then, formation of a close-range interaction (4 nm or less) leads to the establishment of a RBC-merozoite tight junction. This critical structure is the organizing nexus around which invasion events are orchestrated. It acts as the aperture through which the merozoite passes during invasion and segregates RBC membrane from an emerging vacuolar membrane (likely derived in part from the parasite membrane), which fuses to form the parasitophorous vacuole surrounding the parasite after invasion (Cowman et al. 2012).

The merozoite has a shape, very similar to a chicken egg, with a width-to-length ratio of 0.7, but with a characteristic length of only 2 μm (Dasgupta et al. 2014b). The adhesion and wrapping of spherical (Deserno 2004; Bahrami et al. 2016) and non-spherical (Dasgupta et al. 2013, 2014a) nano- and microparticles by membranes have been investigated quite intensively in recent years (Dasgupta et al. 2017). These theoretical and numerical approaches provide the basis for the modeling of merozoite invasion. Particles are expected to adhere to a membrane with its least-curved side, because this configuration provides the largest adhesion area with the lowest cost in membrane deformation energy. Therefore, the reorientation of the merozoite for apical invasion requires a nonuniform adhesion energy, with an adhesion maximum at the apex. This could be facilitated by a transient gradient of adhesive proteins from apex to base on the merozoite surface (Cowman et al. 2012). Once the tight junction has been formed, the wrapping of the merozoite is controlled by four energetic contributions: (i) the adhesion strength, (ii) the membrane bending rigidity and its spontaneous curvature, (iii) the lateral tension of the RBC membrane, and (vi) the effective line tension of the tight junction. Different invasion scenarios can be discussed on the basis of such a model (Dasgupta et al. 2014b). Obviously, if the adhesion strength is very large (or small) and the membrane tension is very low (or high), complete wrapping will always (or never) occur. Large adhesion strengths allow immediate complete wrapping and RBC entry, but might also be associated with unspecific binding to other membranes and problems associated with membrane surface-coat shedding. Thus, the most interesting scenario is where these various contributions nearly balance each other. Also, this scenario for merozoite invasion is plausible, because merozoites can successfully enter RBCs, but not with certainty. As an example, phase diagrams for parasite wrapping from Dasgupta et al. (2014b) show that for a fixed line tension, there is a non-wrapped state for small, reduced adhesive strength, two partial-wrapped states for intermediate adhesion, and a complete-wrapped state for large adhesive strength. The parasite can navigate in the phase diagram to move from the non-wrapped to the complete-wrapped state. For instance, it can move between the partial-wrapped states (shallow wrapped and deep wrapped) by reducing the membrane tension through secretion of unstructured lipids. There is indeed experimental evidence for such a process, the discharge of lipids from the rhoptry organelles (Hanssen et al. 2013; Bannister et al. 1986). Similarly, a change of the spontaneous curvature to a value more favorable for wrapping (e.g., by detachment of the spectrin cytoskeleton from the bilayer or its reorganization

Kabaso et al. 2010) can induce a transition from the deep-wrapped to complete-wrapped state.

It is important to note that the transitions from shallow- to deep-wrapped states and from deep- to complete-wrapped states are associated with large energy barriers. Even though the complete-wrapped state is energetically favorable, it might be difficult to reach it from the deep-wrapped state. Thus, it is conjectured that the barrier crossing is facilitated by active processes. Indeed, there is a long-standing experimental evidence that activity of the parasite actomyosin motor governs successful host-cell entry (Angrisano et al. 2006). The current model for the source of parasite active motor force (see Fig. 4b) posits that an anchored myosin motor inside the parasite (tethered to the RBC cytoskeleton) transmits force directly through a short polymerized actin filament, which is linked to the surface-bound adhesins (Baum et al. 2006). The height of energy barrier obtained from the wrapping model described above now allows an estimate of the magnitude of the required motor activity, which indicates that a few 10s to a few 100s of motor proteins should suffice. Thus, even when membrane-wrapped states are stable, the essential role of the motor lies in overcoming energy barriers between the partial-wrapped and complete-wrapped states.

3.3 RBC Remodeling During Infection

The shapes of iRBCs can be measured, for example, by fluorescence confocal microscopy, and from these data surface area and volume can be deduced. An early study with restricted time resolution has reported relatively constant values (Esposito et al. 2010), in contrast to a colloid-osmotic model, which predicts the total volume of iRBCs to increase dramatically in the later stages (Lew et al. 2003; Mauritz et al. 2009). To resolve this issue, Waldecker et al. (2017) have reconstructed iRBC shapes over the whole intracellular cycle with a time interval of 4 h. Figure 5a shows typical shapes of iRBCs at different times, including the shape of the parasite inside. At the ring stage, the parasite is located at the rim of iRBC, causing a little bump along the edge of the cell. Starting from the trophozoite stage, parasite begins to multiply and the overall parasitic volume increases. At the end of the life cycle, iRBC reaches a nearly spherical shape with around 20 parasites inside the cell. The corresponding changes in the iRBC and parasite volume are quantified in Fig. 5b. The experimental measurements agree well with the predictions of the colloid-osmotic model, which are shown by solid lines (Mauritz et al. 2009; Lew et al. 2003). While the volume increases by 60%, the surface area remains nearly constant throughout the life cycle.

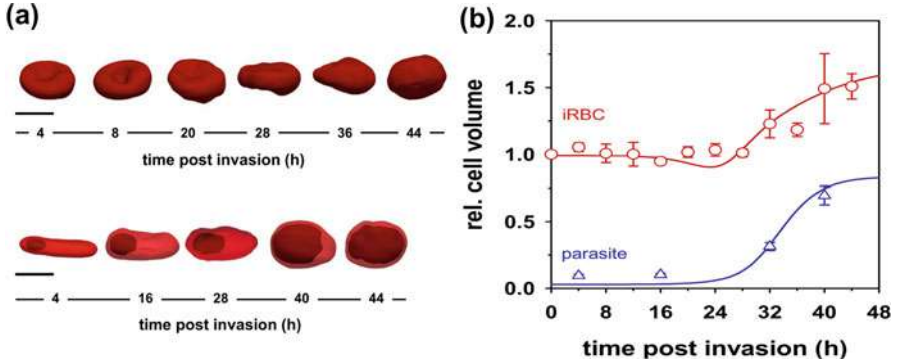
Starting around the midpoint of development, iRBCs induce adhesive protrusions at the membrane, which significantly modify the structure of the iRBC cytoskeleton. Shi et al. (2013) performed AFM imaging of inverted iRBCs to study the changes in the spectrin network during infection, as shown in Fig. 6a. The average length of spectrin filaments is found to be 43 ± 5 nm for healthy RBCs, whereas for the ring stage, the spectrin-filament length becomes about 48 ± 7 nm. For the


Fig. 5 (**a**) Reconstructed shapes from confocal images of iRBCs at different times of the parasite development. The bottom row shows the shapes of a growing parasite inside the iRBC at various times. Scale bar is $5\,\mu m$. (**b**) Relative cell volume and parasite volume as a function of post-infection time. The solid lines are predictions by the osmotic colloid model (Reused with permission from Waldecker et al. 2017)
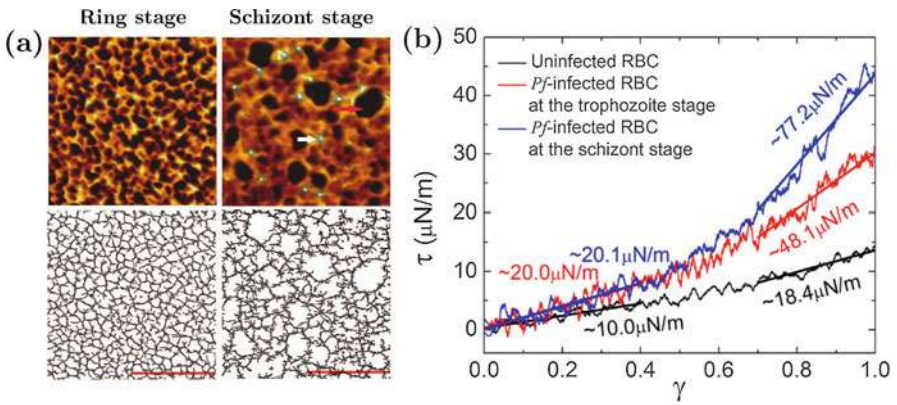

Fig. 6 (**a**) AFM images of spectrin cytoskeleton and image-processed representations for ring and schizont stages. Scale bar is 500 nm. The red arrow in schizont AFM image indicates a hole region, while the white arrow points to a knob Reused with permission from Shi et al. 2013). (**b**) Shear stress-strain response curves for uninfected and infected RBCs from mesoscopic model of RBC membrane (Reused with permission from Zhang et al. 2015)

middle trophozoite stage, the length is $64 \pm 9\,nm$, and for the schizont stage, it is about $75 \pm 11\,nm$, which is roughly twice the spectrin length of healthy RBCs. In addition, spectrin filaments are found to accumulate at the knob areas, but they become sparser in non-knobby areas. Zhang et al. (2015) have studied the effect of knobs and enhanced coupling between plasma membrane and spectrin network using coarse-grained simulations based on these observations. Knobs were modeled as stiff regions of plasma membrane, and coupling between the plasma membrane and spectrin network was increased at the knobby areas. Simulation

of the strain response of this composite membrane to shear stress results in the estimation of shear modulus for uninfected and infected RBCs. Figure 6b shows shear stress-strain response curves for uninfected, trophozoite, and schizont stages with the 2D shear moduli (at large shear strains) $\mu \simeq 18\,\mu\text{N/m}$, $\mu \simeq 48\,\mu\text{N/m}$, and $\mu \simeq 78\,\mu\text{N/m}$, respectively, which are close to values reported in experiments (Suresh et al. 2005). In general, the simulations show strong strain-hardening effects, presumably due to the polymer nature of the spectrin.

3.4 RBC Mechanics During Infection

Progressive stiffening of iRBCs has been measured by optical tweezers (Suresh et al. 2005) and by diffraction phase microscopy through monitoring thermal fluctuations (Park et al. 2008). Figure 3 shows a comparison of RBC stretching between simulation results for healthy and infected RBCs at different stages and experimental results (Suresh et al. 2005). Fitting of RBC stretching in simulations to the experimental data leads to 2D shear moduli $\mu = 14.5\,\mu\text{N/m}$ for the ring stage, $\mu = 29\,\mu\text{N/m}$ for the trophozoite, and $\mu = 40\,\mu\text{N/m}$ for the schizont (Fedosov et al. 2011b). Note that the geometry of an iRBC at the schizont stage is taken to be of ellipsoidal shape with the axes $a_x = a_y = 1.2a_z$, which is not very far from a sphere. Taking a biconcave shape for the schizont stage in simulations results into a prediction with a larger shear modulus than that for the near-spherical shape. In the case of the deflated biconcave shape, the form of an iRBC is altered first in response to stretching and followed by membrane deformation, while for the near-spherical shape, the fluid restricts shape deformation and membrane stretching has to occur right away. In conclusion, the cell geometry plays an important role in the quantification of experimental data.

3.5 Adhesion of Infected Cells

Adhesion of iRBCs lies at the heart of parasite survival, as it prevents elimination of iRBCs in the spleen. Adhesive receptors on iRBC surface (PfEMP-1 encoded by the family of var genes) are localized to the knobs and can bind multiple ligands (mainly ICAM-1 and CD36) on vascular endothelial cells. The precise roles of different ligands in iRBC adhesion are quite complex, as the knob receptors bind to the various ligands with distinct adhesion strength (Yipp et al. 2000). For instance, experiments with flow assays hint at an increase of ICAM-1 adherence of iRBCs with shear stress (i.e., displaying characteristics of a catch bond), while CD36 does not show this behavior (Nash et al. 1992). Enhancement of adhesion under flow is not uncommon for cells in shear flow, including WBCs and bacteria, and has been demonstrated for iRBCs adhering to supported bilayers (Rieger et al. 2015). Experiments using single-bond force spectroscopy (Lim et al. 2017) have shown that iRBCs form slip bonds with CD36 and catch bonds with ICAM-1, as suggested before by flow chamber experiments. The characteristic rupture force for

both slip and catch bonds is close to 10 pN, which is also comparable with the force for WBC bonds in the range of 10–50 pN (Marshall et al. 2003; Hanley et al. 2004). On the modeling side, the slip bond can be simulated by Bell's model (Bell 1978), while the catch bond is often described by Dembo's model (Dembo et al. 1988).

The standard model for the adhesion of single cells under flow has been established with adhesive dynamics for round cells. Originally developed for WBCs (Hammer and Apte 1992; Korn and Schwarz 2007), this approach has recently been applied to iRBCs at the schizont stage (Helms et al. 2016; Dasanna et al. 2017). A phase diagram with different dynamic states (free motion, transient adhesion, rolling adhesion, and firm adhesion) has been simulated for the slip-bond model as a function of molecular on- and off-rates (Korn and Schwarz 2008; Helms et al. 2016), which can serve as a reference case to interpret experimental data. In the rolling adhesion regime, rolling velocity as a function of shear rate can be used to estimate molecular data. Hence, it has been estimated that ICAM-1 receptor distance should be between 100 and 400 nm to yield the observed rolling velocity around 100 μm/s at a shear rate of about $100\,s^{-1}$ (Dasanna et al. 2017).

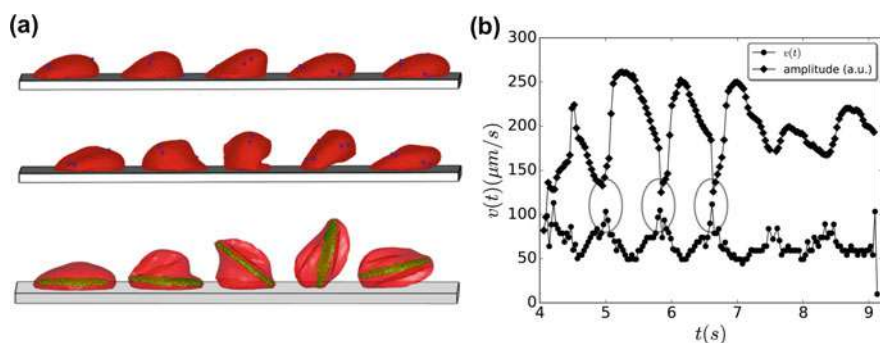
An interesting aspect of iRBC adhesive motion is the nature of single trajectories, which often displays an oscillatory pattern in velocity and has been studied both numerically and in experiments (Fedosov et al. 2011a; Dasanna et al. 2017). Unlike WBCs, iRBCs have a non-spherical shape for the majority of parasite's life cycle, except the schizont stage. Mesoscopic modeling of iRBCs (Fedosov et al. 2011a) has demonstrated that cells at the trophozoite stage flip rather than roll on a substrate because of their discoid shape. For a Young's modulus similar to that of healthy RBCs, crawling motion is observed, while a large enough Young's modulus (more than three times that of healthy RBCs) leads to a rather regular flipping motion. The flipping may become less regular with the presence of parasite inside the cytosol


Fig. 7 (**a**) Snapshots of modeled flipping iRBCs with a small membrane Young's modulus (top), a large Young's modulus (middle), and, when it contains a rigid body, imitating the presence of parasite (bottom) (Reused with permission from Fedosov et al. 2011a). (**b**) Representative trajectory of a rolling trophozoite cell on endothelial layer, showing cell velocity and fluorescence intensity of the parasite inside the iRBC (Reused with permission from Dasanna et al. 2017)

(Fedosov et al. 2011a). Figure 7a shows snapshots of RBC motion for the three cases: (top) a crawling cell with a Young's modulus of $Y = 18.9\,\mu\text{N/m}$, (middle) a flipping iRBC with a Young's modulus of $Y = 168\,\mu\text{N/m}$, and (bottom) a flipping cell with a parasite body inside. Dasanna et al. (2017) have studied rolling adhesion of iRBCs at the trophozoite and schizont stages on endothelial cells in flow chamber experiments. The effect of the parasite on the iRBC rolling dynamics has been investigated, and therefore both the iRBC and fluorescently labeled parasite were tracked. Figure 7b presents translational velocity and fluorescence amplitude of the parasite inside the iRBC for a rolling trophozoite. The elliptic markings of the peaks in velocity and fluorescence amplitude indicate the anticorrelation between them, which is significant for flipping. Thus, when the iRBC starts a flip, the parasite moves away from the substrate (fluorescence amplitude thereby decreases), and when it comes down, the fluorescent amplitude increases. It has been also shown that this anticorrelation disappears and the fluorescent amplitude does not oscillate for iRBCs at the schizont stage, as they are round and rigid, so that the flipping transforms to rolling. Rolling velocities of schizont-stage iRBCs are found to be smaller than those of trophozoites, presumably because of the larger number of knobs (Dasanna et al. 2017).

3.6 Blood Rheology in Malaria

Bulk viscosity of blood is a macroscopic characteristic that depends on single-cell properties and their collective interactions (Fedosov et al. 2011d; Lanotte et al. 2016). The bulk viscosity of blood in malaria increases with the parasitemia level (or fraction of iRBCs) because of the increased stiffness of iRBCs (Raventos-Suarez et al. 1985) in comparison to healthy RBCs. A significant viscosity increase leads to an increased blood flow resistance and a reduced blood perfusion. Numerical simulations (Fedosov et al. 2011b) predict an increase of blood flow resistance in microvessels in malaria up to 50% for high parasitemia levels.

Bulk viscosity of infected blood in malaria for different parasitemia levels, hematocrit 30%, and shear rate $230\,\text{s}^{-1}$ has been measured experimentally (Raventos-Suarez et al. 1985) and estimated in simulations (Fedosov et al. 2011c), as shown in Fig. 8. In the simulations, infected blood is modeled as a suspension of healthy and infected RBCs at the schizont stage with $\mu = 40\,\mu\text{N/m}$. The simulated viscosity as a function of the parasitemia is in excellent agreement with the corresponding experimental data, which show a roughly linear dependence of the infected blood viscosity on parasitemia level.

iRBCs adhere not only to the endothelium but also to other healthy and infected RBCs. Simulations with attractive interactions between infected and healthy RBCs for the parasitemia of 25% show that the blood viscosity does not increase significantly (see Fig. 8). This is likely due to the fact that the simulated shear rate is high enough to disperse RBCs within the suspension and to diminish aggregation effects on the bulk viscosity. Thus, a much stronger effect of the aggregation

Fig. 8 Viscosity of the malaria-infected blood at hematocrit 30% for different parasitemias in comparison to experimental data (Raventos-Suarez et al. 1985). The diamond symbol corresponds to a simulation with aggregation interactions among RBCs (Reused with permission from Fedosov et al. 2011c)
interactions should be expected at low shear rates. Furthermore, iRBCs at later stages form specific bonds with other cells, which should generally be stronger than the attractive interactions modeled by Fedosov et al. (2011c).

3.7   Blood Flow in Malaria

It is intuitive that blood flow resistance in malaria should increase due to an elevated stiffness of iRBCs and their cytoadherence. A simple model for the estimation of blood flow resistance is Poiseuille flow of blood in tubes, which mimics blood flow in microvessels. Blood flow in malaria has been simulated as a suspension of healthy and infected RBCs at the trophozoite stage ($\mu = 29 \, \mu\text{N/m}$) and hematocrit 45%. Figure 9 shows the relative apparent viscosity in malaria for several parasitemia levels from 25% to 100% and microvessels with diameters $10 \, \mu\text{m}$ and $20 \, \mu\text{m}$. The relative apparent viscosity is computed as $\eta_{\text{rel}} = \eta_{\text{app}}/\eta_s$, where η_s is the plasma viscosity and $\eta_{\text{app}} = \pi \Delta P D^4/(128 Q L)$ is the apparent viscosity. Here, ΔP is the pressure difference, Q is the flow rate, and L is the length of the tube. The relative apparent viscosity is a measure of flow resistance, as it compares apparent viscosity of blood with the viscosity of blood plasma.

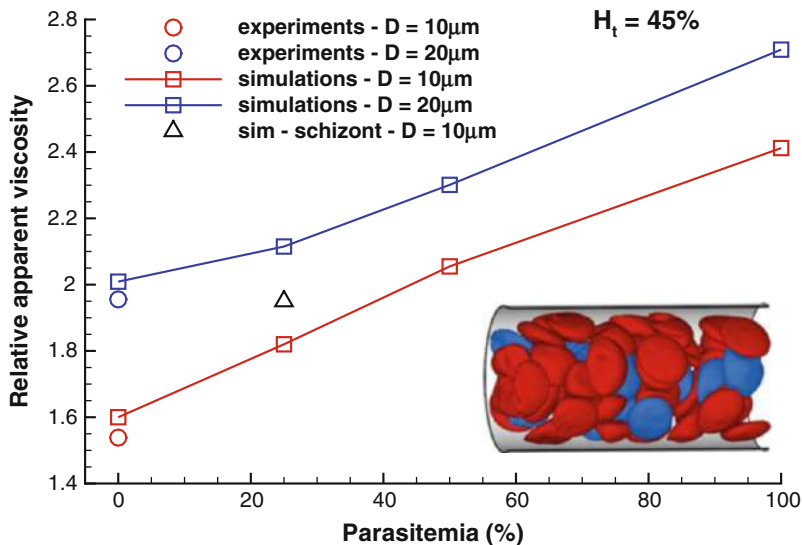
The inset of Fig. 9 shows a snapshot of RBCs flowing in a tube of diameter $20 \, \mu\text{m}$ at a parasitemia level of 25%. The effect of parasitemia level on the flow resistance in Fig. 9 appears to be more prominent for small diameters and high hematocrit values. Thus, at $H_t = 45\%$ blood flow resistance in malaria may increase up to 50% in vessels of diameters around $10 \, \mu\text{m}$ and up to about 40% for vessel diameters around $20 \, \mu\text{m}$. Note that these increases do not include any contributions from the adhesive interactions between iRBCs and other cells. Therefore, the inclusion of cytoadhesion would result in a further increase in blood flow resistance in malaria.


Fig. 9 Flow resistance in malaria. Healthy (red) and infected RBCs (blue) in tube flow with a diameter $D = 20\,\mu m$, hematocrit 45%, and parasitemia 25%. The relative apparent viscosity of blood in malaria is plotted for various parasitemia levels and tube diameters. Triangle symbol corresponds to the schizont stage with a near-spherical shape. Experimental data from the empirical fit are from Pries et al. (1992)

3.8 Malaria and Microfluidics

Microfluidic devices offer unique opportunities for the detection and manipulation of different suspended particles and cells. One of the first observations of iRBCs in microfluidics is a study of the passage of iRBCs through small constrictions driven by fluid flow (Shelby et al. 2003). The experiments have been performed for different channel sizes and stages of parasite development and have shown that the late stages, such as trophozoite and schizont, may result in blockage of microvessels with diameters smaller than about $6\,\mu m$. Corresponding simulation studies (Imai et al. 2010; Wu and Feng 2013) have also come to a similar conclusion, suggesting that the smallest vessel in the microvasculature can be blocked by single iRBCs in the trophozoite and schizont stages.

The filtration concept has been also employed in another microfluidic device with many obstacles (Bow et al. 2011), where both healthy and infected RBCs are able to pass constriction geometries (no blockage is observed). However, iRBCs exhibit lower average velocities in comparison to healthy RBCs. This speed difference between healthy and infected RBCs is attributed to an increased membrane stiffness and viscosity of the iRBCs in comparison to healthy cells. Deformability-based sorting has been also proposed in the context of deterministic lateral displacement (DLD) microfluidic devices (Henry et al. 2016; Krüger et al. 2014). DLDs utilize micropost arrays, which have been originally designed to continuously sort spherical
Fig. 10 Stroboscopic images of RBC deformation in a DLD device, taken from simulations and experiments. The viscosity contrast C between the cell's cytosol and suspending medium, which is (**a**) $C = 5$ and (**b**) $C = 1$, affects RBC dynamics and determines its traversal through the device (Reused with permission from Henry et al. 2016)

colloidal particles according to their size (Davis et al. 2006; Holm et al. 2011). However, DLDs do not directly follow the filtration concept, because the gaps between the posts are generally larger than suspended cells, as shown in Fig. 10. Sorting in DLDs is achieved by invoking differences in cell deformation and dynamics, which determine the trajectories of the cells within DLD devices (Henry et al. 2016; Krüger et al. 2014). For example, in Fig. 10, the differences in RBC trajectories within the DLD device are governed by different viscosity contrasts between the RBC cytosol and suspending medium. Hence, a proper tuning of DLD device geometry and flow conditions can turn them into accurate and precise deformability-based sensors useful in the context of malaria.

4   Discussion and Outlook

The development of quantitative models for malaria infections is very important, because they allow the explanation of experimental results, the testing of various hypotheses, and the proposition of new biophysical mechanisms in disease development and progression. Due to the long evolutionary history of malaria and its complicated life cycle, this is not an easy task and it requires close cooperation between theoreticians and experimentalists. In particular, future studies have to further incorporate molecular information, for example, the molecular details of how the spectrin network is remodeled by the parasite, and the exact nature of the adhesion receptors localized to the knobs and their ligand counterparts in the vascular endothelium.

From the conceptual point of view, the most important aspect of malaria modeling is the multiscale nature of blood flow, which involves a wide range of spatiotemporal scales starting from single molecules for parasite-RBC interactions and the adhesion of iRBCs, to the deformation and dynamics of single cells, and, finally, to multicellular flow in large microvascular networks. Current models have proven to be sophisticated enough to be used successfully for the quantification of

experiments with a few blood cells. Computational models of blood flow rapidly move to multicellular problems and already attempt to go beyond experimental predictions by generating and testing new physical and biological hypotheses. Thus, such simulations can be used to guide and optimize experimental settings for biophysical investigations and disease diagnosis (e.g., microfluidic devices).

Modeling of the malaria disease is very challenging, and many open questions remain, even in the context of the advances achieved over recent years, ranging from molecular mechanisms to cell deformation and adhesion under realistic blood flow conditions in the microcirculation. For instance, it is not fully understood how parasite can efficiently reorient itself after the initial random adhesion and then invade RBCs. Furthermore, exact changes and modifications of RBC membrane stiffness and cytoadherence by the parasite during its development need to be determined. In addition, it is unclear how the developing parasite, which can be thought of as a rigid-like body inside a RBC, affects the cell behavior in flow. Another important direction for future research concerns the characterization of the adhesive interactions between iRBCs and healthy RBCs, other blood cells (e.g., WBCs), and the endothelium, as this input is needed for realistic malaria modeling. Answers to these open questions for a single cell will allow the progression toward realistic modeling of blood flow in malaria, where a mixture of healthy and infected RBCs at different stages and complex flow geometries have to be generally considered.

Even though the impact of numerical modeling on malaria diagnosis and treatment is still rather limited, the development of new quantitative models and their application in practice acquire more and more momentum. Computational models have a great potential to provide guidance on how to improve disease detection and treatment and to optimize existing therapeutic tools, for instance, by introducing novel microfluidic approaches. Another substantial advancement needed for computational models is the development of predictive simulation approaches, which enable the modeling of long-time disease progression. This development requires the improvement of current models to much longer time scales including the ability of modeling various dynamic processes (e.g., parasite invasion, intra-RBC parasite development, dynamic adhesion changes).

Abstract

Sickle cell anemia is a genetic blood disorder exhibiting heterogeneous cell morphology, decreased deformability, and abnormal adhesion. The primary pathogenic event of the disease is the intracellular nucleation and polymerization of sickle cell hemoglobin followed by sickling of red blood cells that result in vaso-occlusive crises and other pathophysiological aspects of the disease. In this chapter, we present the morphological, rheological, and adhesive properties of sickle cells and their relevance to the vaso-occlusion under physiological conditions.

Fig. 1 Vaso-occlusive crisis in SCA. The polymerization of HbS molecules causes cell sickling and damage to the cell membrane. The abnormal, sickle-shaped RBCs obstruct microcapillaries and restrict blood flow leading to vaso-occlusion

1 Introduction

Sickle cell anemia (SCA) is a genetic disorder of the blood that draws its name from the abnormal sickled shape of the affected red blood cells (RBCs) (Pauling et al. 1949; Gravitz and Pincock 2014). It afflicts about 100,000 individuals in the United States and millions of people worldwide (Modell and Darlison 2008). In addition, SCA is one of the most common cause of stroke in children. Despite modern health care and technology, the average lifespan of an individual with SCA in the United States still only hits 40–50 years. Patients with SCA have significant morbidity and reduced quality of life as a result of stroke, frequent painful vaso-occlusive crisis events, and other serious clinical complications such as acute chest syndrome (Bunn 1997; Barabino et al. 2010).

The origin of SCA has been traced to the intracellular polymerization of sickle cell hemoglobin (HbS) under deoxygenation conditions (Hofrichter et al. 1974; Noguchi and Schechter 1981), causing a substantial increase in intracellular viscosity and elastic stiffness as well as a severe damage to RBC membrane (Samuel and Briehl 1990; Liu et al. 1991). The affected sickle RBCs (SS-RBCs) become stiff, sticky, and abnormally shaped, so they tend to get stuck in the microcirculation, thereby clogging blood flow (Kaul et al. 1989; Kaul and Fabry 2004) (Fig. 1). Here, we present experimental and computational studies related to morphological, rheological, and adhesive properties of RBCs in SCA.

2 Intracellular Polymerization of Sickle Hemoglobin

SCA is characterized as the first molecular disease (as early as 1947 by Linus Pauling) (Pauling et al. 1949), being linked to the mutation of a single nucleotide, from glutamate to valine, in the hemoglobin molecule. The HbS polymerization has been characterized by a double nucleation mechanism (Ferrone et al. 1985a, b; Vekilov et al. 2008). According to this mechanism, the HbS polymerization process is initiated by homogeneous nucleation in solution and followed by heterogeneous

nucleation on preexisting HbS polymer fibers (Ferrone et al. 1985a, b). A different two-step nucleation mechanism has also been proposed (ten Wolde and Frenkel 1997; Shiryayev and Gunton 2004; Lutsko and Nicolis 2006): first, formation of a dense liquid droplet and, then, formation of HbS fiber nuclei inside the liquid droplet. Consequently, HbS polymer fibers grow spontaneously and distort the RBCs into abnormal sickle shape.

Numerical models provide valuable insights into the molecular mechanism of HbS fiber nucleation and polymerization. Here, we briefly describe a few of the major achievements. A precursory work was presented by Turner and co-workers (2006), who proposed a theoretical model of HbS polymer fibers and demonstrated that twist plays an essential role in stabilizing the polymerized fibers. Yang et al. performed Metropolis Monte Carlo simulations of self-assembled filamentous bundles (Yang et al. 2010). They found that the molecular chirality and attractive interactions can control the assembly size of HbS polymer fibers. Li and Lykotrafitis employed a coarse-grained particle-based HbS model to investigate the mechanical properties of HbS polymer fibers (Li and Lykotrafitis 2011; Li et al. 2012). They demonstrate that HbS polymer fiber frustration and compression play a critical role in fiber zipping and unzipping dynamics.

To provide new details of how SCA manifests inside RBCs, we have developed a mesoscopic patchy particle HbS model to study the polymerization of HbS and the fiber growth dynamics (Lu et al. 2016). In the patchy particle model, an HbS molecule is modeled by a rigid spherical particle with three patches on its surface, representing the locations of double-stranded contact sites among HbS molecules (Fig. 2a). In addition, to model the helical twist effect, we consider an angle-bending potential of two adjacent HbS particles within the same strand (Fig. 2b). The corresponding potential is taken as

$$V_a = k_a(\theta - \theta_0)^2, \quad V_l = k_l(\beta - \beta_0)^2, \tag{1}$$

where k_a and k_l are the bending constant and $\theta = \cos^{-1}(\hat{\mathbf{p}}_i \cdot \hat{\mathbf{p}}_j)$ and $\beta = \cos^{-1}(\hat{\mathbf{q}}_i \cdot \hat{\mathbf{q}}_j)$ are the instantaneous angles between the axial vectors ($\mathbf{p}_i$ and $\mathbf{p}_j$) and lateral vectors ($\mathbf{q}_i$ and $\mathbf{q}_j$) of these two adjacent HbS particles (Fig. 2b), respectively. This HbS model was then employed to simulate the HbS polymerization with pre-existing HbS nuclei (Fig. 2c), showing that the growth dynamics of HbS polymer fiber is achieved by the addition of HbS monomers.

The study of intracellular HbS polymerization and consequent RBC sickling provides an important basis for understanding the implications and treatment routes of SCA; however, modeling the integrated process from HbS fiber nucleation and polymerization to RBC sickling and then to vaso-occlusion is challenging due to the multiple temporal and spatial scales of the entire process. To make progress toward understanding the integrated processes, in a follow-up study, we proposed a hybrid HbS fiber model, by coupling the aforementioned microscopic patchy particle model with a mesoscopic HbS polymer fiber model (Lu et al. 2017). In this proposed multiscale hybrid model, the function of microscopic patchy particle model is to simulate the dynamic polymerization process of HbS molecules,
Fig. 2 Mesoscopic modeling of polymerization of HbS. (**a**) Molecular structure of sickle cell hemoglobin (*upper*) and the corresponding patchy particle model (*lower*). (**b**) Double-stranded structure of HbS filament (*left*) with its representation within patchy particle model. (**c**) HbS filament polymerized from HbS particles. (**d**) Interaction of two growing HbS fibers. (**e**) Modeling fiber bundle and domain formation. (Reproduced with permission from Lu et al. 2016, 2017)

whereas the mesoscopic fiber model represents the major body of HbS polymer fiber. In addition, the hybrid HbS fiber model undergoes a dynamics coarse-graining process during HbS polymerization through a mesoscopic adaptive resolution scheme (MARS). As a result, the hybrid method reduces the computational cost by reducing the number of degrees of freedom in the HbS polymer fiber model. Herein, it can be used to simulate the HbS polymer fiber growth and branching process. As an attempt, we applied the hybrid HbS fiber model to simulate the growth dynamics of two interacting HbS polymer fibers (Fig. 2d) and fiber-branching process of multiple HbS polymer fibers (Fig. 2e), which shows that the fiber-fiber orientation and interaction range play key roles in determining the structural and mechanical properties of HbS polymer fibers and filament bundles.

3   Biorheology of Sickle RBCs and Sickle Cell Blood

As shown in the previous section, SS-RBCs exhibit abnormal shapes due to the interaction between intracellular HbS polymer and the cell membrane. Furthermore, SS-RBC suspensions exhibit abnormal rheology and hemodynamics (Usami et al. 1975; Kaul et al. 1983; Kaul and Xue 1991; Kaul and Liu 1999) due to the heterogeneous cell morphology and elevated cell rigidity (Evans et al. 1984; Itoh et al. 1995). In this section, we employ the constructed SS-RBC model to investigate the abnormal rheology and hemodynamics of SS-RBC suspension under shear and tube flow.

Since the collective properties of the SS-RBC suspension is mainly determined by the cell morphology and rigidity, we ignore the modeling of intracellular HbS polymer on molecular level. Alternatively, we directly model the interaction between the intracellular polymer and the cell membrane as the stretching force applied on the cell membrane exerted by the growing HbS fibers. As shown in Fig. 3, the letters "A," "B," "C," and "D" represent four anchor points where the intracellular growing fibers can potentially approach the cell membrane. Depending on the MCHC, the intracellular HbS polymer may exhibit different configurations. Accordingly, as the growing HbS fibers may approach the cell membrane from multiple directions, various stretching forces are applied on the four anchor points. Detail simulation parameters are summarized in Table 1.

With the constructed SS-RBCs of various morphologies, we investigate the abnormal rheology of SS-RBC suspension in shear flow. We first consider the shear flow system with hematocrit Hct = 45% following the previous experiment (Usami et al. 1975). The viscosity of blood plasma is chosen to be $\eta_0 = 1.2$ cp. Figure 4

Fig. 4 Shear viscosity of the healthy blood and SS-RBC suspensions with Hct = 45%. The dash lines represent the fitted curve to the simulation result by $\eta = be^{-a/\gamma^{0.5}} + c$, where γ is the shear rate. a, b, and c equal to $1.43\,s^{-1/2}$, $-6.04\,cp$, and $8.78\,cp$ for healthy blood and $1.08\,s^{-1/2}$, $-5.5\,cp$, and $23.9\,cp$ for deoxygenated SS-RBC suspension. The inset plot shows a snapshot of the "granular" SS-RBCs in shear flow (From Lei and Karniadakis 2012)
shows the viscosity computed for both healthy and diseased blood under different shear rates. For both types of blood, good agreement with the experimental results is obtained. It is well-known that healthy blood behaves as non-Newtonian fluid with shear-dependent viscosity (Fedosov et al. 2011). Under high shear rate, blood cells undergo large deformation with fluid properties pronounced; in contrast, blood cells behave as solid-like and less deformed under low shear rate conditions, resulting in relatively higher viscosity. Therefore, the viscosity of healthy blood increases as the shear rate decreases, as shown in Fig. 4. On the other hand, the deoxygenated SS-RBC suspension shows elevated viscosity values, which are nearly independent of the shear rate. This result is mainly due to the largely elevated cell rigidity; the deoxygenated SS-RBC cannot be deformed under the high shear rate employed in the experiment (Usami et al. 1975). Therefore, SS-RBCs exhibit "solid" behavior throughout the entire shear rate regime, leading to this transition from non-Newtonian to Newtonian flow.

Furthermore, experimental studies show that the rheology of SS-RBC suspension further depends on the morphology of the SS-RBCs. Kaul et al. investigated the shear viscosity of SS-RBC suspensions subjected to both fast and gradual deoxygenation procedures (Kaul and Xue 1991) that were measured. Two distinct stages were observed for SS-RBC suspensions subjected to the fast deoxygenation. The shear viscosity of the SS-RBC suspensions exhibits fast elevation within the first 7 min of deoxygenation accompanied with the cell morphology transition to granular shape. However, the shear viscosity gradually decreased during increased deoxygenation, accompanied with a large portion of cells transitioned into extremely elongated shape with the intracellular HbS fibers aligned in one direction. In contrast, SS-RBC suspensions subjected to gradual deoxygenation procedure showed monotonic elevation of shear viscosity and the formation of the sickle shape of blood cells over a period of 30 min until the full deoxygenated state was achieved. Following this experimental study, we computed the shear viscosity of SS-RBC suspensions with the three distinct types of sickle cell reported in the experiment (Hct = 40%). Figure 5 shows the shear viscosity values under shear rate from 25 to 75 s^{-1} with similar cell rigidity applied to all the three types. Similar to Fig. 4, the SS-RBC suspensions show shear-independent Newtonian behavior. Moreover, shear viscosity further depends on individual cell shapes, with the value 13.8, 13.1, and 9.6 cp for the granular, sickle, and elongated shape, respectively. The simulation results are consistent with the experimentally observed progressive decrease of the viscosity during the increased deoxygenation, since a large portion of granular
Fig. 5 Shear viscosity of the sickle blood flow with different cell morphologies reported in Kaul and Xue (1991), Hct = 40% (From Lei and Karniadakis 2012)

cell transforms into the elongated shape during the procedure. This result reveals the heterogeneous "effective volume" among the different types of SS-RBC under the shear flow system (Kaul and Xue 1991). Given the same Hct, heterogeneous cell morphologies may further affect the momentum transport between the cells, resulting in different shear viscosity values.

Next, we further examine the hemodynamics of SS-RBC suspensions in an isolated vasculature with different cell groups. While the oxygenated SS-RBC suspensions exhibit hemodynamics similar to healthy blood flow, the deoxygenated SS-RBC suspensions show heterogeneous hemodynamics among the different cell groups. Similar to the experimental study (Kaul et al. 1983), we simulate SS-RBC suspensions in a tube flow system with Hct = 30%. We set the diameter of the tube to $9.0\,\mu m$ as in capillary flow, since the detailed size and topology information of the microvasculature for the experiment are unknown. In this sense, we do not expect the apparent viscosity obtained from the simulation to match exactly with the experiment results. Instead, we focus on the effect of different SS-RBCs groups on the flow resistance in the microcirculation.

Deoxygenated blood flow is modeled as a suspension of SS-RBCs with sickle and granular shapes, where the same cell rigidity is applied to both cell groups. The viscosity of the cytosol is set to $4\eta_0$ and $50\eta_0$ for the healthy and deoxygenated blood flow, where $\eta_0 = 1.2\,cp$ is the viscosity of the blood plasma. The increase of the flow resistance for the sickle and granular shapes under different oxygen tensions is shown in Fig. 6a. While SS-RBC suspension of both cell groups shows further increased flow resistance at deoxygenated state, the granular type of blood flow shows a more pronounced elevation compared with the sickle shape. This result is also consistent with the experimental study of SS-RBCs transiting in a micro-fluidic channel conducted by Du et al. (2015). Figure 6b shows the transit velocities of individual SS-RBCs with different cell morphologies (discocyte, oval, sickle) through a periodic array of obstacles ($4\,\mu m$ between the two obstacles). The cell group of the "sickle" shape exhibits the largest cell velocity.

One possible explanation for the above result, as proposed by Kaul et al., is the different orientational distribution of SS-RBCs in the capillary: a cell of sickle shape tends to flow along the axis of the tube as also observed by La Celle et al. in experimental studies in LaCelle (1977). This is consistent with the inset snapshots of the sickle and granular cells in Fig. 6a. To quantify this phenomenon, we computed the *cell orientation angle distribution* for different cell groups in the tube flow, as shown in Fig. 7. The cell orientation is defined by the angle θ between the flow direction and the eigenvector of the gyration tensor V_1 defined by

$$G_{mn} = \frac{1}{N_v} \sum_i (r_m^i - r_m^C)(r_n^i - r_n^C), \tag{2}$$

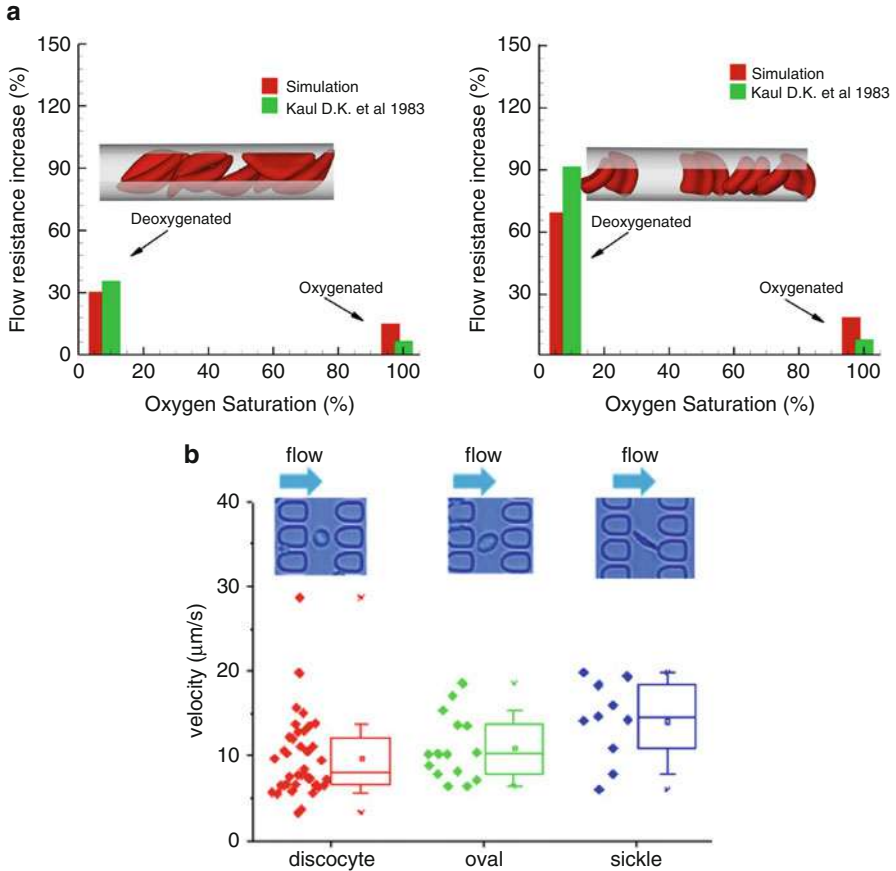
where r^i is the coordinate of RBC vertex i, r^C is the center-of-mass coordinate, and m and n represent the x, y, or z direction. λ_1, λ_2, and λ_3 represent the three eigenvalues obtained from the gyration tensor, where $\lambda_1 < \lambda_2 < \lambda_3$. Compared with the granular cell, the orientation angle of the sickle cell shows a wider distribution


Fig. 6 Top: increase of the flow resistance induced by the sickle blood flow for both granular and sickle shapes. The inset plot shows a snapshot of the sickle cells in the tube flow. Bottom: experimental study on SS-RBC cell transition velocity for different cell morphologies through a periodic array of obstacles in the microchannel, provided by Du and Dao at MIT (From Lei and Karniadakis 2012)

for larger value, indicating that the sickle-shaped SS-RBCs are more likely to orient along the flow direction, which results in a lower flow resistance compared with the granular cells.

Finally, we note that the simulation of SS-RBC suspension in tube flow does not induce blood occlusion in the present study. We performed several sets of simulations with different combinations of cell rigidities and cytosol viscosity; however, no full occlusion was observed in any of these simulations. Moreover, the sickle-shaped SS-RBC, the widely believed precursor of the vaso-occlusion crisis, actually may result in lower flow resistance than other cell groups. We note that this is mainly due to the omission of the cell-endothelium adhesive interaction in the present study; we address this issue in the next section.

Fig. 7 Cell orientation angle distribution $f(\theta)$ for healthy, sickle, and granular cells in pipe flow. The cell orientation is defined by the angle θ between the flow direction (x) and the eigenvector $V1$ of the gyration tensor, as shown in the inset plot (From Lei and Karniadakis 2012)
4 Adhesive Properties of Sickle RBCs

Vaso-occlusion crisis may trigger serious stroke or death for SCA patients. Early experimental studies suggested that this crisis is triggered by the blockage of single sickle/elongated SS-RBC in capillaries; later studies (Kaul et al. 1989, 1994; Kaul and Fabry 2004; Barabino et al. 2010) have shown that vaso-occlusion mainly occurs in post-capillaries (the microvasculatures following the capillaries). Moreover, some studies demonstrated that there exists no direct correlation between the percentage of the dense SS-RBCs and the disease severity (Ballas et al. 1988). Recent studies further revealed that vaso-occlusion is a complex process triggered by the interactions between multiple cell groups (Ballas and Mohandas 2004; Chiang and Frenette 2005; Turhan et al. 2002). In this section, we employ computational approach to explore the mechanism of the vaso-occlusion in SCA.

4.1 Adhesive Dynamics

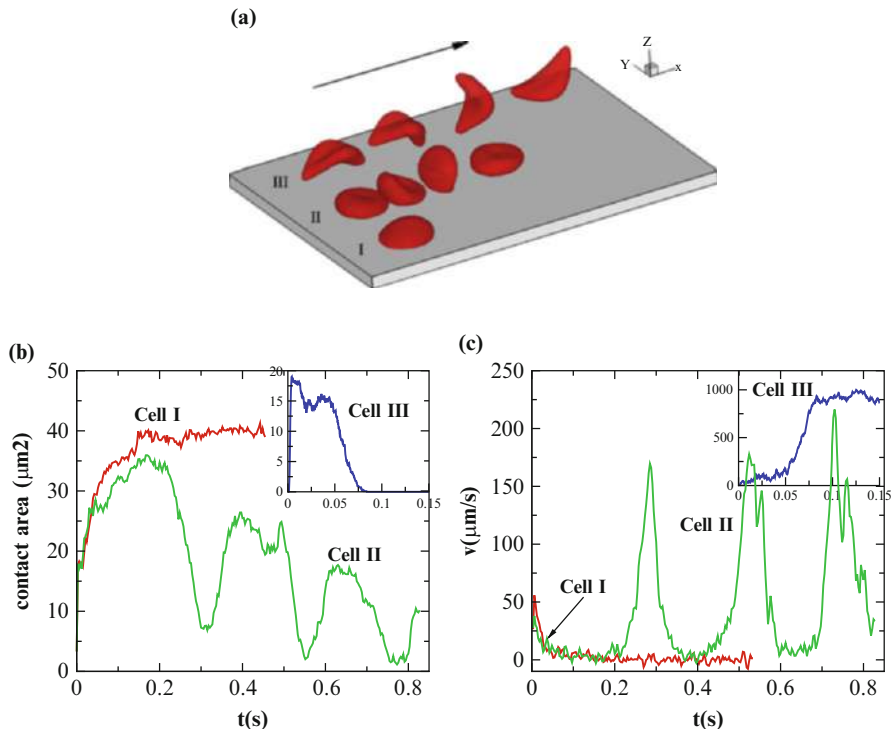
In vitro studies by Barabino et al. (1987) show that SS-RBCs exhibit heterogeneous cell adhesivity among different density groups. The light density group shows the largest adhesion, while the densest irreversible sickle cells (ISCs) show the least adhesion. Ex vivo studies by Kaul et al. (1994) further examined the alteration of SS-RBC adhesivity after a dehydration/rehydration treatment on individual cell groups and found that the cell adhesivity of the deformable SS2 and the dense SS4 cells can be reversed after controlled treatment. They suspected that different cell groups have similar "adhesion potential," while the heterogeneous cell adhesivity is


Fig. 8 Sickle cells in shear flow: (**a**) successive snapshots of SS-RBCs in shear flow. The labels I, II, and III correspond to a deformable SS2 cell, rigid SS3 cell, and ISC, respectively. The arrow indicates the flow direction. (**b–c**) Instantaneous contact area and velocity for SS-RBC in shear flow conditions (From Lei and Karniadakis 2013)

mainly attributed to the different cell morphological and biomechanical properties among the multiple cell density group. Accordingly, we investigate this hypothesis by simulating the adhesive dynamic of SS-RBCs with different cell rigidities and morphologies.

As shown in Fig. 8, we consider three different SS-RBCs under shear flow. Cell I represents a SS2 deformable discocyte. The cell rigidity is similar to the healthy RBC, and we set the shear modulus $\mu_0 = 6.8\,\mu N/m$ and bending rigidity $k_{c0} = 2.4 \times 10^{-19}$ J, i.e., similar to healthy cell rigidity (Hupert and Baumann 2003; Mills et al. 2004; Suresh et al. 2005). Cell III represents an ISC generated through the deoxygenation-reoxygenation process; we set the shear modulus $\mu = 10\,\mu_0$ following (Itoh et al. 1995; Clark et al. 1980). Modification to cell bending rigidity in the deoxygenation-reoxygenation process is unknown; here we set $k_c = 10k_{c0}$ and also conduct sensitivity studies. Cell II represents a rigid discocyte (Evans and Mohandas 1987) with medium MCHC value; we set $\mu = 3\,\mu_0$ and $k_c = 3k_{c0}$ for the comparative study.

Following Kaul et al. (1994), we assume that the three cells have similar "adhesive potential" and set identical adhesive parameters. With the same shear rate $\dot{\gamma} = 192\,\text{s}^{-1}$, the three cells exhibit substantially different adhesive dynamics as shown in Fig. 8a. Cell I exhibits firm adhesion to the lower plate with contact area around $40.5\,\mu\text{m}^2$. Cell II, however, shows weaker adhesivity than cell I. Although it also exhibits transient adhesion to the lower plate initially, it undergoes a periodic flip movement along the flow direction and eventually detaches from the plate after two to three flips, as characterized by the peak values of the instantaneous cell velocity at 0.30, 0.53, and 0.72 s. Accordingly, the contact area achieves minimum values at those times. Different from cells I and II, cell III does not show any adhesion to the plate; instead, it directly detaches from the lower plate and moves freely without adhesive bonds established thereafter. Given the same "adhesive potential," the present results validate the hypothesis that heterogeneous cell adhesive dynamics is mainly due to the different cell rigidities and peculiar cell morphologies. To further investigate this effect, we use free energy analysis to quantify the cell adhesion in static condition.

We compute the instantaneous contact area for each cell until steady state is reached, as shown in Fig. 9a. While the contact area for all of the cells increases sharply to $10\,\mu\text{m}^2$ within the initial stage, the contact area between the plate and cells I and II further increases to 30 and $21\,\mu\text{m}^2$ at the later stage. This inverse relationship is consistent with the different cell adhesive dynamics in shear flow system, and it can be understood by the free energy analysis during the adhesion process. If we define the cell and the ligand particles as a single system, the change of total free energy ΔE during the process can be written as

$$\Delta E = \Delta E_{\text{deform}} - \Delta E_{\text{adhesion}}, \tag{3}$$

where ΔE_{deform} represents the increase of the cell free energy due to the deviation of cell shape from the equilibrium state. $\Delta E_{\text{adhesion}}$ represents the absolute value of the energy decrease due to the adhesive bond formation between the cell and the ligand particles. The final state is determined by the balance between the two free energy terms. A deformable SS2 cell is prone to form larger contact area than the rigid cell; it can be understood as follows: for SS2 cell with smaller cell rigidity, the energy barrier induced by the cell deformation is relatively small, and free energy decrease induced by cell adhesion plays a dominant role, resulting in further cell deformation and larger cell contact area. In contrast, the rigid SS4 cell exhibits "solid"-like properties with a larger energy barrier for cell deformation. The adhesive interaction between the cell and plate is more like the attraction between two solid objects where the cell deformation plays a less important role. After the initial incubation stage, the adhesive interaction driven by the bond formation cannot overcome the free energy increase induced by the cell deformation, and therefore it prohibits further increase of the contact area.

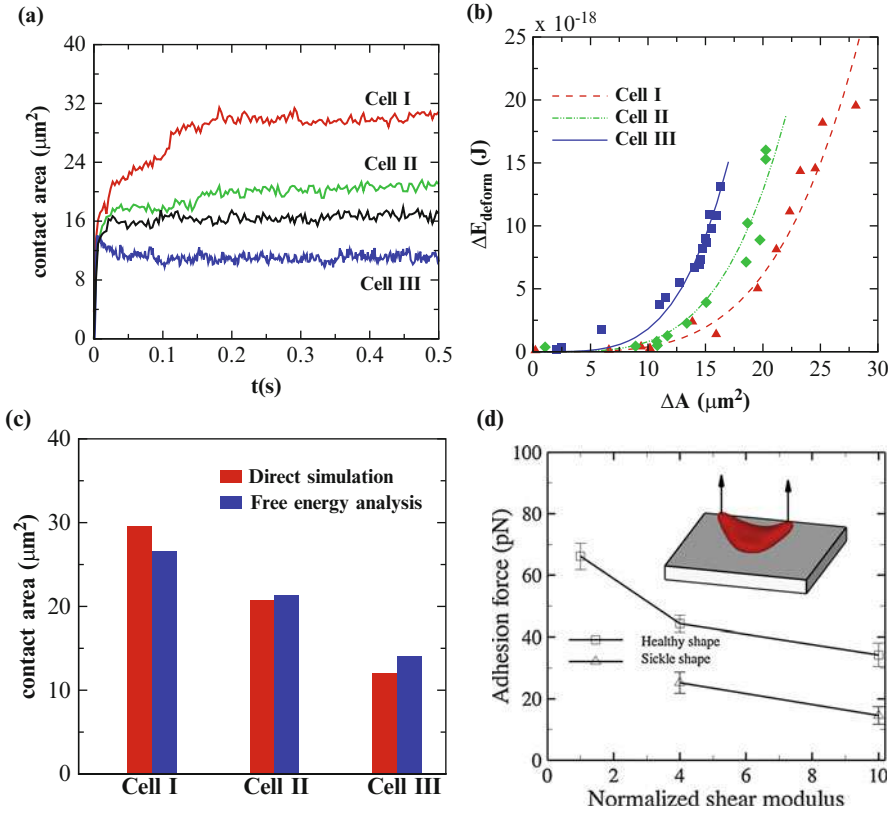
Figure 9b shows the ΔE_{deform} as a function of the contact area ΔA for the three cells induced by different adhesive affinities. The numerical results are fitted by $\alpha\Delta A^4$, where α depends on the cell rigidity of individual cells. The adhesion free


Fig. 9 Adhesion in static conditions: (**a**) instantaneous contact area between the SS-RBC and the plate coated with adhesive ligands. The black curve represents the contact area of a discocyte with cell rigidity similar to the ISC (cell III). (**b**) Increase of the cell free energy as a function of the contact area. (**c**) Cell contact area ΔA computed from direct simulation and free energy analysis by Eq. (4). (**d**) Adhesive force between the cell and the plate as a function of the membrane rigidities for cell morphologies. The error bar represents the adhesive force computed from four independent simulations. The inset plot shows a sketch of the simulation setup, where a uniform lift force is applied on the upper part of an ISC (From Lei and Karniadakis 2013)

energy $\Delta E_{\text{adhesion}}$ can be approximated by $\beta \Delta A$, where β is the energy coefficient determined by the adhesive affinity. In the present work, the adhesive interaction is modeled by the adhesive bond interaction between ligands coated on the substrate and the receptors on the cell membrane. While each receptor on the cell membrane can form multiple adhesive bonds with ligands, each ligand can only form one adhesive bond with the receptor. Therefore, β can be approximated by $k_s l_s^2 n_{\text{ligand}}$, where k_s is the adhesive spring bond constant, l_s is the cutoff length of the adhesive bond interaction and n_{ligand} is number density of the ligands on the substrate. The equilibrium state is determined as the state with minimum free energy term, e.g.,

$$\Delta A = \left(\frac{\beta}{4\alpha} \right)^{1/3}.$$ (4)

According to Fig. 9b, α is about 3.8×10^{25}, 8.0×10^{25}, and 1.8×10^{26} J/m^8 for cells I, II, and III. The contact area $A = A_0 + \Delta A$ yields approximately 26.5, 21.3, and 14.0 μm^2 for cells I, II, and III, where A_0 is the initial contact area without any adhesion, which is 3.5 μm^2 for cells I and II and 0.6 μm^2 for cell III. This result agrees well with the direct simulation results of 29.5, 20.7, and 12.0 μm^2, as shown in Fig. 9c. Compared with the shear flow system, the contact area of cell I computed in static condition is smaller. This discrepancy is mainly due to the increased cell deformation induced by the hydrodynamic interaction under shear flow condition. The extended cell membrane facilitates the bond formation and results in larger contact area. For cell III, we note that the contact area is smaller than the value for a discocyte with similar cell rigidity. This result indicates that the peculiar cell morphology may further affect the cell adhesivity.

To quantify the effects discussed above, we directly compute the adhesive force between the plate and SS-RBCs with different cell rigidities and morphologies. The adhesive force is determined as the lift force that detaches the cell from the plate in quasi-static process, as shown in Fig. 9d. Similar to the contact area, the adhesive force also exhibits an inverse relationship with the cell rigidity. Moreover, compared with the discocyte, the ISC exhibits smaller adhesive force given the similar cell rigidity, indicating less adhesivity induced by its peculiar cell morphology.

4.2   Vaso-Occlusion Crisis

We model blood circulation of SS-RBC suspensions in post-capillaries as in a tube with diameter $D = 10$ μm and hematocrit Hct = 30% similar to Kaul et al. (1989) and Kaul et al. (1994). As shown in Fig. 10, small green particles represent the adhesive ligands which can interact with the SS-RBCs. To quantify the distinct role of different cell groups, we infuse suspensions of different cell groups into the tube by applying a pressure gradient $\Delta P / \Delta x = 8.7 \times 10^4$ Pa/m.

First, we consider suspensions composed of SS2 cells (labeled by blue) and ISC cells (labeled by red) with the ratio 1 : 1. We prepare the steady flow by turning off the adhesive interaction. The mean flow velocity at the initial stage is around 150 μm/s. Starting from the steady state ($t = 0$ s), we turn on the adhesive interaction between the SS-RBCs and the ligand particles and compute the instantaneous flow velocity across the tube, as represented by the red curve in Fig. 10. Blood flow maintains steady state until one of the SS2 cells adheres to the vessel wall, triggering a sharp decrease of blood flow around $t = 0.5$ s. As a positive feedback, the decreased blood flow induces more SS2 cells adherent to the vessel wall, leading to a further decrease of flow rate at $t = 0.63$ and $t = 0.7$ s. Moreover, these adherent cells decrease the effective vessel lumen near the adherent region resulting in a secondary trapping of the ISC groups.
Fig. 10 Vaso-occlusion in post-capillaries: instantaneous mean velocity of blood flow in a cylindrical tube of $D = 10\,\mu m$ infused with different SS-RBC suspensions. The red curve represents the resultant velocity infused with SS2 and ISC cell groups. The inset plots represent the instantaneous snapshots where SS2 cells adhere to the vessel wall, consequently trapping the ISCs and resulting in cell blockage. The green curve represents the blood velocity infused with SS2 and ISC cell groups, where adhesive interaction is only applied to the ISC group. The time axis is scaled by 0.5 for better visualization. The inset plot represents a snapshot where transient adhesion is established between ISC and the tube wall. Steady flow is recovered as the cell detaches from the tube wall. The blue curve represents the instantaneous velocity of blood flow infused with SS2 and healthy cell groups. Blood flow exhibits a slowdown but not a full occlusion (From Lei and Karniadakis 2013)

The final occlusion state is reached around $t \approx 2\,s$ with cell patterns similar to the experimental observations (Kaul et al. 1989, 1994). This result demonstrates that under physiological conditions similar to microcirculation in post-capillaries, the *interplay* of deformable SS2 cells and ISCs can potentially trigger full blood occlusion. Although the same adhesive parameters are applied to the two cell groups, no adherent ISC is observed in the present simulations. Several independent sets of simulation were conducted with different initial conditions, and similar patterns of full occlusion were observed.

To identify the unique contribution of the deformable SS2 cell group, we performed a similar simulation for the suspension consisting of ISC and healthy RBCs. Starting from the steady flow at $t = 0\,s$, we compute the instantaneous velocity of the blood suspension for 6 s, as represented by the green line in Fig. 10. Blood flow shows decreased velocity due to the ISC-ligand interaction, where transient adhesive bonds can be formed. However, blood occlusion is not observed in this simulation since blood flow can recover the initial flow rate when the adherent ISCs detach from the tube wall, as consistently observed in ex vivo studies (Kaul et al. 1994), where the ISCs, when infused alone, did not result in microvascular blockage. This

result reveals the specific contribution of the SS2 cell group in the vaso-occlusion crisis and is consistent with clinical investigation results (Ballas et al. 1988).

In contrast, the ISC cell group contributes differently to the occlusion crisis. We investigate its unique contribution by simulating the blood suspension mixed with the deformable SS2 and healthy cells. Starting from the steady flow at $t = 0$ s, we compute the instantaneous velocity of the blood flow, as represented by the blue line in Fig. 10. Although blood flow slows down due to the cell adhesion at $t = 0.25$ and $t = 0.48$ s, full occlusion is not observed in the present simulation. In particular, we find that healthy RBCs can squeeze through the sievelike region formed by adherent SS2 cells due to its high deformability. The present result, in turn, identifies the specific contribution of the ISC group in the vaso-occlusion crisis. Although the ISC group may not participate in the cell adhesive interaction with the vascular wall, it serves as the particular cell group trapped by adherent cells in the post-capillaries.

Besides the cell interaction among the SS-RBCs, recent studies (Kaul and Hebbel 2000) have shown that SCA is often accompanied with an inflammatory endothelial phenotype with elevated leukocyte recruitment in blood circulation, where the inflammation-stimulated leukocytes may further interact with SS-RBC, leading to blood occlusion in venular flow. We refer to Turhan et al. (2002) and Lei and Karniadakis (2013) for details.

5   Summary

In this chapter, we overview the pathogenesis of vaso-occlusive crisis in sickle cell anemia (SCA) that involves several processes across multiple time and length scales. We cover the morphological, rheological, and adhesive abnormalities of sickle red blood cells and discuss individual and environmental factors underlying the process of SCA vaso-occlusion. The genetic basis and molecular causes of the disease have been understood for more than half a century; however, progress in developing treatments to prevent painful vaso-occlusion and the other myriad of associated symptoms has been slow. Therefore, the need to develop new therapeutic interventions and treatment strategies for SCA remains paramount.

Abstract

The blood coagulation cascade that leads to thrombus formation may be ini-
tiated by flow-induced platelet activation, which prompts clot formation in
prosthetic cardiovascular devices and in arterial disease processes. Upon activa-
tion, platelets undergo complex morphological changes of filopodia formation
that play a major role in aggregation and attachment to surfaces. Numerical
simulations based on continuum approaches fail to capture such molecular-scale
mechano-transduction processes. Utilizing molecular dynamics (MD) to model
these complex processes across the scales is computationally prohibitive. We
describe multiscale numerical methodologies that integrate four key components
of blood clotting, namely, blood rheology, cell mechanics, coagulation kinetics
and transport of species, and platelet adhesive dynamics across a wide range
of spatiotemporal scales. Whereas mechanics of binding/unbinding for single-
molecule receptor-ligand complexes can be simulated by molecular dynamics
(MD), the mechanical structure of platelets in blood flow and their interaction
with flow-induced stresses that may lead to their activation can be efficiently
described by a model at coarser scales, using numerical approaches such as
coarse-grained molecular dynamics (CGMD). Additionally, CGMD provides
an excellent platform to inform other coarser-scale models in a bottom-up
approach in the multiscale hierarchy. The microenvironment of most biological
systems such as coagulation normally involves a large number of cells, e.g.,
blood cells suspended in plasma, limiting the utility of CGMD at the larger
transport scales of blood flow. However, dissipative particle dynamics (DPD),
along with its sub-models such as energy conserving and transport DPD,
provides a very flexible platform for scaling up these mesoscopic systems.
At the macroscopic top scales of the vasculature and cardiovascular devices,
simulating blood and tissues using continuum-based methods becomes viable
and efficient. However, the challenge of interfacing these larger transport scales
with the orders of magnitude smaller spatiotemporal scales that characterize
blood coagulation, and given the issue of the slow-dynamic timescales of bio-
logical processes, makes long-term simulations of such systems computationally
prohibitive. In this chapter, we describe various numerical remedies based
on these methodologies that facilitate overcoming this multiscale simulation
challenge.

1 Introduction

Hemostasis (thrombus formation) is the normal physiological response that prevents significant blood loss after vascular injury. The resulting clots can form under different flow conditions in the veins as well as the arteries. The excessive and undesirable formation of clots (i.e., thrombosis) in our circulatory system may lead to significant morbidity and mortality. Some of these pathologies are deep vein thrombosis and pulmonary embolism and atherothrombosis (thrombosis triggered by plaque rupture) in coronary arteries, to name a few. The process of clot formation and growth at a site on a blood vessel wall involves a number of simultaneous processes including multiple chemical reactions in the coagulation cascade, species transport, and platelet adhesion, all of which are strongly influenced by the hydrodynamic forces.

Platelets are fundamental to both hemostasis and thrombosis in many vascular diseases. Normal platelets do not interact with the healthy arterial wall. In cases of endothelial injury or exposure of extracellular matrix to blood flow, however, platelets can quickly activate and cover the injured area to stop bleeding. The initial adhesion of platelets on the thrombogenic area can be attributed to a variety of platelet membrane receptor-ligand interactions, such as glycoprotein Ib (GPIb)-V-IX with immobilized von Willebrand factor (vWF), GPIIb–IIIa ($\alpha_{\text{IIb}}\beta_3$) with vWF, GPVI with collagen, $\alpha_2\beta_1$ with collagen, $\alpha_{\text{IIb}}\beta_3$ with fibrinogen, and so on, depending on the nature of the lesion and the local shear rate of blood flow. At low shear rates ($\dot{\gamma} < 1000\,\text{s}^{-1}$), platelets adhere to the thrombogenic area through different pathways, relying on the exposed extracellular matrix (ECM) proteins. On the other hand, as shear rate increases, interactions between immobilized vWF and GPIb become exclusive in initializing platelet aggregation, while other interactions are broken down due to high bond failure rates. The reason that vWF-GPIb interactions persist at such high shear rates ($25{,}000\,\text{s}^{-1}$ shown in in vitro experiments) is that the vWF proteins, which are normally in a coiled state, tend to extend severalfold in high-shear environments. The conformational change of vWF exposes the repeating functional A1 domains in multimeric vWF, leading to enhanced adhesive interactions between GPIb and vWF (Schneider et al. 2007) (Fig. 1).

While platelet activation may be induced by biochemical agonists, shear stresses arising from pathological flow patterns enhance the propensity of platelets to activate and initiate coagulation cascade, causing thrombosis. Flow stresses acting on the platelets can be represented down to the order of microns by continuum models. However, processes such as the morphological changes in platelets upon activation happen at the molecular scales. Continuum approaches fail to capture such processes. Mesoscopic particle-based methods were developed to model blood cells and thrombosis in flowing blood, using dissipative particle dynamics (DPD) for modeling the blood, blood flows in microvessel, interactions of cells, and thrombosis growth. However, complex processes such as platelet activation require drastically
Fig. 1 *Bio-chemo-mechanics of platelet aggregation and coagulation.* (**a**) Platelet adhesion receptors and their ligands. Each platelet surface bears $\approx$25,000 GPIb receptors that bind to surface-bound von Willebrand factor; $\approx$50,000 integrin $\alpha_{IIb}\beta_3$ receptors that bind to fibrinogen and vWF; $\approx$4,000 GPVI receptors; and 1,000–4,000 integrin $\alpha_2\beta_1$ receptors that bind to several types of collagen. The integrins must be activated to form strong long-lived bonds. Collagen is a major constituent of the subendothelial (SE) matrix; fibrinogen is an abundant plasma protein; and vWF is adsorbed to SE collagen, circulates in plasma, and is secreted by endothelial cells. (**b**) Schematic illustration of coagulation reactions. Most coagulation proteins exist in an inactive (FVIII) and active form (FVIIIa). FIIa (also known as thrombin), FVIIa, FIXa, FXa, and FXIa are enzymes; their inactive precursors are called zymogens. FVa and FVIIIa are cofactors for the enzymes FXa and FIXa, respectively, and must be activated from their precursors FV and FVIII. Tissue factor (TF) is a cofactor for FVIIa. The coagulation enzyme-cofactor complexes form on SE and platelet surfaces and have enzymatic efficiencies 10^5-10^6-fold those of the enzymes alone. The activation of a coagulation protein is by proteolysis (i.e., cutting) of the precursor by another enzyme. Thrombomodulin (TM) on ECs is a cofactor for thrombin in producing the inhibitor activated protein C (APC). Other major inhibitors are antithrombin (AT) and tissue factor pathway inhibitor (TFPI). Surface-bound enzyme complexes TF:VIIa, VIIIa:IXa, Va:Xa, and TM:IIa and other surface-bound species are shown in boxes. Also shown are cell or chemical activation (purple lines), movement in fluid or along a surface (dark blue lines), enzyme action in a forward direction (solid gray lines), the feedback action of enzymes (dashed gray lines), binding to or unbinding from surface (light blue double-headed arrows), and chemical inhibitors (red circles). (Reprinted with permission from Fogelson and Neeves 2015)

different modeling approaches in order to achieve highly resolved microstructural mechanics and the mechano-transduction process of hemodynamic stresses that may induce platelet activation. Such approaches are needed for more accurately describing the platelets intracellular structure and the mechano-transduction processes of platelet activation by hemodynamic forces.

Incorporating all these processes that occur at different spatiotemporal scales, however, remains a rather challenging task. For example, platelet-wall and platelet-platelet interactions through receptor-ligand bindings occur at a subcellular

nanoscale, whereas the blood flow dynamics in the vessel around the developing thrombus is described as a macroscopic process from several micrometers to millimeters. Here, we describe a hierarchical multiscale numerical approach that may seamlessly unify and integrate different subprocesses within the clotting process.

1.1   Significance and Rationale for a Multiscale Model

Cardiovascular diseases account for over 31% of deaths globally and in the USA annually. Whether due to acute thrombosis associated with myocardial infarction or progressive intermittent atherothrombotic events, significant ventricular dysfunction may result, leading to heart failure. Presently over 6.5 million patients suffer from heart failure in USA, and their number is expected to grow by nearly 50% by 2030. Of those, a significant proportion will become candidates for mechanical circulatory support and prosthetic cardiovascular devices, also burdened with thromboembolic risk and complications, mandating antithrombotic medications for their recipients. Despite antithrombotic therapy, ventricular assist device patients have approximately a 12% stroke rate, of which 18% prove fatal. The alarming thrombosis rates, coupled with complex antithrombotic and anticoagulant management, necessitate a solution to save numerous lives and drastically reduce the ensuing healthcare costs.

Thrombosis in vascular disease is potentiated by the interaction of blood constituents with an injured vascular wall and the nonphysiologic flow patterns characterizing cardiovascular pathologies. Both initiate and enhance the hemostatic response through chronic platelet activation. Similarly, the thrombus and thromboemboli generated in devices are composed primarily of platelets. The elevated flow stresses they induce chronically activate platelets despite aggressive antithrombotic therapy. However, limitations in characterizing the mechanical stimuli, and the complex biochemical and morphological changes platelets undergo in response, still hamper our ability to successfully model such intricate phenomena. The coupling of the disparate spatiotemporal scales between molecular-level events and the macroscopic transport represents a major modeling and computational challenge, which requires a multidisciplinary integrated multiscale numerical approach. Continuum approaches are limited in their ability to cover the smaller molecular mechanisms such as filopodia formation during platelet activation. Utilizing molecular dynamics (MD) to cover the multiscales involved is computationally prohibitive. Innovative multiscale approaches are essential for elucidating this vexing problem (Bluestein et al. 2014; Zhang et al. 2014).

1.2   Flow-Induced Mechanisms of Platelet Activation, Aggregation, and Thrombosis

The "Virchow's triad" of altered blood, surface, and flow establishes the latter as the most complex component of the triad – the local flow patterns role in

platelet activation and aggregation, interaction with the vascular wall, and deposition onto foreign surfaces. It determines where a thrombus will form, its size, and composition and whether it will remain at its initiation nidus or embolize (Sorensen et al. 1999). Shear-induced platelet activation (SIPA) shows consistent "dose" and time response characteristics of biochemical agonists. It causes both aggregation and thrombin generation – the most potent platelet activator, with an established activation threshold (Kroll et al. 1996). Aggregation of platelets and deposition onto thrombogenic surfaces (Jackson 2007) have three distinct shear ranges:

(i) Low-intermediate shear in veins and larger arteries ($<10^3 \, \mathrm{s}^{-1}$). Aggregation is predominantly mediated by $\alpha_{IIb}\beta_3$ on free-flowing platelets which engage fibrinogen (Fg) adsorbed on platelet monolayers that compose the initial thrombi.
(ii) High shear in arterial microcirculation or moderate arterial stenosis ($10^3 - 10^4 \, \mathrm{s}^{-1}$). Aggregation is more vWF-dependent and involves the activity of both GPIba and $\alpha_{IIb}\beta_3$.
(iii) Pathological or "hyper" shear in atherothrombosis and cardiovascular devices ($>10^4 \, \mathrm{s}^{-1}$). Aggregation is mediated exclusively by vWF-GPIb bonds, not requiring platelet activation or adhesion via $\alpha_{IIb}\beta_3$.

1.3 Aggregation, Adhesion, and Wall Interaction

Shear-induced flow mechanisms are enhanced by eddies, flow vortices, and flow separation (Nesbitt et al. 2009), with prothrombotic agonists trapped in regions of recirculating flow. Shear-induced aggregation has two characteristic phases: (i) reversible phase between two discoid platelets and the presence of unstable platelet aggregates and (ii) stable phase that involves platelet shape change and granular release (Maxwell et al. 2007; Nesbitt et al. 2009). Unstable aggregates are formed with vWF alone, while stable aggregates require both vWF and fibrinogen, allowing for a shorter formation time and increased recruitment of platelets to aggregates (Maxwell et al. 2007). Initial aggregates typically involve clustering of platelets around a single activated platelet via membrane tethers, not pseudopodia, whereas stable aggregates require platelet sphering and filopodial projections. Increasing the shear rate from 1,800 to 5,000 s^{-1} increases the number of discoid platelet aggregates converting to stable aggregates, and $\alpha_{IIb}\beta_3$ is required for membrane tether formation between platelets in reversible aggregates (Maxwell et al. 2007). In stenotic regions, initial platelet recruitment occurs at the stenosis apex, and aggregates form at the downstream expansion zone where the flow decelerates. Larger decelerations result in larger aggregates embedded in the growing thrombus.

1.4   Continuum Approaches for Blood Flow at the Microscale

Several continuum approaches try to couple the timescales between molecular and macroscopic transport. In those the cellular level is represented by field equations and moving boundaries to allow the cell to change its shape with interfaces that have different timescales and properties (N'Dri et al. 2003; Shyy et al. 2001). Models of, e.g., adhesion of rolling leukocytes to endothelium are based on either equilibrium concepts (Bell 1978; Berk and Evans 1991; Evans 1985a, b) or kinetics approach (Dembo et al. 1988; Hammer and Lauffenburger 1987; Dong et al. 1999). Bond association and dissociation occur according to the forward and reverse reaction rates (N'Dri et al. 2003; Shyy et al. 2001). Initial models (Skalak et al. 1981a, 1989, 1981b; Weiss 1990) neglected cell rheological properties and were limited in their predictive capability (Bell 1978; Dembo et al. 1988). Flow-induced stresses acting on a cell may weaken the adhesion bonds or extract receptor molecules from the cell surface (Alon et al. 1997, 1998) with progress toward understanding the receptor-mediated cell adhesion process (Lauffenburger et al. 1987; Linderman and Lauffenburger 1986, 1988). Detailed review on such simulations using probabilistic and Monte Carlo approaches was published (Zhu 2000). Flow-mediated transport and initiation and inhibition of coagulation were modeled extensively by the Fogelson group (Fogelson and Tania 2005).

1.5   Coarse-Grained Particle Methods at the Mesoscale

CFD simulations are limited to continuum systems (Dwinzel et al. 2002; Groot and Warren 1997), representing a 10 nm to 100 μm gap between microscopic biochemistry and macroscopic scales. DPD models possess important properties of mesoscopic systems: DPD can easily model heterogeneous fluids, allowing simulations of processes which are very difficult to model by continuum approaches. Initial work focused on multiphase nature of these flows (Espanol 1998; Boek et al. 1996) to address limitations of continuum approaches that represent them consistently (Albert et al. 1998; Kechagia et al. 2002; Davis 2002). Blood flow was modeled with DPD (Dzwinel et al. 2003) with plasma represented by dissipative fluid particles, and red blood cells (RBCs) and capillary walls by coarse-grained (CG) particles ensemble (Boryczko et al. 2003, 2004), demonstrating aggregation and deformation. A triple-decker MD-DPD model interfaced atomistic-mesoscopic-continuum flow regimes (Fedosov and Karniadakis 2009). A flow-cell interaction model (Sweet et al. 2011) used subcellular elements to simulate cell motion, with the cell coupled to the plasma flow by the Langevin equation (Skeel and Izaguirre 2002). DPD was initially used in simple geometries (Fedosov and Karniadakis 2009; Soddemann et al. 2003; Espanol and Warren 1995) for modeling viscous flows with no-slip boundary conditions (Koplik and Banavar 1995a, b; Revenga et al. 1999; Pivkin and Karniadakis 2005), expanding to higher Reynolds numbers (Qian and Wang 2005), and more recently in a stenosis model (Gao et al. 2017).

2 Hierarchical Multiscale Modeling of Platelet Thrombosis

Numerical modeling of thrombus formation and growth is a challenging problem due to multiscale and multiphysics nature of clotting process, which involves fluid mechanics, cell mechanics, and biochemistry. Diverse studies have addressed this problem on different scales such as cellular, meso, and continuum levels, whereas attempts have been made to bridge these different scales to model the process at the initial phase of platelet activation and aggregation (cf. Xu et al. 2010, Zhang et al. 2014, and Grinberg et al. 2013). These studies may be broadly put in three distinct modeling strategies: cellular/subcellular modeling of adhesive dynamics, platelet transport, and aggregation in whole blood; continuum-based modeling of blood flow treating platelets as Lagrangian particles; and continuum-based modeling of thrombus formation and growth using empirical correlations for platelet deposition rates.

A major challenge for multiscale modeling of thrombogenesis is the coupling of the disparate spatiotemporal scales characterizing flow effects on deformable platelets and the resulting adhesion/aggregation bond scales. A schematic flowchart depicts flow-induced processes leading to clotting and thrombosis and the feedback between the scales (Fig. 2). A successful multiscale model requires molecular-level characterization of mechano-transduction processes activating platelets, the ensuing clotting reactions, and their interactions with the flow. Departing from traditional continuum approaches, a multiscale model is proposed by combining DPD interfaced with coarse-grained molecular dynamics (CGMD) – this integrated "DPD-CGMD" multiscale model that can bridge the gap across the vast range of the spatiotemporal scales. Starting with flow patterns with high propensity to activate and aggregate platelets, macro-to-mesoscale flow scales are modeled using DPD and micro-to-nanoscales using CGMD. An interactive DPD-CGMD dynamic coupling interface scheme will reflect any changes in platelets and thrombus morphology and feed back to affect the hemodynamics and vice versa, resulting in a multiscale model to bridge the gap between the macroscopic flow scales and the cellular/molecular scales.

2.1 Molecular Dynamics Modeling of Receptor-Ligand Interactions

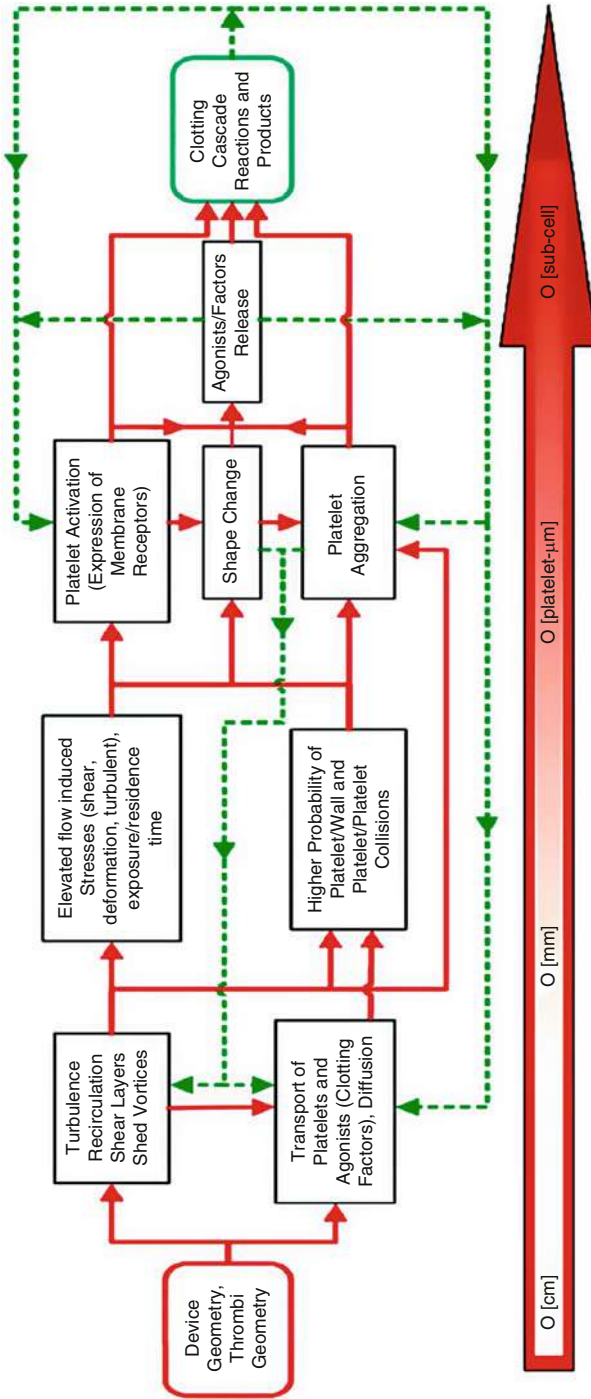
Understanding how force affects receptor and ligand binding and unbinding is a long-standing effort in mechanobiology. Bond dissociation rates typically increase under mechanical stress; however, bond stability can be enhanced through specialized mechanisms induced by force, including *catch bonds* and switching to a *slip bond* with a slower off-rate (*flex bonds*) (Kim et al. 2015). At sites of vascular injury, hydrodynamic force in the bloodstream acting on vWF is pivotal in regulating the binding of the vWF A1 domain to GPIba on platelets and commencing the cross-linking of platelets by vWF to form a platelet plug. vWF circulates in the form of long, disulfide bonded concatemers, with tens to hundreds of monomers,


Fig. 2 Schematic flowchart of the multiscale flow-induced clotting, including mechanical and biochemical interactions

which mostly adopt a compact, irregularly coiled conformation during normal hemodynamics (see Fig. 3). At sites of hemorrhage, flow changes from shear to elongational. On the transition from low to high shear and from shear to elongational flow, irregularly coiled molecules extend to a threadlike shape, and elongational (tensile) force is exerted throughout their lengths. Molecular elongation exposes the multiple A1 binding sites in vWF concatemers for multivalent binding to GPIba (Springer 2014).

Atomic force microscope (AFM) experiments have been used extensively to probe the force required to rupture single-molecule complexes and have provided additional insights into their binding properties. By performing force spectroscopic measurements of binding/unbinding force distributions at different relaxation/pulling rates, these AFM experiments have been able to quantify the kinetics of ligand-receptor interactions.

To reveal the microscopic processes underlying the AFM observations, numerical simulations of binding/unbinding events for different complexes have been performed using steered molecular dynamics (SMD) technique. SMD allows us to explore these processes on timescales accessible to MD simulations. The basic idea behind any SMD simulation is to apply an external force to one or more atoms. In addition, you can keep another group of atoms fixed and study the behavior of the complex under various conditions. The only major difference between the AFM experiment and simulations concerns the value for the pulling velocity. Whereas the AFM experiment is carried out on a millisecond timescale, MD simulations

Fig. 3 *Conformation of vWF under elongation and structural form of its A1 domain bound to GPIba.* (**a**) Schematic organization of domains in vWF and head-to-head and tail-to-tail linkage of vWF monomers into concatemers. (**b**) The vWF A1-GPIba complex forms a super β-sheet at the interface between the A1 $\beta3$ and GPIba $\beta14$ strands. (Reprinted with permission from Springer 2014)
are limited to nanoseconds; therefore, one has to consider thermal fluctuations and dissipation. Because of these nonequilibrium phenomena, the rupture force should vary systematically with rupture speed, and thus the computed rupture forces should be able to be extrapolated to the experimental timescale (Grubmüller et al. 1996).

2.2   An Integrated DPD-CGMD Modeling Approach

The multiscale approach (Fig. 4) incorporates (i) top/macro blood flow scale using DPD fluid, with length scales down to $\mathcal{O}$(m), where multiple platelets each composed of an ensemble of attractive particles are suspended in a discrete particle medium with viscous fluid properties and interact with the blood vessel walls and each other, and (ii) bottom/cellular scale employing CGMD, $\mathcal{O}$ (nm) scales, in which platelets with multiple sub-components (actin filaments cytoskeleton, bilayer membrane, and cytoplasm) evolve during activation as pseudopodia grow and platelets lose their quiescent discoid shape. The fully interactive DPD-CGMD dynamic coupling interface passes the information across the scales as individual platelet activation evolves at the cellular bottom scale in response to viscous shear. This multiscale approach (Fig. 4) depicts the (a) scale exchange of shear from the DPD blood flow and (b) state exchange based on the coarse-graining of MD modeling of the individual platelets, and their shape change is transferred – interactively affecting the DPD fluid hemodynamics.
Fig. 4 Multiscale DPD-CGMD approach for modeling flow-induced platelet activation
Fig. 5 *CGMD model of the intercellular constituents structure of human platelets.* Detailed connections of the filamentous core with actin filaments and the membrane particles are shown in the upper left corner. The rigid filamentous core made by carbon-70 structure at the center of platelet. One end of the actin bundles is attached to the core, and the other end is attached to the membrane. The cytoplasm fills the space between the membrane and the cytoskeleton. (Reprinted with permission from Zhang et al. 2017)

2.2.1 Coarse-Grained Molecular Dynamics Model of Platelet Cellular Structure

The cellular and subcellular structure of a resting platelet can be modeled using a CGMD approach in Fig. 5 (Zhang et al. 2017). A resting platelet has a discoid shape with a $2\,\mu m$ semimajor axis and $0.5\,\mu m$ semiminor axis. The peripheral zone is modeled as a homogeneous elastic material bilayer constructed by 2D triangulation method. A shell of $300\,AA$ thickness represents the phospholipid bilayer membrane ($100\,AA$) and an exterior coat (150–$200\,\text{Å}$). The membrane is allowed to deform under strain. The organelle zone, represented by the cytoplasm, is composed of homogeneous nonbonded particles filling the gap between the membrane and the cytoskeleton. At the fluid-platelet interface, the membrane prevents fluid particles from penetrating while maintaining the flowing platelet flipping dynamics.

The cytoplasm rheology is modeled using a Morse potential (Morse 1929). The cytoskeleton consists of two types of actin-based filaments: (a) a rigid filamentous core and (b) an assembly of radially spanning elastic actin filaments that mediates the contractility. A carbon-70 structure is used to generate the oval-shaped core.

Each actin filament is individually extensible and is tethered to the core. An α-helical structure mimics the spring-loaded molecular mechanism, with its spiral conformation continuously stretchable under external force.

A CGMD potential for the elastic membrane and filamentous core along with a Morse potential for the cytoplasm and the MD force fields for the actin filaments are adopted in this platelet model. The CGMD describes the lowest scale of the platelet intracellular constituents, including the bilayer membrane, the cytoplasm, and a cytoskeleton composed of extensible actin filaments of the pseudopods at the micro- to nanoscales. CGMD potential is written as

$$V_{CGMD}(r) = \sum_{bonds} k_b(r - r_0)^2 + \sum_{LJ} 4\varepsilon_{ij}\left[\left(\frac{\sigma_{ij}}{r}\right)^{12} - \left(\frac{\sigma_{ij}}{r}\right)^6\right], \tag{1}$$

and describes the deformability of the membrane (the first term) and the interaction between the membrane and intercellular particles (the second term). A MD potential without an electrostatic term for the actin-based filaments is

$$V_{MD} = \sum_{bonds} k_b(r - r_0)^2 + \sum_{angles} k_\theta(\theta - \theta_0)^2 + \sum_{torsion} k_\phi(1 + cos(n\phi - \sigma))$$

$$+ \sum_{LJ} 4\varepsilon_{ij}\left[\left(\frac{\sigma_{ij}}{r}\right)^{12} - \left(\frac{\sigma_{ij}}{r}\right)^6\right], \tag{2}$$

where k_b, k_θ, and k_ϕ are force constants for the α-helical structure, r_0 and θ_0 are the equilibrium distance and angle, and n is the symmetry of the rotor and δ is the phase. In the L-J term, ε_{ij} is the well depth of the L-J potential, σ_{ij} is the finite distance and r is the interparticle distance, and θ is the angle and ϕ is the torsional angle. Morse potential is used for the cytoplasm

$$V_{Morse}(r) = \varepsilon[e^{\alpha(1 - \frac{r}{R})} - 2e^{\frac{\alpha}{2}(1 - \frac{r}{R})}], \tag{3}$$

describing a pairwise nonbonded interaction for viscous flows at coarse-grained scales. R is the distance of minimum energy ε, and α is a parameter that measures the curvature of the potential around R, where r is the interparticle distance.

2.2.2 Modeling Blood Plasma Using DPD Fluid Model

In the standard DPD method, the pairwise forces consist of three components: (i) conservative force, $\mathbf{f}_{ij}^C = a_c(1 - r_{ij}/r_c)\hat{\mathbf{r}}_{ij}$; (ii) dissipative force, $\mathbf{f}_{ij}^D = \gamma\omega_d(r_{ij})(\hat{\mathbf{r}}_{ij} \cdot \hat{\mathbf{v}}_{ij})\hat{\mathbf{r}}_{ij}$; and (iii) random force, $\mathbf{f}_{ij}^R = \sigma\omega_r(r_{ij})(\zeta_{ij}/\sqrt{\Delta t})\hat{\mathbf{r}}_{ij}$. Hence, the total force on particle i is given by $\mathbf{f}_i = \sum_{i \neq j}(\mathbf{f}_{ij}^C + \mathbf{f}_{ij}^D + \mathbf{f}_{ij}^R)$, where the sum acts over all particles j within a cutoff radius r_c, and a_c, γ, and σ are the conservative, dissipative, and random coefficients, respectively, r_{ij} is the distance with the corresponding unit vector $\hat{\mathbf{r}}_{ij}$, $\hat{\mathbf{v}}_{ij}$ is the unit vector for the relative velocity, ζ_{ij} is a Gaussian random number with zero mean and unit variance, and Δt is the

simulation time step size. The parameters γ and σ and the weight functions are coupled through the fluctuation-dissipation theorem and are related by $\omega_d = \omega_r^2$ and $\sigma^2 = 2\gamma k_B T$, where k_B is the Boltzmann constant and T is the temperature of the system. The weight function $\omega_r(r_{ij})$ is given by

$$\omega_r\left(r_{ij}\right) = \begin{cases} (1 - \frac{r_{ij}}{r_c})^k & r_{ij} < r_c \\ 0 & r_{ij} \geq r_c \end{cases} , \qquad (4)$$

with $k = 1$ in the original DPD form, whereas $k < 1$ is used to increase the plasma viscosity. A hybrid DPD-Morse model for blood flow simulations through severe stenotic microchannel is proposed by combining the Morse potential and classical DPD conservative force and is being used in order to reduce the fluid compressibility (Gao et al. 2017). The compression simulation presents a much smaller isothermal compressibility of the DPD-Morse fluid than that of the DPD fluid with $\kappa_T^{DM}/\kappa_T^{DPD} \approx 0.3$, which shows DPD-Morse fluid is more resistant to compression under the same condition.

2.2.3 DPD-CGMD Spatial Interfacing

Hybrid force field is developed for describing the dynamic fluid-platelet interaction (Zhang et al. 2014) and is written as

$$d\mathbf{v}_i = \frac{1}{m_i} \sum_{j \neq i}^{N} (\nabla U(r_{ij})dt + \mathbf{f}_{ij}^D dt + \mathbf{f}_{ij}^R \sqrt{dt}) , \qquad (5)$$

where $U(r_{ij})$ is the standard Lennard-Jones potential, with ε_p and σ_p the same as the energy and length characteristic parameters in CGMD, and $\mathbf{f}_{ij}^D$ and $\mathbf{f}_{ij}^R$ are the standard DPD dissipative and random forces, respectively. The L-J force term helps the cytoskeleton-confined shapes and the incompressibility of platelets against the applied shear stress of circumfluent plasma flow. The dissipative and random force terms maintain the flow local thermodynamic and mechanical properties and exchange momentum to express interactions between the platelet and the flow particles. A no-slip boundary condition was applied at the fluid-membrane surface interface. A dissipative or drag force was added to enforce the no-slip boundary condition at the fluid and membrane interface, so that the fluid particles are dragged by the dissipative forces of the membrane particles as they are getting closer to the membrane surface, mimicking boundary layer mechanism where one layer drags its adjacent layers. The hard-core L-J force simultaneously provides a bounce-back reflection of fluid particles on the membrane (to prevent fluid particles from penetrating through the platelet membrane) with the no-slip achieved by slowing down the fluid particles as the fluid particles are getting closer to the membrane surface.

Determination of the parameters for the spatial interface is conducted through numerical experiments for maintaining the Jeffery's orbits of spheroids in a shear

flow. The Jeffery's orbits solution (Jeffery 1922) describes the rotation of isolated ellipsoidal particles immersed in viscous shear flow and is widely used as a benchmark analytical solution. Zhang et al. (2014) presented the comparison of this multiscale fluid-platelet simulation results with Jeffery's orbit solution in Couette flows.

The shapes of the rigid and the deformable platelet models following the immersion are widely different: the rigid model maintains an ideal ellipsoidal shape, but the deformable model responds to the interactions between platelet and the hemodynamic flow stresses around it (Fig. 6(left)). The accumulation of shear stress-exposure time produced over time (Fig. 6(right)) indicated that the flow-induced stresses in the rigid platelet model are on average about 2.6 times larger than those of a deformable model. The hydrodynamic stress will be less on deformable objects, as the surface will move and deform absorbing part of the external force. Thus, the rigidity of the platelet model is not a negligible factor when estimating flow-induced stresses on the platelets. Neglecting the platelet deformability may overestimate the stress on the platelet membrane, which in turn may lead to erroneous predictions of the platelet activation under viscous shear flow conditions.

2.2.4   Modeling the Highly Resolved Mechano-Transduction Process of Hemodynamic Stresses in Platelets

The DPD-CGMD multiscale model described above enables an accurate study for the mechano-transduction process of the hemodynamic stresses acting onto the platelet membrane and transmitted to such intracellular constituents as cytoplasm and cytoskeleton. The platelets constituents continuously deform in response to the flow-induced stresses. Figure 7 shows the mapping of hemodynamic stresses on the membrane, cytoplasm, and cytoskeletal structure of the flowing and flipping platelet under a shear flow of 45 dyne/cm^2. Comparatively, the cytoplasm experiences a slightly lower stress level of 51.46 dyne/cm^2, implying that the deformable membrane absorbs part of the extracellular hemodynamic forces. The spread of the stress distribution on cytoplasm has a much larger standard deviation of 34.72 than the membrane's. This is expected, as the cytoplasm is more fluidic than the membrane, thereby affecting the spread of the stress distributions. The distribution of mechanical stresses on the actin filaments is 48.15 ± 11.33 dyne/cm^2. The actin-based filament structure experiences the smallest average stress level than the membrane and cytoplasm. The stress distribution on the actin filaments indicates that mostly the membrane-adjacent apical tips of the filaments that are attached to the membrane base experience higher stresses than the innermost parts. It is evident that simplifying the mechano-transduction process by using a completely rigid platelet model leads to erroneous estimation of the hemodynamic stresses acting on the platelet membrane and intracellular constituents.

2.2.5   Modeling the Activation of Platelets and Formation of Filopodia

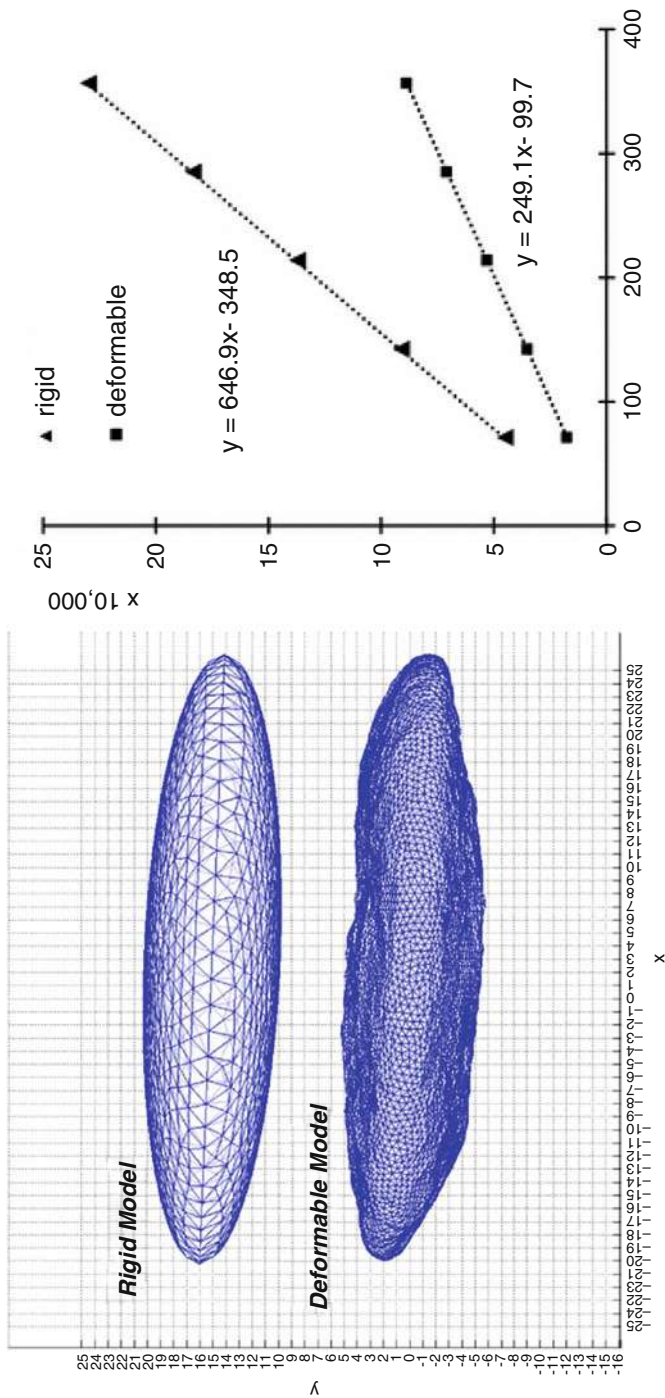
Formation of filopodia observed during early-stage platelet activation is modeled in Pothapragada et al. (2015). Simulating the dynamics of varied filopodia formations


Fig. 6 *DPD-CGMD spatial interfacing for a platelet cell.* (left) Shapes of the rigid and the deformable platelet models following immersion in the plasma fluid. (right) Accumulation of shear stress-exposure time product (y-axis) on the rigid and deformable platelet models over time (x-axis in μs). (Reprinted with permission from Zhang et al. 2014)
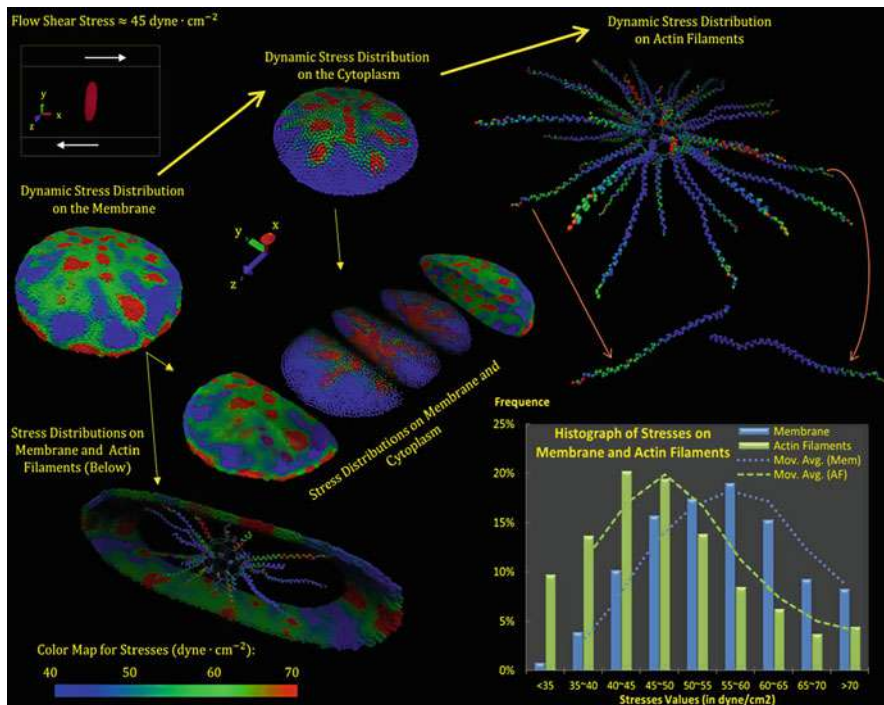

Fig. 7 *The shear flow-induced mechano-transduction process.* Hemodynamic stress distributions on the membrane, cytoplasm, and cytoskeleton (actin filaments). (Reprinted with permission from Zhang et al. 2017)

is enabled by exploring the parameter space of this CGMD platelet model. The dynamic simulation of the filopodia formation is achieved by incrementing the length and thickness parameters of filopod. The rest of the parameters remain constant during the simulation to preserve the structural integrity of the platelet during the formation of filopodia. The change of the filopod length and thickness is determined by correlating with in vitro experiments. In experiments, the platelets are exposed to constant shear stresses over a defined duration. Figure 8 shows (a) the scanning electron microscopy (SEM) images of filopodia formations under varied combinations of shear stress and exposure time and (b) corresponding simulated formation of filopods on the deformable platelet model.

Flow-mediated platelet shape change can be induced by exposing the platelets to a range of physiologic and pathologic shear stresses encountered during blood flow. Platelets isolated by gel filtration are diluted in Hepes-buffered modified Tyrodes solution with 0.1% bovine serum albumin, recalcified with a physiological concentration of $CaCl_2$, and exposed to shear stresses ranging from the physiologic 1 dyne/cm^2 to the pathologic 70 dyne/cm^2 for up to 4 mins in the hemodynamic shearing device (HSD), a programmable cone-plate-Couette viscometer that exposes cell suspensions to uniform dynamic shear stresses (Sheriff
Fig. 8 *Visual comparison of experimental and simulated filopodia formation.* (**a**) SEM image after exposure to (i) 1 dyne/cm² for 4 min, (ii) 70 dyne/cm² for 4 min, and (iii) 70 dyne/cm² for 1 min. (**b**) Simulated filopodia formation. (Reprinted with permission from Pothapragada et al. 2015)

et al. 2013). During exposure, samples are withdrawn using a LabView-controlled syringe-capillary viscometer and immediately fixed in 1% paraformaldehyde to block additional shape change (Pothapragada et al. 2015). Fixed platelets are then placed on glass slides precoated with poly-L-lysine, dehydrated through a graded ethanol series, and sputter-coated with gold particles prior to imaging. Images are obtained at 30,000x magnification in a SEM and analyzed using a MATLAB image processing toolbox (Pothapragada et al. 2015). Platelet boundary parameters, such as the major and minor axis lengths, and circularity are measured by fitting an ellipse to the platelet perimeter, while filopod thickness is obtained by manually defining the intersection with the elliptical platelet body. Filopod lengths are then obtained by morphological erosion of the central filopod axis. These parameters are then recorded in a database and grouped by shear condition (i.e., shear stress and exposure time). The analyzed images are compared with snapshots of the simulation results in Fig. 8. The lengths of filopodia generated due to shear stresses in this study range from 0.24 to 2.74 μm and thicknesses range from 0.06 to 0.73 μm, and the simulations are able to achieve results within this range (Pothapragada et al. 2015).

2.2.6 Measuring Platelet Stiffness and Deformation with Dielectrophoresis-Mediated Electro-Deformation

A critical component of any biological model is validation through in vitro or in vivo experiments. Platelets behave as viscoelastic materials, storing energy as they are subject to shear deformation until their capacity to store and withstand this deformation is exceeded, resulting in shape change, fragmentation, and subsequent activation and thrombus formation. A variety of methods have been used to quantify single cell stiffness, including atomic force microscopy (AFM), cytoindenter, flow cytometry, magnetic tweezers, magnetic twisting cytometry, microfluidics, micropipette aspiration, microplate manipulation, molecular force spectroscopy, optical stretchers, and optical tweezers. Many of these methods require anchored, adhered, or shear-insensitive cells and are unsuitable for platelets, which are free-floating and sensitive to both shear forces and foreign surfaces. These limitations have been bypassed through the use of dielectrophoresis (DEP), in which neutral particles are exposed to a nonuniform electric field, leading to their translational motion. This method has been adapted as a means of cellular electro-deformation (EDF), in which mechanical properties are determined by trapping and deforming platelets exposed to an oscillating electric field without the need for surface contact, substratum attachment, or induction of membrane indentation or damage (Leung et al. 2015). This approach utilizes a microelectrode chip consisting of a patterned thin-film titanium-gold array on a glass substrate, covered by hollow silicone-coated polymer space for the fluid chamber and topped by a coverslip for microscopic observation. Isolated platelets placed in the fluid chamber are exposed to an electric current in a sine-wave pattern formed using a function generator coupled with a current amplifier, allowing modulation of the applied voltage. Platelet deformation is imaged via fluorescence microscopy, recorded with a CCD camera, and analyzed using NIH ImageJ software (Leung et al. 2015). Time-averaged electromagnetic force (F) on the platelet surface is calculated by integrating Maxwell's stress tensor

(**T**) over the cell body Ω, multiplied by the out-of-plane thickness d, with stress calculated over the platelet surface area (Chen et al. 2011):

$$F = d \int_{\partial\Omega} n \cdot T\, dS \,, \tag{6a}$$

$$\mathbf{T} = \begin{bmatrix} \varepsilon_0 \varepsilon_r E_x^2 - \frac{1}{2}\varepsilon_0 \varepsilon_r (E_x^2 + E_y^2) & \varepsilon_0 \varepsilon_r E_x E_y \\ \varepsilon_0 \varepsilon_r E_x E_y & \varepsilon_0 \varepsilon_r E_y^2 - \frac{1}{2}\varepsilon_0 \varepsilon_r (E_x^2 + E_y^2) \end{bmatrix} \,, \tag{6b}$$

where the electric field intensities in the x- and y-directions are given as E_x and E_y, respectively, and ε_r and ε_0 are the respective medium and vacuum relative permittivity. An increase in voltage yields an increase in deformation that is stiffness-dependent, as verified by comparing with platelets fixed with paraformaldehyde. The magnitude of DEP forces increases by the square of the electric field strength (15–90 V), yielding a Young's modulus of 3.5 ± 1.4 kPa for resting platelets, comparable to those measured using micropipette aspiration and AFM.

2.3 Seamless Multiscale Modeling of Thrombosis Using Dissipative Particle Dynamics

Dissipative particle dynamics, a mesoscopic particle-based hydrodynamics approach, has been effectively used to model plasma and suspending cells in blood in many applications. The advantage is the seamless integration of hydrodynamics and cell mechanics in a single framework. Further, a new submodel of DPD that is able to address chemical transport has been formulated (Li et al. 2015). The multiscale model of thrombosis includes four main processes: the hemodynamics, coagulation kinetics and transport of species, blood cell mechanics, and platelet adhesive dynamics. DPD can provide the correct hydrodynamic behavior of fluids at the mesoscale, and it has been successfully applied to study blood, where a coarse-grained representation of the cell membrane is used for red blood cells and platelets.

Transport of chemical species in the coagulation cascade is typically described by a set of continuum advection-diffusion-reaction (ADR) partial differential equations (cf. Eq. 12). In the context of Lagrangian particle-based methods such as DPD, these equations can be written as

$$\frac{d[C_i]}{dt} = \nabla(D_i \nabla[C_i]) + Q_i^S \,, \tag{7}$$

where $[C_i]$ denotes the concentration of ith reactant and D_i is the corresponding diffusion coefficient. This system can be modeled by transport DPD, which is developed as an extension of the classic DPD framework with extra variables for describ-

ing concentration fields. Therefore, equations of motion and concentration for each particle of mass m_i are written by ($d\mathbf{r}_i = \mathbf{v}_i\,dt$; $d\mathbf{v}_i = \mathbf{f}_i/m_i\,dt$; $dC_i = Q_i/m_i\,dt$) and integrated using a velocity-Verlet algorithm, where C_i represents the concentration of a specie per unit mass carried by a particle and $Q_i = \sum_{i\neq j}(Q_{ij}^D + Q_{ij}^R) + Q_i^S$ is the corresponding concentration flux. We note that C_i can be a vector $\mathbf{C}_i$ containing N components, i.e., $\{C_1, C_2, \ldots, C_N\}_i$ when N chemical species are considered. In the transport DPD model, the total concentration flux accounts for the Fickian flux Q_{ij}^D and random flux Q_{ij}^R, which are given by

$$Q_{ij}^D = -\kappa_{ij}\omega_{dc}(r_{ij})\left(C_i - C_j\right)\,, \tag{8a}$$

$$Q_{ij}^R = \varepsilon_{ij}\omega_{rc}(r_{ij})\zeta_{ij}\Delta t^{-1/2}\,, \tag{8b}$$

where κ_{ij} and ε_{ij} determine the strength of the Fickian and random fluxes. Q_i^S represents the source term for the concentration due to chemical reactions. Further, the fluctuation-dissipation theorem is employed to relate the random terms to the dissipative terms, i.e., $\omega_{dc} = \omega_{rc}^2$, and the contribution of the random flux Q_{ij}^R to the total flux is negligible.

To describe the cell mechanics, a coarse-grained representation of the cell membrane structure (lipid bilayer + cytoskeleton) can be adopted for RBCs and platelets. The membrane is defined as a set of N_v DPD particles with Cartesian coordinates $\mathbf{x}_i$, $i \in 1, \ldots, N_v$ in a two-dimensional triangulated network created by connecting the particles with wormlike chain (WLC) bonds. The free energy of the system is given by

$$V_t = V_s + V_b + V_a + V_v\,, \tag{9}$$

where V_s is the stored elastic energy associated with the bonds, V_b is the bending energy, and V_a and V_v are the energies due to cell surface area and volume constraints, respectively. RBCs are extremely deformable under shear, whereas platelets in their resting (i.e., unactivated) shape are nearly rigid. We parametrize the RBC membrane such that we can reproduce the optical tweezer stretching tests (see Fig. 9). In the case of platelets, we choose shear modulus and bending rigidity sufficiently large to ensure its rigid behavior. Platelets become more deformable upon activation through reordering the actin network in their membrane, which is accompanied by the release of their content to the plasma.

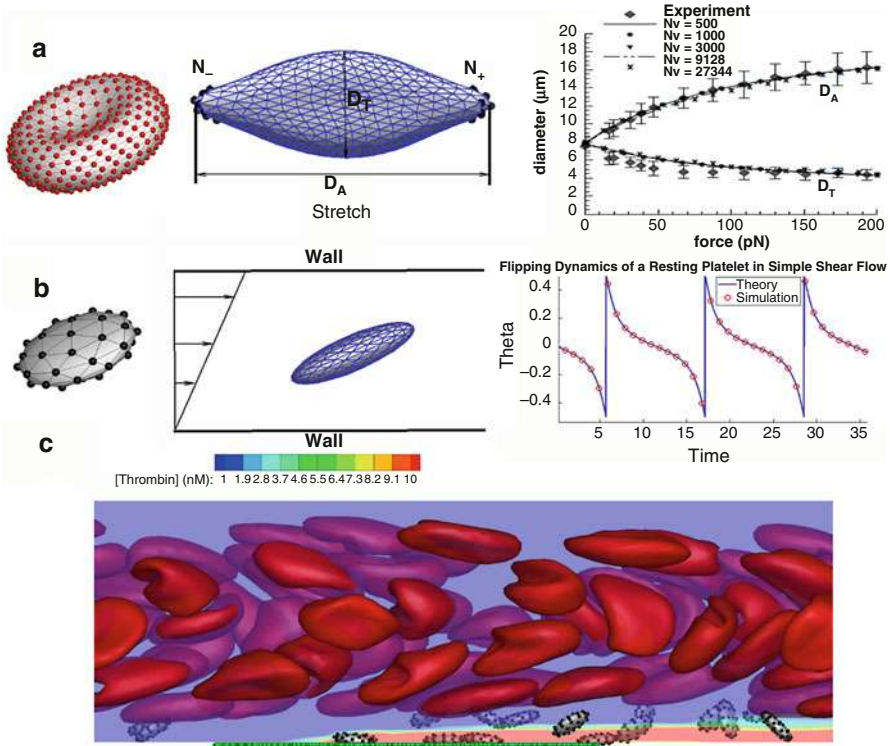
The platelet adhesive dynamics model describes the adhesive dynamics of receptors on the platelet membrane binding to their ligands. The cell adhesive dynamics model was first formulated in the work of Hammer and Apte (1992) and extended to platelets by others. This model utilizes a Monte Carlo method to determine each bond formation/dissociation event based on specific receptor-ligand binding kinetics. The probability of bond formation P_f and probability of bond rupture P_r are estimated using the following equations:


Fig. 9 *Particle representation of blood cell structure and their mechanics and simulation of clotting in whole blood.* (**a**) Coarse-grained DPD model of RBC membrane and the stretching response of stress-free RBC model for different coarse-graining levels compared with the optical tweezer stretching experiment. (**b**) Coarse-grained model of platelet membrane and its flipping dynamics when placed in a linear shear flow (theory of rigid particle dynamics in shear flow can be found in Jeffery 1922). (**c**) Seamless DPD simulation of whole blood flowing over a site of injury in a channel showing RBCs, platelets, and vWF ligands (green particles on the lower wall). Contours of thrombin concentration are plotted as the solution of the coupled ADR equations for the coagulation cascade

$$P_f = 1 - \exp(-k_f \Delta t), \tag{10a}$$

$$P_r = 1 - \exp(-k_r \Delta t), \tag{10b}$$

where k_f and k_r are the rates of formation and dissociation, respectively. Following the Bell model (cf. Bell 1978), the force-dependent k_r is evaluated by

$$k_r = k_r^0 \exp\left(\frac{\sigma_r |F_b|}{k_B T}\right), \tag{11}$$

where k_r^0 is the intrinsic dissociation rate and σ_r is the corresponding reactive compliance derived from atomic force microscope (AFM) experiments and F_b is the pulling force applied to the bond.

2.4   Continuum and Particle/Continuum Modeling of Thrombosis

At the continuum level, macroscopic numerical models have been developed by treating blood as incompressible Newtonian fluid (or non-Newtonian in small arterioles and capillaries), thus leading to continuum fields for blood velocity and pressure and the transport of enzymes, which can be resolved using an Eulerian description. To study thrombosis in both physiological and pathological conditions, some of these models treat platelets as concentration fields similar to chemical species that follow specific ADR transport equations. The governing equations for the incompressible blood flow coupled with the ADR equations related to the biochemistry of coagulation are written as

$$\rho(\frac{\partial \mathbf{u}}{\partial t} + \mathbf{u} \cdot \nabla \mathbf{u}) = -\nabla p + \nabla \cdot \boldsymbol{\tau} \,, \tag{12a}$$

$$\nabla \cdot \mathbf{u} = 0 \,, \tag{12b}$$

$$\frac{\partial c_i}{\partial t} + \mathbf{u} \cdot \nabla c_i = D_i \nabla^2 c_i + S_i \,, \tag{12c}$$

where $\mathbf{u}$ is the flow velocity, p is the pressure and $\boldsymbol{\tau}$ is the deviatoric viscous stress tensor, c_i and D_i are the concentration and diffusion coefficient for each reactant, respectively, and S_i represents the rate of production or destruction of that reactant. The shear stress tensor can be written as $\boldsymbol{\tau} = 2\mu\mathbf{D}$ where $\mathbf{D}$ is the strain rate tensor. The viscosity μ may be assumed constant for Newtonian blood or a function of the local shear rate using an empirical correlation for non-Newtonian blood. The system of equations (12) are usually solved using a finite element Galerkin formulation subject to proper Dirichlet and Neumann boundary conditions for velocity, pressure, and concentrations at the inlets/outlets and on the wall.

   It is also possible to take individual platelets into account by treating them as Lagrangian particles using a method that is able to couple particle-particle particle-wall interactions with the background flow. Force coupling method (FCM) provides such platform for *two-way coupling* of platelets (treated as rigid spherical particles) with the background flow (cf. Yazdani et al. 2017). This numerical approach has the advantage of tracking thousands of platelets forming aggregates at the site of injury and effectively capturing the shape and extent of thrombus. As a result, the thrombus shape modeled by FCM is affected by the local hydrodynamics and fluid stresses. FCM can be easily incorporated in the Navier-Stokes equation by introducing a body-force term due to the particles

$$\mathbf{f}(\mathbf{x}, t) = \sum_{n=1}^{N} \mathbf{F}^n \, \Delta\, (\mathbf{x} - \mathbf{Y}) \,, \tag{13}$$

where $\mathbf{F}^n$ is the force due to particle n. The effect of platelets is transferred to the flow field through the body force term $\mathbf{f}(\mathbf{x}, t)$ on the right-hand side of the

Navier-Stokes Equation 12a. Further, a phenomenological model based on a Morse potential V_{Morse} may be used to describe the attractive/repulsive forces between platelets. The contribution of each platelet whose center of mass is located at $\mathbf{Y}^n$ to the flow at position $\mathbf{x}$ is smoothed by a Gaussian distribution kernel $\Delta (\mathbf{x} - \mathbf{Y})$.

3 Concurrent Coupling Using a Domain Decomposition Approach

Most current work on multiscale modeling is in the setting of the so-called *concurrent coupling* methods, i.e., the microscale and the macroscale models are linked together on the fly as the computation goes on (Weinan et al. 2007). In most biological problems such as blood clotting, localized processes occur in isolated regions. For these problems, the microscopic model is only necessary near the local biologically active domains. Further away it is adequate to use the macroscopic model. In this case, the macro-micro coupling is localized, and *domain decomposition* can be used by either using overlapping interfaces or embedded subdomains. For example, in modeling of blood clotting in cerebral aneurysm shown in Fig. 10, an approach is adopted in which the flow field is solved in the full geometry using a continuum 3D solver, while small atomistic subdomains are embedded in isolated regions identified with higher platelet residence times and higher propensity of platelet deposition inside the sac of the aneurysm.

The bridging of scales is achieved through designing appropriate interface conditions between the heterogeneous solvers. The interface conditions are derived to respect the physical conservation constraints and the requirements of each solver. Specifically, mass conservation is of primary importance, while momentum and energy conservation are desirable but present several challenges, with the latter being nearly impossible in practice. Interface conditions are concurrently enforced by constructing appropriate projection, interpolation, denoising, and statistical moment-matching techniques that aim to transfer information across the different domains in a compatible way with the requirements and data format of each solver.

Coupling of atomistic and continuum solvers requires the calculation and communication of averaged properties, such as fluid velocity and density, across heterogeneous solver interfaces. For example, atomistic solvers require a local velocity flux to be imposed at each voxel of the atomistic domain. This is achieved through constructing appropriate interpolation and projection operators that are capable of mapping the continuum velocity field onto the atomistic domain. Specifically, to enforce mass conservation, the continuum solver computes the fluxes through the surface interfaces with the atomistic domains, and particles are inserted in the atomistic domain in such a way that these fluxes are preserved.

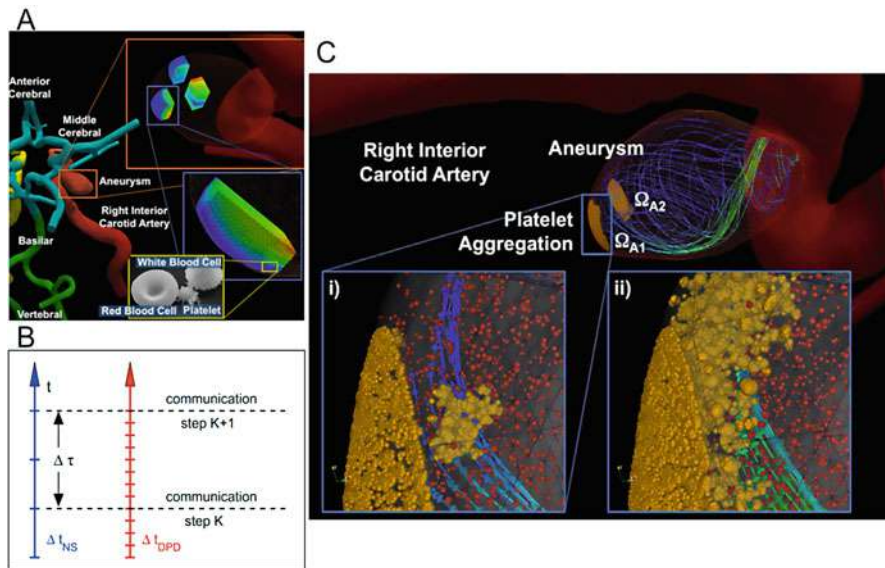
Accurate computing of averaged fields through processing of non-stationary atomistic data presents several challenges including geometrical complexity of the atomistic domains, thermal fluctuations, and flow unsteadiness. Therefore, effective averaging and filtering techniques are required before the data are transmitted to the continuum domains. In particular, to filter out the stochastic component


Fig. 10 *Concurrent coupling of continuum-atomistic modeling of platelet aggregation at the wall of an aneurysm.* (**a**) The patient-specific geometry was constructed from MRI imaging and contains three embedded atomistic domains to resolve the microrheology. Continuum blood flow is computed with $\mathcal{O}(0.1\,mm)$ resolution and platelet aggregation with $\mathcal{O}(1\,\mu m)$ resolution. (**b**) Asynchronous time-matching and synchronization of the continuum and atomistic (based on DPD) solvers. (**c**) Platelet aggregation at the wall of the aneurysm. Two atomistic domains $\Omega_{A1,A2}$ in which the platelet aggregation initiates are fully embedded in the continuum domain. Yellow dots correspond to active platelets and red dots to resting platelets (both modeled by hard spheres in DPD). Streamlines depict instantaneous velocity field in the (i) onset of clot formation and in (ii) clot formation as it progresses in time and space. (Reprinted with permission from Grinberg et al. 2013)

(thermal fluctuations) at all interfaces with the continuum domain, a window proper orthogonal decomposition (WPOD) has been used and shown to be very effective (Grinberg et al. 2014).

4 Multiple Time-Stepping (MTS) Algorithm for Efficient Multiscale Modeling

The disparate spatial scales between the DPD flow and the CGMD platelet model are handled by a hybrid force field. However, the disparity in temporal scales between the two models represents a huge challenge that may become prohibitive in the practice of multiscale modeling. A multiple time-stepping (MTS) algorithm is the necessary solution for this kind of multiscale models. Conventional MTS algorithms manage to differentiate multi-stepping for up to one order of magnitude of scale (Han et al. 2007) and are being applied to classical MD simulations. In order to

handle three to four orders of magnitude disparity in the temporal scales between DPD and CGMD, a novel improved MTS scheme hybridizing DPD and CGMD is developed through utilizing four different time-stepping sizes. In this MTS scheme, the DPD-based fluid system advances at the largest time step, the fluid-platelet interface at a middle time step size, and the non-bonded and bonded potentials for the CGMD-based platelet system at two smallest time step sizes (Zhang et al. 2015).

MTS for top-scale DPD uses a modified velocity-Verlet integrator that is derived from stochastic Trotter formula and is written as

$$r(\Delta t) = r(0) + \Delta t \cdot v(0) + \frac{\Delta t^2}{2m} F[r(0), v(0)], \tag{14a}$$

$$\tilde{v}(\Delta t) = v(0) + \lambda \cdot \frac{\Delta t}{m} \cdot F[r(0), v(0)], \tag{14b}$$

$$\text{compute} \quad F[r(\Delta t), \tilde{v}(\Delta t)], \tag{14c}$$

$$\tilde{v}(\Delta t) = v(0) + \lambda \cdot \frac{\Delta t}{m} \cdot \big(F[r(0), v(0)] + F[r(\Delta t), \tilde{v}(\Delta t)] \big), \tag{14d}$$

where the empirical factor λ accounts for the additive effects of stochastic interactions and $\lambda = 0.5$ restores the velocity-Verlet integrator with $\mathcal{O}(\Delta t^2)$. MTS for the bottom-scale CGMD subdivides the pairwise forces into short- and long-ranged forces with different time steps δt and $n\delta t$ where n is a positive integer. It uses the velocity-Verlet integrator as follows:

$$v\big(\frac{\Delta t}{2}\big) = v(0) + \frac{\Delta t}{2m} \cdot F[r(0)], \tag{15a}$$

$$r(\Delta t) = r(0) + \Delta t \cdot v\big(\frac{\Delta t}{2}\big), \tag{15b}$$

$$v(\Delta t) = v\big(\frac{\Delta t}{2}\big) + \frac{\Delta t}{2m} \cdot F[r(\Delta t)]. \tag{15c}$$

DPD-CGMD temporal interfacing scheme decomposes the whole integrator process into four levels as shown in Fig. 11. The topmost two levels use the scheme in Eq. 14, referred to as DPD-MTS, because both of them employ the DPD thermostatting method. The bottommost two levels use the scheme in Eq. 15, referred to as CGMD-MTS, since both of them employ the conservative potentials. In each of DPD-MTS and CGMD-MTS, the integrator is subdivided into two timescales, one for the soft potential with a larger step size and the other for the hard potential with a smaller step size.

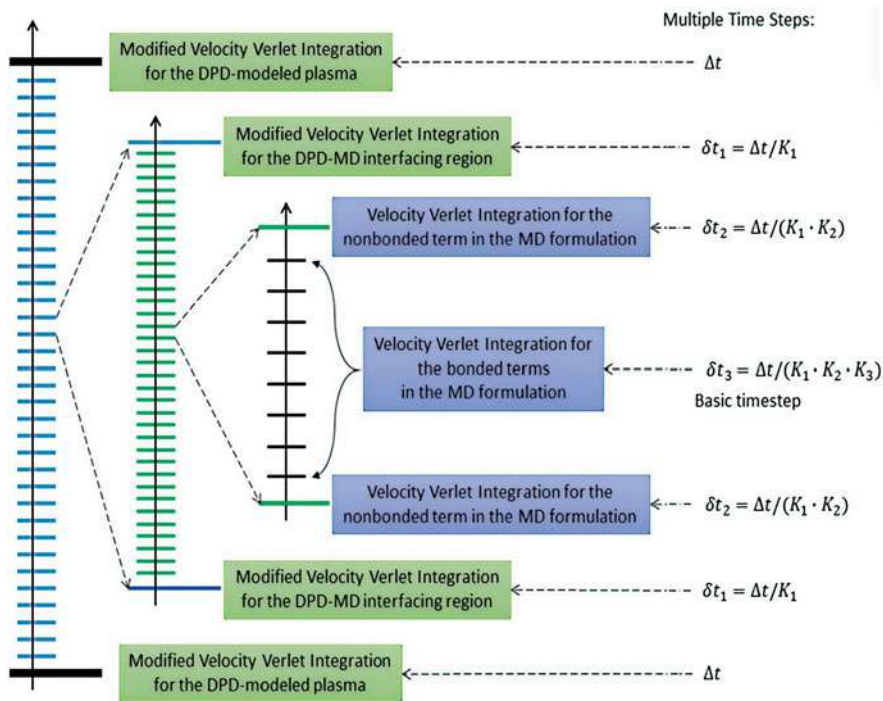
MTS algorithm is a trade-off between speed and accuracy for multiscale modeling. Energy conservation and maintenance of adequate precisions of other measures must be verified while accelerating computations. We investigate the microscopic shape changes of platelets in response to macroscopic flow-induced stresses. Thus, in measuring numerical solutions, we focus on the accuracy of characterizing the


Fig. 11 *Multiple time step sizes in MTS for multiscale DPD-CGMD model.* (Reprinted with permission from Zhang et al. 2015)

hybrid system and the flowing platelets, as well as the accuracy of calculating the dynamic flow-induced stresses on the surface membrane. To compare, the standard time stepping (STS) that operates a single time step size is examined against MTS. The numerical results demonstrated that the microscopic measures for single platelets are more sensitive to the MTS parameters than the macroscopic measures for the hybrid system. The results reaffirm that a separation of temporal scales in MTS considerably improves the efficiency of utilizing parallel computing resources, as compared to conventional single-scale methods in which considerable time is wasted conducting massive unnecessary computations. For example, completing 1-ms multiscale simulation of a 10-million particle system is reduced from 2.6 years to 3.5 days only (Zhang et al. 2015, 2016).

5   Comments on Long-Term Modeling of Thrombus Formation

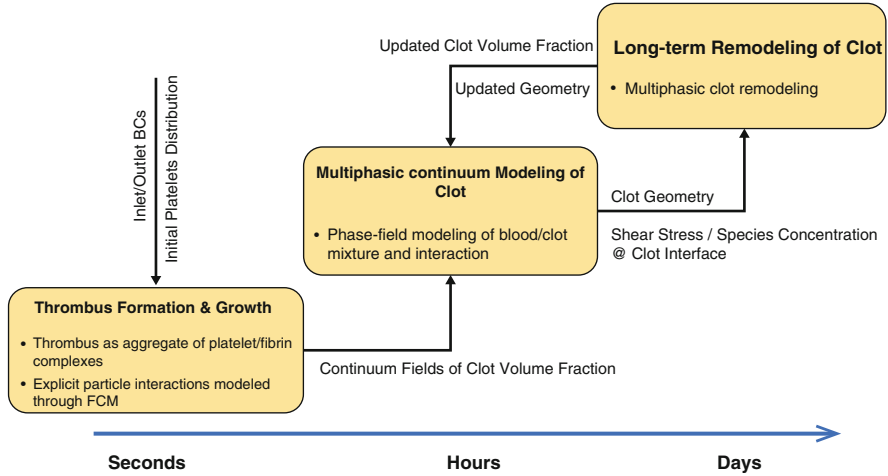
Any proposed multiscale numerical model for thrombus formation has to account for short-term platelet aggregation, midterm thrombus growth, and long-term clot


Fig. 12 *Serial/concurrent coupling of numerical models of thrombus formation and growth/remodeling in a dissecting aneurysm.* The platelet activation/aggregation model, based on FCM, is the most expensive subprocess in this framework and, thus, is only used to model the formation and propagation of the clot for several seconds after the injury. Once a stable thrombus is formed, we transform the platelets Lagrangian distribution in the aggregate clusters into continuum fields of clot volume fraction, which can be subsequently used in a phase-field numerical approach to model interaction of blood with thrombus and its further remodeling in a concurrent scheme

stabilization and remodeling (see Fig. 12). The physiologic timescales of blood coagulation dynamics and thrombosis are in the order of minutes, hence making long-time CGMD or DPD computations of such systems at the cellular level impractical. In addition, resorting to coarse-scale simulations at the macroscale may not necessarily resolve this difficulty as acceleration in the chemical reactions in the coagulation model is needed. Despite the importance of temporal scale bridging in biological applications, there has been less attention than spatial scale coupling in the literature.

In contrast to the concurrent coupling, *serial coupling* schemes determine an effective macroscale model from the microscale model in a preprocessing step and use the resulted macroscale model subsequently. Such serial coupling methods are largely limited to *parameter passing* yet are very useful in addressing long-term biological processes provided there is a timescale separation between its relevant subprocesses. For example, in Fig. 12, a possible strategy to tackle the long-term simulation of clot formation and remodeling upon arterial wall injury that normally occurs over days is proposed. Here, the subprocesses are identified as (i) the acute formation of thrombus and platelet aggregation over the first tens of seconds, (ii) the midterm formation of fibrin network at the site of thrombus and stabilization of the clot, and (iii) the long-term remodeling of the clot, which occurs over days. As noted in the figure, due to the separation of timescales between phases (i) and (ii), a serial coupling between the fine-scale particle/continuum (based on FCM)

and the coarse-scale multiphasic continuum models is possible. The challenge is the long-term simulation of particles actively coupled with flow; the complexities in geometry and flow conditions and the large size of injuries may require hundreds of thousands of FCM particles to represent platelets, which imposes a restrictively high computational cost for such simulations in large domains. To overcome this difficulty, it is possible to initially distribute particles in the regions of interest that contain thrombogenic surfaces. The timescales of phases (ii) and (iii) are not separated, which implicates a concurrent coupling scheme between these two subprocesses.

Abstract

Accurate prediction of airflow distribution and aerosol transport in the human lungs, which are difficult to be measured in vivo but important to understand the structure and function relationship, is challenging. It is because the interplay between them spans more than two orders of magnitude in dimension from the trachea to alveoli. This chapter reviews the techniques and strategies for modeling lungs both within and between subjects, viz., subject specificity versus generalization from individuals to populations, with both exhibiting multiscale characteristics. For "within-subject" modeling, a computed tomography (CT)-derived subject-specific computational fluid dynamics (CFD) lung model is presented. The pipeline for building such an imaging-based lung model is composed of image segmentation and processing, geometrical modeling labeled with anatomical information, image registration, three-dimensional (accurate) and one-dimensional (approximate) coupling techniques, and a high-fidelity turbulent flow model. The subject-specific model is essential in predicting local structural and functional interactions. For "between subjects" modeling, machine learning is employed to identify homogeneous subpopulations (clusters), among healthy and diseased populations, aiming to bridge individual and population scales. For this purpose, three major issues need to be addressed. They are intersubject variability (due to, e.g., gender, age, and height), inter-site variability (due to scanner and imaging protocol differences), and definition of quantitative CT imaging-based metrics at multiple scales (due to alterations at different disease stages) needed for clustering. The use of the cluster membership to select representative subjects for detailed CFD analysis enables an examination of the cluster-specific structural and functional relationships.

1   Introduction

Machine learning (ML) is a data-driven technique in the field of artificial intelligence. It can generate a self-learning program to achieve exact knowledge from a cycle of learning and self-adjustment (Magoulas and Prentza 2001; Deo 2015). ML can help interpret patterns (Uppaluri et al. 1997, 1999; Xu et al. 2006a, b) or extract insightful information from heterogeneous data sets. Each data set used in ML algorithms is represented by a set of features. The features may be continuous or categorical. If an algorithm uses features assigned with a priori labels (related correct outputs), it is called supervised learning. On the other hand, it is called unsupervised learning if data are unlabeled (Deo 2015). For supervised learning, the data used can be classified into two types: (1) a training set used for learning and parameter fitting and (2) a test (validation) set used for assessing the performance of a fully trained ML algorithm (prediction). Decision tree, Naïve Bayes, and support vector machine are common ML supervised algorithms. An unsupervised learning algorithm learns features from unlabeled input data and uses these learned features to recognize the class of new data. Clustering methods, such as K-means,

hierarchical, Gaussian mixture models, and self-organizing maps, are unsupervised learning algorithms.

Healthcare enterprise includes the acquisition, processing, and storage of medical information for diagnosis and disease treatment. Applications in healthcare deal with large amounts of data of differing types, including medical imaging (such as computed tomography (CT), X-ray plates, magnetic resonance), DNA sequences, unstructured text, etc. ML can be employed to process and interpret these medical data, providing a critical tool for personalized treatment and ultimately shifting toward the paradigm of precision medicine (Mesko 2017). Precision medicine has been a core theme for future advances in medicine since the Precision Medicine Initiative was announced by the National Institutes of Health (NIH) and President Obama in 2015 and 2016 (Collins and Varmus 2015; Ledford 2016). Precision medicine not only means individualized medicine but also seeks to advance changes in medicine through the active participation of patients.

This chapter is focused on a review of the application of ML to spatially linked medical image data sets to improve the understanding and treatment of human lung diseases. This application is multiscale in two distinct aspects: (1) within and (2) between individuals. First, structural and functional alterations within individuals at different stages of the pathologic processes associated with lung disease can occur regionally (at a segmental or local scale), globally (at a lobar, organ, or global scale), or both. Thus, it is essential to examine variables at both local and global scales to capture a wide spectrum of pathologic states. In addition, some in vivo data are difficult, if not impossible, to be measured; but they are important to better understand the interplay between structural and functional variables at multiple scales over time. Thus, it is desirable to develop subject-specific lung models to capture these missing data. Second, due to heterogeneity of lung diseases, a tailored treatment for one individual may not be applicable to others. To bridge individual and population scales (viz., between individuals), identification of subpopulations (clusters) characterized by similar structural and functional alterations and clinical features may greatly facilitate the design of cluster-specific treatments and assessment of outcomes.

NIH-sponsored multicenter trials have enabled studies of lung diseases by collecting diverse data sets from large cohorts, such as the Severe Asthma Research Program (SARP) (Wenzel and Busse 2007) and the Subpopulations and Intermediate Outcome Measures in Chronic Obstructive Pulmonary Disease (COPD) Study (SPIROMICS) (Couper et al. 2014; Sieren et al. 2016). SARP was established by the National Heart, Lung, and Blood Institute (NHLBI) in 2001 to study severe asthma in multiple centers, aiming to identify phenotypes that differentiate severe asthma from those with mild-moderate asthma. Thus, SARP allows for a comprehensive phenotyping with clinical, biologic, genetic, and imaging data. Likewise, COPD is currently the third leading cause of death in the United States (Gibson and Simpson 2009). SPIROMICS aims to identify and validate surrogate markers of disease severity for intermediate outcome measures. For this purpose, high-quality quantitative data assessment is one of the key elements in these studies. Imaging data, gathered under a protocol common to both SARP and

SPIROMICS (Sieren et al. 2016), have a great potential to advance knowledge of basic lung physiology and pathophysiology of various diseases providing structural and functional characteristics at local and global scales. Due to highly dynamic characteristics of lung functions, intra-subject, intersubject, interpopulation, and inter-subpopulation variations are of important issues. This uniqueness calls for correct understanding of underlying physics and appropriate treatment of variability in parameterization. ML provides a viable approach to parameterization as well as classification.

This chapter is organized as follows. Section 2 reviews the modeling pipeline for building a subject-specific CT imaging-based multiscale computational fluid dynamics (CFD) lung model that spans generations of airways for simulation of airflow and particle deposition. The model can be used to predict missing data that are essential to understand disease progression. Section 3 discusses the ML methods employed for clustering and classification of asthma cohorts, COPD cohorts, or both. Section 4 presents some applications that utilize cluster membership to guide CFD analysis for improved treatment. Finally, future work is presented in regard to utilization of longitudinal data to further advance the above CFD-ML integrated framework.

2   CT-Based Multiscale Lung Model

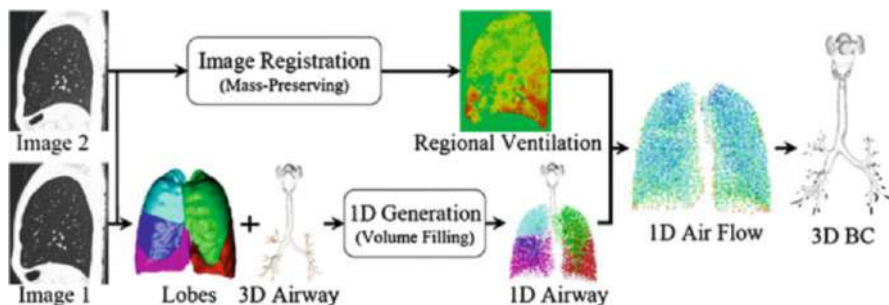
The characteristic length scale of the human airways changes from centimeters in the mouth-nose and trachea to micrometers at the terminal bronchioles. As the airflow in the proximal end of the tree divides repeatedly leading eventually to tens of thousands of terminal bronchioles, the primary fluid flow parameter, Reynolds number (Re), scales between three orders of magnitude for a peak flow rate of normal breathing: 1000–2000 at the trachea and 1 at the terminal bronchioles. In the proximal sites, the geometrical complexity such as glottal constriction triggers jet-induced turbulence, causing coexistence of laminar, transitional, and turbulent flows. Thus, it is challenging to build a subject-specific lung model that can capture the structure and function relationships at multiple scales. Despite the complex nature of airflow in the lung, the most common clinical measures of lung function are obtained through the use of global lung function metrics, dubbed the pulmonary function test (PFT). PFTs include such measures as the forced expiratory volume for the initial 1 s (FEV1) when a maximal effort is made to exhale from full inspiration (total lung capacity or TLC) and forced vital capacity (FVC) which represents the maximum amount of air that an individual can force out of their lungs when exhaling as rapidly as possible from TLC down to residual volume (RV) or full expiration. Individual differences in lung size are accounted for by relating FEV1 and FVC through the ratio FEV1/FVC. The device through which the patient blows is known as the spirometer.


Fig. 1 A flow chart of the imaging-based CFD lung modeling procedure. *LUL* left upper lobe, *LLL* left lower lobe, *RUL* right upper lobe, *RML* right middle lobe, *RLL* right lower lobe (Yin et al. 2010)

2.1   Pipeline for a Lung Model

Recent advances in CT imaging and image processing techniques have been integrated with CFD for simulations of turbulent flows using three-dimensional and one-dimensional (3D-1D) coupled framework (Lin et al. 2009, 2013; Yin et al. 2010; Choi 2011). The pipeline for building a subject-specific imaging-based CFD lung model is illustrated in Fig. 1, comprising five steps of (1) image segmentation and processing, (2) airway geometrical modeling (for building airway structure), (3) image registration (for deriving regional ventilation function), (4) linking structure and function for boundary conditions (BCs), and (5) turbulence modeling and CFD simulation, to predict airflow and particle deposition in the lungs.

2.1.1   Image Segmentation and Processing

State-of-the-art CT provides the best resolution among various imaging modalities when one seeks to capture an image of the integrated lung anatomy. Advanced CT scanners can resolve in plane detail of 0.5×0.5 mm or better, capturing about ten generations of the airways, including segmental and sub-segmental airways. The geometries of lungs, lobes, airways, and vasculature (including arteries and veins) can be segmented from volumetric CT image via an automated software program, such as Apollo (VIDA, Coralville, IA, USA) (Hoffman and McLennan 1997; Hoffman and Chon 2005; Hoffman et al. 2016). Subsequently, structural and functional imaging-based metrics, such as luminal area, airway diameter, wall thickness, air and tissue volumes of the lungs, lobes, and among others, can be extracted. Also airway branches from the trachea to the segmental airways are labeled anatomically, and 1D airway skeleton is generated. With the introduction of dual-energy CT, it is also possible to image regional ventilation and perfusion via the use of radio-dense contrast agents such as xenon gas or iodine, respectively (Fuld et al. 2013; Iyer et al. 2016)

2.1.2 Airway Geometrical Modeling

The surface geometry and 1D skeleton of segmented airways are edited for airway geometric model for CFD simulation. For CT-unresolved small airways, of which the diameter is usually less than 1 mm, a 1D skeletonized airway model is reconstructed by use of a space filling algorithm within each of five lobes as color-coded in Fig. 2 left (Tawhai et al. 2000, 2004), linking large proximal airways to the lung periphery. The CT image obtained at full inspiration, or TLC is used in this process for the best resolution. Then, a CT-fitting technique is used to complete a 3D-1D coupled airway geometrical model (Miyawaki et al. 2017a), in which a 3D model is used in the regions of interest for a detailed flow simulation (see Fig. 2 right (a)) whereas the 1D model allows bridging of the 3D airways and lung parenchyma where ventilation function takes place and gas exchange occurs with the blood in the capillary beds. In the 3D geometrical model, a volumetric mesh is generated for CFD simulation (see Fig. 2 right (b–e)). The upper airways sit proximal to the tracheal inlet. Through the pharynx and the larynx, respectively, the upper airways precondition the flow and induce a laryngeal jet, which becomes transitional or turbulent flow under normal breathing conditions (Lin et al. 2007; Choi et al. 2009). However, CT scans of the lung which include the upper airways are not commonly acquired as part of clinical protocols. For this reason as well as the need to reduce computational cost, a synthetic eddy model (SEM) is employed in conjunction with a glottal constriction extended from the trachea to produce a laryngeal turbulent jet (Miyawaki et al. 2017b).

2.1.3   Image Registration

With two or more lung CT images obtained at different static lung volumes (typically TLC and one or more expiratory lung volumes), image registration is a key technique to obtaining functional variables, e.g., regional ventilation (distribution of the inspired air bolus), from the images, thus providing BCs for CFD lung simulation. Image registration determines the optimal local-to-local correspondence between medical images collected at different times or using different imaging modalities. Methods for image matching and linking multiple lung volumes have proven useful in linking structure and function to assess their longitudinal alterations (Crum et al. 2004; Choi et al. 2013a, 2017a; Jahani et al. 2017). The similarity measure of the sum of squared tissue volume difference (SSTVD) (Yin et al. 2009) has been demonstrated to successfully improve registration of lung images with large deformation. This approach takes into account changes in the reconstructed Hounsfield unit (HU) due to inflation in lung motion. Also faster and more accurate methods for image registration are essential in population-based studies that require the processing of large numbers of CT data sets. For example, Ellingwood et al. (2016) proposed a computation- and memory-efficient Diffeomorphic Multilevel B-Spline Transform Composite (DMTC) method to implement nonrigid mass-preserving registration of two CT lung images on graphics processing units (GPUs). Later, Haghighi et al. (2017a) developed a symmetric multilevel nonrigid registration by employing an inverse consistent (IC) transformation to impose the inverse consistency (Yang et al. 2014) and improve the accuracy of image registration. Besides providing subject-specific BCs for CFD, registration-derived variables provide functional metrics that can be used in clustering analysis discussed in Sect. 3.

2.1.4   Linking Structure and Function for BCs

Local air volume differences derived from image registration are used to approximate regional flow volume fractions at the ends of terminal bronchioles (Yin et al. 2013; Jahani et al. 2014, 2015, 2017). Then, through the 3D-1D coupled airways, flow rate fractions are computed at the distal ends of the 3D airway (Yin et al. 2010; Choi 2011; Lin et al. 2013; Miyawaki et al. 2016a), allowing calculation of flow BCs at a given total flow rate imposed at the proximal entrance of the mouth and supraglottis. The approach to extract 3D BCs for the terminal branches through the lung accounts for heterogeneous lobar ventilation in healthy subjects. However, a recent study (Wongviriyawong et al. 2013) has argued that static air volume change can predict the effect of regional compliance, but it cannot describe the effects of airway resistance on the distribution of regional ventilation. Using a 1D network structure, Choi et al. (2016) combined the effects of compliance and resistance to predict regional airflows allowing for 3D CFD simulation. The approach demonstrated the effect of airway resistance on regional airflows in asthmatic patients with airway narrowing. Thus, the new 1D network approach can be applied to improve BCs for patients with airway narrowing to avoid unphysiological pressure drops. It is noted

that the 1D resistance model has been sensitively estimated considering branching angle, flow rate, and flow direction (inspiration vs. expiration) (Choi et al. 2018).

2.1.5 Turbulence Modeling and CFD Simulation

The three common methods for modeling 3D turbulent flows are direct numerical simulation (DNS), large eddy simulation (LES), and Reynolds averaged Navier-Stokes models (RANS) (Kleinstreuer and Zhang 2003; Lin et al. 2013; Tawhai et al. 2009; Tawhai and Lin 2011). DNS resolves all turbulent eddies, thus being computationally expensive. In contrast, RANS does not resolve any turbulent eddies but parameterizes them, thus being the most inaccurate but computationally efficient. LES resolves energy-containing large turbulent eddies but parameterizes small eddies. LES has been demonstrated to capture high-fidelity turbulent flow structures in the complex human branching airways (Lin et al. 2007; Choi et al. 2009, 2010; Yin et al. 2010, 2013; Miyawaki et al. 2016a). Thus, LES is adopted in the CFD lung model presented in Sect. 2.2. In addition, temperature, humidity, heat, and water vapor transfer from the oropharyngeal region to the terminal bronchioles in the human lung can be predicted by 3D thermodynamic models (Wu et al. 2014).

2.2 CFD-Predicted Variables in the Human Lungs

2.2.1 Turbulent Flow in the Airways

Contrary to many conventional assumptions, airflow in the human airways features turbulent or transitional characteristics even under normal tidal breathing conditions (Lin et al. 2007; Choi et al. 2010, 2013b). Glottal constriction induces a laryngeal jet, which undergoes turbulent transition during the inspiratory phase of tidal breathing. Turbulence in the trachea efficiently mixes air together with embedded particulate matter before they enter the branching airways. Turbulence decays over several airway generations depending on the individual's breathing pattern and airway diameters (Lin et al. 2007; Choi et al. 2009, 2010; Yin et al. 2013). Figure 3 shows the turbulent jet structure obtained by 3D-1D coupled CFD simulation of tidal breathing in a healthy human lung. Turbulent velocity and pressure fields at a peak inspiratory flow are demonstrated.

2.2.2 Inhaled Particle Transport and Deposition

Lagrangian particle-tracking simulation allows quantification of transport and deposition of inhaled aerosols in the lungs by generation and lobe (Zhang et al. 2002; Lambert et al. 2011; Longest et al. 2012; Miyawaki et al. 2012, 2016b). For example, Miyawaki et al. (2012) compared particle transport characteristics embedded in air, helium (He), He-O_2, xenon (Xe)-O_2, and Xe at the same flow rates to investigate the effect of carrier gas on particle deposition efficiency in the human lungs. Due to the density difference, Re differs by more than tenfold between He and Xe-O_2. Figure 4 shows that the laryngeal jet of the light gas He remains laminar, where particles flow in separate streams. The heavy gas mixture Xe-O_2 becomes turbulent both in the upper airway and the trachea, where particles in the trachea
Fig. 3 CFD results of air flow in the multiscale lung model. (**a**) A frontal view of laryngeal jet color-coded with pressure, combined with skeletonized entire conducting airway model color-coded for each lobe; (**b**) A right side view of the laryngeal jet (velocity), with velocity vectors imposed at 3D ending branches (pink) (Lin et al. 2009)

were well mixed and dispersed. Thus, CFD is able to predict airflow structure and particle deposition in different carrier gases for assessment of deposition efficiencies of inhaled aerosols.

3   Machine Learning of CT Imaging Lung Data in Multicenter Setting

3.1   Machine Learning of Asthma Populations

3.1.1   Multiscale Imaging-Based Metrics

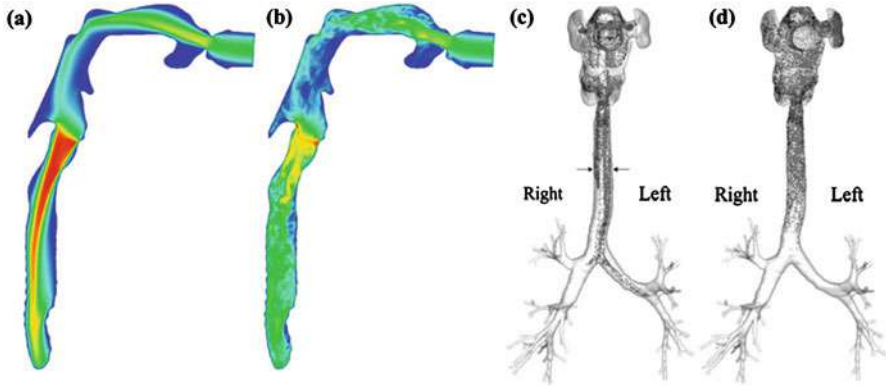
Multiscale metrics aim to capture structural and functional phenotypes at different stages of lung diseases. Quantitative CT (QCT) imaging-based metrics are used to characterize asthmatic phenotypes such as airway narrowing and chronic inflammation (Busse and Lemanske 2001). For instance, luminal diameter and wall thickness (Montaudon et al. 2009) measured by QCT imaging indicate the


Fig. 4 Instantaneous gas speed distributions in a vertical plane cutting through the center of the trachea looking from right at peak inspiration of normal breathing for (**a**) He and (**b**) Xe-O_2 and the resulting 2.5 μm particle flows in (**c**) He and (**d**) Xe–O_2, viewed from the front (Miyawaki et al. 2012)

quantitative degrees of airway narrowing and airway wall thickening. In addition, an air-trapping metric (voxels < -856 HU on the expiratory image) (Busacker et al. 2009) serves as a measure of what has been termed functional small airway disease or fSAD. These imaging-based metrics have been individually used to identify either structural or functional alteration, but they have not been integrated (until recently) to identify clinically meaningful subgroups. A recent use of ML technique allows for identifying predominant structural and functional variables as well as classifying asthma subpopulations (clusters) acquired by an imaging center (Gupta et al. 2014). However, the results of ML technique could be affected by the quality of given imaging data, as well as the number of samples. For the purpose of deriving unbiased and reproducible clusters with larger data sets, Choi et al. (2017b) developed a multiscale imaging-based cluster analysis (MICA) and employed QCT imaging data of asthmatic subjects acquired by SARP. Furthermore, they improved existing imaging-based metrics by eliminating intersubject and inter-site variations.

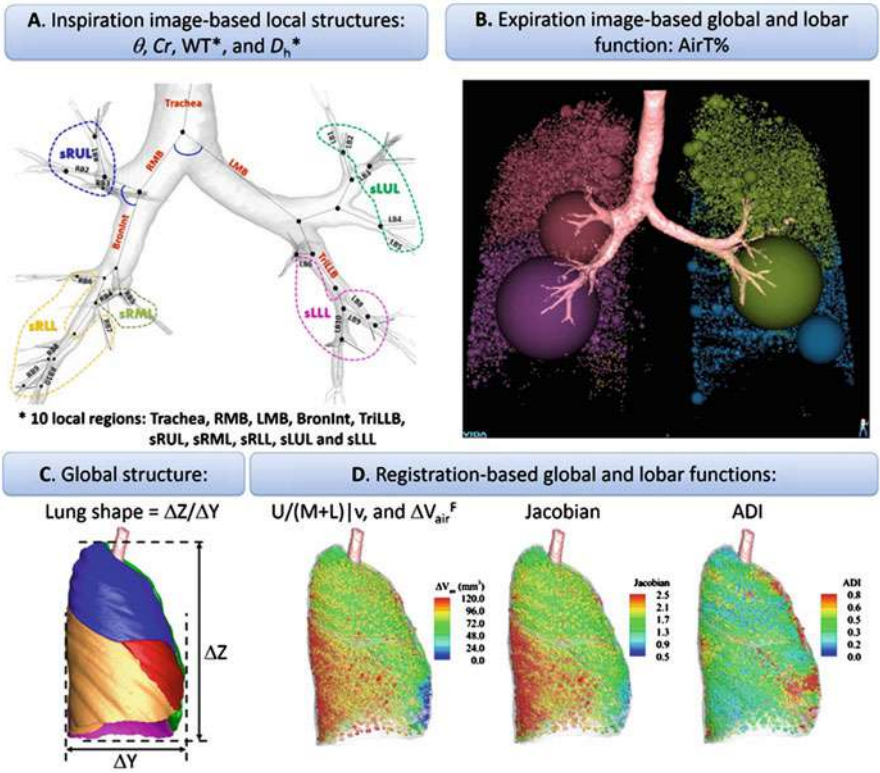
SARP (Wenzel and Busse 2007) has contributed to characterize disease phenotypes within a heterogeneous asthmatic population. Besides collecting demography, blood/sputum sample, and PFTs, the multicenter protocols included a CT imaging protocol acquiring images at two static scans at the levels of TLC and functional residual capacity (FRC). The acquisition of two volumetric scans at inspiration and expiration is a critical step in the use of CT for the assessment of both airway structure and lung function. First, registering two static volumetric images provides the means for quantifying peripheral local mechanical strains (Choi et al. 2013c). In addition, airway diameter and wall thickness can be assessed at TLC, while air trapping is evaluated at FRC or RV, and these metrics are integrated through the fact that lung volumes have been linked (Choi et al. 2014, 2015). Such a post-processing


Fig. 5 QCT structural and functional imaging-based metrics obtained at multiscale levels (Choi et al. 2017b)

with image segmentation and image registration successfully identifies structural and functional metrics at multiscale levels.

More specifically, using an automated segmentation software Apollo (VIDA Diagnostics), four local structural variables including branching angle (θ), airway circularity (Cr), wall thickness (WT), and hydraulic diameter (D_h) are extracted from TLC scans. The θ, Cr, WT, and D_h indicate altered skeletal structure, heterogeneous airway shape, airway wall thickening (or thinning), and airway luminal narrowing, respectively. In order to reflect regional features, these metrics are extracted from ten segmental airways (Fig. 5). Using the same software, air trapping (AirT%) is extracted from the FRC image acquired in SARP. (It should be noted that FRC was the lung volume chosen for the expiratory image but more recently SPIROMICS has adopted the more traditional volume of RV for the assessment of air trapping). Furthermore, a lung shape at TLC is extracted to evaluate a global lung structure. Using a customized image matching-based software (Yin et al. 2009), Choi et al. (2017b) obtained three functional variables including fractional regional air volume change (ΔV_{air}^{F}), regional volume change (Jacobian),

and an anisotropic deformation index (ADI) between TLC and FRC. The ΔV_{air}^{F}, Jacobian, and ADI indicate preferential air volume change, local expansion, and nonuniform stretch, respectively, in parenchymal regions. The metrics acquired at the voxel level were reduced to lobar metrics taking fraction (ΔV_{air}^{F}) or medians (Jacobian and ADI) in five lobes and a whole lung (a total of six regions). All of the listed imaging-based metrics at both local (segmental) and global (lobar/whole lung) scales are illustrated in Fig. 5.

3.1.2   Coping with Intersubject Variability

For statistically reliable results from ML, potential bias should be eliminated. In the QCT imaging analysis, the first potential factor causing data bias is intersubject variation. Without using a normalization scheme, there have been conclusions from an asthmatic population suggesting that asthmatics have thinner walls than healthy subjects (Montaudon et al. 2009). This conclusion runs contrary to the general view that asthmatic airways are thicker, at least in severe asthma through a process of airway remodeling Busacker et al. (2009). Choi et al. (2015) observed that airway diameter and wall thickness appear to be significantly associated with gender, age, and height, among them with gender being the most sensitive variable to determine normal airway size. Thus, an unbalanced number of samples due to gender can potentially cause large variations within groups, masking disease-related airway alterations. In the same study, Choi et al. (2015) developed novel normalization methods for airway diameter and wall thickness. Using 61 healthy subjects, they performed multiple linear regression with the given gender, age, and height to derive predicted values of tracheal diameter and wall thickness. These quantities were used to normalize QCT-based D_h and WT, being denoted as D_h^{*} and WT*.

3.1.3   Coping with Inter-site Variability

The second potential factor that may cause statistical bias is associated with inter-site variability. For the purpose of increasing the sample size, a key element of successful machine learning, it is essential to employ multicenter data acquired by multiple scanners. This requires matching imaging protocols (Sieren et al. 2016) since different scanners and associated calibrations may introduced variations in standard CT densities, especially at the lower end of the HU range where air should be represented as -1000 HU and blood should be approximately 55 HU (with water at 0 HU). The difference is critical in evaluating CT density-based measure, e.g., air trapping, and emphysema. Note that HU < -850 (or -856) is commonly used when evaluating air trapping (Busacker et al. 2009). Choi et al. (2014) demonstrated the effects of CT scanners to air-trapping measure between three different imaging centers, namely, University of Iowa, University of Pittsburgh, and Washington University in St. Louis. They concluded that using different CT scanners causes significant variation by data distribution which goes beyond actual patient differences. Therefore, they introduced a normalization scheme to control CT density distribution. This approach employs a fraction-threshold measure rather than density-threshold measure by assuming tracheal CT density on a given scanner

as a representation of air density. The new air-trapping method successfully reduced inter-site variation.

3.1.4   Dimensional Reduction and Clustering

ML techniques, especially unsupervised learning, are very sensitive to the given data distribution. Since Choi et al. (2014, 2015) reduced the potential bias due to intersubject and inter-site variations using newly derived normalization schemes, the use of an unsupervised learning approach has led to the extraction of altered features due to disease rather than due to population and scanner differences. Using QCT imaging-based metrics, Choi et al. (2017b) hypothesized that multiscale imaging-based metrics alone could be employed to derive clinically meaningful clusters. Imaging features are highly correlated such that airway narrowing within the central airway segments may be associated with air trapping in peripheral regions. Since the number of imaging-based metrics is relatively large compared with the number of samples, dimensional reduction via principal component analysis (PCA) was employed. Due to their significant correlations, the 57 imaging-based metrics were reduced to only 7 principal components (PCs). The seven PCs were determined with a parallel analysis with uncorrelated random data. They then used these seven PCs to perform a clustering analysis. K-means, hierarchical, and a Gaussian mixed model with various numbers of clusters were evaluated. They found that K-means with four clusters provided the most reproducible results based on higher Jaccard index than two other methods and other number of clusters.

Fig. 6 A summary of imaging and clinical features between QCT imaging-based clusters (Choi et al. 2017b)

Four imaging-based clusters were successfully identified based upon their unique imaging features (Fig. 6). Cluster 1 demonstrated normal airway feature with hyperinflation measured by Jacobian and ADI. The patients within Cluster 1 were early-onset younger non-severe asthmatics with reversible airflow obstruction. Cluster 2 demonstrated airway narrowing without airway wall thickening. The patients within Cluster 2 were a mix of non-severe and severe asthmatics with marginal inflammation. Cluster 3 demonstrated significant airway wall thickening without airway narrowing. The patients within Cluster 3 were dominated by obese females with reversible airflow obstruction, along with a lack of lymphocyte. Cluster 4 demonstrated most of the alterations such as airway narrowing, wall thickening, and air trapping and reduced lung deformation. The patients within Cluster 4 were late-onset older males with persistent airflow obstruction along with a neutrophil dominant signature.

3.2   Extension of MICA to COPD Populations

With recent advances in unsupervised clustering of patient populations (Paoletti et al. 2009; Cho et al. 2010; Garcia-Aymerich et al. 2011), there has been an increased effort to employ unsupervised learning for the purposes of grouping subpopulations of subjects within COPD communities (Burgel et al. 2012). To extend the above MICA to COPD populations, it is necessary to define new imaging-based variables to capture the COPD heterogeneity due to a complex condition associated with pulmonary and extrapulmonary manifestations.

3.2.1   New QCT Imaging-Based Metrics for COPD

Sixty nine CT imaging-based metrics were employed at both segmental and lobar levels, which is an expanded set of the existing 57 MICA variables used for asthma cluster analysis (Fig. 5). These three new variables are functional small airways disease percentage (fSAD%) to quantify diseased small airways at expiration, emphysema percentage (Emph%) to quantify emphysematous tissues at inspiration, and tissue fraction at TLC (β_{tissue}) indicating the portion of tissue volume in each voxel to assess a possible alteration of local tissue. The new features fSAD% and Emph% can be used to construct a parametric response map (PRM) (Galban et al. 2012) that tracks the progression of a diseased lung. It should be noted that the PRM-based measure of emphysema eliminates emphysematous voxels which on expiration are not air trapped and it also eliminates those voxels on expiration which appear air trapped but on inspiration are found to be emphysematous.

3.2.2   Clustering of Current Smoker Clusters

Using a batch of current smokers ($N = 284$) from SPIROMICS, four statistically stable clusters ($N = 96/45/88/55$) were identified with K-means clustering (Haghighi et al. 2017b). Cluster 1 had relatively normal airway structures; Cluster 2 had wall thickening with an increase of tissue fraction along with an increase of fSAD%; Cluster 3 exhibited decreased wall thickness and luminal narrowing; Cluster 4 had

a significant increase of emphysema and a decrease of luminal diameter along with significant elevation of small airways disease and significant reduction of lung deformation. Association tests of imaging-based clusters with clinical metrics were performed. Cluster 4 showed relatively low FEV1/FVC. In contrast, Cluster 1 showed normal FEV1/FVC with younger age. Association of imaging-based clusters with existing clinical metrics used for diagnosis of COPD suggests the sensitivity of MICA in differentiating clinically meaningful subpopulations.

3.3   Sensitivity of Multiscale Approach in Differentiating Overlap Syndrome

The traditional perspective of differentiating asthma from COPD has relied on reversibility of airflow obstruction by corticosteroids and/or bronchodilators, along with sputum biomarkers to differentiate eosinophilia and neutrophilia. According to recent reports (Gibson and Simpson 2009; De Marco et al. 2013), about 15–45% of patients with COPD may have asthma-COPD overlap, so-called ACO. This implies that two respiratory diseases are difficult to differentiate, because they may share common features. Misdiagnosing these respiratory diseases leads to incorrect treatments. Choi et al. (2017c) hypothesized that multiscale QCT imaging-based metrics could aid in the differentiation of the COPD and asthma.

Choi et al. (2017c) mixed SARP and SPIROMICS data sets together to determine the ability of imaging to differentiate between COPD and asthma. Overall, more significant structural and functional alterations were observed in COPD patients, compared with asthmatic patients. Compared with healthy subjects, asthma and COPD patients demonstrated similar alterations of Cr and $D_h{}^*$. On the other hand, density-based measures between asthma and COPD are significantly different. For example, fSAD% and Emph% are elevated in asthma and COPD but more prominently in COPD subjects. β_{tissue} is significantly increased in asthma and decreased in COPD subjects, compared with healthy subjects.

4   Integration of CFD and MICA for Cluster-Guided Analysis

The information on cluster membership is valuable in several ways because each cluster has unique features of structure and function. For example, it can provide representative patients who can then be used to guide CFD analysis to generate model data on distribution and deposition of inhaled aerosols representative of each individual cluster for the development of improved pulmonary drug delivery approaches. Note that a CFD simulation requires significant computational cost due to the complexity of airway structure and inherent feature of turbulent flows. By studying only small numbers of subjects through their membership in a given cluster, the need for large population CFD efforts can be reduced considerably.

Another example of utilizing the cluster membership is to help understand the success of some interventions, such as bronchial thermoplasty (BT) in severe

asthma. The study of Choi et al. (2017b) identified two severe asthma clusters (Cluster 3 and Cluster 4), one non-severe cluster (Cluster 2) and one severe cluster (Cluster 4) as shown in Fig. 6. Note that Cluster 3 is characterized by airway wall thickening but no airway narrowing, differing from that of Cluster 4 with constricted airways. Proximal airway narrowing may limit transport of inhaled particles into the distal small airways, and that BT enlargement of constricted airway lumens may allow more drugs to penetrate into the distal airways, consequently increasing drug efficacy. Thus, severe asthmatic subjects within Cluster 4 may benefit more from release of airway constriction by BT than those in Cluster 3.

5   Conclusions

This chapter has reviewed the pipeline to construct a subject-specific imaging-based CFD lung model, the development of QCT imaging-based metrics and MICA machine learning to identify homogeneous subpopulations (clusters), and the utilization of cluster membership to guide CFD analysis to generate model data for assessment of therapeutic interventions. The ultimate goal is to advance precision medicine. Both CFD model and MICA are multiscale in nature, within and between individuals, respectively. The former, a realistic personalized lung model, is based on local airway geometry (structure) and global ventilation distribution (function) derived from CT images, spanning from the trachea to parenchyma, as well as physical principles to predict data needed to understand the complex dynamics in the lungs, such as airflow and particle deposition, that are difficult, if not impossible, to be measured in vivo. The latter aims to bridge individual and population scales, enabling application of the former, the CFD lung model, to subpopulations exhibiting similar imaging (structural and functional) and clinical characters. The QCT imaging-based metrics used in ML are extracted at both local and global regions, aiming to capture a wide spectrum of structural and functional phenotypes manifested at different stages of disease progression. As an example, MICA was applied to identify subpopulations in respective asthma and COPD patients. MICA was further applied to a combined cohort of asthma and COPD subjects with overlap syndrome measured by traditional PFTs, demonstrating its sensitivity in identifying significant variables in classification.

Moving forward, it is essential to use longitudinal data to assess stability and transition of cluster membership over time for outcome assessment. It is because all of the methods and analyses presented herein were based on cross-sectional data at one time point. In addition, more advanced machine learning techniques should be employed for more sensitive clustering. For example, deep learning, a machine learning technique based on neural network, can catch the nonlinear features of data and may lead to breakthrough results if equipped with parallel hardware such as GPU and cluster computers to tackle with big data sets. Deep learning can be used to rank the important features in disease severity and then to build a model to predict the severity of each patient in large populations. While PCA can only capture linear structure of the data, t-Distributed Stochastic Neighbor Embedding (t-SNE) focuses

on preservation of the local distance of high-dimensional data and therefore is able to capture nonlinear patterns (van der Maaten and Hinton 2008). Moreover, a self-organizing map, also known as the Kohonen network (Kohonen 1998), is a type of neural network using unsupervised learning for reduction of high-dimensional data and for visualization of data in a two-dimensional space, serving as an alternative method for PCA.

Contents

Abstract

Accurate and efficient computational tools for crystal structure prediction play an important role in accelerating the pace of new materials discovery and technological advances. In the last decade, there has been considerable progress in this area due to advances in both the development of computational algorithms and the rapid growth in the computational power of modern computers. The chapters in this section will describe the development and current status of algorithms and methods for crystal structure prediction and present several successful examples of utilization of these tools for the discovery of materials across a variety of applications.

1   Introduction

Advanced materials are essential for energy and economic security. The urgent demand for new energy technologies has greatly exceeded the capabilities of today's materials and chemical processes. Accurate and fast computational structure/property determination would complement traditional experimental efforts in materials design and discovery and accelerate the pace of technological advances. Additionally, the combinatorics of multicomponent compounds suggests that there are large numbers of currently unknown phases awaiting discovery. Hence, the opportunity for new materials discovery through a synergy of computational crystal structure prediction and experimental synthesis is very promising.

Knowledge about the structure of a crystal or nanoparticle at the atomic level is essential for the accurate calculation and understanding of materials properties. However, there are large numbers of experimentally synthesized compounds for which the crystal structure has not been solved. From the materials design and discovery perspective, it is also desirable to have reliable computational tools that can use modern high-performance computers to predict material structures based solely on chemical compositions with no prior assumptions about the system. However, to predict crystal or nanoparticle structures solely from the knowledge of chemical composition has long been recognized as a grand challenge in condensed matter physics, materials science, and solid-state chemistry (Maddox 1988; Eberhart and Clougherty 2004; Woodley and Catlow 2008). This "crystal structure prediction" problem is particularly challenging because it involves optimization (energy minimization) over a complex energy landscape with many local minima, and the number of these minima grows exponentially with the size of the system.

Early attempts for finding the lowest-energy structure of a given number of atoms and chemical composition involved simulated annealing using molecular dynamics (MD) or Monte Carlo (Kirkpatrick et al. 1983; Wille 1986; Doll et al. 2007). However, these approaches often prove computationally inefficient, since an effective exploration of the structure-energy landscape requires easily overcoming the transition barriers among different local minima in the system. In the past two decades, a number of algorithms and methods have been developed to tackle this challenging problem. As early as 1995, Ho et al. introduced a genetic algorithm (GA) scheme for global structure optimization by adopting a real space representation of the structures and a geometrical cut-and-paste operation to generate offspring from parent structures (Deaven and Ho 1995). This type of GA approach was successfully applied to structure optimization for atomic clusters (Deaven and Ho 1995; Ho et al. 1998; Lu et al. 2010), surfaces (Chuang et al. 2004, 2005), and interfaces (Zhang et al. 2009; Chua et al. 2010), as well as nanowires (Chan et al. 2006; Lu et al. 2007). In 2008, Oganov extended the GA method to the case of crystal structure prediction (Oganov and Glass 2008; Lyakhov et al. 2013) and consequently developed a computational crystal structure prediction package called Universal Structure Predictor: Evolutionary Xtallography (USpex)

(http://uspex-team.org/en/) which is now widely used in the community. Another widely used package for crystal structure prediction called CALYPSO (http://www.calypso.cn/) was introduced by Ma et al. in 2010 (Wang et al. 2010, 2012) which is based on a particle swarm optimization strategy. In both GA and particle swarm optimizations, the most time-consuming part of the computation is the structural relaxation and energy evaluation. These portions of the algorithm can be accelerated using classical empirical potentials but with the caveat of limited accuracy and predictive power. On the other hand, first-principles calculations based on density functional theory have increased accuracy, but with concomitant increased computational cost. In order to overcome this problem, in 2014 Wang et al. proposed an adaptive genetic algorithm (Wu et al. 2014; Zhao et al. 2014) which uses classical potentials for the structural optimization and energy evaluation, but the potentials are adaptively trained on the fly by first-principles calculations. In parallel to methods based on GA or particle swarm optimization, other approaches based on basin or minima hopping strategies have also been developed (Wales and Doye 1997; Goedecker 2004; Amsler and Goedecker 2010). These approaches modify the traditional simulated annealing method to more efficiently accelerate the sampling of the energy landscape of a system through MD simulations. Recently, Liu et al. 2017 extended the basin hopping strategy and introduced a stochastic surface walking (SSW) method targeting both global potential energy surface (PES) exploration and reaction pathway sampling (Shang and Liu 2013; Shang et al. 2014). In addition to the methods mentioned above, other methods such as ab initio random structure search method (Pickard and Needs 2011) and methods combining experimental information with computational approaches for crystal structure solution (Meredig and Wolverton 2013) have also been developed.

The methods for crystal structure prediction mentioned above have been successfully applied to materials discovery in a large variety of energy-related areas in the past decade, including superconducting materials, superhard materials, magnetic materials, and energy storage, solar energy, and thermal energy materials. For example, combining the CALYPSO method for crystal structure prediction with first-principles electron-phonon-coupling calculations has led to predictions of many unexpected superconducting phases in H-rich compounds at high pressure. Strikingly, a T_c of about 80 K predicted for dense H_2S (Li et al. 2014) stimulated the experimental discovery and synthesis of H_2S and H_3S phases above megabar pressures with superconducting T_c values in the range of 30–203 K (Drozdov et al. 2015). Very recently, a theoretical prediction of a high pressure superconducting phase of LaH_{10} using the methods mentioned above has also been successfully confirmed by experimental synthesis of this compound (Liu et al. 2017). Evidence for record-breaking superconductivity of $T_c \sim$ 260 K for this hydrogen-rich compound has also been reported (Somayazulu et al. 2019). These examples, among others given in the following chapters in this section, demonstrate that advances in computational methods for crystal structure prediction can greatly accelerate the pace of new materials discovery and technological advances.

2   Contributions

In the first edition of the *Handbook of Materials Modeling* published in 2005, the topic of crystal structure prediction and materials discovery was not included since most of the exciting development in this area has just emerged in the last 10 years. The purpose of this section is to give overviews and tutorials on some of the important algorithms and methods developed in this area along with their applications in design and discovery for various energy-related materials. The contributions to this part are briefly outlined below.

▶ Chapter 114, "CALYPSO Method for Structure Prediction and Its Applications to Materials Discovery," provides an overview of the basic theory and main features of the CALYPSO approach, which is based on a particle swarm optimization strategy, for atomic level of structure prediction based only on chemical composition of the system. Applications of the method to design and discovery of superconductors and superhard materials are also discussed.

▶ Chapter 115, "Adaptive Genetic Algorithm for Structure Prediction and Application to Magnetic Materials," introduces an adaptive genetic algorithm (AGA) method for atomic-level structure prediction. This method uses a genetic algorithm (GA) to explore the atomic configuration space with computationally fast classical interatomic potentials, but the potentials are adaptively trained on the fly by first-principles calculations along with the GA search. Therefore, the method holds the speed of classical potential searches and at the same time retains the accuracy of first-principles calculations for energy evaluations. Applications of the method to discovery of novel magnetic materials are discussed. Note that the concept of on-the-fly adaptive interatomic potential fitting can also be applied to other optimization methods (e.g., particle swarm in CALYPSO).

▶ Chapter 116, "Multi-objective Optimization as a Tool for Material Design" deals with materials design where multi-objective optimizations are required. It explains the concepts of Pareto optimality and Pareto dominance and uses these concepts in solving multi-objective (MO) optimization problems. Several practical case studies are presented, and the efficiency of this method is assessed for optimization of double-objective problems.

▶ Chapter 117, "Minima Hopping Method for Predicting Complex Structures and Chemical Reaction Pathways" describes the minima hopping method (MHM) for predicting complex structures and chemical reaction pathways. The MHM is a structure prediction method that uses short molecular dynamic escape trials to explore potential energy landscapes and a fingerprinting approach to avoid sampling previously visited minima. The MHM has been successfully employed in studying molecular clusters, bulk solids, and surfaces. The application of MHM to the discovery of high pressure materials is also discussed.

▶ Chapter 118, "Stochastic Surface Walking Method and Applications to Real Materials" introduces a stochastic surface walking (SSW) method for both global potential energy surface (PES) exploration and reaction pathway sampling. The SSW PES sampling is automated and unbiased and takes into account second derivative information which allows the structural evolution to follow low-energy

pathways while being able to overcome high barriers. Several examples of PES exploration by combining SSW with first principles and neural network potential calculations are presented. These examples illustrate the power of SSW for unbiased PES exploration and reaction pathway searching.

▶ Chapter 119, "First-Principles-Assisted Structure Solution: Leveraging Density Functional Theory to Solve Experimentally Observed Crystal Structures" discusses the first-principles-assisted structure solution (FPASS) method. FPASS is a genetic algorithm-based approach, but optimizes based on a hybrid of computational (minimization of energies from density functional theory) and experimental (refinement to known, experimental powder diffraction pattern) information. The goal of FPASS is to solve crystal structures with reduced guidance from experts typically required for Rietveld refinement alone. A number of case studies are presented that show the breadth of structure types that have been solved using this method, including those run in a high-throughput mode.

▶ Chapter 120, "Computational Modeling and the Design of Perovskite Solar Cells" focuses on materials modeling for solar energy applications. It discusses the key material parameters for photovoltaic application such as the bandgap, effective mass, and optical absorptions. It also takes perovskite solar cell as an example, to show how materials modeling and high-throughput computational screening of crystal structure-property relationship can help understand and engineer practical materials for solar energy applications.

3 Future Perspectives

It should be pointed out that despite considerable progress and success in methodology development and applications of crystal structure prediction and materials discovery over the past 10 years, there still a lot of room for further exploration. For example, the rapid progress in artificial intelligence and data science has opened the door to possible new approaches to computational crystal structure prediction and materials discovery. Future work in integrating crystal structure prediction algorithms with the advances in machine learning and materials informatics will be very fruitful.

It is also worthwhile to note that knowledge of stable structures does not provide detailed synthesis pathways. It is highly desirable to know whether and how any identified new materials can be eventually synthesized experimentally. The theoretical prediction of synthesis conditions leading to a desired structure remains a grand challenge in computational materials science. Prediction of synthesis pathways will require not only thermodynamic free energies at finite temperatures for the phases of interest but also for competing phases and decomposition pathways.

The future of structure prediction methods should also address other limitations of current approaches. Structure prediction of defects and interfaces remains a difficult problem for most methods. Also, nearly all the methods in this section deal with perfectly ordered, stoichiometric compounds. A large fraction of known material phases are partially ordered or disordered, and incorporation of these

aspects into structure prediction methods will enable a much larger search space of potential new compounds. Finally, most of the methods in this section are predicted on energy minimization as a route to materials discovery. However, a large number of known compounds are either metastable or stabilized at non-ambient conditions (e.g., high temperatures) and hence are not zero-temperature ground states. Crystal structure prediction for these non-ground-state phases (where straightforward energy minimization will not be sufficient) remains another challenge for future advances.

Abstract

Atomic-level structure prediction for condensed matters, given only a chemical composition, is a major challenging issue in a broad range of science (e.g., physics, chemistry, materials, and planetary science, etc.). By combining the global swarm optimization algorithm with a number of specially designed structure-dealing techniques (e.g., symmetry constraints, structure fingerprints, etc.), we developed the CALYPSO (Crystal structure AnaLYsis by Particle Swarm Optimization) structure prediction method that is able to predict the

structures of a wide range of materials including isolated clusters/nanoparticles, two-dimensional layers and reconstructed surfaces, and three-dimensional bulks and holds the promise for the functionality-driven design of materials (e.g., superhard, electride, and optical materials, etc.). It has been demonstrated in a wide range of applications that CALYPSO is highly efficient when searching for the structures of materials and becomes an invaluable tool for aiding materials discovery. In this chapter, we provide an overview of the basic theory and main features of the CALYPSO approach, as well as its versatile applicability to the design of superconductors and superhard materials. Finally, the conclusion and opportunities for further research on CALYPSO method are presented.

1 Introduction

The traditional way of discovering new materials is by Edisonian iterations of trial and error, which choose materials to synthesize and test depending on chemical intuition, experience, or theoretical knowledge until some combination of success and exhaustion is achieved. This approach is painstaking, long, and costly due to the extraordinary number of experimental attempts required. Advances in computing now allow new materials with target properties to be simulated and analyzed theoretically before their synthesis (Agrawal and Choudhary 2016; Jain et al. 2013), significantly reducing the necessary trials (and errors) and thus the expected cost of discovery (Jain et al. 2016; Oganov et al. 2010; Needs and Pickard 2016).

A material's structure determines its properties and functionalities. Therefore, theoretical structure prediction is critical in aiding materials discovery (Wang and Ma 2014). The goal of crystal structure prediction is to develop an efficient computational scheme to explore the high-dimensional potential-energy surface (PES) in order to identify the global energy minimum that corresponds to the global stable ground-state structure observable in experiment. Empirical observations and heuristic estimates indicate that the number of local minima grows exponentially as the system size increases (Stillinger 1999; Gavezzotti 1994). Therefore, an efficient computational approach is urgently needed to find quickly the most stable structure of a large assembly of atoms in the vast configuration space of the PES.

Various strategies to generate hypothetical structures have been recently pursued in the field of crystal structure prediction, and several efficient structure prediction methods (e.g., data mining (Gavezzotti 1994), simulated annealing (Kirkpatrick et al. 1983; Schön and Jansen 1996), genetic algorithms (Deaven and Ho 1995; Oganov and Glass 2006; Abraham and Probert 2006; Trimarchi and Zunger 2007; Kolmogorov et al. 2010), minima hopping (Goedecker 2004; Amsler and Goedecker 2010), basin hopping (Wales and Doye 1997; Doye and Wales 1998), metadynamics (Laio and Parrinello 2002), random sampling (Pickard and Needs 2011; Shang and Liu 2013), and CALYPSO (Wang et al. 2010)) have been developed. Their applications to materials science have led to a number of breakthroughs, as exemplified by a series of theory-driven discoveries of novel functional materials (Ceder 2010; Ma et al. 2009; Oganov et al. 2009; Zhu et al. 2011; Pickard and Needs 2006; Drozdov

et al. 2015; Ceder et al. 1998; Teter 1998; Li et al. 2014). Structure prediction is now becoming an irreplaceable tool to accelerate the discovery of materials. Several reviews consider structure prediction methods and their applications (Wang and Ma 2014; Woodley and Catlow 2008; Oganov 2011; Ciobanu et al. 2013; Wang et al. 2015; Zhang et al. 2017a), but this work focuses only on our CALYPSO method and its application to superconductive and superhard materials.

This chapter is organized as follows. Section 2 briefly introduces the basic theory and general features of the CALYPSO methodology, including swarm intelligence algorithm. Several recent applications of CALYPSO in discovering superconductive and superhard materials are provided in Sect. 3, followed by general conclusions and future prospects in Sect. 4.

2 CALYPSO Structure Prediction Method

2.1 General Theory of the CALYPSO Method

The CALYPSO method for structure prediction run comprises several main steps (Fig. 1). Initial structures are randomly generated with symmetry constraints. Once a new structure is generated, structure characterization is performed to examine its similarity to all the previous ones, where duplicate or similar structures are eliminated. After all the structures of each population have been generated, local structural optimizations are performed to reduce the noise of the energy surface and drive the systems to local minima. Structural evolution via the particle swarm optimization algorithm is then carried out to produce new structures for the next generation. These steps are iterated until a termination criterion (such as a prescribed threshold or a fixed number of iterations) is attained (Wang et al. 2012a). Below we give an introduction to the general theory of the CALYPSO method.

2.1.1 Generation of Random Structures with Symmetry Constraints

Most natural structures of materials are governed by symmetry rules; any crystal structure must belong to one of the 230 crystallographic space groups. For a given space group, only a subset of the optimized variables (lattice parameters and atomic coordinates) is independent, while the rest are determined via symmetry rules. It is found that the majority of randomly generated structures (particularly for

Fig. 1 The flow chart of CALYPSO

large systems, e.g., >30 atoms per simulation cell) without symmetry constraints exhibits unreasonably low symmetries, while proper consideration of symmetry constraints can significantly reduce the optimization variables and enrich the diversity of structures during structure evolution. Symmetry constraints on random structure generation are therefore implemented in CALYPSO to improve the starting structures for the subsequently evolutionary structure searches. Different strategies for dealing with 0D-isolated molecule/clusters, 2D layers or surfaces, and 3D crystals are designed to generate random symmetric structures. In particular, the generation of random structures is constrained by $\sim$40 point groups for isolated systems (e.g., molecules, clusters, and nanoparticles), 17 planar space groups for 2D layers or surfaces, and 230 space groups for 3D crystals. For example, the space group of initial crystal structures is randomly selected among 230 ones for a crystal structure prediction. Once the space group is selected, the lattice parameters are generated within the chosen symmetry according to the defined volume, and the corresponding atomic coordinates are obtained by a combination of a set of symmetrically related coordinates (Wyckoff positions) in accordance to the number of atoms in the simulation cell. Notably, a backup database of space groups of all generated structures is established in order to compare them with the space groups of newly generated structures. The appearance of identical space group is forbidden with a certain probability (80%). This allows the initial samplings to cover different regions of the search space and generate the diverse structures, which are found to be crucial for a high efficiency of a global minimization.

To demonstrate the effects of symmetric constraints on structure generation, bulk crystals (Wang et al. 2012a) and isolated clusters (Lv et al. 2012) are chosen as two test systems, where crystalline TiO_2 consists of 16 formula units per cell, while the cluster contains 100 atoms described by the Lennard–Jones potential. For each system, a large number of structures (3,250 for the crystal and 10,000 for the cluster) were randomly generated with and without symmetric constraints, respectively, and then locally optimized using the GULP code (Gale 1997). The obtained energy distributions of crystal and cluster are shown in Fig. 2a and b, respectively. The results (Fig. 2a) showed that the rutile structure, i.e., the global stable structure, cannot be generated without symmetry constraints. However, once symmetric constraints were employed in the generation of random structures, 203 ($\sim$6.2% of the total) rutile structures were successfully produced. The generated cluster structures (Fig. 2b) without symmetric constraints have a Gaussian-like energy distribution with a well-defined sharp peak centered at a high energy of 0.3 ε/atom. Many of the cluster structures appeared disordered or liquid-like; their generation greatly reduced structural diversity. Instead, once point group symmetry was applied, a much broader energetic distribution emerged with the generation of a large number of lower-energy structures.

2.1.2   Structural Characterization Techniques

During the structural evolution process, many trial structures are produced for each generation, and some may be very similar or even identical. The existence of similar structures decreases the diversity of the population, potentially leading to stagnation.
Fig. 2 Energetic distributions of randomly generated structures for (**a**) TiO_2 and (**b**) LJ_{100} clusters with and without symmetries

Moreover, given that the most computationally expensive parts of the algorithm are the energy calculations and local structural optimizations, repetitive optimizations of similar structures will significantly increase the computational cost and impede the structure searching efficiency. Thus, efficient searching must employ techniques to fingerprint each structure, measure its similarities to other structures, and eliminate similar structures. Two effective methods, the bond characterization matrix (BCM) (Lv et al. 2012) and the coordination characterization function (CCF) (Su et al. 2017), have been developed based on the geometrical information of a structure.

The BCM is an advanced version of the bond-orientational order parameter technique originally introduced by Steinhardt et al. (Steinhardt et al. 1983). For a given structure, a bond vector r_{ij} between atoms i and j is defined if the interatomic distance is less than a given cutoff distance. This vector is associated with the spherical harmonics $Y_{lm}(\theta_{ij}, \varphi_{ij})$, where θ_{ij} and φ_{ij} are the polar angles. A weighted average over all bonds formed by, for instance, the type A and B atoms is then evaluated by Eq. 1:

$$Q_{lm}^{\delta_{AB}} = \frac{1}{N_{\delta_{AB}}} \sum_{i \in A, j \in B} e^{-\alpha(r_{ij} - b_{AB})} Y_{lm}\left(\theta_{ij}, \phi_{ij}\right), \tag{1}$$

where δ_{AB} and $N_{\delta_{AB}}$ denote the type and the number of a bond, respectively. To avoid dependence on the choice of reference frame, it is important to consider the rotationally invariant combinations:

$$Q_l^{\delta_{AB}} = \sqrt{\frac{4\pi}{2l+1}\sum_{m=-l}^{l}\left|Q_{lm}^{\delta_{AB}}\right|^2}, \tag{2}$$

where each series of $Q_l^{\delta_{AB}}$ for $l = 0, 2, 4, 6, 8,$ and 10 can be used to represent a type of bond and is thus an element of the BCM. Only even-l spherical harmonics are used to guarantee invariant bond information with respect to the direction of the bonds. By including the complete structural information of bond lengths and angles, this technique unambiguously fingerprints the structures. As a result, the similarity of any two structures (u and v) can be quantitatively evaluated by the Euclidean distance between their BCMs:

$$D_{uv} = \sqrt{\frac{1}{N_{type}}\sum_{\delta_{AB}}\sum_l\left(Q_l^{\delta_{AB},u} - Q_l^{\delta_{AB},v}\right)^2}, \tag{3}$$

where N_{type} is the number of bond types.

Two LJ_{38} clusters with different structural motifs are chosen as examples to test the BCM. The first structure is the global stable structure, having a face-centered cubic structural motif (LJ_{38}-O_h), while the second one is a metastable incomplete Mackay icosahedron (LJ_{38}-C_{5v}). Their BCMs, shown by histograms in Fig. 3a, are dramatically different. Except for Q_2 and Q_{10}, the LJ_{38}-O_h structure has obviously larger Q_l values than those in the LJ_{38}-C_{5v} structure. The resultant distance between these two structures is a very large value of 0.618, characterizing their large structural differences. The distances to the isotropic system are 0.728 for LJ_{38}-O_h and 0.163 for LJ_{38}-C_{5v}, illustrating a high degree of order in LJ_{38}-O_h. Randomly distorting LJ_{38}-O_h, and plotting its distances to the unaltered structure as a function of distortion (Fig. 3b), illustrates that the distances increase linearly with the distortions at the initial stage, reflecting correctly the structural deviations. Eventually, the curves become flat at a distortion of about $0.4r_0$. At this stage, the distances are approaching those distances relative to the isotropic limits favorable for disordered systems.

Although the BCM can provide a precise measurement of structures, it suffers from heavy computational costs for large systems (e.g., the number of atoms per simulation cell >30) since all the geometrical information (bond lengths and angles) is considered and evaluated. To reduce the computational cost, CCF, an alternative and fast method depending only on the two-body correlation function (interatomic distance), was developed to fingerprint large structures. The CCF method employs a matrix involving different atomic types:

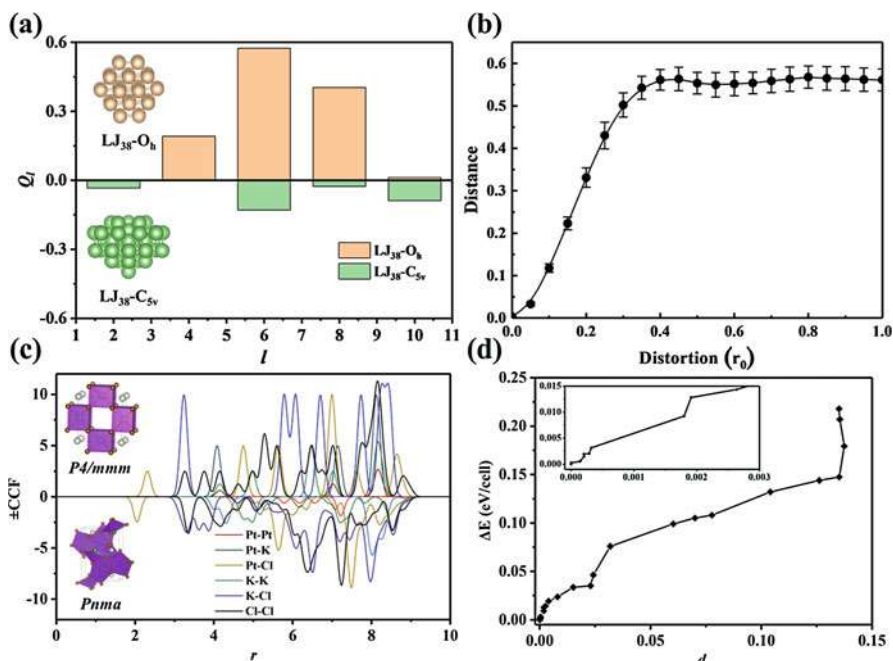
$$M = \begin{bmatrix} ccf_{11} & \cdots & ccf_{1Nt} \\ \vdots & \ddots & \vdots \\ ccf_{Nt1} & \cdots & ccf_{NtNt} \end{bmatrix}. \tag{4}$$


Fig. 3 (**a**) Histograms of BCMs for LJ$_{38}$-O_h and LJ$_{38}$-C_{5v}. (**b**) BCM distances with respect to the unaltered structures as a function of distortions for LJ$_{38}$-O_h. Each data point was obtained by averaging over the distances of 100 randomly distorted structures, and the error bar denotes the standard deviation. (**c**) Comparisons of the CCFs of different structures of $P4/mmm$ and $Pnma$ for PtK$_2$Cl$_4$. For ease of comparison, the plots show -CCFs for the $Pnma$ structure. (**d**) Calculated ΔE and structural distances between the optimized structure of CuInS$_2$ and all intermediate structures in each ionic step. Inset shows the detailed optimization procedure approaching the equilibrium point

Here, each matrix element related to different pairs of atomic types i and j is calculated as follows:

$$
\mathrm{ccf}_{ij}(r) =
\begin{cases}
\frac{1}{N}\sum_{n_i}\sum_{n_j} f\left(r_{n_i n_j}\right)\sqrt{\frac{a_{pw}}{\pi}}\exp\left[-a_{pw}\left(r - r_{n_i n_j}\right)^2\right], & (i \neq j), \\
\frac{1}{2N}\sum_{n_i}\sum_{n_j} f\left(r_{n_i n_j}\right)\sqrt{\frac{a_{pw}}{\pi}}\exp\left[-a_{pw}\left(r - r_{n_i n_j}\right)^2\right], & (i = j),
\end{cases}
\tag{5}
$$

where n_i runs over all the atoms of the i-th type within the cell, n_j runs over all the atoms of the j-th type within the extended cell, $r_{n_i n_j}$ is the interatomic distance less than the cutoff radius (usually 9.0 Å), $f\left(r_{n_i n_j}\right)$ is the weighting function for different interatomic distances, N is the number of atoms in the cell, a_{pw} is an empirical parameter that controls the peak width of the Gaussian function, and $\sqrt{\frac{a_{pw}}{\pi}}\exp\left[-a_{pw}\left(r - r_{n_i n_j}\right)^2\right]$ is the normalized Gaussian function. As a result, the similarity of two structures can be estimated by the distance between their CCF

matrices. The Pearson correlation coefficient was employed to measure the degree of similarity between two matrices, and the corresponding distance (d) is defined as $d = 1 - R$ from their correlation coefficient (R). A detailed description of the CCF can be found in Su et al. (2017).

Two distinct crystal structures of PtK_2Cl_4 with space groups of *P4/mmm* and *Pnma* are chosen to test the CCF method. The CCFs calculated for the two structures (Fig. 3c) are clearly rather different, with a large calculated distance of 0.655, giving a good measure on the degree of dissimilarity between the two structures. Note that our tests recommend a user-defined threshold of 0.075 as a good number to identify dissimilar structures. CCF is a continuous function with respect to the motion of the atoms. Through the optimization of a $CuInS_2$ structure with *Pbam* symmetry, it is seen from the calculated ΔE and structural distances between the optimized structure and the intermediate structures of each ionic step (Fig. 3d) that the structure closest to the equilibrium point tends to have the smaller ΔE and distance values.

2.1.3 Structural Evolution via Particle Swarm Optimization Algorithm

The CALYPSO method adopts a "self-improving" strategy to locate the global minimum of the PES via particle swarm optimization (PSO) (Kennedy 2011). The PSO algorithm is a typical swarm-intelligence scheme inspired by natural biological systems (e.g., ants, bees, or birds) and has been applied to a variety of fields in engineering and chemistry (Ourique et al. 2002; Call et al. 2007). Its application to extended systems for structure prediction started only recently (Wang et al. 2010, 2012b). Within the CALYPSO method, the structures at the $t + 1^{th}$ generation (x^{t+1}) evolve in the energy landscape through velocity. In practice, the lattice parameters (unit cell) of new structures remain unaltered or are randomly generated, while the atomic positions are updated according to the following formula:

$$x^{t+1} = x^t + v^{t+1}. \tag{6}$$

It is noteworthy that the velocity plays a significant role in governing the speed and direction of particle movement. The updated velocity (v^{t+1}) is calculated based on its previous location (x^t), previous velocity (v^t), current location $(pbest^t)$ derived from geometrical optimization of this individual, and the global best location $(gbest^t)$ for the entire population as follows:

$$v^{t+1} = wv^t + c_1r_1 \left(pbest^t - x^t \right) + c_2r_2 \left(gbest^t - x^t \right), \tag{7}$$

where w denotes the inertia weight controlling the momentum of the particle, which dynamically varies and decreases linearly from 0.9 to 0.4 during the iteration in our methodology; the self-confidence factor (c_1) and swarm confidence factor (c_2) are equal to 2, which give the best overall performance; r_1 and r_2 are random numbers distributed in the range [0, 1]. The velocity formula includes random parameters (r_1) and (r_2) that ensure good coverage of the searching space and avoid entrapment in local optima. The initial velocity of each structure is generated randomly, while
Fig. 4 The schematic diagram of global (**a**) and local (**b**) PSO

the updated one is calculated using both its individual properties and those of the entire population.

Two versions of the PSO algorithm (local and global) have been implemented in CALYPSO (Lv et al. 2012; Wang et al. 2011). The global PSO, outlined in Fig. 4a, has only one global best structure acting as the learning example or attractor for the entire structure population, and all particles seek new positions only in the regions close to the uniquely overall best position. This method converges quickly for small systems (i.e., those with fewer than $\sim$30 atoms in the simulation cell), but it may be less effective for larger systems because the PES becomes much more complex. The local PSO method is outlined in Fig. 4b. Each particle (i.e., a candidate structure) selects a set of other particles as its neighbors, and its velocity is adjusted according to both its position and the best position achieved so far in the community formed by its neighborhood. Thus, at each iteration, the particle will move toward its own best position and the best position of its local neighborhood, rather than the overall best position in the swarm. By maintaining multiple attractors corresponding to different regions of the PES, the local PSO allows for a finer exploration of the PES and can effectively avoid stagnation during the structure searches.

2.1.4   Local Structure Optimization

The PES of a material can be regarded as a multidimensional system of many peaks and valleys connected by saddle points. Given that the global minimum is one of the possibly many local minima, local structure searching is an inevitable part of the global search and therefore should be included in any efficient structure searching method. The CALYPSO method currently has interfaces with various ab initio and force-field-based total-energy packages (e.g., VASP (Kresse and Furthmüller 1996), SIESTA (Soler et al. 2002), Quantum ESPRESSO (Giannozzi et al. 2009), CASTEP (Segall et al. 2002), CP2K (Vandevondele et al. 2005), LAMMPS (Plimpton 1995), and GULP (Gale 1997)) for local structural optimization. Other external total-energy programs can also be easily interfaced with CALYPSO as required.

2.2   Features of the CALYPSO Method

CALYPSO can be used to perform unbiased searches of the energetically sta-
ble/metastable structures of a given chemical composition (Wang et al. 2015,
2016a). Several attractive features have been implemented in CALYPSO to resolve
various structure prediction problems, including 3D solids (Wang et al. 2010), 2D
layers (Wang et al. 2012b; Luo et al. 2011) and atomic adsorption (Gao et al.
2015), 2D surfaces (Lu et al. 2014), 0D nanoclusters or molecules (Lv et al.
2012), X-ray diffraction data-assisted structure searches (Gao et al. 2017a), and the
inverse design of novel functional materials (e.g., superhard, electride, and optical
materials) (Zhang et al. 2013, 2017b; Xiang et al. 2013).

2.2.1   3D Crystals

A crystallographic structure can be regarded as an infinitely repeating array of 3D
boxes, termed unit cells, represented by lattice parameters and atomic coordinates.
As shown in Fig. 5a, there are six lattice parameters: three lengths and three angles
of the lattice vectors. Each atom has three coordinates coded as a fraction of each of
the lattice vectors. Structure searches of 3D crystals evolve both types of variables
simultaneously to achieve the global minimum on the PES with $3N + 3$ dimensions,
where $3N - 3$ degrees of freedom are the atomic positions, and the remaining six
dimensions are the lattice parameters. To reduce the search space, several hard
constraints, including the minimum interatomic distances, the minimum lattice
lengths, and constraints on the range of angles between the lattice vectors, are
imposed in the CALYPSO method. For example, the distance between two atoms
should not be smaller than a threshold or the sum of their covalent radii, and the
angles between lattice vectors are free to vary between $30°$ and $160°$. An advantage
gained by using these constraints is to force attention onto regions containing
physically reasonable minima. The CALYPSO method has been widely applied
to the prediction of crystal structures for various systems (Wang and Ma 2014;
Zhu et al. 2011; Lv et al. 2011; Nishio-Hamane et al. 2012; Li et al. 2016; Chen
et al. 2013), some of which have already been experimentally confirmed (see, e.g.,
Guillaume et al. (2011), Bai et al. (2015), Ma et al. (2012), and Yang et al. (2017)).
Section 3 describes its applications to the discovery of novel superconductive and
superhard materials.

2.2.2   2D Layers and Atomic Adsorption

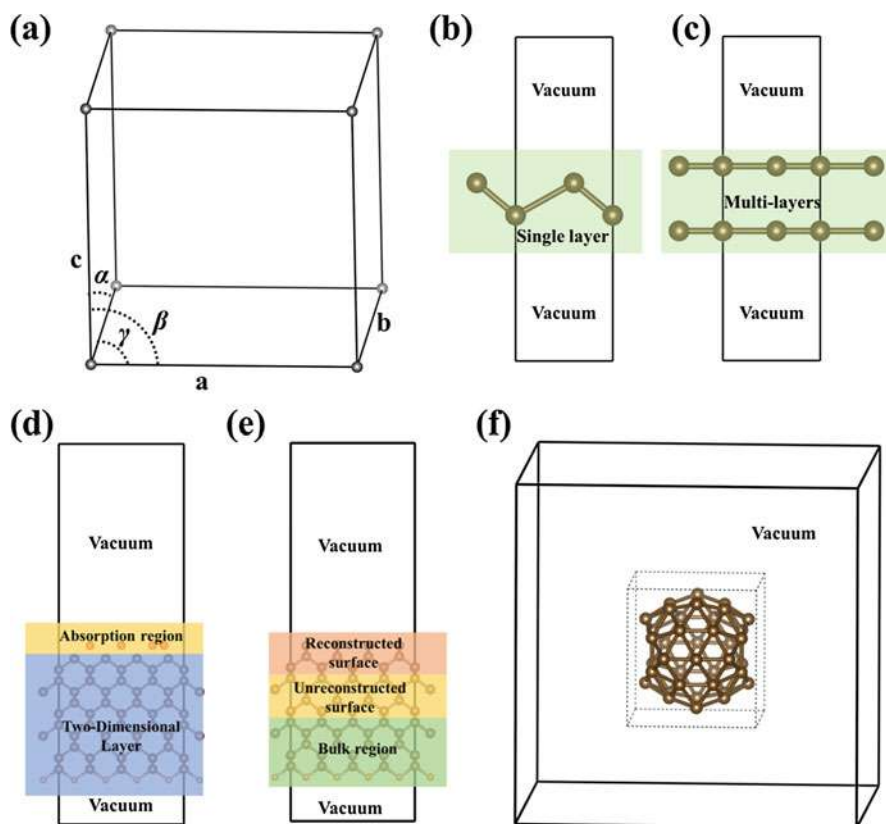
A 2D material is defined as having a finite thickness in one dimension and an
infinite extent in the other two. The slab model is employed to simulate 2D-layered
structures in the CALYPSO method (Wang et al. 2012b). As illustrated in Fig. 5b
and c, these models contain two regions: the layered material and vacuum. The
vacuum ensures that the studied layers are isolated from their periodic images.
Any 2D-layered structure can be characterized by 1 of 17 planar space groups. To
ensure unbiased sampling of the energy landscape, the lattice parameters and atomic
positions are randomly generated with 2D symmetry constraints. A distortion


Fig. 5 The models used in CALYPSO for (**a**) 3D crystal structure, (**b**) single-layer structure, (**c**) multilayer structure, (**d**) 2D atomic adsorption structure, (**e**) surface reconstruction structure, and (**f**) cluster structure

parameter perpendicular to the in-plane layer (z in Fig. 5b) can also be activated to search for buckled layers, and a van der Waals gap parameter (i.e., the distance between two adjacent layers, as in Fig. 5c) is introduced for multilayered systems. Structural evolution in 2D space is achieved by a constrained PSO algorithm. The CALYPSO method has been widely applied to various 2D materials with exotic structures, including Be_5C_2 (Wang et al. 2016b), FeB_2 (Zhang et al. 2016), and Si (Luo et al. 2014). Because of their intriguing structures and properties, these materials are expected to be promising candidates for future applications in specific fields (Gu et al. 2017).

The adsorption of atoms can efficiently functionalize two-dimensional layer materials with desirable properties. Therefore, structural information about the atoms adsorbed on 2D layers is crucial for understanding their functional properties. A new method was developed to predict the structures of atoms adsorbed on 2D-layered materials based on the CALYPSO methodology. The structural model

used is shown in Fig. 5d; it contains three regions: vacuum, adsorption region, and 2D substrate. Several specially designed techniques (e.g., fixed adsorption sites, symmetry constraints, and a constrained PSO algorithm) were employed to improve the search efficiency. Application of our method to investigate fully and partially hydrogenated graphene and graphene oxide successfully predicts their energetically most favorable structures (Gao et al. 2015). In general, our method is promising for the prediction and design of structures of atoms adsorbed on 2D-layered materials (Li et al. 2015a; Zhou et al. 2016).

2.2.3 2D Surfaces

Surfaces play a decisive role in determining the properties and processing of almost all engineering materials, especially at the nanoscale. However, surface structures are often elusive, impeding significantly the engineering of devices. To predict surface structures, we developed an efficient method based on the CALYPSO methodology (Lu et al. 2014). Structure searches for surfaces are conducted using a slab model comprising three regions (Fig. 5e): the bulk material region, the unreconstructed surface, and the reconstructed surface. Generally, the bulk region (6–8 layers) remains fixed to preserve the bulk nature of the material, and the bottom side of the slabs is passivated by hydrogen atoms with integer or partial charges. The atoms in the unreconstructed surface region (usually composed of 2–4 layers) are subject to local structural relaxation, but they are not involved in the structural evolution. In contrast, the atoms in the reconstructed surface region are fully evolved during structure searching, and the choice of thickness for this region depends strongly on the specific energetic situation of the system. The surface excess free energy is calculated as the fitness during structure evolution by $\triangle \gamma \left(\mu \right) = \frac{1}{A} \left(E_{surf}^{tot} - E_{ideal}^{tot} - \sum_i n_i * \mu_i \right)$, where A is the area of the studied surface (usually a 1×1 planar unit cell), E_{surf}^{tot} and E_{ideal}^{tot} are the total energies of the reconstructed and unreconstructed surfaces, respectively; and n_i and μ_i denote the number and chemical potential of the ith species in the surface region. Additionally, several specially designed methods have been incorporated into the search procedure to improve its efficiency. For example, symmetry operations of various two-dimensional space groups are applied, while the initial surface structures and surfaces of semiconductors are constructed using the electron-counting rules (Lu et al. 2014). Our approach is evaluated via its application to various semiconductor surface reconstructions (Gao et al. 2017b; Xu et al. 2017), including C, Si, SiC, AlN, and ZnO. Experimentally observed surfaces are readily reproduced by the CALYPSO method from input knowledge of only the chemical compositions, thus validating our approach (Lu et al. 2014).

It is noteworthy that application of new method to a simple diamond (100) surface reveals an unexpected surface reconstruction featuring self-assembled carbon nanotubes arrays (Lu et al. 2014). Such a surface is energetically competitive with the known dimer structure under normal conditions, but it becomes more favorable under a small compressive strain or at high temperatures. The novel surface

structure exhibits a unique feature of carrier kinetics (i.e., one dimensionality of hole states, while two dimensionality of electron states) that could lead to novel design of superior electronics. The finding of a previously unknown formation of self-assembled carbon nanotubes on the diamond (100) surface highlights the power of our intelligent surface structure searching method.

2.2.4   0D Nanoclusters or Molecules

Clusters or molecules belong to 0D nonperiodic materials systems. They usually exhibit geometrical frustration due to the competition between surface and bulk, leading to various structural motifs that do not exist in periodic system. The CALYPSO method has been generalized to perform structure searches for these 0D systems (Call et al. 2007). In contrast to periodic systems with translational symmetry, only the point group symmetries are utilized in generating candidate structures of isolated systems, and Cartesian coordinates are used straightforwardly to represent structures. To comply with usual total energy calculations requiring periodic boundary conditions, a big box (Fig. 5f) is built, and the cluster is located at its center. The vacuum surrounding the clusters should be large enough to avoid interactions between the cluster and its periodic images. The main algorithm of PSO is properly revised to allow the structural evolution of 0D systems. The module for cluster structure searching has been extensively benchmarked using Lennard–Jones cluster systems of various sizes (up to 150 atoms), and high search efficiency was achieved, demonstrating the reliability of the current methodology (Lv et al. 2012). Many cluster systems have been investigated using the CALYPSO method (Lv et al. 2014, 2015; Lu et al. 2016; Li et al. 2013a), leading to the discovery of several intriguing structures with interesting chemical bonding. For example, we have used CALYPSO to investigate the structures for neutral boron clusters containing 38 atoms. A symmetric cage-like configuration is found to be the global minimum structure, which can be seen as an all-boron fullerene. Furthermore, a quasi-planar structure with a double-hexagonal vacancy is also revealed with nearly degenerate energy. This quasi-planar structure is recently confirmed by experiments as the ground-state structure for the anionic B_{38} cluster (Chen et al. 2017).

2.2.5   X-Ray Diffraction Data-Assisted Structure Searches

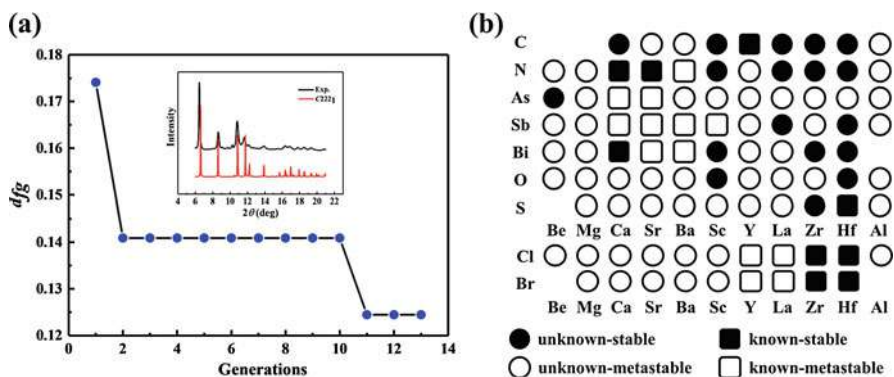
X-ray diffraction (XRD) is the most powerful technique for determining crystal structure information at the atomic level. However, it remains challenging to determine the crystal structure from only experimental powder XRD data because estimated structural information (e.g., unit cell parameters and space group) is required. This is exemplified by about half of the 300,000 Powder Diffraction Files having some unrefined atomic coordinates (Meredig and Wolverton 2012). Traditional structure prediction uses only energy as the fitness function, and the development of a structure prediction method that can effectively use XRD data is highly desirable. This issue is recently addressed by a first-principles-assisted structure solution (FPASS) method (Meredig and Wolverton 2012), which will be


Fig. 6 (**a**) CALYPSO structure search history for $CaLi_2$. Inset shows experimental and simulated XRD patterns of predicted structure. (**b**) Inverse-design results for binary electrides. Stability map of A_2B (top) and AB (bottom) electrides. A and B elements are shown in horizontal and vertical directions, respectively

given in detail in the other chapter of this book. We also propose a versatile global search method based on the CALYPSO method to determine crystal structures from experimental powder XRD data without guessed structural information (Gao et al. 2017a). This search method uses the degree of dissimilarity between the simulated and experimental XRD patterns as the fitness (instead of energy), and a weighted cross-correlation function is used to compare the dissimilarity of two powder diffraction patterns. The efficiency and robustness of the new method are demonstrated by exploring the high-pressure phase of a binary compound, $CaLi_2$. The resultant (Fig. 6a) candidate structure of $C222_1$ for $CaLi_2$ at 54 GPa gave a simulated XRD pattern matching with the experimental data (Debessai et al. 2008).

2.2.6 Inverse Design of Functional Materials

Metastable structures can exist in nature even though they are not thermodynamically stable. However, traditional structure prediction methods that concentrate on finding the ground-state structure of the PES may miss these metastable structures. It is therefore highly desirable to develop an inverse-design approach to design functional materials directly from certain target properties (Franceschetti and Zunger 1999; Zhang et al. 2015a). The inverse design aims to establish an efficient computational scheme to explore the structure–functionality landscape. The fitness function here is the intrinsic material property such as hardness, bandgap, or interstitial electron localization rather than energy as used in traditional structure searching methods. Our CALYPSO method implements a number of computer-assisted inverse-design techniques to search for functional materials (Zhang et al. 2013, 2017b; Xiang et al. 2013) (e.g., superhard, optical, and electride materials). Here, we demonstrate the performance of the CALYPSO inverse-design method by applying it to the design of inorganic electride materials by screening 99 binary compounds (Zhang et al. 2017b). Before our work, the known inorganic electrides

at ambient pressure are only limited to several of them, e.g., C12A7 (Patel 2003) and Ca_2N and its variants (Lee et al. 2013; Inoshita et al. 2014; Tada et al. 2014). With the use of the advanced inverse-design method, we are able to identify 89 new electrides, among which 18 are existing compounds that have not been identified as electrides (solid squares, Fig. 6b), while the other 71 electrides (circles, Fig. 6b) are unknown compounds that have not been synthesized, of which 18 (solid circles, Fig. 6b) are thermodynamically stable in their lowest-energy states and dynamically stable with the absence of any imaginary frequency in phonon spectra; the other 53 (void circles, Fig. 6b) are metastable with positive formation energies. In reality, these metastable electrides might be synthesizable, as various metastable electrides have already been synthesized (void squares, Fig. 6b). Our work provides a useful tool for aiding the discovery of electride materials and reveals the rich abundance of inorganic electrides in nature.

3 Materials Discovery Using CALYPSO

3.1 Superconductors

Superconductivity is among the most exciting properties in condensed-matter physics, and considerable effort in the past century has been devoted to the discovery of new superconductors (Bardeen et al. 1957). A significant boost came with the establishment of the microscopic theory of superconductivity by Bardeen, Cooper, and Schrieffer (BCS) (Bardeen et al. 1957) in 1957, which provides important guidance for the design of superconductors with high T_c (critical temperature for superconductivity). According to BCS theory, T_c is intimately tied to one key parameter, the electron–phonon coupling (EPC) constant, which can be estimated by first-principles calculations based on the band structure and Eliashberg theory (Eliashberg 1960). This EPC constant is clearly the critical factor in the design of high-T_c superconductors and is strongly correlated with crystal structure. The determination of crystal structure is therefore a critical step in the design of novel superconductors.

Advances in crystal structure prediction in the past decades have greatly aided the design of superconductors; many have been predicted theoretically, and some confirmed experimentally. Here, we provide an overview of recent advancements in the discovery of superconductors aided by the CALYPSO method. As most of the discoveries are related to hydrides, the overview is divided into two parts: one concerning hydrogen-rich compounds and the other non-hydrogen compounds.

3.1.1 Hydrogen-Rich Compounds

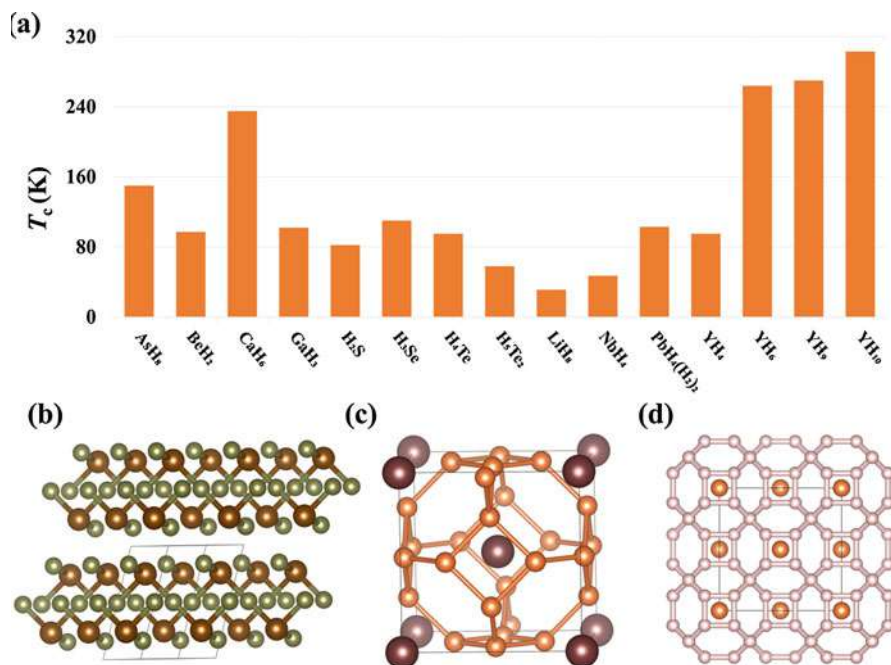
It has been suggested that the lightest element, H, forms metallic solids with sufficiently strong EPC necessary for a high-T_c phonon-mediated superconductivity at high pressures (Ashcroft 1968). However, the metallization of hydrogen had not been observed at low temperature at up to 388 GPa (Dalladay-Simpson et al. 2016). Metallization of solid H at 495 GPa has recently been reported (Dias and Silvera


Fig. 7 (**a**) Histogram of calculated T_c of some hydrogen-rich compounds predicted by CALYPSO. Crystal structures of (**b**) H_2S, (**c**) CaH_6, and (**d**) YH_{10}

2017), but additional experimental measurements are required to verify this claim (Liu et al. 2017a; Silvera and Dias 2017). Hydrogen-rich compounds have been considered as an alternative because they are expected to metallize at considerably lower pressures owing to the chemical "precompression" caused by other elements (Ashcroft 2004). Combining the CALYPSO method with first-principles EPC calculation leads to predictions of many unexpected superconducting phases in H-rich compounds (Zhang et al. 2017a; Wang et al. 2017). Theoretically calculated T_c values for some hydrogen-rich compounds are summarized in Fig. 7a. These works suggest the possibility of superconductivity with estimated T_c values up to 303 K. Strikingly, a T_c of about 80 K predicted for dense H_2S has stimulated experimental observation of hydrogen sulfide superconductors above megabar pressures with T_c in the range of 30–200K (Drozdov et al. 2015). Results for sulfur hydrides (Li et al. 2014), calcium polyhydrides (Wang et al. 2012c), and yttrium polyhydrides (Peng et al. 2017; Liu et al. 2017b) will be introduced here in detail.

H_2S is a typical molecular solid at ambient pressure. At high pressure, it transforms into three high-pressure phases, whose crystal structures are the subject of intense debate. H_2S is not considered a superconductor as it has been proposed to dissociate into its constituent elements before metallization (Rousseau et al. 2000). Li et al. performed extensive structure searches on solid H_2S at pressures of

10–200 GPa (Li et al. 2014). In addition to the identification of candidate structures for the nonmetallic phases IV and V, two metallic structures with P-1 (Fig. 7b) and $Cmca$ symmetry were predicted to be stable above 80 GPa, thus contradicting with the traditional belief (Rousseau et al. 2000) on elemental dissociation at high pressure. The subsequent EPC calculations revealed T_c values of 80 K for the P-1 structure at 158 GPa and 82 K for the $Cmca$ structure at 160 GPa. Motivated by this prediction, electrical measurements of compressed H_2S observed the appearance of superconductivity with a T_c in a range of 30–150 K in a sample prepared at 100–150 K, in a good accordance with our prediction in the low T_c regime of 30–80 K; a higher T_c of ~200 K was observed in another sample prepared at above 220 K (Drozdov et al. 2015; Duan et al. 2015), which is later on suggested as H_3S through the decomposition of H_2S (see, e.g., (Li et al. 2016; Duan et al. 2015; Einaga et al. 2016; Errea et al. 2015)).

Extensive structure searching on calcium polyhydrides (CaH_x) at high pressure (Wang et al. 2012c) showed the CaH_6 stoichiometry (Fig. 7c) to be stable at above 150 GPa: it had a body-centered cubic structure, with hydrogen forming unusual "sodalite" cages containing enclathrated Ca at the center of the cage. Its stability is derived from the acceptance by two H_2 of electrons donated by Ca to form an "H_4" unit as the building block for the construction of the three-dimensional sodalite cage. This unique structure has partially occupied degenerate orbitals at the zone center. The resultant dynamic Jahn–Teller effect helps to enhance the EPC, leading to the superconductivity of CaH_6. A T_c of 220–235 K at 150 GPa obtained by solving the Eliashberg equation is the highest among all hydrides studied thus far. Similar sodalite-like structures of MH_6 (M = Mg and Y) compounds (Li et al. 2015b; Feng et al. 2015) are also high-T_c superconductors at high pressure, with T_c reaching as high as 264 K. These findings suggest that metal polyhydrides with clathrate structures are potential high-T_c superconductors.

Two recent works conducted structure searches using CALYPSO for stable H-rich clathrate structures in rare earth hydrides at high pressures (Peng et al. 2017; Liu et al. 2017b). Hydrogen clathrate cage structures with stoichiometries of H_{24}, H_{29}, and H_{32}, in which H atoms are weakly covalently bonded to one another, forming cages around rare earth atoms are predicted to be thermodynamically stable at high pressures, some of which exhibit high superconductivity. It is found that high-T_c superconductivity is closely associated with H clathrate structures, with large H-derived electronic densities of states at the Fermi level and strong electron–phonon coupling related to the stretching and rocking motions of H atoms within the cages. In particular, an yttrium H_{32} clathrate structure of stoichiometry YH_{10} (Fig. 7d) is predicted to be a potential room-temperature superconductor with an estimated T_c of up to 303 K at 400 GPa (Peng et al. 2017). In the same structure of LaH_{10}, the estimated T_c reaches 288 K at 200 GPa (Peng et al. 2017; Liu et al. 2017b). But it is unstable with respect to LaH_3 and LaH_{11} at 200 GPa. There might be a need of very high temperature to synthesize it (Geballe et al. 2018). Encouragingly, two recent independent experiments seem support the predicted superconductivity of LaH10 at high pressures, where the measured T_c can reach

as high as 260-280 K at 190 GPa (Maddury et al. 2019) and 215 K at 150 GPa (Drozdov et al. 2019)

3.1.2   Non-hydrogen Compounds

Despite a wealth of high-T_c hydrogen-rich hydrides theoretically predicted at high pressure, experimental exploration of these compounds remains a great challenge. The potentially broader ranges of stability make non-hydrogen compounds attractive. Combining CALYPSO with first-principles EPC calculations has predicted many unexpected superconducting compounds of light elements.

Tin telluride is an established high-pressure superconductor, but understanding the underlying mechanism of its transition from semiconductor has been impeded by unsettled issues concerning its structural identification and phase boundary at high pressure. Zhou et al. investigated the high-pressure phase transitions of SnTe using angle-dispersive synchrotron X-ray diffraction combined with the CALYPSO method (Zhou et al. 2013). Three coexisting intermediate phases of *Pnma*, *Cmcm*, and GeS-type structures were identified. The *Pnma* and *Cmcm* phases were predicted to be superconducting by first-principles calculations, with T_c values of 0.70–0.37 K and 0.01–0.03 K, respectively.

As a sister of CO_2, CS_2 is a transparent liquid under ambient conditions and found to transform a molecular solid with a *Cmca* structure at 1 GPa. Upon compression, it became a superconductor with a T_c of 6 K which remains almost constant from 60 to 170 GPa (Dias et al. 2013). However, the lack of an accurate structural determination impedes further understanding the origin of this superconductivity. The later theoretical work using the particle swarm optimization and genetic algorithm methods investigated the crystal structures of CS_2 at high pressures (Zarifi et al. 2015). The predicted structure with $P2_1/m$ symmetry was found to be the most stable from 60 to 120 GPa. The calculated pair distribution functions are in agreement with the experimental assignment. By calculating the electron–phonon coupling parameters, the estimated T_c at 60 GPa is 13 K that is slightly higher than observed 6 K in experiment. The computed Eliashberg spectral function reveals that the S-S vibrations play a critical role in determining the superconductivity of CS_2.

The binary semiconductor boron phosphide (BP) with the zinc blende crystal structure has attracted tremendous attentions due to novel properties such as high hardness, high temperature stability, and high thermoelectric powers for direct energy conversion. In order to understand the pressure-induced structural behavior of BP, the CALYPSO method was employed to determine the crystal structures of boron phosphide at high pressure. A novel *C2/m* structure, which possesses zigzag phosphorus chain structure, was uncovered at 113 GPa, followed by another $P4_2/mnm$ structure above 208 GPa (Zhang et al. 2015b). Theoretical calculations indicate that the *C2/m* phase was superconductor with T_c (9.4–11.5 K). This work reveals that pressure-induced zigzag phosphorus chain in BP exhibits high superconducting temperature, opening a new route to design superconductors with zigzag phosphorus chains.

3.2   Superhard Materials

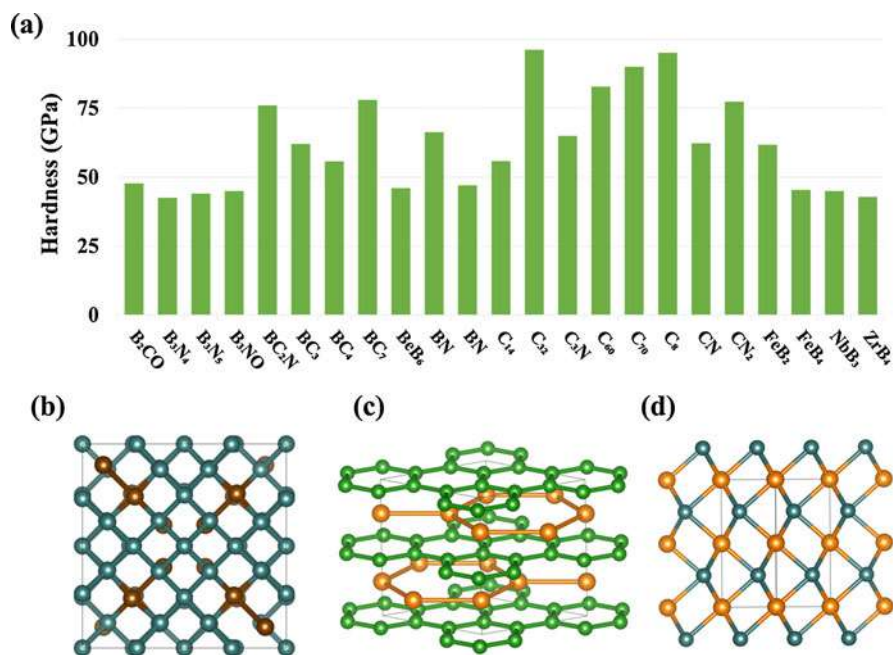
To be superhard, a material should have a Vickers hardness exceeding 40 GPa. Superhard materials are widely used industrially in cutting, polishing, abrasives, protective coatings, etc. The origin of their excellent mechanical properties is strong directional covalent bonds with high electron density that resist both elastic and plastic deformation. Diamond has the highest Vickers hardness of 60–120 GPa but is incompatible with ferrous metals and high temperatures due to its low thermal and chemical stability (Haines et al. 2001). The theoretical design of new superhard materials has become a major research focus and is greatly desirable to assist experimental investigations (Kaner et al. 2005; Zhao et al. 2016). Over the past several decades, covalent compounds formed by light elements, namely, boron (B), carbon (C), nitrogen (N), and oxygen (O), have been the preferred targets owing to their ability to form strong and densely packed 3D covalent bonding networks (Kaner et al. 2005). A new family of materials formed by heavy transition metals and light elements has recently been proposed as potential superhard materials, given that heavy transition metals can introduce high valence electron density into the compounds to resist both elastic and plastic deformations. Our CALYPSO method has helped to design new superhard materials comprising light elements or heavy transition metals and light elements (Fig. 8a, Zhang et al. 2017a).


Fig. 8 (**a**) Histogram of calculated hardness of some compounds predicted by CALYPSO. Crystal structures of (**b**) BC_3, (**c**) WB_3, and (**d**) WN

3.2.1 Light-Element Compounds

Boron-doped diamond has been expected to show better oxidation and ferrous resistance than diamond, thus expanding its applicability in electronic devices (Zinin et al. 2012; Dubrovinskaia et al. 2007; Liu et al. 2015; Solozhenko et al. 2004). However, it remains a huge challenge to introduce a high amount of B into the cubic diamond cell. Encouragingly, diamond-like BC_3 with one-quarter B content has been synthesized at high pressure and high temperature. Several structures have been proposed for this novel diamond-like BC_3; however, none of the proposed sp^3 structural models satisfy the experimentally observed cubic symmetry, thus severely impeding further exploration of its properties. The CALYPSO method has solved the crystal structure of recently synthesized cubic BC_3 (Zhang et al. 2015c). In contrast to previously proposed tetragonal and orthorhombic structures, our predicted highly symmetric BC_3 phase for the cubic diamond structure has a space group of I-43m symmetry and 64 atoms per unit cell, denoted as d-BC_3 (Fig. 8b). It becomes stable above 41.3 GPa, in good agreement with the reported synthesis pressure of 39 GPa. Simulated X-ray diffraction and Raman spectra of the predicted d-BC_3 phase agree well with the experimental data (Zinin et al. 2012). The calculated hardness (62 GPa) and ideal strength (52.5 GPa) demonstrate d-BC_3 as an intrinsic superhard material with intriguing bond elongation and sequential bond-breaking processes that lead to remarkable extended ductility and elastic response. These results represent a significant advance in the understanding of a distinct type of superhard material that exhibits superior ductility to diamond or c-BN.

The prediction of several superhard materials with C_3N_4 stoichiometry has motivated intense experimental interest to synthesize and characterize them and also intense debate. To design new stoichiometric carbon nitrides with four-coordinated carbon and three-coordinated nitrogen atoms, a body-centered tetragonal CN_2 with I-42d space group is predicted at high pressure using CALYPSO (Li et al. 2012). The current predicted structure is built up by strong covalent C–N bonds and N–N bonds, denoted bct-CN_2, which resist decomposition into a mixture of diamond + N_2 or $1/3(C_3N_4 + N_2)$ above 45.4 GPa. The strong covalent C–N bonds, N–N bonds, and non-bonding lone-pair are together the driving force for its high bulk (407 GPa) and shear (386 GPa) modulus and simulated hardness (77 GPa) at equilibrium. Our results show that the lone-pair non-bonding states are much more flexible and mobile than the covalent bonds under large strain, and thus bct-CN_2 possesses lower ideal strength (47 GPa).

We used CALYPSO method to design two potential superhard ternary materials, B_2CO and B_3NO, that are isoelectronic with diamond (Li et al. 2015c). For B_2CO, two energetically competitive diamond-like structures with space groups of P-4m2 (tP4) and I-42d (tI16) with all sp^3 bonding states are predicted. Our simulated results show that they exhibit excellent and similar mechanical properties: e.g., high bulk modulus (~31 GPa), high shear modulus (~260 GPa), high hardness (~50 GPa), and low Poisson's ratio (~0.17). For B_3NO, we further performed a superhard-driven search, finding a variety of new structures with short and strong 3D covalent bonds. Among them, two orthorhombic structures with space groups of Imm2 (oI20)

and *Pmn*2$_1$ (oP20) were found to be dynamically stable. They are both superhard materials with simulated Vickers hardnesses above 45 GPa, exceeding the criterion for superhardness. Electronic results show that the oI20 and oP20 structures are semiconductors with optimal bandgaps of 0.87 and 0.12 eV, respectively, and thus have broad prospects for industrial application.

3.2.2   Transition-Metal–Light-Element Compounds

Tungsten borides are transition-metal–light-element compounds that exhibit diverse polymorphism, excellent functional properties, and potential industrial applicability; for example, they have strong mechanical properties, inexpensive components, and feasible synthesis conditions achievable in a cubic anvil apparatus at relatively low pressures. The conventional expectation is their high boron concentration forms a strong covalent bonding network to enhance their hardness/strength. However, the latest theoretical studies show the structural determination and even the chemical composition of these synthesized tungsten borides still to be open questions. Using CALYPSO, we identified the thermodynamically stable structures as well as many metastable structures over a wide range of boron concentrations for tungsten borides (Li et al. 2013b). Comparison of experimental and simulated X-ray diffraction patterns leads to the identification of previously synthesized *I*4/*m*-4u W$_2$B (γ-phase), *I*4$_1$/*amd*-8u WB (α-phase), *P*6$_3$/*mmc*-4u WB$_2$ (ε-phase), and *P*6$_3$/*mmc*-4u WB$_3$ (Fig. 8c). Based on the calculated convex hull, *P*6$_3$/*mmc*-2u WB$_2$, *R*-3*m*-6u WB$_3$, and *P*6$_3$/*mmc*-2u WB$_4$ are thermodynamically stable and thus viable for experimental synthesis. Our first-principles calculations reveal that, contrary to common expectations, increasing the boron content does not raise the mechanical strength of boron-rich tungsten borides; instead, ideal strength show little improvement or even decreases with rising boron content in most cases. This intriguing behavior is fundamentally rooted in boron's ability to form versatile bonding states, which produces distinct structural configurations (Li et al. 2015a). This work represents a comprehensive study of boron-rich tungsten borides based on a global structure search, and the results have important implications for a large class of transition-metal borides that share the same boron concentration range, along with likely similar bonding configurations and deformation mechanisms as revealed in the present study.

Transition-metal nitrides are another class of materials that can be tailored into a new generation of superhard solids. CALYPSO structural searching yields many crystal structures for tungsten nitrides (Lu et al. 2017). X-ray diffraction indicates the presence of hP4-WN in a recently synthesized specimen. Here we report findings from first-principles calculations for two tungsten nitrides, hP4-WN (Fig. 8d) and hP6-WN$_2$, which exhibit extraordinary strain stiffening that remarkably enhances their indentation strengths above 40 GPa, raising exciting prospects for nontraditional superhard solids. Calculations show that hP4-WN is metallic both at equilibrium and under indentation, making it the first known intrinsic superhard metal.

4   Conclusions and Prospects

This chapter briefly introduced the basic theory and general features of our CALYPSO approach. Its validity has been extensively demonstrated via successful applications to various material systems, including 3D bulk crystals, 2D layers and surfaces, and 0D clusters. Its successful application to the discovery of superconductive and superhard materials was presented, demonstrating its great promise for designing functional materials.

Design-orientated experiments guided by structure prediction offered, for example, by CALYPSO have greatly expedited materials discoveries. However, they are sometimes hampered by the high computational costs needed for structural optimizations, especially for multicomponent or large systems. Machine learning as a data-driven method for making prediction, decision, or classification is now starting to enter the heart of computational physics, chemistry, and material sciences in a manifold way. Several machine learning potentials have been developed, which show accuracy comparable to those of quantum mechanical simulations but require less computational effort by many orders of magnitude (Behler and Parrinello 2007; Behler 2016). The replacement of the heavy computational cost of DFT calculations with a state-of-art machine learning potential is a viable route for structure prediction in large systems (Tong et al. 2018; Deringer et al. 2018).

The structural prediction at finite temperature remains challenging due to the requirement of accurate calculation of free energy. The harmonic/quasi-harmonic lattice dynamics models (Van de Walle and Ceder 2002) can be used to estimate the free energy. However, numerous trial structures are required to estimate free energy for structure prediction. It is computationally unaffordable to calculate phonons of all structures. In principle, metadynamics or molecular dynamics simulations (Martoňák et al. 2003; Parrinello and Rahman 1981) can be widely used to predict structures at finite temperatures. However, in reality, metadynamics or molecular dynamics simulations may suffer frequently from the constraint of short simulation run, especially when time-consuming first-principles simulations are performed. Short simulation runs naturally lead to inadequate sampling of free-energy landscape, limiting the wide use of these methods on prediction of high-temperature structures. Future development of cheaper and more efficient methods in calculations of free energy is essential to accomplish the goal of structure prediction at high temperature.

Knowledge of stable structures does not automatically provide detailed synthesis pathways. It is highly desirable to know whether the identified new materials can be eventually synthesized experimentally, but the theoretical prediction of synthesis conditions leading to a desired structure remains challenging. This requires us to compute the stability of a material with respect to alternative atomic configurations. For doing so, it is worth developing relevant methods to address the minimum-energy path of phase transition or chemical reaction after new materials are predicted.

Contents

Abstract

We present an adaptive genetic algorithm which can be used to predict the atomistic structures of crystals, interfaces, and nanoparticles based on the chemical composition of the materials. The method combines the speed of structure exploration by classical potentials with the accuracy of total energy calculations using first-principles density functional theory (DFT). This method increases the efficiency of structure prediction based on DFT calculations by several orders of magnitude and allows considerable increase in size and complexity of systems that can be studied. The performance of the method is demonstrated by successful structure identifications of complex binary and ternary intermetallic compounds

with the number of atoms in the unit cell as large as 150 atoms. Applications of the method to discovery of novel magnetic materials are discussed.

1   Introduction

Crystal structure prediction based solely on chemical composition information of the materials has been one of the long-standing challenges in theoretical solid state physics, chemistry, and materials science (Maddox 1988; Eberhart and Clougherty 2004; Woodley and Catlow 2008). Advances in this area are highly desirable as computational approaches have been playing a more and more important role in materials discovery and design in the digital age. In the past two decades, several computational methods have been proposed to tackle this challenging problem. These methods include simulated annealing (Kirkpatrick et al. 1983; Wille 1986; Doll et al. 2007), genetic algorithm (GA) (Deaven and Ho 1995; Woodley et al. 1999; Harris et al. 1998; Woodley 2004; Oganov and Glass 2008; Lyakhov et al. 2013; Ji et al. 2011; Wu et al. 2011), basin (or minima) hopping (Wales and Doye 1997; Goedecker 2004), particle swarm optimization (Wang et al. 2010, 2012), and ab initio random structure search (Pickard and Needs 2011). While considerable progress has been achieved, exploration of complex systems requires more advanced algorithms that can provide fast and efficient configuration space samplings and at the same time retain the accuracy of energy evaluation.

The most time-consuming step in all methods for structure predictions mentioned above is the local structure relaxation and energy evaluation since many structures need to be evaluated during the structure search. While first-principles density functional theory (DFT) calculations can offer total energies for many (although not all) crystal structures with acceptable accuracy, its computational cost imposes the bottleneck to fast structure exploration of complex materials. Although size of the order of 1000 atoms can now be handled by many DFT codes in modern computers, determining the low-energy crystal structures for one given chemical composition using genetic algorithm (or similar algorithms) generally would require structure relaxations and energy evaluations for 10^3 to 10^5 structures or more. Therefore, DFT calculations to search for the crystal structures with unit cells containing a few hundred atoms and with variable stoichiometry will be very time-consuming and expensive. By contrast, calculations based on classical empirical potentials are fast even for very large systems, but they are limited in accuracy. Moreover, reliable classical empirical potentials are not even available for many systems.

In order to overcome this bottleneck, we have recently developed an adaptive genetic algorithm (AGA) method (Wu et al. 2014; Zhao et al. 2014a) which combines the speed of classical potential searches and the accuracy of first-principles DFT calculations. The AGA method enables us to investigate crystal structures previously intractable within current computer capabilities.

In this chapter, we will describe the concept and practical operations of the AGA for atomistic structure prediction of crystals, interfaces, and nanoparticles, using

the information of the chemical compositions of the materials. Applications to the discovery of novel materials for magnetic applications will also be discussed.

2   Adaptive Genetic Algorithm

The main idea of the AGA is to use much inexpensive empirical interatomic potentials for the labor intensive local structure relaxation during the genetic algorithm (GA) search, while these classical auxiliary potentials are supervised by accurate DFT calculations through the training and correction iterations (Wu et al. 2014; Zhao et al. 2014a).

The flowchart of the AGA scheme is illustrated in Fig. 1. The left-hand side of the flowchart is the traditional GA loop. The GA is an optimization strategy inspired by the Darwinian evolutionary process and has been widely adopted for atomistic structure optimization in the last 20 years (Deaven and Ho 1995; Woodley et al. 1999; Harris et al. 1998; Woodley 2004; Oganov and Glass 2008; Lyakhov et al. 2013; Ji et al. 2011; Wu et al. 2011). During the GA optimization process, inheritance, mutation, selection, and crossover operations are included to produce new structures and select most fit survivors from generation to generation. For structure optimization, the total energy of the system is commonly used as the fitness function for the survival during the GA process, although other properties of the materials can also be included in the fitness function. The most time-consuming step in the traditional GA-loop is the local optimization of the new off-springs by DFT calculations. For complex structures, GA search usually iterates over more than several hundred generations to converge so that many structures need to be evaluated. In the AGA scheme, this most time-consuming step is performed by using auxiliary classical potentials. An *adaptive*-loop is added to the conventional GA loop as shown in the right side of Fig. 1 to guide the adjustment of the auxiliary classical potentials to fit the accurate results of DFT calculations from iteration to iteration. Only single point DFT calculations performed on a small set of candidate structures obtained in the GA-loop by the auxiliary classical potentials are needed at each iteration. Energies, forces, and stresses of these structures from first-principles DFT calculations are used to update the parameters of the auxiliary classical potentials, e.g., by force-matching method with stochastic simulated annealing algorithm as implemented in the *potfit* code (Brommer and Gahler 2006, 2007). Another cycle of GA search is then performed using the newly adjusted potentials, followed by the re-adjustment of the potential parameters, and the AGA iteration process is then repeated. In this way, the auxiliary classical potentials can help in fast sampling of configuration space though GA and expensive DFT calculations are kept at the minimal without losing the accuracy of the structure search.

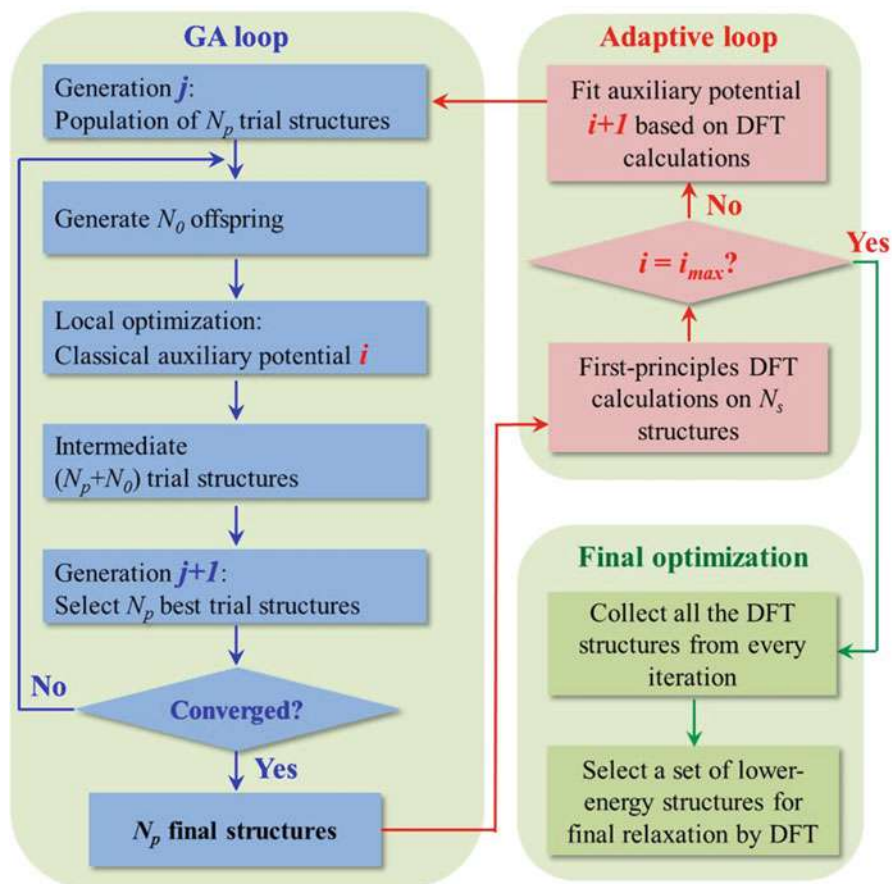
In practice, the numbers of parent N_p in the GA pool and off-spring structures N_o to be set depend on the complexity of the system investigated. For systems with 10–50 atoms, $60 < N_p$ or $N_o < 200$ would be a reasonable choice. Therefore, the use of classical auxiliary potentials for the structure relaxations reduces the computational load by approximately five to six orders of magnitude. It usually takes 30–50


Fig. 1 Flowchart of the adaptive genetic algorithm. An adaptive loop (with i as the iteration counter) is added to the regular GA-loop (with j as the generation counter). Optimization of offspring structures in the GA loop is performed using auxiliary classical potentials whose parameters are adjusted adaptively according to the DFT calculations in the adaptive loop. When the preset maximum number of iterations i_{max} is reached, all structures calculated by DFT from every iteration are collected and ranked according to their energies. Finally, a set of low-energy structures selected from the DFT pool are fully relaxed by DFT calculations to locate the ground-state structure

AGA-iterations to obtain the final structures and the net computational time of the entire AGA search can be reduced by more than three orders of magnitude. Since the classical potentials are adjusted according to DFT results, the AGA can explore the configuration space more effectively and accurately. Structures collected over all AGA iterations can be used to select a subset of low-energy metastable structures which can be finally refined by DFT relaxations. Therefore, the AGA can essentially search for structures almost with the efficiency of classical potentials but

with DFT accuracy. Not only the ground state structures but also a set of low-energy metastable structures can be obtained for a given chemical composition.

In order to show how AGA works in practice and the power of AGA for complex crystal structure prediction, we present two benchmark examples of searching for structures of the Hf_2Co_7 binary alloy with 36 atoms per unit cell and of the $ZrCo_3B_2$ ternary alloy with 54 atoms per unit cell, respectively. Ground-state structures of these alloys have been known experimentally (Buschow et al. 1978; Voroshilov et al. 1971). The AGA searches were performed using only chemical compositions as input information. Initial structures were generated by placing atoms randomly in the unit cell. Classical empirical potentials based on Embedded-Atom Method (EAM) (Daw and Baskes 1984) were used in the GA-loop. As shown in Fig. 2, initially the unit cell shapes, atomic positions, and energies of Hf_2Co_7 and $ZrCo_3B_2$ structures are far from the ground-state. AGA searches then quickly locate the correct ground-state structures for these alloys within 8 and 15 iterations, respectively. These results demonstrate that the AGA is a powerful computational tool for predicting complex crystal structures.

We note that the AGA approach is different from the conventional approach of combining classical potentials with DFT calculations for structure optimization which use a *single* set of classical potentials to screen *all* candidate structures followed by a refinement by DFT calculations. The conventional approach would require accurate and transferable classical potentials to capture the global complex energy landscape of the system. In comparison, the auxiliary classical potentials used in each iteration in AGA only need to be able to represent some local basins of potential energy surface. The system during the AGA search can hop from one basin to another through the adjustment of the auxiliary classical potentials from iteration to iteration through the adaptive loop. From the energies of the final structures at each iteration as plotted in the Fig. 2, we can see that the AGA uses different adjusted potentials to sample structures located in different basins of the energy landscape. Each auxiliary classical potential may not just sample the structures in the same basin, it can sample the structures in a subset of the basins in the energy landscape and some of the basins may overlap with those from other potentials. While it is very difficult or even impossible to fit a classical potential to accurately describe a system under various bonding environments, especially for binary and ternary systems, it is possible to adjust auxiliary potentials to describe structures located within different subset of basins in the energy landscape with DFT accuracy. This is why AGA can work efficiently and accurately in the global low-energy structure search.

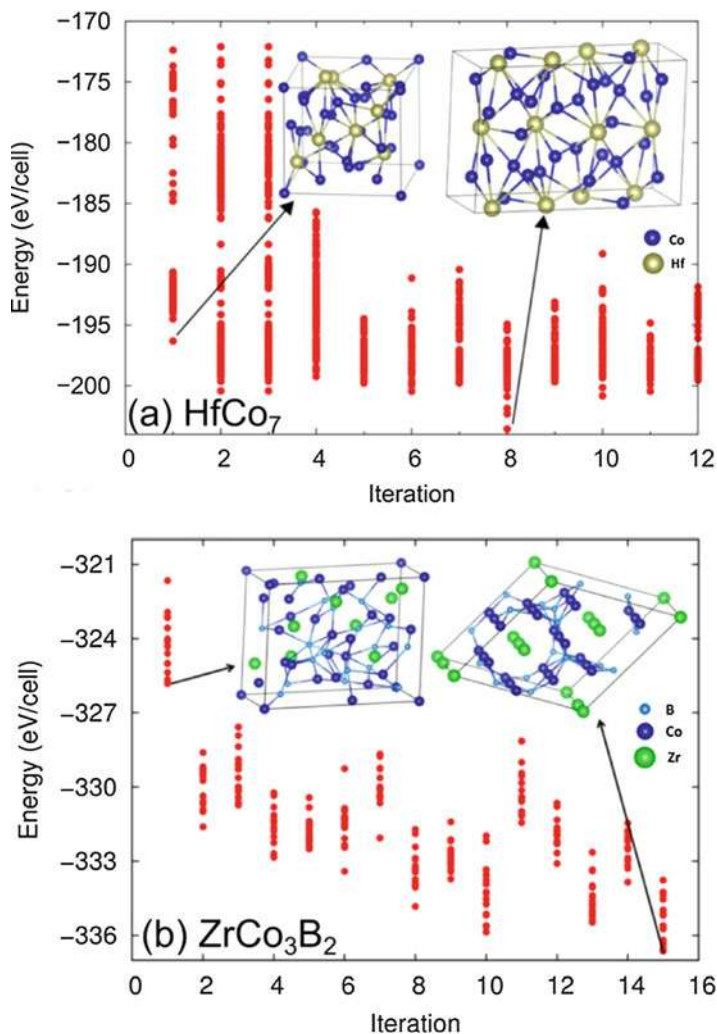
Finally, we note that the AGA described above can be applied not only to the structures of periodic crystals, but also to the structures of nanoparticles (or cluster) and interfaces (or surfaces). The only difference is in the operations for the offspring structure generation. In all cases, the cut-and-paste operation proposed by Deven and Ho in 1995 (Deaven and Ho 1995) for GA on clusters seems to be the most simple yet efficient operation for generating offspring structures from the existing pool of parent structures. Such a cut-and-paste operation can be applied straightforwardly to the nanoparticle search in AGA scheme. For periodic


Fig. 2 Structural and energetic evolution versus iteration number of the AGA-loop for (**a**) Hf$_2$Co$_7$ and (**b**) ZrCo$_3$B$_2$ alloys. EAM-type potentials were used in inner GA-loop. Plots show only DFT energies obtained at the end of each AGA-iteration

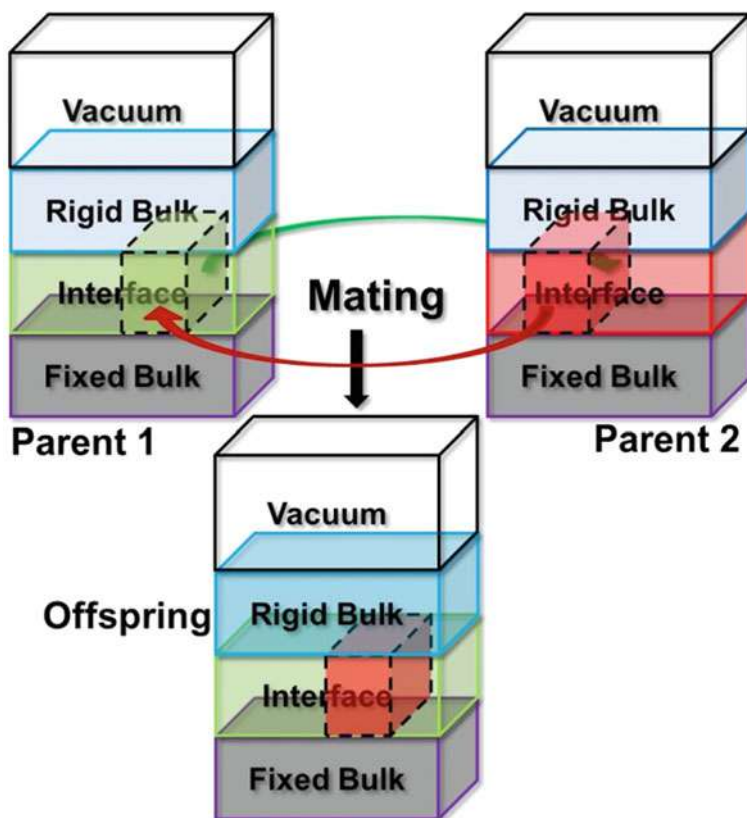
crystal structures, the atomic positions can be generated by the same cut-and-paste operation, while the shape of the unit cell of the offspring structure can be obtained by averaging the unit-cell matrix elements (which represented the 3 lattice vectors of the unit cell) of the parent structures. For structure prediction of interfaces and surfaces, the unit cell can be divided into several zones as shown in Fig. 3. The cut-and-paste operation can be applied only to those atoms in the interfaces (or surface) zone, while the atoms in the bulk zones can only be rigid shift and relaxed to better match the interfaces (Zhao et al. 2014a).


Fig. 3 Schematic representation of the interface model and mating operation in our adaptive genetic algorithm. Four parts are included in the model: fixed bulk where all atoms are fixed; interface where atom positions are to be optimized; rigid bulk which can move as a rigid body relative to the fixed bulk during the search; and a vacuum region to avoid interactions between the two surfaces of the slab. During the mating process, part of the parent structures as indicated by the dashed cuboids will be exchanged to generate the offspring structure

The AGA method has been applied to the prediction and discovery of a range of novel stable and metastable materials (Nguyen et al. 2013, 2018; Zhao et al. 2014b, c, 2015a, 2016a, b, 2017a, b; Dong et al. 2017; Wu et al. 2017). The readers are referred to these references for more details. In the following, we will describe the application of AGA to the prediction and discovery of magnetic materials.

3 Application to Magnetic Materials

As one of the oldest functional materials, permanent magnets are widely used in modern technologies. Permanent magnets are an essential component in electrical

generators using wind, water, geothermal, and carbon-based fuels. Permanent magnets are also essential in computer hard drives and in electric motors for vehicles and other electro-mechanical devices, including levitators. Because of the role of such devices in new energy economies, there has been an increase in demand for stronger permanent magnet materials. Currently, the most widely used permanent-magnet materials are $Nd_2Fe_{14}B$ and $SmCo_5$ discovered in 1980s and 1960s respectively, both containing rare-earth (RE) elements. Owing to limited RE mineral resources and limited RE supplies, there is a strategic need to discover replacement magnet materials for $Nd_2Fe_{14}B$ and $SmCo_5$ to meet performance and cost goals for advanced electric drive motors and generators (Bauer et al. 2011).

It should also be noted that materials synthesis under far-from equilibrium conditions has become an important route for materials design and discovery. Metastable phases formed during the fast cooling process often possess remarkable physical properties. Atomistic structures of some of these metastable phases would be very complex and hard to be resolved by experimental techniques, impeding the understanding and further optimization of the materials for applications. In many cases, metastable structures with desirable properties are hard to be predicted *a priori* by studying the equilibrium phase diagram of the alloys and compounds. With modern computing power, advances in computational algorithms and methods for ab initio crystal structure prediction can speed up the investigation of complex materials and aid the discovery and development of technologically relevant new materials (e.g., magnetic materials).

Using the AGA described above, the crystal structures of several RE-free binary and ternary intermetallic compounds have been systematically explored for possible candidates in magnetic materials applications (Zhao et al. 2014c, 2015a, 2016a, b, 2017a, b). In what follows, we will choose two examples from our recent studies to illustrate the usefulness and the power of the AGA in material design and discovery. The first example is on the determination of the atomistic structures and magnetic properties of complex Zr_2Co_{11} polymorphs with the number of atoms in the unit cell up to 150 atoms (Zhao et al. 2014c). Another example describes the discovery of novel phases of Co-N compound for RE-free magnets by the AGA prediction (Zhao et al. 2016a, b) which leads to the success in experimental synthesis of one of the new phases for potential magnetic materials application (Balasubramanian et al. 2018).

3.1   Unraveling the Structural Mystery of Zr_2Co_{11} Polymorphs

As a potential candidate for RE-free magnetic materials, various phases around the composition of Zr_2Co_{11} have received a lot of interests (Demczyk and Cheng 1991; Gabay et al. 2001; Ivanova et al. 2007; Ivanova and Shchegoleva 2009; Zhang et al. 2013). Studies have shown that some of these metastable phases with composition close to the Zr_2Co_{11} intermetallic compound, resulting from the rapid quenching, exhibit large magnetocrystalline anisotropy energy (MAE) and

with Curie temperatures around 500 °C (Demczyk and Cheng 1991; Gabay et al. 2001). However, the crystal structures of these phases remain unsolved. Mixed phases with small grain sizes in experimental samples make it difficult to determine the atomic positions in the crystal structures of these phases using standard X-ray techniques. Even the exact compositions, the shape and size of the unit cells of the observed phases are under debate. The uncertainty in the crystal structures greatly hinders further development and optimization of the material for practical applications.

In 2007 and 2009, Ivanova et al. (2007; Ivanova and Shchegoleva 2009) were able to obtain samples with larger gains which enable the determination of the crystal Bravais lattice of the phases using X-ray diffraction (XRD). A high temperature phase was identified to be rhombohedral structure with $a_{rhomb} = 4.76$ Å and $c_{rhomb} = 24.2$ Å (in the hexagonal setting). Evidence for a hexagonal, high-temperature phase with $a_{hex} = a_{rhomb}$ and $c_{hex} = 2c_{rhomb}/3$ was also observed from their transmission electron microscopy (TEM) analysis. As the temperature is lowered, a transformation to an orthorhombic structure with $a_{orth} = 4.71$ Å, $b_{orth} = 16.7$ Å, and $c_{orth} = 24.2$ Å takes place. These phases were later confirmed by Zhang et al. (2013). However, these experiments were not able to determine the Wyckoff positions of the proposed crystal structures.

In order to resolve the long-standing structural puzzle of Zr_2Co_{11} polymorphs, we have performed a systematic crystal structure search for $ZrCo_{5+x}$ compounds with x = 0.0, 0.1, 0.2, 0.25, and 0.5 using the AGA (Wu et al. 2014; Zhao et al. 2014c). The structure search was performed without any assumptions on the Bravais lattice type, atom basis, or unit cell dimensions. The auxiliary classical potentials used in the AGA search take the form described by EAM formalism (Daw and Baskes 1984). The potential parameters were adjusted adaptively according to the AGA scheme described in the previous section by fitting to the DFT energies, forces, and stresses of selected structures. For this system, the ab initio calculations were performed using spin-polarized density functional theory within generalized-gradient approximation (GGA) in the form proposed by Perdew-Burke-Ernzerhof (PBE) (Perdew et al. 1996) and with the projector-augmented wave (PAW) method (Blochl 1994; Kresse and Joubert 1999) as implemented in the VASP code (Kresse and Furthmüller 1996a, b). We note that for different systems, exchange-correlation energy functional and other parameter settings need to be properly chosen in order to achieve desirable accuracy. For systems with weak interactions such as layered transition metal dichalcogenides (Ci et al. 2017), van-der-Waals corrections in Chap. 13, "Van der Waals Interactions in Material Modelling" by Hermann and Tkatchenko also need to be included.

Many crystal structures with closely competitive energies were obtained from the AGA search. In particular, three low-energy structures with lattice vectors and simulated X-ray diffraction spectra match well with experimental measurement are obtained. These structures are identified as an orthorhombic structure shown in Fig. 4a with composition of $ZrCo_{5.25}$ and lattice parameters a = 4.68 Å, b = 16.54 Å, c = 24.08 Å, a $ZrCo_5$ rhombohedral structure shown in Fig. 4b with space group R32 and lattice parameters a = 4.69 Å and c = 24.02 Å, and a
Fig. 4 Three low-energy structures with lattice vectors and simulated X-ray diffraction spectra match well with experimental measurement: (**a**) the orthorhombic structure with a composition of $ZrCo_{5.25}$; (**b**) the rhombohedral structure with the composition of $ZrCo_5$; (**c**) the hexagonal structure with the composition of $ZrCo_5$

$ZrCo_5$ hexagonal structure shown in Fig. 4c with space group P-62c, a = 4.69 Å, and c = 16.1 Å, respectively. The lattice parameters of these structures agree well with those determined by experimental studies of Ivanova et al. (2007; Ivanova and Shchegoleva 2009) and Zhang et al. (2013). It is worth noting that the orthorhombic structure is very complicated with 150 atoms in the unit cell yet it can be determined by the AGA search. The simulated XRD spectrum of orthorhombic structure obtained from the AGA search agrees well with the experimental data as can be seen from Fig. 5a. The simulated TEM images also agree well with experiment, indicating the atomic arrangement in the unit cell predicted from the AGA are accurate. Energy-dispersive X-ray spectroscopy analysis by experiment shows that Co/Zr ratio in the orthorhombic phase is very close to 5.25, agreeing well with our theoretical prediction.

The main features of the simulated XRD patterns of the rhombohedral and hexagonal structures from the AGA prediction also agree with the experimental data. However, due to overlapping reflections from multiple low symmetry phases and broadened peaks from nanoscale grains, the resolution of experimental spectra is not good enough for detail comparison. On the other hand, the structure of the rhombohedral and hexagonal phases can also be revealed by selected-area electron diffraction (SAED) pattern and high-resolution electron microscopy (HREM) image. The simulated SAED patters and HREM images using the AGA predicted structures are in good agreement with experimental ones, indicating the atomistic structures obtained from the AGA search are correct (Zhao et al. 2014c).

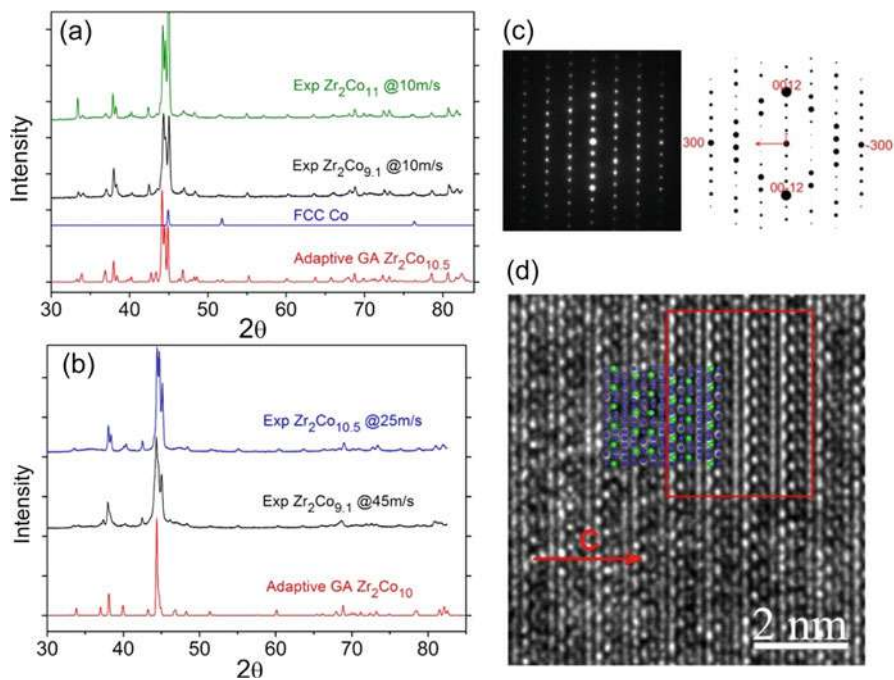
The atomistic structures of the above mentioned three phases are also validated by comparing the magnetic properties calculated using the predicted structures


Fig. 5 Comparison between the simulation and the experimental measurement: (**a**) XRD spectrum of the low-temperature orthorhombic phase; (**b**) XRD spectrum of the high-temperature rhombohedral phase; (**c**) selected-area electron diffraction (SAED) pattern; and (**d**) high-resolution electron microscopy (HREM) image with the simulated results shown in the red box

with those measured by experiment. The magnetization in these structures (0.9–1.1 μ_B/atom) is much smaller than that of elemental hcp-Co (1.6 μ_B/atom), in agreement with experimental results. Magnetocrystalline anisotropy energies (MAE) are very different for different structures. The largest anisotropy energy was found in the rhombohedral and hexagonal structures ($\sim$1.3 MJ/m^3), while the MAE is almost zero for the orthorhombic structure. The calculation results are consistent with the experimental measurements and indicate that the high temperature rhombohedral/hexagonal phases correspond to the hard magnetic phase in Zr_2Co_{11} compounds.

This example demonstrates that the AGA can help experiment in resolving complex structures which allows us to elucidate the physical origin of high coercivity observed in this system and provides useful insight guiding further development of these materials for use as high performance permanent magnets without rare earth elements. Resolving complicated atomistic structures with up to 150 atoms per cell by a first-principle computational approach in such a complex multiple-phase system demonstrates a new capability to aid the accelerating of materials discovery through the use of state-of-the-art supercomputers.

3.2   Prediction of Metastable Transition Metal Nitride Structures with High Magnetic Anisotropy

Nitrides of *3d* transition metals (TM) have interesting magnetic properties and have been used in various magnetic devices. For example, it has been shown that Fe atoms in $Fe_{16}N_2$ thin film exhibit magnetic moment larger than that of pure Fe in BCC crystal (Kim and Takahashi 1972; Sugita et al. 1991). Recently, Co_4N thin films prepared using a reactive magnetron sputtering process were also reported to have magnetic moment higher than that of pure Co bulk structure (Gupta et al. 2015). Discovery of new phases in *3d* TM nitrides for magnetic materials applications has attracted considerable interest. In this regard, structure and property prediction based on computational approaches to provide guidance to experimental synthesis will be greatly beneficial to accelerating the materials design and discovery.

Using the AGA (Wu et al. 2014) and first-principles calculations by VASP code (Kresse and Furthmüller 1996a, b), we have systematically investigated the structures and magnetic properties of pure and Fe-doped cobalt nitrides with different compositions (Zhao et al. 2016a, b). Crystal structure search has been performed for Co_nN compounds with n = 1, 2 ... 8, respectively. New lower-energy structures are obtained from the AGA searches and some are shown to have intriguing magnetic properties. In particular, the calculated MAE of the new structures can be as high as 195.4 μeV/Co atom ($\sim$2.45 MJ/m^3). For the purpose of comparison, typical room temperature MAE value is $\sim$0.5 MJ/m^3 for hexagonal Co, $\sim$5 MJ/m^3 for tetragonal $Nd_2Fe_{14}B$ and 17 MJ/m^3 for hexagonal $SmCo_5$ (Skomski and Sellmyer 2009). It is also found that substituting Co with Fe in the Co_nN structures results in larger magnetic moment and at the same time further increases the magnetic anisotropy. The newly discovered structures are promising prototypes to design strong permanent magnets without using RE elements.

In Fig. 6, several representative structures that have large MAE are plotted. For Co_3N, two structures obtained from the AGA search are plotted in Fig. 6a, b, respectively. Co_3N-1 structure (space group *R-3c*) is found to have slightly lower energy ($\sim$1 meV/atom) than the experimental phase (space group *P6$_3$22*) according to GGA calculations. The *R-3c* and the *P6$_3$22* structures share the same Co packing (ABAB ... type of stacking), but the arrangements of N atoms are different, resulting in different unit cell sizes. The orthorhombic Co_3N-2 structure (space group *Cmcm*) in Fig. 6b has an ABCABC ... Co stacking, i.e., Co atoms are in an fcc-like lattice. However, one of the six N-Co bonds (2.05 Å) in the Co_3N-2 structure is noticeably larger than the others (1.85 Å) as indicated in the figure, resulting in large distortions in the structure. The formation energy of the Co_3N-2 structure is higher than that of the ground-state structure by $\sim$45.5 meV/atom.

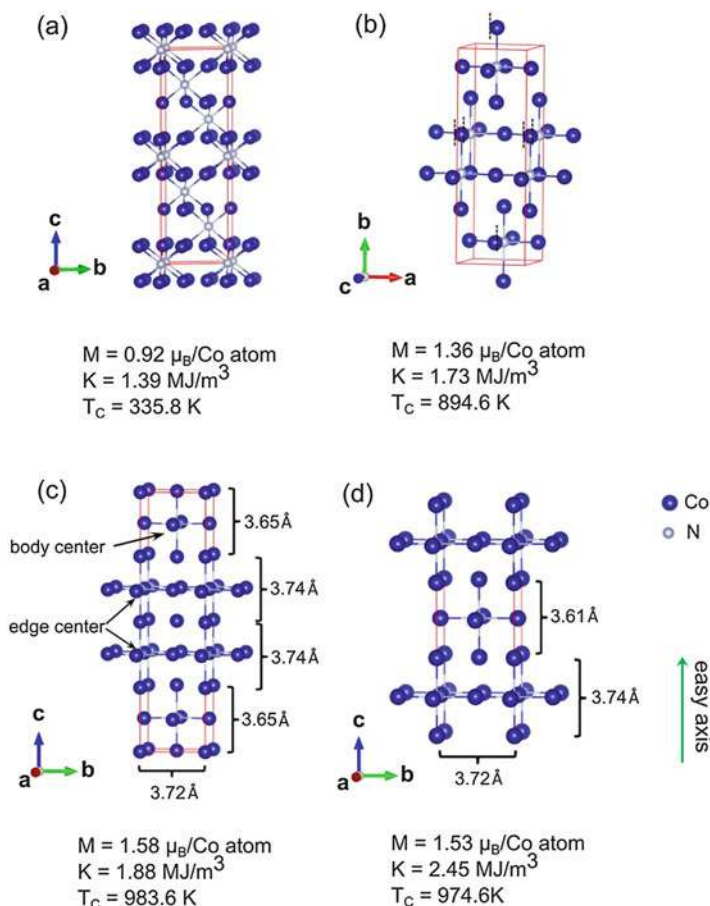
From the MAE calculations, the *P6$_3$22* structure observed in experiments has nearly zero anisotropy, while the Co_3N-1 (*R-3c*) structure obtained from the AGA search exhibits a uniaxial anisotropy of 1.39 MJ/m^3 with the easy axis along its **c** axis. This MAE value is comparable to what found in the high temperature


Fig. 6 Structures of Co_nN with large magnetic anisotropy energies: (**a**) Co_3N-1 (*R-3c*); (**b**) Co_3N-2 (*Cmcm*); (**c**) Co_4N-1 (*I4/mmm*); (**d**) Co_4N-2 (*I4/mmm*). Red box indicates the unit cell. The easy axis in the MAE calculations is represented by the green arrow

"Zr_2Co_{11}" phases discussed above (Zhao et al. 2014c). The *Cmcm* structure has a bigger volume, thus much larger magnetic moments than that of Co_3N-1 *R-3c* structure. Calculation also shows a larger MAE value of 1.73 MJ/m^3 with the easy axis along its lattice vector **b** and a large enough Curie temperature ($\sim$895 K) for the *Cmcm* structure. The prediction of large MAE in the Co_3N -1 (*R-3c*) structure has inspired experimental studies and the Co_3N -1 (*R-3c*) structure has been recently synthesized and characterized by experiment (Balasubramanian et al. 2018). The results from the experimental measurement agree well with the theoretical predictions as one can see from the comparison of XRD in Fig. 7.

For Co_4N, experiments have shown that the synthesized *Pm-3m* phase has the same structure as other tetra transition metal nitrides, in which metal atoms are
Fig. 7 XRD comparison between the experiment measurements and simulation using our Co_3N structure

arranged in fcc lattice and N atoms occupy the body centered positions. Several structures obtained from the AGA search are found to have lower energies than the experimental *Pm*-3*m* structure. Several low-energy structures are found to have large MAE. Two Co_4N structures that have large magnetic anisotropy energies are plotted in Fig. 6c, d, respectively. Both structures are tetragonal with a space group of *I4/mmm*. The Co_4N-1 structure has a uniaxial anisotropy of 1.88 MJ/m^3, while the MAE for Co_4N-2 is even larger, $\sim$2.45 MJ/m^3. The Curie temperatures for the two Co_4N structures are close to 1000 K, which is higher than that of Co_3N. These two new structures of Co_4N predicted by the AGA would be useful for magnetic materials applications.

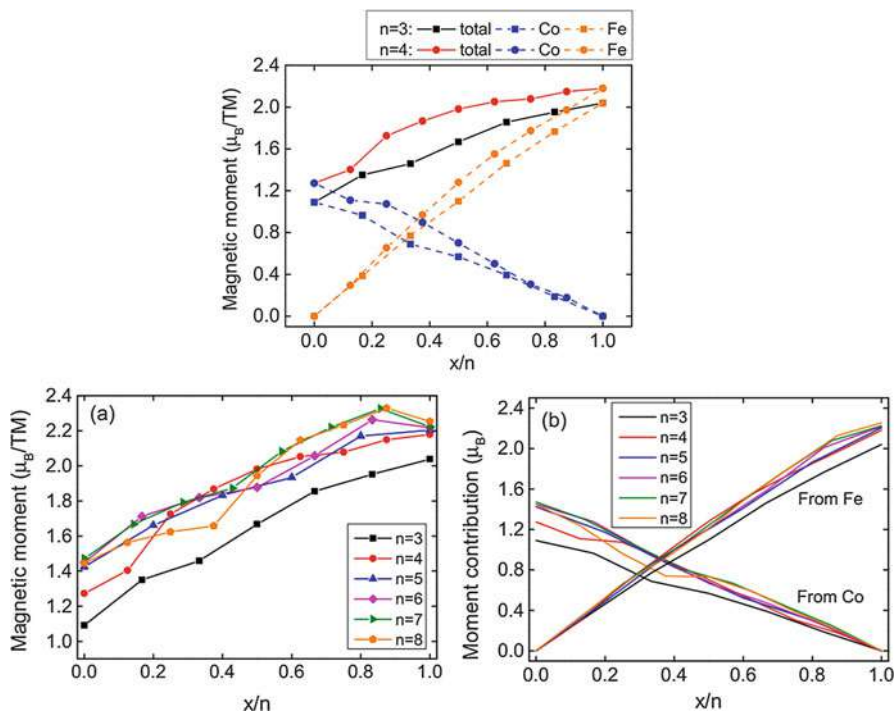
Since Fe is much more abundant and cheaper than Co, it would be interesting to see if some of the Co in the Co-N compounds can be replaced by Fe. We have also studied the Fe substitution effects on the stability and magnetic properties of cobalt nitrides based on the structures obtained from the AGA search for cobalt nitrides, since the structures of iron nitrides and cobalt nitrides are very similar due to the similarities between Fe and Co elements. We found that many structures obtained by Fe substitution have negative formation energies meaning the substitution of Co with Fe in cobalt nitrides is energetically favorable. The effect of Fe substitution on the magnetic moment of $Co_{n-x}Fe_xN$ is plotted in Fig. 8 which clearly shows that increasing Fe composition significantly increases the magnetic moment of the system. However, it is also noticed that the largest average values of magnetic moment are not found in Fe_nN, but around $Co_{0.15}Fe_{0.85}N$, i.e., before all the Co


Fig. 8 (**a**) Effect of Fe substitution on the magnetic moments in $Co_{n-x}Fe_xN$. TM represents transition metal, i.e., Fe and Co atoms. (**b**) Magnetic moment contributions from Fe and Co separately, summation of which equals to the total moment of the system plotted in (**a**)

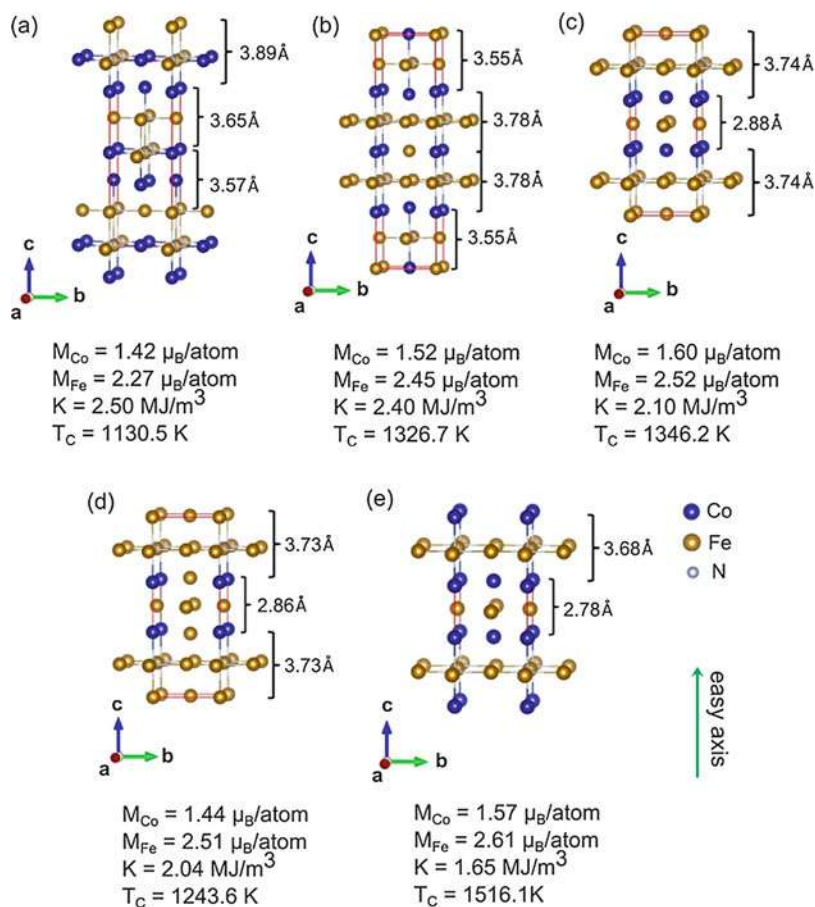
atoms are substituted by Fe. For magnetic anisotropy, many structures with Fe substitutions are found to have MAE values larger than 1 MJ/m³. The largest MAE number is obtained in one of the Co_2Fe_6N structures, which reaches ∼3.18 MJ/m³ (∼245.6 μeV per TM atom) (Zhao et al. 2016b). In Fig. 9, we plotted several structures of $Co_{n-x}Fe_xN$ that have large MAE and at the same time belong to a different type of structures compared with the well-known tetragonal Fe_8N phase. From Fig. 9, we see that the $Co_{n-x}Fe_xN$ structures with relatively large MAEs are all in ABCABC ... type of stacking, i.e., Co/Fe atoms are in fcc lattice. In fact, all the structures in Fig. 9 belong to the same type as those plotted in Fig. 6b–d, and we believe the high MAE comes from the structural anisotropy introduced by N atoms. Similarly, N atom sitting at the edge center makes the length of the fcc units different along **c** axis. The structures in Fig. 9a–d all have MAE larger than 2 MJ/m³. The structure plotted in Fig. 9e is the lowest-energy structure for Co_4Fe_4N. Different from other $Co_{8-x}Fe_xN$ structures adopted from *I4/mmm* Fe_8N (Zhao et al. 2016b), all the nitrogen atoms in the lowest-energy structure of Co_4Fe_4N are located at the edge centers, introducing the structural anisotropy and achieving an MAE value of 1.65 MJ/m³ from first principles calculation. Our calculations also show the


Fig. 9 Structures of $Co_{n-x}Fe_xN$ with high magnetic anisotropy energies: (**a**) $Co_3Fe_3N_2$ (*Amm2*); (**b**) $Co_3Fe_5N_2$ (*I4/mmm*); (**c**) Co_2Fe_4N (*P4/mmm*); (**d**) $CoFe_5N$ (*P4/mmm*); (**e**) Co_4Fe_4N (*P4/mmm*). The easy axes of all above structures are along the direction of their lattice vector **c**

Fe-substituted structures being discussed here have much larger Curie temperatures than binary cobalt nitrides.

Combining the results of Co_nN and Fe-substituted Co_nN, we see that mixing Fe and Co brings more structure anisotropy thus higher magnetic anisotropy energies. Moreover, magnetic moment increases significantly with Fe substitution and in some cases reaches values even higher than that of Fe_nN. Among the newly discovered prototype structures, those structures in which Co/Fe atoms are in fcc stacking and part of the N atoms locate at the edge centers are of particular interest and could be further explored for better magnets, because these structures possess both lower formation energies and higher magnetic anisotropy.

4   Concluding Remarks

In summary, we showed that the AGA is a very efficient and powerful method for predicting the atomistic structures of materials based on minimal information such as chemical compositions. Although we only gave some examples in application to the prediction and discovery the crystal structures of magnetic materials to demonstrate the usefulness of the method, the method can be applied to any other materials including 2D materials, surfaces and interfaces, 1D and 0D material such as nanowires and nanoclusters. The concept of using the adaptively adjusted auxiliary empirical potentials for the labor intensive local structure exploration can also be easily adopted by other structure prediction methods such as the minima hopping and particle swarm optimization methods described in this section.

While the AGA has been demonstrated to be powerful, there are still a lot of rooms for further improvement of the method. Currently, the adaptive interatomic potentials adjustment is done through the force-match fitting within a given mathematical form using the *potfit* code. In general, more reliable and robust adaptive empirical potentials without preassumption of mathematical form can be obtained by deep machine learning (e.g., neural network) process (Behler and Parrinello 2007; Behler 2017; Artrith et al. 2017; Onat et al. 2018; Zhang et al. 2018). Another key step that can greatly improve the efficiency of the GA loop is machine learning -guided offspring structure generation. The currently adopted random cut-and-paste operation for offspring structure generation may not be the most efficient one, particularly for structures with certain motif preference (e.g., tetrahedral or octahedral motif in many oxide materials). Therefore, identifying the preferring motifs by machine learning (Zhao et al. 2015b; Lv et al. 2017) during the GA search and use the knowledge in situ to guide the offspring structure generation will also greatly enhance the efficiency of the AGA scheme. Some more details of the machine learning methods can also be found in the section edited by N. Marzari in the Vol. 1 of this Handbook.

Abstract

In this chapter, we explain the concept of Pareto optimality and Pareto dominance and use these concepts in solving multi-objective (MO) optimization problems. Then, we discuss a few different MO optimization methods and show how MO optimization can be used as a tool for designing new materials. A simple Pareto-based MO optimization method is examined on a few practical case studies to assess how efficient is this method in optimizing double-objective problems.

1   Introduction

In today's world, computational optimization is essential for solving the problems in a wide area of scientific, technological, and engineering applications. Generally, these problems can be classified into single-objective (SO) and multi-objective (MO) problems. SO problems are problems with only one objective to be optimized. But MO problems are problems with more than one objectives which have to be optimized simultaneously. MO optimization is usually more complex than SO, since instead of a single objective, several, often conflicting objectives need to be optimized. This means that improving one objective usually ends up in degrading the other objectives. In MO problems there is a set of optimal solutions which is called Pareto front. The task of MO optimization methods is to find this optimal set of solutions, so that a decision-maker can then select solutions preferable from various considerations (e.g., cost, or expected ease of synthesis, etc.). Optimizing energy alone gives one the stable phase, which usually (but not always) is easy to synthesize, but does not necessarily possess the best properties. Optimizing physical properties alone gives the theoretical limit for the property of interest – but the predicted phase may be so high in energy that its chances to be synthesizable are negligible. MO optimization, simultaneously optimizing energy and the property of interest, is the best way known to us to find solutions that are practically interesting, possessing attractive properties and with a high chance (albeit not a guarantee) of being synthesizable. In this chapter, it is shown that how MO optimization methods can be useful in solving the central problem of computational material design, which is the discovery of new materials optimal in multiple properties; therefore, at first, several different MO optimization methods are discussed and it is shown how MO optimization can be used as a tool for designing new materials. Then, a simple Pareto-based MO optimization method is applied to a few practical cases, demonstrating the efficiency of this method in optimizing double-objective problems.

2   What Is the Pareto Front?

The goal of MO optimization methods is to find the set of optimal solutions with a trade-off between the objectives. This set of solutions is called Pareto front. To understand how the Pareto front is obtained, the concept of dominance is useful.

Fig. 1 Illustration of dominance concept
Pareto dominance, Pareto optimality, and Pareto front are the concepts that are commonly used for comparison of candidate solutions in a population. A solution *a* is said to dominate solution *b*, if *a* is at least as good as *b* in every objective and better than *b* in at least one objective. Figure 1 is a schematic representation of solutions on the Ashby plot (Ashby 2011) (Ashby plot is a two-dimensional plot of any two objectives where each objective is plotted along one of the axes of the plot). The goal in this illustration is to find the set of solutions that minimize X and Y objectives in the best way. In this figure, solution *c* dominates solution *d*, because *c* has lower (or better) value of both objectives than *d*. *a* and *b* dominate *e* for the same reason. But *a*, *b*, and *c* do not dominate each other. For example, *a* is better than *b* and *c* in one objective, while it is worse than them in the other objective. Solutions *a*, *b*, and *c* that are not dominated by any other solutions are said to be non-dominated solutions. In fact, Pareto front is a set of non-dominated solutions.

In mathematical terms, for a set of solutions $\{S_n\}$ $(n = 1, \ldots, N)$, each solution with F_m $(m = 1, \ldots, M)$ objectives, MO optimization can be formulated as follows:

```
S = [S₁, S₂, ... Sₙ];              #  The set of solutions,
F = [F₁, F₂, ... Fₘ];              #  The set of objectives,
counter = 0;
Pcounter= Ø;
while length({S}) ≠ 0              # While there are solutions in
                                     the population.
    S = (S ∪ Pcounter) - (S ∩ Pcounter)      # Removing the non-
                                                dominated solutions
                                             # from population
    Sᵢ dominates Sⱼ,  (i,j = 1,...,N and i≠j)
    If     Fₖ(Sᵢ) ≤ Fₖ(Sⱼ)  (k = 1,...,M),   for all objectives
           and
           Fₖ(Sᵢ) < Fₖ(Sⱼ),    At least in one objective
    S*= Sᵢ if   Sᵢ is not dominated by any other solutions
    counter = counter + 1;
    {Pcounter} = S*          # copying non-dominated solutions to {P}
end
```

A solution S^* is not dominated by any other and is, therefore, Pareto optimal. $\{P_t\}$ ($t = 1, \ldots, T$ and $T \leq N$) is a set of non-dominated solutions. After finding the set of non-dominated solutions, $\{P_1\}$ or first Pareto front, these solutions are removed from the main population, and again the non-dominated solutions of the rest of the population are found – these form the second Pareto front, $\{P_2\}$. This process is continued until all solutions are classified in different Pareto fronts. In the worst situation, that each Pareto front only includes one solution, T can be equal to N. This usually happens when objectives are not conflicting, i.e., a linear relation exists between all objectives.

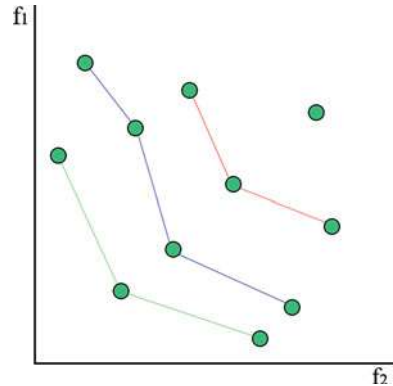
In MO optimization, if one solution can be found which is more optimal than all other solutions in every objective, it is called Utopian solution. For single objectives, there is always a utopian solution, while generally there is no utopian solution for MO problems.

3 Different MO Methods

For designing an efficient Pareto-based MO optimization method, generally, two important factors need to be optimized. The distance to the optimal front is to be minimized, and the diversity of the generated solutions is to be maximized. The latter is useful when more than two objectives are optimized. In the following, we discuss simple Pareto ranking method which is already sufficient for double-objective optimization as well as a few more complex methods in MO optimization.

3.1 Layer Classification (A Simple Pareto Ranking)

The set of non-dominated solutions (solutions forming the Pareto front) are determined using dominance concept. These are the most optimal solutions in the current population, thus the best rank (highest probability of selection) is assigned to this set of solutions. Then these solutions are eliminated from the population temporarily, and again, Pareto front for the rest of population is found. This procedure is repeated until all solutions are classified into different Pareto fronts (Fig. 2). To all the solutions of the same Pareto front, the same fitness is assigned, and there is no priority in selecting the structures of the same Pareto front. Obviously, the highest probability of selection is given to the solution of the first Pareto front, the second highest probability to the second Pareto front, and so on. Then the selection can be performed using any binary selection method (like tournament selection). We call this method "layer classification Pareto technique." Some of the methods that are introduced in this chapter are using this layer classification technique. However, since this method fails in some cases particularly when the number of objectives increases, all of the following methods use some additional technique to make sure that successful results are accessible even if the number of objectives increases.

Fig. 2 Layer classification of solutions in different Pareto fronts for minimizing both objectives


3.2   Vector Evaluated Genetic Algorithm (VEGA) (Schaffer 1985)

This method is not based on Pareto optimality techniques. This method works as a typical genetic algorithm with one difference, which applies in the way of parent selection method. Let us assume an *m-objective* problem with *N*, number of best fraction of solutions in each generation that are allowed to be selected as a parent. At the end of each generation, the population is ranked for each single objective, and the *N/m* of best ranked solutions is added to a hypothetical archive. In this way, if a solution is optimal in *n* objectives *(n ≤ m)*, it is *n* times more likely to be selected than a solution optimal in only one objective. However, this method is susceptible to the shape of the Pareto front, and it fails to generate solutions which do not necessarily excel in one objective but optimal in a sense of Pareto front (Ngatchou et al. 2005).

3.3   Non-dominated Sorting Genetic Algorithm (NSGA)

In the proposed NSGA (Srinivas and Deb 1994), a layer classification method is used, and a sharing function is then applied to the solutions of each Pareto front in the way that some priorities are given to the solutions in the less crowded regions. This sharing function is totally dependent on the choice of sharing parameter, δ_{share}, which is a user-predefined parameter. This parameter denotes the largest value of distance metric within which two solutions share each other's fitness (Deb et al. 2002). But because of the user dependencies and other failures of this fitness sharing method (for more details please refer to reference (Srinivas and Deb 1994)), it was replaced with "crowded-comparison approach" in NSGA-II (Deb et al. 2002) to overcome the failures of fitness sharing method. This approach again gives some priorities to the solutions placed in the less crowded regions of each Pareto front, while it has no user-dependent parameter.

Fig. 3 Illustration of
selection method in PESA
3.4 Pareto Envelope-Based Selection Algorithm (PESA)

In this method, only the non-dominated solutions (Pareto front solutions) are permitted to be ranked and selected. Here, after determining the Pareto front, a hypervolume is defined as a result of finding the closest distance of two neighbor solutions for each objective. This hypervolume estimates the isolation factor for solutions in the way that each solution in a hypervolume with the maximum number of solutions gets the minimum isolation value and vice versa (Fig. 3). The probability of selection of these solutions is proportion to their isolation value. The goal is to give a higher probability to the solutions in the isolated regions than those in the crowded regions. This way of selecting individuals – based on the probability which is given to each of them – is called "individual-based selection." But this method was replaced with "region-based selection" in PESA2. In the region-based selection, instead of giving an isolation value to each individual, the isolation value is given to hypervolumes, and as a result, selection is applied on hypervolumes instead of solutions. This way, the hypervolume which contains less solutions is considered to be more isolated than the one with more solutions (hypervolumes with higher isolation values are preferred). After selection of a hypervolume, one of its solutions is chosen randomly. This method is shown to be more efficient and preferred by the author (Corne et al. 2001) than individual-based selection. For more details on distribution of probabilities and selection mechanism, we refer to the original paper (Corne et al. 2001).

3.5 Strength Pareto Evolutionary Algorithm (SPEA)

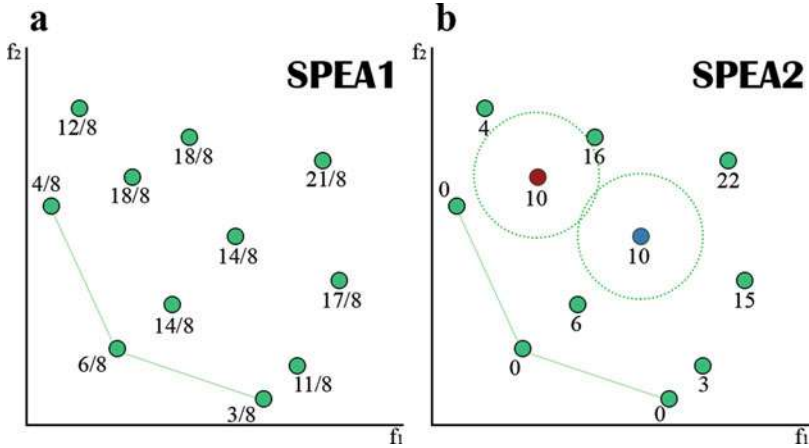
Like NSGA and PESA, there are two versions for SPEA, the first version was published on 1999 (Zitzler and Thiele 1999), but later it turned out that this method has serious problems in special situations and was claimed in some works (Corne et al. 2001; Zitzler et al. 2001; Deb et al. 2002) to be unsuccessful in finding the


Fig. 4 Different fitness assignment in (**a**) SPEA1 and (**b**) SPEA2 for the same distribution of solutions. According to the density estimation technique which is used in SPEA2, the blue solution has the higher chance of being selected than the red one, since it is placed in the less crowded region

optimal solution. However, in SPEA2 (2001) (Zitzler et al. 2001), the selective fitness assignment method was totally changed, and a more solid algorithm was proposed. Here, we discuss the way of fitness assignment in both methods and briefly mention the main failures of SPEA1.

SPEA1: In this method (Zitzler and Thiele 1999), the population is divided into two groups, *external* (non-dominated solutions) and *internal* (dominated solutions). In SPEA1 optimal solutions can be selected from both external and internal population; hence, fitness is assigned to all population members. This fitness is evaluated using a predefined strength function. For a non-dominated solution (in external population), strength is equal to the number of other solutions it dominates, divided by N, in which N is the size of internal population. For a dominated solution (in the internal population), strength is obtained by summing up the strength of non-dominated individuals that dominate it, divided by N. The selective fitness is equal to the strength of the solution if the solution is a member of external population. Otherwise, selective fitness is equal to the strength of solution plus one (to make sure non-dominated solutions are always preferred to dominated solutions) (Fig. 4a). However, the method fails when many solutions are dominated by the same non-dominated individuals (and consequently, they all have the same fitness). For example, in the particular case that only one non-dominated solution exists, SPEA behaves like a random search algorithm. Moreover, SPEA is mostly unsuccessful in convergence/quick convergence to the optimal solutions.

SPEA2: For the sake of eliminating the deficiencies of SPEA, SPEA2 method was proposed (Zitzler et al. 2001). In fact, the fitness assignment in this method totally differs from the previous version. In SPEA2, for improving the convergence

rate to the best optimal solutions, an archive with a fixed size is defined in which only the solutions of this archive are allowed to be selected. If the number of non-dominated solutions fits the archive's size, then only these solutions are selected. But if the number of non-dominated solutions exceeds the archive's size, non-dominated solutions from the dense regions (regions containing many non-dominated solutions in each other's vicinity) are eliminated from the archive. For more details on density estimation technique which is used in SPEA2, we refer to the original paper (Zitzler et al. 2001). In the case that the size of archive is larger than the number of non-dominated solutions, free places will be filled by dominated solutions according to their fitness (in the case of same fitness value for many solutions, density estimation technique is used).

Fitness assignment: At first, strength is computed for each solution (both dominated and non-dominated), which is equal to the number of other solutions it dominates. Then, a raw fitness is defined which is obtained by summing up the strength of solutions (both dominated and non-dominated) that are dominating the target individual (therefore, raw fitness is zero for all non-dominated individuals). Then a fitness is assigned to each individual, which is equal to the sum of raw fitness and the density of the region (in the case of the same raw fitness for two or more solutions). It must be mentioned that in both SPEA1 and SPEA2, the fitness is to be minimized. Although SPEA2 was claimed to be very effective in MO optimization, it can be clearly seen from Fig. 4b that this algorithm fails in some cases to give a proper ranking to the non-dominated solutions, i.e., the blue solution has better ranking than the red one (because it is placed in a less crowded region), while the red solution belongs to the second Pareto front and blue solution to the third Pareto front.

4   Combining MO Optimization with USPEX for Material Design

We performed MO evolutionary search for materials optimal in two properties: hardness and stability (energy above convex hull), for a few binary systems, i.e., Fe_xB_y, Mo_xB_y, and Mo_xN_y, using the USPEX code (Oganov and Glass 2006; Lyakhov et al. 2013). In these calculations, the simple Pareto ranking method (layer classification Pareto technique) without any further procedures such as fitness sharing, crowded comparison, clustering or any other methods (to consider the density of solutions in the objective space) was used. The reason for this choice is these additional procedures strengthen the MO Pareto-based methods when three or more objectives are under study. Although they can be also useful when dealing with two objectives, it is better to keep it simple as long as it works very well (this method was efficiently used in the prediction of new hard (Kvashnin et al. 2017) and thermoelectric (Núñez-Valdez et al. 2016) materials).

In this method, at the end of each evolutionary generation, a fitness is assigned to each structure, and fitness is derived from the Pareto rank of the structure. Thus,

the highest rank (lowest fitness) will be assigned to the structures forming the first Pareto front, and these structures have the highest probability of being selected as parents. Then structures of the next generation will be created by applying variation operators (heredity and mutation) to these parents. One can expect that the combination of MO optimization and evolutionary search should be very effective. The main reason of this effectiveness is that the method always tries to fill the blank places in the Ashby plot in which structures with multi-optimal properties must be placed. These places are filled by creating new structures that were produced by optimum parent structures chosen from the same region of the Ashby plot. Since an unlimited number of structures can be created, and only optimum structures have a chance to be selected (bad structures are discarded from the population instantly), the blank places of Ashby plot will be filled as long as there are good structures in reality to be placed there (this method is also useful when a divergent Pareto front is obtained). Of course, finding all optimum structures of these regions may need long time and even then is not guaranteed. However, by taking advantage of this well-defined method which intelligently produces optimal solutions, even in a limited time and computations power, useful (even if approximate) Pareto fronts are obtained.

It is worth mentioning that the method of MO optimization discussed here is effective for minimum multidimensionality (two dimensions), and the efficiency decreases dramatically when the number of objectives (properties to be studied for each material) increases. This is obviously due to the increase of the number of optimal structures. The dimensionality of Pareto front is proportional to the number of properties that we wish to optimize. For example, when the dimensionality increases from two to three, the Pareto front is not a line (one-dimensional) anymore. It becomes a plane (two-dimensional). Similarly, for four properties, the Pareto front becomes a 3D hyperplane and so on. Thus, the number of optimal structures which are placed on the Pareto front increases (all having the same highest rank), and the intelligent evolutionary algorithm turns to a useless algorithm with a random parent selection.

In the following, a few examples of crystal structure prediction using evolutionary methodology USPEX in combination with simple Pareto ranking (layer classification) method is given. The goal of these calculations is to find hard and stable structures in target systems using MO optimization method and assess the efficiency of this method along with evolutionary crystal structure prediction. In these examples, all the ab initio calculations were done using the PBE exchange-correlation functional (Perdew et al. 1996) and the projector-augmented wave (PAW) method (Blöchl 1994; Kresse and Joubert 1999), as implemented in the VASP code (Kresse and Furthmüller 1996) with the plane-wave basis set cutoff of 550 eV and Brillouin zone sampling using a grid of spacing $2\pi \times 0.06$ Å^{-1}. Evolutionary calculations for each binary system had initial population size = 120 and subsequent population size of 60 structures and were run for 50 generations. Hardnesses were computed using the Lyakhov-Oganov model (Lyakhov and Oganov 2011).

4.1   Example 1: Mo_xN_y

Since stable compounds of Mo_xN_y system were previously studied (Yu et al. 2016) using SO optimization mode of USPEX, this is a very good example which gives a chance to compare results and consequently realize how efficient is the simplest MO optimization method which is implemented in USPEX.

In the previous work (Yu et al. 2016), MoN, MoN_2, and Mo_4N_3 were the stable compounds under zero pressure. Also, two very low-energy metastable structures for Mo_2N and one metastable structure for Mo_3N_2 were reported (Yu et al. 2016). However, in our search, the results are a little bit different. We found four stable compounds (MoN, MoN_2, Mo_2N, and Mo_3N_2) for this system. The reason for this difference is that in our search, the stable structure of Mo_4N_3 has not been found, and as a consequence, metastable structures of Mo_2N and Mo_3N_2 appeared on the convex hull (Fig. 5a). Although Mo_4N_3 was not found in our search, all other stable and metastable compounds, which were reported in the previous work, were found. Moreover, a new metastable compound (Mo_5N_2) with energy of 2 meV/atom above the convex hull was discovered in our calculation, which has never been reported before. Also, we found another structure for Mo_2N with the *Cmcm* space group that is a little more stable than the computationally predicted $I4_1/amd$ structure (Yu et al. 2016) of this compound. It is worth mentioning that the stable $P6_3/mmc$-MoN_2 structure that was found in our work is in perfect agreement with the stable structure computationally reported for MoN_2 (Yu et al. 2016) and is lower in energy by 0.8 eV/atom (thus, thermodynamically more stable) than the experimentally reported (but later shown by Yu et al. (2016) to be incorrect) R-$3m$ structure.

Altogether, this example shows that MO optimization not only discovered a few unknown low-energy metastable structures but also successfully reported all already studied stable and metastable structures of Mo_xN_y system (except one, Mo_4N_3).
Fig. 5 Convex hull diagram (left) and Ashby plot of hardness and energy above the convex hull (right) for the Mo-N system. The red hollow circle shows the stable Mo_4N_3 compound reported in the literature. Low-energy metastable Mo_5N_2 and *Cmcm* structure of Mo_2N are colored in blue

This indicates that MO optimization method (in the case of optimization of two properties) is almost as efficient as SO optimization.

Figure 5b shows the Ashby plot of hardness and instability of Mo_xN_y system. It can be seen from this figure that several hard and stable/low-energy metastable structures were found in this system. Although most of the structures in this figure are in the hardness range of 10–20 GPa and energy range of 0.1–0.5 eV/atom above the convex hull, it can be clearly seen that the algorithm has tried to focus on the regions where optimal structures in both properties are located.

4.2   Example 2: Fe_xB_y

In the second example, we study the Fe_xB_y system using the same method. For this system two stable binary compounds (FeB and FeB_3) and several metastable compounds (FeB_2, FeB_3, FeB_4, Fe_2B, Fe_3B_5, and Fe_3B_{10}) were found in our work. Some of these compounds were reported to be stable or metastable in the literature (Kolmogorov et al. 2010; Van Der Geest and Kolmogorov 2014), while some are discovered in our work. Below we discuss the differences between our results and reported findings.

In the literature, FeB, FeB_2, and Fe_2B are discussed to be stable, while Fe_2B and FeB_2 turned out to be metastable in our calculation, by 3 meV/atom and 42 meV/atom, respectively. Even though both of these compounds were found in our search, the lowest-energy structures of these compounds still have not been found. The other difference is that two structures of FeB_3 were found in our calculation. Most likely, this compound would not appear on the convex hull if the stable structure of FeB_2 was found; nevertheless, FeB_3 is not reported neither as a stable nor as a metastable compound in the literature. FeB_4 was found to be metastable in our work, which is in agreement with the literature (Kolmogorov et al. 2010; Van Der Geest and Kolmogorov 2014). Fe_4B is one of the reported metastable compounds that have not been detected in our calculation. In this calculation, several simultaneously hard and stable/low-energy metastable phases were detected for this system, and some of these are superhard (Fig. 6b).

4.3   Example 3: Mo_xB_y

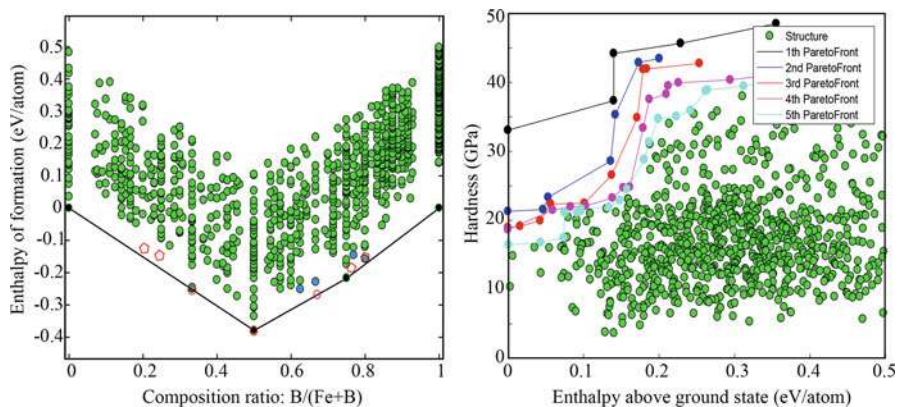
Mo_xB_y system is the third example in our list. For this system, MoB and MoB_2 were found to be stable, which is fully in agreement with the literature (Spear and Liao 1988; Liang et al. 2012). In addition to these stable compounds, many metastable compounds were reported both theoretically (Zhang et al. 2010) and experimentally (Spear and Liao 1988) in the literature, i.e., MoB_3, MoB_4, Mo_2B, Mo_2B_5, Mo_3B_2, and Mo_5B_3. In our search, we found eight low-energy metastable compounds (Mo_2B, MoB_3, MoB_5, Mo_3B_5, Mo_3B_2, Mo_4B, Mo_5B_2, and Mo_2B_3), three of them are already reported metastable compounds (Mo_2B, Mo_3B_2, and MoB_3), and five of them, MoB_5, Mo_2B_3, Mo_3B_5, Mo_4B, and Mo_5B_2, with the


Fig. 6 Convex hull diagram (left) and Ashby plot of hardness and energy above the convex hull (right) for the Fe-B system. The red hollow circles and polygons show the stable and metastable compounds reported in the literature. Low-energy metastable structures found in our work are colored in blue
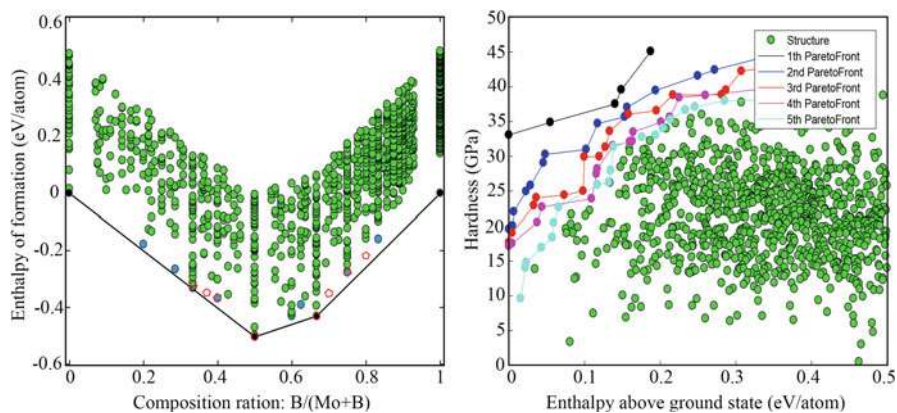

Fig. 7 Convex hull diagram (left) and Ashby plot of hardness and energy above the convex hull (right) of the Mo-B system. The red hollow polygons show the metastable compounds reported in the literature, while blue circles indicate the compounds discovered in our work

55 meV/atom, 29 meV/atom, 57 meV/atom, 23 meV/atom, and 21 meV/atom energy above the convex hull, respectively, are unknown compounds which are discovered in our work. Although three reported metastable compounds (MoB_4, Mo_2B_5, and Mo_5B_3) have not been found in our calculation, the MO optimization acted successfully by discovering five new low-energy metastable compounds of Mo_xB_y system, which indicates the efficiency of the method in crystal structure prediction with multi-optimal properties. In Figs. 6b and 7b, the hardest stable compound (with the hardness of 33.6 GPa) corresponds to pure α-boron.

Stable binary compounds with the highest Lyakhov-Oganov hardness for each of the above examples are MoN_2 (32.6 GPa), FeB_3 (20 GPa), and MoB_2 (19.6 GPa).
Fig. 8 Structures of stable binary compounds with the highest Lyakhov-Oganov hardness in the systems considered here: (**a**) *P6₃/mmc*-MoN2 (Chen's hardness 22.3 GPa), (**b**) *P2₁/m*-FeB3 (Chen's hardness 30.2 GPa), (**c**) *R-3 m*-MoB2 (Chen's hardness 28.5 GPa)

These phases have space groups *P6₃/mmc*, *P2₁/m*, and *R-3m*, respectively, and are shown in Fig. 8. While Lyakhov-Oganov model of hardness is convenient for screening (it is very cheap and numerically robust), more accurate values are predicted using Chen's model (Chen et al. 2011) – the latter, however, requires calculations of the elastic tensor and is therefore much more computationally expensive and is sensitive to numerics. Thus, after initial screening, the final hardnesses were computed using Chen's model.

5   Conclusion

In this chapter, some of the most prominent multi-objective optimization methods were discussed, and the "layer classification" Pareto technique in combination with USPEX was used in search for simultaneously hard and stable materials. The most realistic and favorable outcome of material design is the discovery of new materials with simultaneously optimal multiple properties; i.e., in our examples, unstable hard materials are as useless as soft stable materials. We need to have materials which are optimal in all required properties. Therefore, MO optimization method can be used as a verified tool for materials discovery. Searching for materials with optimal multi-properties is possible using the combination of evolutionary search and MO Pareto ranking. The combination of these two provides a powerful tool for the search and discovery of new materials.

Minima Hopping Method for Predicting Complex Structures and Chemical Reaction Pathways

117

Maximilian Amsler

Contents

Abstract

The arrangement of atoms in a material fundamentally defines its properties. Predicting the crystal structure of a solid or the most stable isomer of a molecule or cluster from computation given solely the chemical composition remains a challenging task, which requires solving a complex optimization problem and identifying the global minimum on a high-dimensional potential energy surface. The minima hopping method uses a walker to explore this energy landscape by performing hops from one local minimum to the next. These hops are based on molecular dynamics trajectories followed by local relaxations, which are tuned to exploit the Bell-Evans-Polanyi principle, and drive the search toward low-energy

solutions. The details of the algorithm are discussed, and its application in materials discovery challenges is illustrated based on two examples.

1   Introduction

Knowing the atomic structure of a condensed matter system is of fundamental importance in materials science and an essential prerequisite for atomistic materials modeling. Structure prediction encompasses the task of finding the arrangement of atoms in a cluster or a crystal that minimizes a specific target thermodynamic potential. For many practical applications, one would like to know the most stable phase given only the chemical composition at a specific pressure and temperature, which corresponds to the minimum of the Gibbs free energy $G = E - TS + pV$. A method which allows to accurately determine this phase prior to synthesis in turn allows the prediction of its properties and, therefore, provides a powerful tool in theoretical materials research.

For a system with N_{at} atoms at zero pressure and temperature, a structure is considered kinetically stable if it corresponds to a local minimum on the potential energy surface (PES) (Wales 2003). For molecules and clusters, the PES is a function of the atomic coordinates $\mathbf{r}_1, \mathbf{r}_2, \ldots, \mathbf{r}_{Nat}$, whereas for periodic systems, additional degrees of freedom describe the cell vectors, commonly summarized by a matrix $h = \{\mathbf{a}, \mathbf{b}, \mathbf{c}\}$. Every local minimum M is located at the bottom of its catchment basin, within which small perturbations of the coordinates will lead to forces that will drive the system back to the structure M. At finite temperature, the displacements due to thermal excitations can be large enough that the system jumps from one catchment basin to the next if the barriers separating them are sufficiently low. In this way, the system can move toward local minima which are lower in energy. Every local minimum which is not the lowest in energy is called metastable and will eventually decay to a lower energy state. Depending on the detailed features of the PES, metastable phases can however persist over a long time scale. The global minimum is considered the thermodynamic ground state, for which no other lower energy local minima exist.

Structure prediction algorithms aim at identifying this ground state structure by globally optimizing the PES. Since the number of possible atomic arrangements in a system scales exponentially with the dimensionality of the search space, an exhaustive sampling of the PES for any system of realistic size is computationally prohibitive. Fortunately, the PES can be significantly simplified by eliminating irrelevant features, thereby reducing its complexity. In particular, one can subdivide the PES into disjoint regions which uniquely correspond to catchment basins of local minima: every point on the PES can be mapped to its local minimum by

simply performing a local geometry relaxation using a steepest descent method with a sufficiently small step size. In this way, all unreasonable structures, e.g., with unphysically short atomic bond lengths, are removed and not considered in the global optimization process.

Despite the reduced complexity of this discretized PES, the number of local minima for any realistic system can be large. In fact, Stillinger (1999) showed that the number of distinguishable local minima increases exponentially with the number of atoms in a system. Hence, mapping out all minima exhaustively and ranking them according to their energies is simply not feasible. Therefore, any optimization algorithm must rely in one way or another on an efficient sampling of only the low-lying local minima of the PES. However, since the sampling is now not exhaustive, there is no way of determining if the lowest energy structure encountered during the search is indeed the ground state.

The reliable representation of a PES poses a further computational challenge. Density functional theory (Parr and Weitao 1994) (DFT) calculations provide accurate results but are computationally demanding and currently only allow reliable structural searches in systems with at most 100 atoms. Classical force fields (Buckingham 1938; Dick and Overhauser 1958; Tosi and Fumi 1964; Daw and Baskes 1984) or semiempirical methods (Goringe et al. 1997; Papaconstantopoulos and Mehl 2003) on the other hand can treat hundreds or thousands of atoms by neglecting or approximating quantum mechanical atomic interactions, but are less accurate and can introduce spurious local minima on the PES which increase the search space (Ghasemi et al. 2010). Very recently, a new class of interatomic potentials have emerged based on machine learning techniques using artificial neural networks (ANN) (Behler and Parrinello 2007). Trained on ab initio date, such ANNs provide high accuracies at computational costs of force fields and therefore represent a promising prospective alternative. A detailed discussion of these methods is beyond the scope of this chapter and can be found elsewhere.

2   The Minima Hopping Method

2.1   Principles of the Minima Hopping Method

The minima hopping method (MHM) (Goedecker 2004; Amsler and Goedecker 2010) aims at mapping out the low-lying local minima of any complex potential energy or enthalpy landscape, to ultimately find its global minimum. For this purpose, the MHM uses a walker to explore the PES by hopping from one local minimum to the next. These hops are performed based on a set of strategic rules that efficiently drive the system toward low-energy structures. On one hand, the walker performs hops that, on average, lead to a decrease in energy. On the other hand, the walker avoids revisiting already known local minima on the PES, since it is inefficient to sample already explored regions on the PES. However, a revisiting of local minima is not completely prohibited. The latter rule is especially important for complex PESs that contain multiple funnels, which might be connected through one

or several low-energy funnels. Such hub-funnels must be permitted to be traversed to get from one portion of the PES to another. Otherwise, the walker could get trapped in a funnel that does not contain the global minimum, thereby failing to find the ground state.

There are many different ways how the hops on the PES could be performed, and several options have been proposed in the past (Sicher et al. 2011). Random displacement of the atomic positions (and the cell vectors for periodic systems) is a simple choice, but is rather inefficient. Better moves exploit the Bell-Evans-Polanyi (BEP) principle (Jensen 1998), which states that exothermic chemical reactions have low activation energies. Since transitions between neighboring local minima are essentially chemical reactions, the BEP principle implies that it is preferable to cross over low-energy barriers, behind which low-energy local minima are more likely to be found. Note that the BEP principle does not strictly apply to every transition between local minima. However, it has been shown that the BEP principle holds on average for pairs of neighboring local minima (Roy et al. 2008), which is sufficient to bias the moves toward a downhill direction in a global structural search.

A natural choice for a move that exploits the BEP principle is to explore all first-order transition states surrounding a local minimum and to propagate the system preferably across the lowest energy barriers toward the neighboring local minimum. Extensive tests have shown that such moves are indeed very efficient and lead to a high success rate in finding the ground state structure with a low number of hops. However, the computational cost to locate a transition state, using, for example, the dimer method (Henkelman and Jónsson 1999), is computationally demanding. On one hand, the number of force evaluations to converge the saddle point search is high compared to the force evaluations needed for local relaxations. On the other hand, new saddle points need to be found and crossed every time a local minimum is revisited to preserve the ergodicity of the system and to avoid the walker from "going in circles." Hence, the saddle point search method is efficient in terms of hops, but inefficient in terms of energy and force evaluations (Sicher et al. 2011).

The most efficient moves are based on short molecular dynamics (MD) trajectories. Using a constant energy (or enthalpy) ensemble and by starting the MD run from a local minimum, the height of the barrier that can be crossed is limited by the initial kinetic energy E_{kin} of the system due to energy conservation. Hence, the BEP principle can be exploited by keeping the value of E_{kin} as low as necessary to preferably cross over low-energy barriers. In practice, an MD trajectory connecting two basins of attraction rarely passes exactly through the saddle point. Nevertheless, the MD moves are on average more efficient than the saddle point search moves, both in terms of hops and the number of force evaluations. The superiority of MD moves can be explained by the fact that several barriers are frequently crossed during a single MD escape trial with less force evaluations than a saddle point search. Another advantage of the MD moves is that MD routines are readily available in many atomic simulation packages or are fairly easy to implement. For molecular systems, a velocity Verlet algorithm can be used (Verlet 1967). For periodic systems, the cell variables are also included in the dynamics to allow transitions between different crystal lattices. Several Lagrangians have

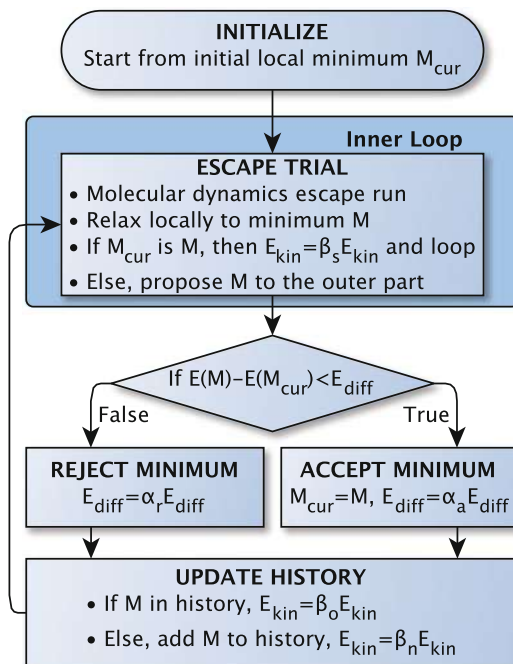
been proposed for variable volume or variable cell shape MD, e.g., the Parrinello-Rahman (1980) or Wentzcovitch (1991) method, which lead to equations of motion for both the atomic and cell coordinates.

2.2   The Minima Hopping Algorithm

The MHM algorithm consists of two parts, an inner loop to perform the moves on the energy landscape and an outer acceptance/rejection part. Fig. 1 shows a flowchart of the algorithm. Starting from an initial seed structure M_{cur} (representing the current local minimum), the inner loop attempts an escape trial by performing a short MD run. The atomic velocities are initialized randomly according to a Boltzmann distribution with an average kinetic energy E_{kin}. The potential energy during the MD simulation is monitored, keeping track of the number of energy minima and maxima encountered along the MD trajectory. As soon as the MD_{min}-th minimum is reached, the MD run is stopped, and the system is relaxed to a local minimum M. With reasonable values of MD_{min} between 2 and 6, the number of time steps is typically in the range of 50–150. If the kinetic energy is not sufficiently high, the system simply oscillates in the vicinity of M_{cur} without crossing a barrier to a neighboring basin and will relax back to the same local minimum $M = M_{\text{cur}}$. In this case, the kinetic energy of the system is slightly increased by a factor $\beta_s > 1$, and an escape trial is performed with a new random velocity distribution. This process is repeated until the escape is successful ($M \neq M_{\text{cur}}$), at which point the structure M is proposed to the outer part.

The outer part introduces a preference for low-energy structures based on a simple threshold approach: the proposed structure M is accepted only if the energy difference with respect to the current local minimum M_{cur} is less than E_{diff}, i.e., if $E(M) - E(M_{\text{cur}}) < E_{\text{diff}}$. This condition is obviously fulfilled in the case of a downhill energy step, which is the most desirable outcome. On the other hand, M is rejected if its energy is higher by more than E_{diff} compared to $E(M_{\text{cur}})$. To avoid the algorithm from getting trapped in any part of the PES, the threshold value E_{diff} is dynamically adjusted throughout the simulation: E_{diff} is increased by a factor $\alpha_r > 1$ whenever M is rejected and decreased by $\alpha_a < 1$ if accepted. Hence, if the inner loop only proposes high-energy structures, they are eventually accepted after a sufficient amount of rejections. The ratio between α_a and α_r determines the fraction of accepted/rejected steps. In practice, a ratio of $\frac{\alpha_a}{\alpha_r} = 1$ leads to good efficiency, where half of all proposed structures are accepted.

An essential component of the MHM algorithm is the second feedback mechanism on the kinetic energy, which is based on a history of visited local minima. After every successful escape step, the minimum M is compared against a list of all known structures visited up to this point. If M is new, it is added to the history and the value of E_{kin} is reduced by a factor $\beta_n < 1$. On the other hand, if M corresponds to a known, old minimum, E_{kin} is increased by $\beta_o > 1$ to drive the system away from portions of the PES that have already been explored. In other words, by keeping track of the visited local minima, the MHM continuously "learns" more about the

Fig. 1 A flowchart of the MHM algorithm. The inner loop is responsible for efficient MD moves on the PES, while the outer part introduces a preference for low-energy structures. A feedback mechanism on the kinetic energy of the MD escape trials drives the search toward new, unexplored regions of the PES


topology of the PES and avoids the least interesting regions. Note that this feature distinguishes the MHM significantly from any thermodynamic method based on a Metropolis algorithm with a Boltzmann factor, like simulated annealing (Salamon et al. 2002) or basin hopping (Doye et al. 1998; Doye and Wales 1998; Wales and Doye 1997), which aims at generating a thermodynamic distribution.

Fig. 2 shows schematically how the two dynamically adjusted parameters E_{diff} and E_{kin} influence the possible and allowed steps on a PES. Points A and B represent two distinct current states M_{cur} of a system at two different stages during a MHM run. Hops from A to A' are allowed but are rejected since the energy difference exceeds E_{diff}, whereas hops from A to A" are accepted. On the other hand, hops from B to B" are impossible due to the limited value of E_{kin}, and only an escape to B' is possible.

The interplay between the parameters α_i and β_j influences the performance of the MHM. Typical values in practice are $\alpha_r = \alpha_a^{-1} = 1.05$ and $\beta_s = \beta_o = \beta_n^{-1} = 1.05$, but slight deviations from these parameters do not significantly affect the efficiency. It is however important that any reasonable choice of the parameters satisfies the so-called explosion condition. It can be shown that the kinetic energy will increase exponentially in well explored regions of the PES by choosing $\frac{\log(\alpha_r)}{\log(1/\alpha_a)} \geq \frac{\log(1/\beta_n)}{\log(\beta_o)}$, while β_s must be greater than 1. This explosion condition not only ensures that the system will never get stuck in any part of the PES during a MHM simulation but more importantly that the walker will efficiently leave already explored funnels.
Fig. 2 A one-dimensional potential energy landscape with two structures at points A and B, corresponding to M_{cur} at two different stages of a MHM run. Orange arrows represent MD escape paths, while blue arrows are local relaxations

2.3   Optimizing Moves on the Potential Energy Surface

Chemical reactions are rare events, and observing a structural transitions can take a long time in conventional MD simulations during which the system mostly oscillates in the catchment basin surrounding a local minimum. To avoid such inefficient oscillations and to accelerate the transition across barriers, the MD velocities are biased prior to every MHM escape step. Instead of using a random direction for the initial velocity, it is approximately aligned along a soft-mode direction of the current local minimum, i.e., along a direction of low curvature. This procedure is called softening and leads to several major benefits for the MHM: first, it eliminates the high-frequency vibrations. Consequently, the integration of the equations of motion can be performed with larger and fewer time steps, thereby reducing the computational cost. Second, the dynamics is biased toward global movements of the whole system which cover a larger distance in the configurational space. Third, there is a higher probability of encountering a low-energy barrier along a soft-mode direction. Fig. 3 shows the strong correlation between the curvature of low-frequency eigenmodes and the barriers encountered along these directions.

Fig. 3 Correlation between the barrier heights and the corresponding curvatures of local minima for a LJ$_{19}$ cluster. The saddle points were found using a mode-following dimer method. The colors indicate the mode index, and the large circles represent the median curvature and barrier values
Hence, trajectories along low-curvature directions will lead to low-energy barriers, behind which one more likely finds low-energy structures according to the BEP.

One way to identify these soft-mode directions is to explicitly compute and diagonalize the Hessian matrix $H_{i,j} = \frac{\partial^2 E}{\partial x_i \partial x_j}$ at the local minimum, where x_i denote the components of a vector in configurational space, and to select the eigenvectors corresponding to the lowest eigenvalues. However, starting the MD trajectories every time along the same direction would lead to a loss of ergodicity. Hence, instead of aligning the velocity vector $\mathbf{V}$ directly along the lowest eigenmode, a superposition $\mathbf{V} = \sum_i \frac{\mathbf{e}_i}{\varepsilon_i}$ of a randomly selected subset of eigenvectors $\mathbf{e}_i$ weighted by the inverse of the corresponding eigenvalues ε_i is a better choice.

Methods to compute the complete Hessian $H_{i,j}$ explicitly are computationally demanding and cannot be employed in practical applications. Instead, if a quasi-Newton method is used to perform the local geometry optimizations, an approximate Hessian is naturally available for each local minimum. Geometry optimizers like the Broyden-Fletcher-Goldfarb-Shanno method use an iterative scheme to update the approximate Hessian based on the gradient vectors along the relaxation pathway (Press et al. 1992; Chong and Zak 2001). These Hessians are symmetric and positive definite by construction and can be readily diagonalized. In most cases, the resulting eigenvectors with low eigenvalues are sufficiently accurate and approximately point in the general direction of soft modes.

Another method is to use a dimer method to iteratively identify the eigenmodes using a minimization scheme. In practice, it is not even necessary to find the exact eigenvectors of the Hessian, but merely to eliminate any components along hard modes, a procedure called softening (Schönborn et al. 2009). Starting from the local minimum at $\mathbf{R}_m$ in the high-dimensional configurational space, an image is created at $\mathbf{R}_d^0 = \mathbf{R}_m + d \frac{\mathbf{V}}{|\mathbf{V}|}$ along the initial, randomly selected escape direction $\mathbf{V}$, where d is the fixed length of the dimer. The energy and forces are evaluated at the image, which is then iteratively moved according to $\mathbf{R}_d^{i+1} = \mathbf{R}_d^i + \alpha \mathbf{F}_{d,\perp}^i$, where $\mathbf{F}_{d,\perp}^i = \mathbf{F}_d^i - \frac{\mathbf{D}^i \mathbf{F}_d^i}{d^2} \mathbf{D}^i = \mathbf{F}_d^i - \mathbf{F}_{d,\parallel}^i$ is the force component perpendicular to the dimer $\mathbf{D}^i = \mathbf{R}_d^i - \mathbf{R}_m$ acting on the image and α is a small step size. This procedure corresponds to an iterative rotation of the dimer toward a direction pointing along a soft mode in the configurational space. The dimer length is rescaled after each iteration to keep it at the value d. Essentially, the energy of the image $\mathbf{R}_d$ is minimized subject to the constraint that it remains on a hypersphere with radius d, centered at $\mathbf{R}_m$.

The curvature along the dimer can be approximately evaluated either by using the second-order finite difference of the energies, $\kappa_e^i = 2 \frac{E(\mathbf{R}_d^i) - E(\mathbf{R}_m^i)}{d^2}$, or from the force acting on the image along the dimer $\kappa_f^i = \frac{|\mathbf{F}_{d,\parallel}^i|}{d}$. In the limit of a small dimer size and assuming that the PES close to the minimum is harmonic, both approximations give the same values of the curvature $\kappa_i := \lim_{d \to 0} \kappa_e^i = \lim_{d \to 0} \kappa_f^i$. Eventually, the dimer will converge to point exactly toward the lowest curvature mode, and one would again sacrifice ergodicity. In fact, there exists an optimal amount of softening steps after which the efficiency of the MHM starts to decrease. In practice, the softening procedure is stopped after a fixed amount of iterations, commonly in

the range of 10–40 steps. Alternatively, the softening is terminated as soon as the approximate curvature drops below a certain fraction of the initial value κ_0, e.g., if $\kappa_i < 0.1\kappa_0$.

2.4   Metrics for Measuring Structure Similarities

Assessing the similarities (or dissimilarities) between two structures is essential in two contexts in the MHM algorithm: to decide if an MD escape trial was successful and to determine if a given structure is present in the history of visited local minima. A proper measure of configurational distances $d(a, b)$ between structures a and b must satisfy the properties of a metric, namely, positiveness $(d(a, b) \geq 0)$, symmetry $(d(a, b) = d(b, a))$, the coincidence axiom $(d(a, b) = 0 \Leftrightarrow a = b)$, and triangular inequality $(d(a, b) + d(b, c) \geq d(a, c))$. Hence, instead of directly comparing the Cartesian coordinates of two configurations, the atomic arrangement in a system is commonly transformed to some structural fingerprint, which can be compared through a norm to measure their differences. For a molecular system, such a fingerprint representation must be invariant with respect to any translation and rotation of a structure. For a periodic system, it must additionally be invariant with respect to the arbitrary choice of the lattice vectors. Most fingerprints that satisfy these criteria rely on a descriptor derived from averaged local atomic environments. Radial distribution functions and approaches based on computed powder diffraction patterns are such examples (Oganov and Valle 2009), but they don't take explicitly into account any angular information. Hence, a large portion of the structural data is lost, and two distinct structures can have identical fingerprints. To alleviate this issue, some fingerprints, like the bond characterization matrix (BCM) (Wang et al. 2012, 2015), explicitly take into account angular information.

The ideal fingerprint metric is sensitive enough to distinguish two different structures, but at the same time tolerates numerical noise on the atomic and cell coordinates, which naturally arise from a limited number of geometry relaxation steps. The computational cost of both fingerprint evaluation and comparison must be low compared to the cost of an energy and force evaluation. Such efficiency considerations might be irrelevant when performing a computationally demanding structural search directly at the ab initio level but can become a bottleneck issue when using classical force fields to approximate the PES.

The MHM relies on fingerprints that are derived from an overlap of Gaussian-type orbitals (GTO) (Sadeghi et al. 2013; Zhu et al. 2016). One or several normalized GTOs $G_i(\mathbf{r})$ with index i are placed at the Cartesian coordinate of each atom $\mathbf{r}_{w(i)}$, where $w(i)$ denotes the index of an atom. To make the fingerprint sensitive toward distinct atomic species, the width of each GTO is given by the covalent radius of the corresponding atom $w(i)$. For a molecular structure with free boundary conditions, the Gaussian overlap matrix $S_{i,j}$ is then the integral over all pairs of GTOs,

$$S_{i,j} = \int G_i(\mathbf{r}) G_j(\mathbf{r}) d\mathbf{r} \tag{1}$$

This matrix is symmetric and positive definite and can be therefore diagonalized. The structural fingerprint is given by the corresponding set of eigenvalues, sorted in descending order in a vector $\mathbf{V}$. For a molecule with N_{at} atoms, the dimension of this vector is $n_{orb}N_{at}$, where n_{orb} is the number of GTO per atom ($n_{orb} = 1$ for s-orbitals, $n_{orb} = 4$ for $s + p$-orbitals, etc.). Hence, the distance between the fingerprints $\mathbf{V}^a$ and $\mathbf{V}^b$ of two structures a and b can be computed simply by the Euclidean distance

$$d(a, b) = \sqrt{\sum_i (\mathbf{V}_i^a - \mathbf{V}_i^b)^2} \tag{2}$$

In a crystal, fingerprints obtained according to Eq. (1) are not invariant with respect to the choice of the periodic cell. This issue is addressed by using atomic fingerprints instead of a global one, arising from atomic overlap matrices $S_{i,j}^k$ which capture the local environment around each atom k individually. For every atom in the unit cell, a large sphere with radius r_c is cut out from a supercell, centered around $\mathbf{r}_k$. To avoid discontinuities in the eigenvalues arising from atoms crossing the border of the sphere, the GTOs are scaled with a radial weight that goes smoothly to zero at the cutoff radius, $f_i^k = \left(1 - \frac{|\mathbf{r}_k - \mathbf{r}_{w(i)}|^2}{r_c^2}\right)^n$. The value of n determines the order of continuous derivatives of the smooth cutoff function at the surface of the sphere, and a value of $n = 3$ is commonly used. The cutoff radius is chosen according to $r_c = \sqrt{2n}\sigma_c$, where the characteristic length scale σ_c is typically twice the largest covalent radius in the system. For this choice of parameters, the selected pseudo-molecule contains in the range of 40–80 atoms, depending on the density of the material.

Within this pseudo-molecule, the environment-dependent atomic overlap matrix is computed according to

$$S_{i,j}^k = \int f_i^k G_i(\mathbf{r} - \mathbf{r}_{w(i)}) f_j^k G_j(\mathbf{r} - \mathbf{r}_{w(j)}) d\mathbf{r} \tag{3}$$

The set of eigenvalues of this atomic overlap matrix in descending order represents the atomic fingerprint vector $\mathbf{V}_k$. Since the number of atoms within the cutoff sphere can vary for different atoms k, the dimensions of $\mathbf{V}_k$ are not uniquely defined. In practice, additional zeros can be appended to $\mathbf{V}_k$ if required for a vector operation. In fact, any atom entering the pseudo-molecule across the surface of the cutoff sphere gives rise to an additional entry in $\mathbf{V}_k$, which continuously transforms from zero to a finite value. Hence, the atomic fingerprint vector changes continuously with respect to any changes in the atomic coordinates.

A metric $d(a, b)$ to define uniquely a configurational distance between two crystal structures a and b must be invariant under the exchange of any two atoms in a given structure. For an atomic fingerprint, this is achieved by minimizing the Euclidean distance over all possible permutations P that matches atom k in a with atom $P(k)$ in b:

$$d(p, q) = \min_P \sqrt{\sum_k^{N_{\text{at}}} |\mathbf{V}_k^a - \mathbf{V}_{P(k)}^b|^2}, \tag{4}$$

The Hungarian algorithm (Kuhn 1955) finds the optimal permutation within an $\mathcal{O}(n^3)$ running time, which needs as its input the cost matrix $C_{k,l}$, given by

$$C_{k,l} = |\mathbf{V}_k^a - \mathbf{V}_l^b|^2$$

2.5   Influence of Seed Structures

Since the MHM walker hops between local minima on the PES sequentially, the funnel in the vicinity of the initial seed structure is explored first. If this funnel contains the ground state, or in the case of a single-funnel system, the global minimum is found quickly within a few MHM steps, independent of the choice of the initial structure. Most realistic systems are however more complex and consist of multiple funnels separated by high barriers, which might take many MHM steps to overcome. A MHM simulation is least efficient if the initial structure is in a funnel which does not contain the global minimum, and the walker spends a long time exploring the wrong region on the PES. Since it is a priori neither known which structure belongs to which funnel nor which funnel contains the global minimum, the efficiency of the MHM strongly relies on the choice of the starting point of the walker.

The efficiency and success rate of the MHM for a multifunnel system increases if multiple MHM walkers are spawned in parallel, which simultaneously sample distinct regions of the PES. The set of these structural seeds must be carefully selected to be as diverse as possible. Using the metric defined in Sect. 2.4, the diversity in a set with N structures can be measured by the sum of inter-structural distances $D = \sum_{i,j}^N d(i, j)$. By selecting only seeds from a pool of structures that give high values of D will ensure that the PES is sampled as uniformly as possible, thereby increasing the chance of quickly finding the global minimum.

The most straightforward approach of generating initial structures, namely, randomly distributing the atoms into the simulation cell, often produces input structures far away from the ground state. Taking into account chemical intuition and considering simple geometrical constraints can significantly improve the quality of the structures (Pickard and Needs 2011). Imposing minimal pairwise distances between atoms avoids strong repulsive forces during the initial geometry relaxation. It is also beneficial to homogeneously distribute the atomic species in a multicomponent system or to use predefined building blocks if the chemistry and geometry of preferred bonding is already a priori known. On top of these considerations, symmetry constraints further improve the diversity of the structures. For molecules and clusters, the structures are randomly generated in one of the axial or polyhedral point groups. Periodic systems on the other hand adopt structures

Table 1 The impact of seeding the MHM simulations with symmetrized input structure is shown for a $A_{16}B_8$ Lennard-Jones mixture, parametrized with $\sigma_{AA} = 1.50$, $\sigma_{AB} = 2.25$, $\sigma_{AA} = 3.00$, and $\varepsilon_{AA} = 1.00$, $\varepsilon_{AB} = 1.25$, $\varepsilon_{AA} = 1.00$. All values are statistical averages gathered from 100 distinct MHM runs for each setting. For every method used to generate the input seed structures, column 2 shows the average number of visited minima $\bar{n}_{\mathrm{min}}$ before reaching the global minimum. The third and fourth columns contain the average number of MHM steps before success if $m = 4$ and $m = 10$ MHM walkers are launched in parallel, respectively.

Input seed	$\bar{n}$	$\bar{n}_{\mathrm{par}}^4$	$\bar{n}_{\mathrm{par}}^{10}$
Random	1293.84	1053.85	932.92
Symmetrized, 1 subcell	632.03	176.30	12.54
Symmetrized, 2 subcells	302.10	21.33	11.75
Symmetrized, 4 subcells	427.26	37.47	12.34

according to one of the 230 space groups. For both clusters and crystals, atoms can be either placed in a general position, where it will spawn equivalent atoms for every symmetry operation of the given point or space group, or on high-symmetry points, which remain invariant under at least one symmetry operation (aside from identity). Particularly for large periodic systems, it is beneficial to first randomly generate subcells of smaller size and use them as building blocks to generate a supercell with the target number of atoms (Lyakhov et al. 2010).

Table 1 shows how the choice of the initial seed structures influences the efficiency of the MHM runs for a binary $A_{16}B_8$ Lennard-Jones benchmark system in a periodic cell. The first column indicates the method used to generate 100 different input structures each, and the performance data in the remaining columns represent corresponding statistical averages. In some cases, the initial randomly generated structure relaxes directly into the ground state. In fact, the number of all such "successful random guesses" corresponds to the success rate of random search algorithms (Pickard and Needs 2011), which is here zero for completely random input structures, but increases to slightly above 20% for symmetrized cells. This improvement in the quality of the input structures is also reflected in the efficiency of the MHM, which increases by a factor of 2–4 as shown in the second column of Table 1. The columns three and four show the number of MHM steps required if m individual MHM runs had been blocked together and were run in parallel. All processes i in each block had been stopped as soon as one of the processes found the ground state structure after l_i steps, hence requiring a total of $n_{\mathrm{par}}^m = l_i m$ MHM steps. Here, the efficiency $\bar{n}_{\mathrm{par}}^m$ for such a parallel executions was computed by blocking the MHM runs randomly and averaging over all blocks. The data shows that combining symmetrized input structures with parallelizing the MHM runs over $m = 4$ and $m = 10$ walkers significantly improves the efficiency. Essentially, using parallel runs is equivalent to the approach used in evolutionary algorithms, where the number m corresponds to the population size in every generation l (Oganov 2010). For example, $\bar{n}_{\mathrm{par}}^{10} = 11.75$ means that the ground state structure is found on average within 1.175 generations with a population size of 10. Using a combination of symmetric input structures and parallelization, a speedup of roughly two orders of magnitude is achieved compared to a serial run with completely random input seeds.

2.6   Finding Chemical Reaction Pathways

The sole knowledge of the local minima on the PES only allows to assess the thermodynamics of a system, but at finite temperatures, kinetic effects govern processes in protein folding, catalysis, nucleation, phase transition, and many more. The study of such chemical reactions and transformations between stable and metastable states requires the knowledge of additional features of the PES (Wales 2003; Henkelman 2017). According to the transition state theory (TST), the properties of the transition state surface between pairs of local minima fundamentally determine the reaction rates. Within the harmonic TST, the rate-determining terms are approximated through the free energies of the first-order saddle points between neighboring local minima, which correspond to the reaction channels. Once these data are available in a so-called stationary point database, methods like the master equation approach or kinetic Monte Carlo are available to map out the dynamic properties of a system.

The physical moves used in the MHM are well suited to construct such stationary point databases (Schaefer et al. 2014a). Within every MHM step out of a local minimum, the system crosses over one or multiple energy barriers which essentially connect the initial and final local minima. Since the MHM trajectory is usually short, the structures of the two minima are geometrically similar and well aligned with each other. Hence, in the minima hopping guided path search approach, these structures are used as end-points for a two-ended or a recursive single-ended saddle point search, directly after each MHM step. By keeping track of both the minima and the saddle points during an MHM run, a stationary point database is constructed on the fly.

To illustrate the efficiency of this method, the minima hopping guided path search was recently applied to the 75-atom and 102-atom Lennard-Jones clusters (Schaefer et al. 2014a). Both of them are multifunnel systems, which are commonly used to benchmark structure search algorithms. In the case of the 75-atom system, new reaction pathways between the two lowest energy local minima were identified with lower rate-determining barriers and shorter reaction path lengths compared to previous reports. For the 102-atom system, shorter path lengths and a new, low-energy funnel were found. The minima hopping guided path search is a promising method to study complex atomistic reaction mechanisms in condensed matter systems and catalytic reactions (Schaefer et al. 2014b).

3   Applications in Materials Discovery

One of the major advantages of the MHM is that it can be easily adapted to study many different systems. Very early MHM structural searches were conducted on silicon clusters, using DFT to model the PES (Goedecker et al. 2005). It was shown that many local minima exist in a very small energy window above the lowest energy structure, making it difficult to conclusively identify the ground state structure at finite temperatures. A similar behavior was observed for neutral and

charged Au26$^{(-)}$ nano clusters, where several competing structural motifs were found with an energetic ordering that strongly depends on the employed DFT exchange-correlation functional (Schaefer et al. 2014b). Photoelectron spectroscopy measurements confirm the theoretical prediction and the presence of multiple isomers with low-symmetry core-shell-type structures.

The MHM has also been successfully employed to study bulk structures in various materials. One of the earliest applications in a periodic system was the prediction of a novel high-pressure phase of carbon, which could readily explain the experimentally observed phase transition in cold-compressed graphite (Amsler et al. 2012b). Our MHM simulations also revealed that a low-energy phase emerges in the LiAlH$_4$ hydrogen storage material with a polymeric structural motif (Amsler et al. 2012a; Huan et al. 2013), a prediction that was subsequently confirmed in experiments (Huang et al. 2015). Other systems that have been studied with the MHM include materials for energy harvesting and conversion, e.g., in thermoelectric (Amsler et al. 2016a, b) and photovoltaic (Botti et al. 2012; Amsler et al. 2015) applications, and in superconducting materials (Flores-Livas et al. 2012, 2016; Amsler et al. 2017a; Amsler and Wolverton 2017). Modified versions of the algorithm have also been applied to investigate the reconstructions of surfaces and the atomic structures at the solid-liquid interface of materials in an aqueous environment (Amsler et al. 2013; Fisicaro et al. 2017).

Since an extensive discussion of all relevant MHM applications is beyond the scope of this chapter, two specific materials discovery efforts are highlighted in detail below.

3.1 High-Pressure Materials Discovery

With the recent advances in high-pressure techniques, static pressures up to ≈ 20 GPa in large-volume and multi-anvil presses, and up to ≈ 400 GPa in diamond anvil cells (DAC) can be meanwhile readily reached. At such pressures, exotic chemical bonds between various elements emerge and new materials are formed, some of which can be recovered and survive as metastable phases at ambient conditions. Many of these high-pressure compounds exhibit exciting physical properties and have therefore attracted significant attention in the search for new superconducting, magnetic, superhard, and other exotic materials (Zhang et al. 2017). A major challenge in high-pressure synthesis remains the accurate in situ characterizations of a material. Although the diamonds in a DAC allow the transmission of X-rays and other radiation to probe the sample, the direct measurement of many physical properties is difficult. This poses significant limitations especially for samples that cannot be recovered for detailed examination outside of the compression chamber. Structure prediction together with quantum mechanical calculations is therefore especially valuable to assist experimental efforts both in the search and characterization of high-pressure materials.

The MHM determines the optimal structure at a fixed composition, and modifications to the algorithm are required to investigate multicomponent systems. In principle, the ground state configuration at every composition must be identified, and only phases with formation energies lower than those of any combination of competing phases are considered thermodynamically stable and constitute the so-called convex hull of stability. Such multicomponent searches are especially important for high-pressure systems, where new compounds often emerge with unexpected stoichiometries.

Adding dimensions in the compositional space however rapidly increases the complexity of the search problem. For a binary system of size N, the number of possible compositions is roughly $\frac{1}{2}\frac{N!}{2!}$. Furthermore, at a fixed composition in a binary system of $n_A + n_B = N$ atoms, there are $\frac{N!}{n_A! n_B!}$ arrangement of atoms in a single structural geometry, so-called homotops (ignoring symmetry-equivalent structures) (Ferrando et al. 2008). Hence, an accurate prediction of the ground state structures as a function of composition and pressure even for binary or ternary systems from ab initio calculations is challenging. In practice, the number of explored compositions is limited by cells containing a few formula units, and system sizes below a threshold value, commonly in the range of a few dozens of atoms. The compositions are either selected based on chemical intuition or on the fly using a genetic algorithm (Cerqueira et al. 2015).

A good example for a high-pressure materials discovery effort with the MHM is the search for novel intermetallics in binary systems. Commonly, high-pressure experiments and structural searches are conducted with constituent elements that are known to form some compound at ambient pressures or at least exhibit known chemical bonds in the solid state. These constraints limit the risk of elemental decomposition and increase the chance of forming new phases upon compression. Materials discovery however becomes significantly more challenging when dealing with elements that do not form any compounds at ambient pressures. An example of such an ambient-immiscible system is Fe–Bi, where the zero-pressure phase diagram shows essentially no solubility of either solid-state element in the other. The successful prediction and synthesis of a Fe–Bi compound is especially attractive since many bismuthides exhibit compelling physical properties, including superconductivity, strong magnetism, and promising thermoelectric performance.

We recently performed a multicomponent MHM search for the Fe–Bi system with up to 4 f.u. per cell at the compositions shown by the gray dashed lines in Fig. 4 (Amsler et al. 2017b). An initial pre-screening of a few compositions had shown that Bi-rich compounds are overall preferred, which were subsequently more extensively sampled. The colored solid bars represent stable phases that lie on the convex hull of stability, which includes various elemental allotropes of Bi and Fe. Two binary phases at the compositions $FeBi_3$ and $FeBi_2$ with *Cmcm* and *I4/mcm* symmetry, respectively, become stable in a pressure range above 35 GPa. While $FeBi_3$ only exhibits a very small stability window between 36.1 and 39.2 GPa, the $FeBi_2$ phase is thermodynamically stable from 37.5 up to at least 100 GPa. Based on this extended pressure range of stability, it is not surprising that so
Fig. 4 Stability ranges of the predicted high-pressure phases in the Fe–Bi system. The gray dashed lines indicate the compositions which were sampled during the structural search, while all thermodynamically stable phases are represented by colored bars (the colors reflect the onset pressure of stability). The four elemental high-pressure phases of Bi between 0 and ≈ 14 GPa are collectively labeled with Bi I-IV

far only the latter phase has been confirmed through high-pressure synthesis in a DAC (Walsh et al. 2016). According to DFT calculations, the ferromagnetic ordering in $FeBi_2$ is suppressed with increasing pressure, which could potentially lead to a (unconventional) superconducting behavior.

3.2 Constrained Structural Searches

By modifying the target optimization function through imposing constraints, one can bias the structural search toward a specific region of the configurational space. Since the hops on the PES are performed based on physical MD moves and local geometry relaxations, such constraints can be easily implemented into the MHM if the derivatives of the penalty function with respect to the atomic and cell variables are available. For example, the bias toward structures around a given target volume V_0 can be included by simply adding a quadratic term $E_{V_0} = k(V - V_0)^2$ to the potential energy E. The additional forces on the cell vectors are given by the derivatives of this penalty term with respect to the cell components, $f_{\alpha\beta} = -\frac{\partial E_{V_0}}{\partial h_{\alpha\beta}} = 2kV(V_0 - V)h_{\beta\alpha}^{-1}$. Such volume constraints can be used to search specifically for low-density phases or strained materials (Amsler and Goedecker 2010).

With a similar approach, the target function can be modified to search for two-dimensional (2D) structures. A 2D confining potential centered at e^z along a nonperiodic direction (here, z-direction) is imposed, given by a sum of atomic contributions, $C = \sum_i c(e, r_i^z)$. Here, every atom i at the Cartesian coordinate $\mathbf{r}_i$ experiences a force $\mathbf{f}_i = -\frac{\partial c_i}{\partial \mathbf{r}_i}$, where $c(e^z, \mathbf{r}_i^z) = A(|e^z - \mathbf{r}_i^z| - r_c)^n$ is a polynomial function of order n beyond a cutoff distance r_c around the equilibrium position e^z. Hence, all atoms are confined within a layer of roughly the width $2r_c$, allowing the search for low-energy 2D structures. Furthermore, a search for multilayer materials or 2D heterostructures is possible by including several potentials centered at different equilibrium coordinates.
Fig. 5 The structure of the TiO_2 hexagonal nanosheet along the top and side view. The red small and green large spheres denote the O and Ti atoms, respectively. The schematic illustration at the bottom left shows how the confinement potential biases the MHM search for 2D structures

As an example of such a constrained search, we recently performed predictive MHM simulations to identify low-energy structures of layered TiO_2 (Eivari et al. 2017). The PES was pre-screened with an ANN potential based on a charge equilibration process, which was initially trained on reference DFT data (Faraji et al. 2017; Ghasemi et al. 2015). After refining the most promising candidates at the ab initio level, we identified a new putative ground state for quasi two-dimensional TiO_2 with a honeycomb lattice. Fig. 5 shows the structure of this hexagonal nanosheet (HNS), together with a schematic illustration of the confinement potential along the out-of-plane direction of the HNS. According to DFT predictions, the HNS is mechanically stable, chemically inert, and exhibits an exceptionally large band gap that can be tuned through strain and defect engineering.

4   Conclusions

Advanced global optimization algorithms like the MHM meanwhile allow the reliable prediction of structures in condensed matter system, given only the chemical composition and the thermodynamic conditions. With increasing computational resources, systems with larger number of degrees of freedom and with higher complexity become predictable. The MHM is a versatile tool that can be adapted and extended to tackle different materials prediction challenges. Using the MHM to sample transition states on the PES in addition to local minima, both the thermodynamic and kinetic properties of a system can be studied in detail.

Stochastic Surface Walking Method and Applications to Real Materials

Cheng Shang and Zhi-Pan Liu

Contents

Abstract

The macroscopic properties of a material are generally governed by its potential energy surface (PES) that determines not only thermodynamics but also kinetics. A thoroughly search of the global PES of material, however, has been a great challenge in theory. Three major hurdles, namely, the high energy barrier in material transformation, the large entropy due to huge structural configurations, and the large atomic degrees of freedom, are often encountered simultaneously in computational simulation of material. Owing to these, the limitation in the timescale of current simulations restricts heavily theoreticians to address many important questions in material science. In this chapter, we introduce a

newly developed theoretical method, stochastic surface walking (SSW) method targeting for both global PES exploration and reaction pathway sampling. The SSW PES sampling is automated, unbiased, and taking into account the second derivative information. The algorithm of SSW is summarized here in detail, focusing on its mechanism to follow low energy pathways while being able to overcome high barriers. SSW simulation has recently been applied to different areas in material and reaction systems. Several typical examples of PES exploration by combining SSW with first principles and neural network potential calculations are presented to illustrate the power of SSW for unbiased PES exploration and pathway searching.

1   Introduction

The structure prediction and the reaction pathway search are two important themes in modern computational simulation. While both of them are closely related to the exploration of the potential energy surface (PES), the former focuses on the thermodynamics properties and the latter aims to provide kinetics quantities on material transformation. Since 1990s, there have been a rapid development on the methodology for structure search and a group of successful methods are now available for identifying the most stable minimum on PES, the global minimum (GM) (Wales and Doye 1997; Martonak et al. 2006; Oganov and Glass 2006; Amsler and Goedecker 2010; Wang et al. 2012) of different systems, including molecules, clusters, and solid crystals. On the other hand, the pathway sampling remains challenging in computational approach even for systems with only a few atoms (Wales 2002; Carr et al. 2005), because of the lack of efficient methods to identify the reaction coordinate (Oganov et al. 2011). To find the minimum energy pathway between minima on PES must rank one of the top challenges in PES exploration.

To search the GM on PES, a typical measure for the efficiency of global optimization method, the current algorithms for structure search generally involve aggressive structure changes, which are required to bypass the transition region of PES and prevent long-time trapping in local minimum. For example, the basin hopping (Wales and Doye 1997) method developed by Wales in 1990s starts from one single entry (one structure) on PES and the structure is perturbed by a random hopping with a magnitude of ~ 0.4 Å for each degree of freedom. The PES seen by basin hopping is therefore a transformed PES without saddle regions. Similar to basin hopping, simulate annealing (Kirkpatrick et al. 1983; Pannetier et al. 1990; Schön and Jansen 1996, 2001) and minimum hopping (Amsler and Goedecker 2010) also start from one single entry but utilize molecular dynamics (via heating to high temperature) to overcome the barrier on PES. On the other hand, the methods starting from multiple entries (a group of different initial structures on PES) developed in 2000s, such as evolutionary algorithm (EA) as represented by USPEX (Oganov and Glass 2006), XtalOpt (Lonie and Zurek 2011) and GSGO (Trimarchi and Zunger 2007), and the particle-swarm-optimization (PSO) algorithm

as represented by CALYPSO (Wang et al. 2012), are more popular in predicting unknown crystal structures of material. The symmetry adaptation in structure generation is one of the key techniques to identify rapidly the stable, ordered structures (Wang et al. 2012). Overall, the structure search methods do not yield a continuous trajectory due to the large change between structures, and thus, it is generally not feasible to obtain the low energy pathways.

The enhanced sampling methods (Siepmann and Frenkel 1992; Voter 1997; Rosso et al. 2002; Woods et al. 2003; Maragliano and Vanden-Eijnden 2006), such as metadynamics using the bias potential constraints (Huber et al. 1994; Laio and Parrinello 2002; Raiteri et al. 2005; Martonak et al. 2006) and adiabatic free energy dynamics (AFED) with temperature acceleration (Yu and Tuckerman 2011), are able to generate continuous trajectory during PES search as intrinsic to MD simulation. Thus, this class of methods has been utilized to identify low energy pathways in crystal phase transition. For example, by imposing the collective variable on the lattice degrees of freedom, metadynamics has been utilized to simulate the phase transition from graphite to diamond (Khaliullin et al. 2011). In general, it is a general concern for MD-based techniques to capture the rare event. Since the occurrence of a reaction event depends exponentially on the reaction barrier, the correct description of the reaction coordinate (e.g., collective variable in metadynamics) and the choice of the simulation temperature are key parameters for producing reactions in simulation. Once the reaction occurs in MD, it is then possible to glean the initial state and the final state from MD trajectory and use the double ended transition state (TS) search method to search for the saddle point. Typical choice for finding the TS in crystal phase transition is the generalized solid-state nudged elastic band method (G-SSNEB) (Sheppard et al. 2012) and variable-cell double-ended surface walking method (VC-DESW) (Zhang and Liu 2015a).

In 2013, Liu's group developed a new PES searching method, namely, the stochastic surface walking (SSW) (Shang and Liu 2013) method. It was initially designed for aperiodic systems, i.e., clusters and molecules, and then extended to periodic solid systems (Shang et al. 2014) in 2015. Unlike the traditional methods for the global PES exploration, the searching in SSW is guided by soft mode directions as computed from the second derivatives and utilizes gentle structure perturbation followed by local optimization to follow low energy pathways. The method can thus be applied to both structure prediction and reaction pathway search (Zhang and Liu 2015b). In this chapter, the algorithm of SSW will be described in detail and some recent applications in material discovery and solid phase transition are then presented.

2   Stochastic Surface Walking (SSW) Method

The central idea of SSW method comes from the bias-potential-driven dynamics (Iannuzzi et al. 2003) and Metropolis Monte Carlo (MC) (Metropolis et al. 1953). It manipulates smoothly the structural configuration from one minimum to another on PES and relies on Metropolis MC at a given temperature to decide the acceptance

of the move. A series of consecutive minimum structures, both local and global, is generated in SSW simulation forming a continuous trajectory, which can provide the key information on the reaction pathways between minima. By applying SSW to a number of systems, Shang and Liu (2013) have shown that the SSW can explore blindly complex PES with high efficiency as demonstrated in Lennard-Jones (e.g., LJ_{75}) and short-range Morse particles (M_{80}).

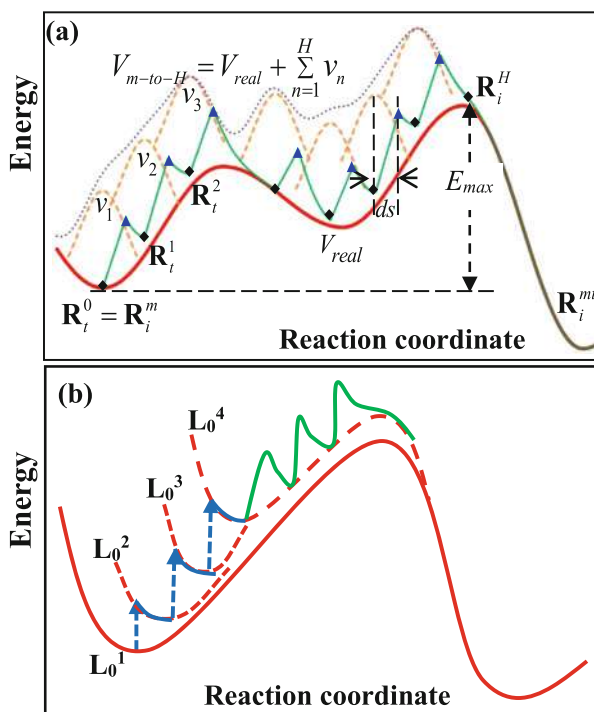
Each step in SSW, also termed as a MC step, comprises three independent parts, namely, (i) the climbing, (ii) the relaxation, and (iii) the Metropolis MC. As schematically illustrated in a one-dimensional PES in Fig. 1a, such a MC step utilizes the climbing module to move up hill and the relaxation module to locate minimum. Once a minimum is reached, the Metropolis MC is used to judge whether the structure will be accepted or refused. The climbing procedure lies at the heart of the SSW method and is elaborated below in detail.


Fig. 1 The illustration of (**a**) the SSW method and (**b**) the SSW-crystal method. The real PES is described by the red curve showing separated minima. (**a**): one SSW step from one minimum to another, where the bias Gaussian potentials are imposed only on the atom degrees of freedom; (**b**): one combined lattice and atom displacement step of the SSW-crystal method. The blue arrows and curves represent the lattice displacement and the local relaxation, respectively, as governed by the CBD-cell module, which gradually lifts up the potential energy of the crystal. The green curve represents the consequent atom displacement (at the fixed lattice) as governed by the SSW-module, being a simplified view of (**a**). (Reproduced from Ref. (Shang et al. 2014) with permission from the PCCP Owner Societies)

The climbing module of the SSW involves repeated bias-potential-driven structure extrapolation and local geometry optimization, which drags gradually $\mathbf{R}_i^0$ to a high energy configuration $\mathbf{R}_i^H$, where "i" is the index of the current MC step (Fig. 1a). Starting from the current minimum $\mathbf{R}_i^0$, SSW first generates a random direction $\mathbf{N}_i^0$, a normalized vector pointing to a direction to change the current geometry.

To enable an unbiased exploration of PES, the initial direction $\mathbf{N}_i^0$ by design combines two randomly generated vectors, the so-called global random mode $\mathbf{N}_i^g$ and the local random mode $\mathbf{N}_i^l$, as Eq. (1).

$$\mathbf{N}_i^0 = \left(\mathbf{N}_i^g + \lambda \mathbf{N}_i^l \right) / \left| \mathbf{N}_i^g + \lambda \mathbf{N}_i^l \right| \tag{1}$$

where the mixing parameter λ controls the relative portion of these two displacement directions. Specifically, $\mathbf{N}_i^g$ in our implementation is set as a randomly generated normalized vector that obeys the Maxwell-Boltzmann velocity distribution at 300 K, as utilized in standard molecular dynamics method for generating initial random velocity. As $\mathbf{N}_i^g$ distributes over a group of atoms, it represents a gentle, global displacement pattern of atoms. By contrast, $\mathbf{N}_i^l$ describes a stiff, local atomic move, and in our implementation it is set as a collision movement between two distant atoms. For example, the $\mathbf{N}_i^l$ associated with an atom A (e.g., the first atom in system) and an atom B (the second atom in system) can be derived as Eq. (2), using their coordinates q_A and q_B. The atom pair A and B can be either chosen randomly or learned from the previous trajectories, as long as the two atoms are not in the close contact (i.e., their distance >3 Å).

$$\mathbf{N}_i^l = \begin{pmatrix} q_B \\ q_A \\ 0 \\ \vdots \end{pmatrix} - \begin{pmatrix} q_A \\ q_B \\ 0 \\ \vdots \end{pmatrix} \tag{2}$$

$$\mathbf{R}_1 = \mathbf{R}_0 + \mathbf{N_t} \cdot \Delta R \tag{3}$$

$$C = \frac{(\mathbf{F}_0 - \mathbf{F}_1) \cdot \mathbf{N_t}}{\Delta R} \tag{4}$$

$$V_{R1} = V_{real} + V_N \tag{5}$$

$$V_N = -\frac{a}{2} \cdot \left[(\mathbf{R}_1 - \mathbf{R}_1) \cdot \mathbf{N}_i^0 \right]^2 = -\frac{a}{2} \cdot \left(\Delta R \cdot \mathbf{N_t} \cdot \mathbf{N_i^0} \right)^2 \tag{6}$$

Because reactions with low barriers generally involve soft normal mode directions, it would be ideal to soften the randomly generated $\mathbf{N}_i^0$ towards one eigenvector of Hessian matrix with small eigenvalues (not necessarily the lowest one). However, the direct computation of Hessian is expensive and not affordable in PES search. To solve this, Shang et al. develop a numerical approach, the bias-potential constrained Broyden dimer (BP-CBD) method (Shang and Liu 2012), to soften $\mathbf{N}_i^0$ using Eqs. (3), (4), (5), and (6). Following the unbiased dimer rotation (Henkelman and Jonsson 1999), Shang et al. define two images separated by a fixed distance of ΔR on PES, namely, $\mathbf{R_0}$ and $\mathbf{R_1}$ [Eq. (3)]. The rotation of the dimer by their force ($\mathbf{F_0}$ and $\mathbf{F_1}$) perpendicular to the dimer vector $\mathbf{N}$ using constrained Broyden optimization (CBD) (Shang and Liu 2010) will converge to the softest eigenvector of Hessian, and the local curvature [C in Eq. (4)] can be computed according to the finite difference equation. The softest eigenvector is, however, often not the desired one for reaction since it corresponds to the translational and rotational modes (C = 0) in the basin region. Therefore, a biased rotation scheme as implemented in BP-CBD is developed, in which the potential of $\mathbf{R_1}$ is modified as Eq. (5), where V_N is the bias potential added to the real PES V_{real} of $\mathbf{R_1}$ that is a quadratic function of coordinates $\mathbf{R_1}$ along $\mathbf{N}_i^0$ [Eq. (6)]. As long as the parameter a [Eq. (6)] is large enough, the biased rotation can guarantee the rotation of dimer will not deviate far away from $\mathbf{N}_i^0$. The force due to the bias potential in constraining the dimer rotation can be evaluated straightforwardly.

$$
V_{m-to-H} = V_{real} + \sum_{n=1}^{H} v_n = V_{real} + \sum_{n=1}^{H} w_n \times \exp\left[-\frac{\left(\mathbf{R}^t - \mathbf{R}_t^{n-1}\right)^2 \cdot \mathbf{N}_i^{n\,2}}{2 \times ds^2} \right]
$$
(7)

$$
\mathbf{F}_{tot} = \mathbf{F}_{real} + \sum_{n} w_n \cdot \exp\left[-\frac{\left(\mathbf{R}^t - \mathbf{R}_t^{n-1}\right)^2 \cdot \mathbf{N}_i^{n\,2}}{2 \times ds^2} \right] \cdot \frac{\left(\mathbf{R}^t - \mathbf{R}_t^{n-1}\right) \cdot \mathbf{N}_i^n}{2 \times ds^2} \cdot \mathbf{N}_i^n
$$
(8)

On moving from $\mathbf{R}_i^m$ to a high energy configuration $\mathbf{R}_i^H$, a modified PES V_{m-to-H} $\left(= V_{real} + \sum_{k=1}^{n} v_k\right)$ is utilized, as shown in Eq. (7), in which a series of bias Gaussian potential v_n (n is the index of the bias potential, $n = 1,2 \cdots H$) is added one by one consecutively along the direction $\mathbf{N}_i^n$ and thus creates a series of local minima $\mathbf{R}_t^n$ along the moving trajectory on the modified PES. Similar techniques have been used in Metadynamics (Iannuzzi et al. 2003). The local minima $\mathbf{R}_t^n$ is identified using local geometry optimization, where the force can be evaluated according to Eq. (8). The w and ds in Eq. (7) control the height and the width of Gaussian function v_n, respectively. While w can be computed on-the-fly to guarantee the success of the uphill, ds is left as an adjustable parameter in SSW simulation.

It should be mentioned that $\mathbf{N}_i^n$ will always be updated from the initial random direction $\mathbf{N}_i^0$ at each $\mathbf{R}_t^n$ and is then refined using BP-CBD rotation.

To sum, the uphill movement from $\mathbf{R}_t^m$ to $\mathbf{R}_t^H$ is a repeated procedure containing (i) updating the direction $\mathbf{N}_i^n$ at $\mathbf{R}_t^n$; (ii) adding a new Gaussian function v_n and displacing $\mathbf{R}_t^n$ along the direction $\mathbf{N}_i^n$ by a magnitude of ds ($\mathbf{R}_t^n + \mathbf{N}_i^n \cdot ds$); and (iii) relaxing to $\mathbf{R}_t^{n+1}$ on the modified PES.

The overall efficiency of SSW method depends on the choice of the step length of surface walking ds and the max number of Gaussian potentials H. A typical value of ds ranges from 0.2 to 0.6 Å, being 10% to 40% bond length of chemical bonding. The max number of Gaussian potentials (H) is also system-dependent and in general a number in the range of 6~15 is a sensible choice. With large ds and large H, a large scope of PES can be explored rapidly, but it is at the expense of the resolution on the reaction pathway between minima. Typically, for complex Lennard-Jones clusters (e.g., LJ$_{75}$ with multiple funnels and high barrier), the SSW simulation requires 300~400 energy/force evaluation per MC step with $ds = 0.6$ and $H = 14$. It takes typically 70~80% computational efforts (energy and gradient evaluation) on the climbing and the left 20~30% on the relaxation to a minimum.

3   SSW-Crystal Method

The SSW method can be extended to explore the PES of periodic crystal systems, named as the SSW-crystal method. Due to the additional degrees of freedom from the lattice, the key issue in the SSW-crystal method is to couple effectively the lattice and the atom movement in the solid structure displacement. In fact, there are a number of possible ways to couple the lattice and atom displacement. One simplest way is as introduced in Shang et al.'s work in 2014 (Shang et al. 2014), in which the cell movement and atom movement are operated alternatively in one MC step. A more sophisticated way is to combine the lattice parameters and atom coordinates into a generalized coordinate, based on which PES is explored. The generalized coordinate approach is similar to that implemented for TS search between two crystal phases in variable-cell double-ended surface walking method (Zhang and Liu 2015a). Below we mainly introduce the simplest way to couple the lattice and atom displacement in the original SSW-crystal method.

The SSW-crystal method is constituted by three parts, the atom displacement module using the SSW method (SSW module), the lattice displacement module using the CBD method to treat cell vector displacement (CBD-cell module), and the Metropolis MC module. The SSW module and the CBD-cell module are responsible for the displacement of atom and lattice coordinates, respectively. By coupling these two modules, the SSW-crystal can mimic the collective movement in crystal phase transition that involves generally both the atom and the lattice degrees of freedom. Shown schematically in Fig. 1b is such a combined CBD-cell (blue curve) and SSW (green curve) displacement to manipulate one crystal structure from one minimum

to another. Compared to the SSW method, only the CBD-cell module is new, and it is elaborated in the following.

The CBD-cell module to displace lattice mimics the way to displace atom in SSW method. In short, a few cycles are performed to displace smoothly the lattice along one soft lattice mode direction. It has been found that the displacement along the soft lattice modes, instead of a random direction or hard lattice modes, is critical for achieving the high efficiency of crystal PES exploration. Each CBD-cell cycle (blue arrows/curves in Fig. 1b) contains three steps, namely, the soft lattice mode identification, the lattice displacement, and the local relaxation of atoms in the fixed lattice. Specifically, the lattice displacement is achieved by displacing the current lattice $\mathbf{L}_0^n$ (n is the index of the current CBD-cell cycle) along a soft lattice mode direction $\mathbf{N_{cell}}$ to yield a new lattice $\mathbf{L}_0^{n+1}$, as described in Eq. (9). The lattice $\mathbf{L}$ is a nine dimensional (3 × 3) vector. After the lattice displacement, the local energy minimization is then performed on the fixed lattice.

$$\mathbf{L}_0^{n+1} = \mathbf{L}_0^n + \Delta L \cdot \mathbf{N_{cell}} \tag{9}$$

In the equation, ΔL represents a small displacement for the lattice, which is under the constraints for the maximum change in the lattice length (e.g., *a*, *b,* and *c* **axis**) and the volume. Typically, $\Delta L = 0.15 \times \sqrt{\sum l_{ij}^2}, l_{ij} \in L_0^n$, i.e., ΔL being about 15% change in the cell vector. It is obvious that the quality of $\mathbf{N_{cell}}$ determines largely how efficient the PES exploration of solid will be.

$$\mathbf{L}_1 = \mathbf{L}_0 + dL \cdot \mathbf{N}_{cell}^t \tag{10}$$

$$F_{rot}^L = 2\left(\dot{\mathbf{L}}_0 - \dot{\mathbf{L}}_1\right) - 2\left[\left(\dot{\mathbf{L}}_0 - \dot{\mathbf{L}}_1\right) \cdot \mathbf{N}_{cell}^t\right] \cdot \mathbf{N}_{cell}^t \tag{11}$$

$$\dot{L}_{ij} = \partial H / \partial L_{ij} = -\Omega \sum_k (\sigma_{ik} - p_{\text{ext}}) \left[\left(\mathbf{L}^t\right)^{-1}\right]_{kj} \tag{12}$$

To generate a physically meaningful $\mathbf{N_{cell}}$, Shang et al. also use CBD rotation method (Shang and Liu 2010) to identify one soft mode of the lattice Hessian, starting from a random vector $\mathbf{N}$ (a nine-component vector, three rotational modes are projected out in CBD rotation). The CBD rotation algorithm for lattice is summarized in Eqs. (10) and (11), where $\dot{L}$ denotes the first derivative of the enthalpy (H) with respect to the lattice; σ is the stress tensor, Ω is the volume, and p_{ext} is the external pressure; $\mathbf{L_1}$ and $\mathbf{L_0}$ are two lattice configurations, namely, a dimer, separated by a fixed Euclidean distance of dL along $\mathbf{N}_{cell}^t$. In CBD rotation, the dimer will rotate to minimize the rotation force ($\mathbf{F}_{rot}^L$) until a preset criterion is reached. $\mathbf{N_{cell}}$ will in principle converge to the softest eigenstate of the lattice Hessian matrix. The curvature (eigenvalue) of the $\mathbf{N_{cell}}$ can then be derived using the numerical finite difference as:

$$C_{cell} = \left(\dot{\mathbf{L}}_0 - \dot{\mathbf{L}}_1\right) \cdot \mathbf{N}_{cell}^t / dL \tag{13}$$

The CBD rotation method is able to fast identify one soft lattice mode starting from a random vector, typically within a few steps of energy/force evaluations. Taking α-quartz $(SiO_2)_{12}$ crystal as an example where the SiO_2 PES is described by the BKS (Beest, Kramer and Santen) potential (van Beest et al. 1990), Shang et al. have performed the numerical experiment to examine the efficiency of CBD for the softest lattice mode finding. The six lattice modes of quartz can be numerically calculated and the curvature C_{cell} of them are 4.98, 5.81, 8.47, 20.1, 21.7, 35.0 ($\times 10^{-2}$ a.u.). As the representatives, the calculated softest ($\mathbf{N}_{cell}^1$) and hardest ($\mathbf{N}_{cell}^6$) lattice modes are shown in Eqs. (14) and (15). Obviously, the softest lattice mode represents the expansion along c axis and the compression along a and b axes, while the hardest lattice mode represents the compression along all three directions. Averaged over 5000 independent runs initialized from random vectors, the CBD rotation prefers clearly the soft lattice modes: the probability for converging to three soft modes and to three hard modes are 57.8% and 4.7%, respectively. The rest 37.5% converges to the hybrid modes.

$$N_{cell}^1 = \begin{pmatrix} -0.16 & 0.08 & -0.03 \\ 0.52 & -0.74 & -0.02 \\ -0.04 & -0.03 & 0.38 \end{pmatrix} \tag{14}$$

$$N_{cell}^6 = \begin{pmatrix} 0.33 & 0.24 & 0.02 \\ 0.08 & 0.35 & 0.00 \\ 0.03 & 0.00 & 0.83 \end{pmatrix} \tag{15}$$

4   SSW Reaction Sampling (SSW-RS)

4.1   Reaction Sampling

Because the SSW simulation produces a continuous trajectory between minimum and each displacement follows the soft mode direction, the SSW simulation can also be utilized to identify low energy reaction pathways. The SSW reaction sampling (SSW-RS) developed in 2015 (Zhang and Liu 2015b), as illustrated in Fig. 2, aims to generate an ensemble of reactant-product (R/P) pairs between two connected minima on PES. The two structures of the R/P pair can be utilized later for TS location using the double-ended TS searching method.

As shown in Fig. 2, the SSW reaction sampling starts from one random configuration of reactant, which is the input structure and may well not be the most stable configuration of the reactant. During the simulation, the structures nearby this reactant will be visited, including the conformation isomers of the same reactant (the same phase region) and the likely products with different bonding patterns (the other phase regions). Different from the Metropolis MC scheme in the global structure search, a special structure selection module (to decide whether a new minimum is accepted or refused) is designed to judge whether a (desirable) reaction occurs

Fig. 2 The flow chart of SSW-RS method
or not. If a new minimum in the other phase regions is identified, it is recorded as the product of the current SSW step. Then the program will reject the new minimum and continue the PES exploration from the reactant; on the other hand, if the new minimum identified is still at the same reactant phase, the simulation will accept the new isomeric structure and continue the structure exploration. The whole procedure will be repeated until a large number of R/P pairs are collected. Typically, a few hundreds of R/P pairs are required to reveal the lowest energy pathway of an elementary reaction step (see Fig. 2).

The probability for accepting a new minimum in the structure selection module is thus described by P_r in Eq. (16)

$$P_r = \begin{cases} 0, \text{reaction occurs} \\ 1, \text{otherwise} \end{cases} \tag{16}$$

where the occurrence of reaction is characterized by a group of preset conditions, e.g., a dramatic change of system energy, the making/breaking of chemical bonds and the change of the local chirality of atom for molecular reactions, the change of crystal symmetry, and the change of structure order parameter for crystal phase transition. These conditions need to constitute a sensitive measure for detecting the occurrence of a desirable reaction from SSW trajectory. The probability P for recording an R/P pair is given in Eqs. (17) and (18).

$$P = (1 - P_r) \cdot P_{mc} \tag{17}$$

$$P_{mc} = \begin{cases} \exp\left[\frac{E(\mathbf{R}^m) - E(\mathbf{R}^{mt})}{kT}\right], when\ E\left(\mathbf{R}^m\right) < E\left(\mathbf{R}^{mt}\right) \\ 1, otherwise \end{cases} \tag{18}$$

where P_{mc} is the Metropolis MC probability for accepting the new minimum $\mathbf{R}^{mt}$ or reverting to the starting minimum $\mathbf{R}^m$. The Metropolis NC scheme in reaction

sampling helps to screen the highly endothermic reactions, which will not be considered for subsequent pathway building.

4.2   Pathway Building

Once enough R/P pairs are collected, the low energy pathways connecting these R/P pairs can then be determined by building the pathway between them. The pathway building tool utilized in our work is the double-ended surface walking (DESW) method (Zhang et al. 2013), which can treat both aperiodic and periodic systems (Zhang and Liu 2015a). The DESW method follows the same uphill mechanism in SSW method, i.e., repeated bias potential addition and local relaxation. It can fast connect a pseudopathway between an R/P pair, which has been shown to mimic the true MEP at the TS region. The DESW pseudopathway building helps to screen unlikely pathways in an efficient way: only those with relatively low energy pseudopathway will be considered further to locate the TS explicitly. In DESW, because the reactant and the product obtained from the SSW reaction sampling may be separated by more than one minimum, the highest energy TS along the pathway will be first identified. The barrier calculated with respect to the GM energy of reactant will be utilized a quantitative measure to compare different pathways and to select finally the low energy pathways. The exact knowledge on the minimum energy pathway (MEP) at this stage is in fact not essential (MEP may be calculated only for a few lowest energy pathways that are important for kinetics).

The pathway sampling in the multiple-step reaction systems is even more challenging for the presence of multiple intermediates. Liu group (Wei et al. 2017; Zhang et al. 2017a, b) have shown recently that by carrying out the SSW-RS sampling from every likely intermediates, the whole reaction network can be established eventually. The methods, such as Dijkstra's algorithm (Dijkstra 1959), can be utilized to analyze the network and identify the reaction mechanism. If the overall rate of the reaction system is the concern, one can construct the transition rate matrix and utilize the kinetics methods (such as kinetic MC) to simulate the reaction kinetics.

While the key elements of the SSW-RS for reactivity prediction share common features with the approaches proposed in recent years (Maeda et al. 2009; Maeda et al. 2014; Schaefer et al. 2014), the SSW-RS has its own advantages in both the reaction sampling and the pathway building. Thanks to the generality of the SSW method, the SSW-RS is also a general purpose tool for sampling different type of reactions, ranging from the association and dissociation molecular reactions (Zhang and Liu 2015b), to the surface catalytic reaction (Zhang et al. 2017a) and to the solid phase transition reactions (Zhu et al. 2015). This leads to the easy implementation and high transferability of the SSW-RS method for different applications. Taking molecular reactions as example, the SSW-RS can sample simultaneously both the reactant conformations, a very flat PES with many likely conformations, and the bond making/breaking reactions that have high reaction barriers. These features of the SSW-RS method will be demonstrated in the following section.

5   Application Examples

For the distinct features of SSW method (and the derived methods), such as the evaluation of second derivatives of the PES and the gentle structure perturbation, the SSW provides a unique tool to explore unbiasedly the global PES of a material and in the meantime to identify the reaction pathways between phases of concern. Besides, the gentle movement helps greatly the electronic structure calculation, allowing one to use the one-electron wavefunctions and the charge density of the earlier configuration, enabling a long-time stable PES sampling.

In this section, we describe a few typical applications of the SSW methods, including the global PES and phase transition searching of TiO_2, ZrO_2, and carbon. All these simulations are based on density-functional theory (DFT), where the exchange-correlation functional used is the generalized gradient approximation as parameterized by Perdew, Burke, and Ernzerhof (GGA-PBE) (Perdew et al. 1996). Corrections for van-der Waals dispersion are added in the case of carbon crystal systems using the Grimme-D3 approximation (Grimme et al. 2010). The interaction between atomic cores and valence electrons is described using the projector augmented wave method (Kresse and Joubert 1999). All calculations use plane-waves basis sets. For more details, the reader is referred to the original articles cited below.

5.1   Global PES and New Crystal Phases of TiO_2

The SSW method can be utilized to establish the global PES of material and thus identify new crystal phases. This is exemplified in TiO_2 system, an important functional material widely utilized as coating materials and catalysts in many fields. In particular, the photoactivity of TiO_2 was hotly investigated for water splitting (Li et al. 2010; Li and Liu 2011; Zhao and Liu 2014; Zhao et al. 2015). The PES of TiO_2 is highly complex as evident by the fact that many possible polymorphs are present in nature (the most common phases of TiO_2 at the ambient conditions are rutile, anatase, brookite, and TiO_2-B (Penn and Banfield 1999; Bakardjieva et al. 2006; Cheng et al. 2015)). New stable TiO_2 phases have long been searched for in material science.

In 2017, Huang et al. (2017) constructed TiO_2 neural network (NN) potential using SSW global PES data generated from first principles density functional theory (DFT) calculations in small unit cells (below 12-atom). Six independent SSW global search using NN potential (SSW-NN) were then carried out in a larger supercell (48-atom), 10,000 minima visited in each run. In total, 6151 distinct minima were obtained after removing duplicated structures. Figure 3a shows the global PES contour plot projected onto the structural order parameter (OP_2) and the total energy (E). The corresponding density of states (DOS) is plotted in Fig. 3b.

The global PES shows that the crystalline region of TiO_2 is below ~0.2 eV per formula unit (eV/f.u.) with respect to the GM (TiO_2-B phase), and contains 224
Fig. 3 (**a**) PES contour plot for TiO$_2$ distinct minima sampled from SSW-NN global search. (**b**) Density of states (DOS) plot for TiO$_2$ phases in (**a**), showing that amorphous structures appear in the 0.2~0.7 eV/f.u. window. (**c**) The percentage of differently coordinated Ti for TiO$_2$ structures. [TiO$_5$] and [TiO$_6$] are main structural features for amorphous structures. (Reproduced from Ref. (Zhang et al. 2017b) with permission from the PCCP Owner Societies)

distinct crystal phases (180 of them are newly found from SSW-NN simulation). It is noted that the number of distinct crystalline structure is substantially large considering that there are only ∼10 TiO$_2$ phases reported from experiment (Cheng et al. 2015). From 0.2 to 0.7 eV/f.u., one can see a salient deep-blue zone due to the energy degeneracy of structures, featuring a high, continuous, and broad peak in the DOS plot (Fig. 3b). This zone is dominated by amorphous structures.

The Ti coordination number x ([TiO$_x$]) for all structures is analyzed to understand the difference between amorphous and crystalline phases. The evolution of the Ti coordination in solids with the increase of energy is plotted in Fig. 3c. This is done by counting and averaging the Ti coordination for structures in the same energy interval, E to E + dE (5 meV/f.u.). Figure 3c shows that [TiO$_4$], [TiO$_5$], [TiO$_6$], and [TiO$_7$] constitute the major coordination environment for Ti. For the low energy crystal phases (e.g., rutile, anatase, TiO$_2$-B), they generally contain only TiO$_6$ octahedra (100% [TiO$_6$], energy lower than 25 meV/f.u.). The [TiO$_5$] starts to appear above 30 meV/f.u. This and [TiO$_6$] correspond to the dominant coordination for amorphous structures. By contrast, [TiO$_4$] and [TiO$_7$] are rare coordination in TiO$_2$ solids: they appear at high energies and are found either in high pressure phases ([TiO$_7$]) or in open structures ([TiO$_4$], e.g., cage, 2-D layer).

Interestingly, the SSW-NN PES exploration discovers stable porous structures, which could be potentially useful as molecular sieves and catalysts. Two such phases with open cages labeled as phase-87 (I4/m, #87) and phase-139 (I4/mmm, #139) rank 10 and 23 in the minimum energy spectrum respectively, having the similar stability as the common rutile phase that ranks 30 in the spectrum. The [TiO$_5$] coordination is the key structure feature in these porous TiO$_2$ structures, and they are found to be good candidates for anode material in Li ion battery (Ma et al. 2017). Importantly, the calculated barrier for the phase-87 to anatase transition is 0.22 eV/f.u., which is quite high considering that the barrier from TiO$_2$-B to anatase is only 0.12 eV/f.u. (Zhu et al. 2014) and the experimental temperature for TiO$_2$-B to

anatase conversion is ∼673 K (Zhang and Banfield 1999). Our results indicate that the porous phase-87 is kinetically stable. One can argue then that, once synthesized, the new phase could be stabilized at ambient conditions.

5.2　Zirconia Phase Transitions

The crystal-to-crystal phase transition has long been a great challenge for computer simulations. Recently, the SSW-RS method has been utilized to provide important insights into the phase transition mechanism and kinetics. As a prototype system for crystal phase transition, the tetragonal-to-monoclinic (t-m) phase transformation in ZrO_2 (Kelly and Rose 2002) is widely exploited in mechanical ceramic toughening (Jin 2005) and in heterogeneous catalysis for tuning surface activity (Wang, et al. 2007). This phase transition is rapid and reversible above ∼1000 °C and incurs an appreciable volume increase (by 4.2%) that is in accompany with the decrease in the coordination number of Zr from 8 to 7. Although it was long regarded as a diffusionless Martensitic phase transition (Wolten 1963; Bhattacharya et al. 2004), the transformation kinetics at the atomic level has been debated for over 60 years.

Using SSW-RS method, Guan et al. (2015) in 2015 have determined the lowest energy transition pathways and resolve the physical origin of two types of orientation relationship (OR) in ZrO_2 t-m phase transition. From 269 pathways of t-m phase transition obtained from SSW-RS, they identified three distinct lowest energy pathways. The overall potential energy profiles of these pathways are shown in Fig. 4a. Path I and Path II are pathways for t-m phase transition with the same apparent OR, i.e., $(100)_m//(110)_t$; $[001]_m//[001]_t$, being the Type-C OR in literatures. Unlike Path I, Path II is an indirect channel involving an intermediate orthorhombic phase, o-phase (Pbc2/1, #29), with OR as $(100)_m//(001)_o$; $[001]_m//[100]_o$ and $(001)_o//(110)_t$; $[100]_o//[001]_t$. The 3-D contour plot of Path II is illustrated in Fig. 4b. Path III is a branch channel involving the ferroelastic transformation of the t-phase itself by switching the **c** and **b** axis of crystal. The OR is $(110)_t//(110)_{t'}$; $[001]_t//[1\bar{1}0]_{t'}$. When Path III (t-t') is followed by Path I or II (t-m), the apparent OR of t-m phase transition is switched to $(100)_m//(110)_t$; $[010]_m//[001]_t$, which turns out to be Type-B OR in literature.

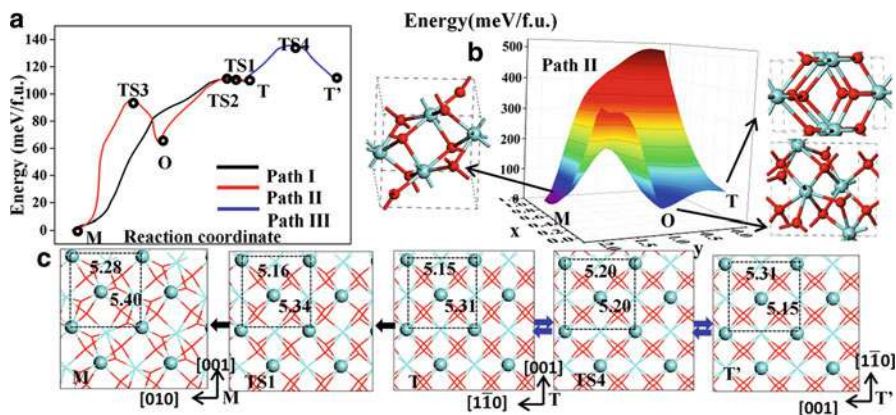
The calculated barriers of Path I and II leaving t-phase are extremely low, 2.6 and 3.5 meV/f.u. relative to t-phase, respectively, while that for Path III is 29.2 meV/f.u., being much higher than the previous two pathways. Compared to the t-phase to o-phase (t-o), the o-phase to m-phase (o-m) in Path II needs to overcome much higher barrier (32.1 meV/f.u.), which indicates the o-phase is a trapping state at low temperatures. Because o-phase is only 0.60% larger than t-phase in volume, the transformation toughening is largely prevented as the o-phase forms at low temperatures. Although the volume of o-phase is close to t-phase, the Zr in o-phase is 7 coordinated; half of the O atoms are 4 coordinated and the others are 3 coordinated, which are the same as those in m-phase. In short, in Path II, the t-o phase transition breaks four Zr-O bonds per cell (12-atom) but has little change in


Fig. 4 (**a**) Potential energy profile for the lowest energy pathways from tetragonal phase (T or T')
to monoclinic (M) phase. (**b**) The 3-D PES of Path II obtained by the linear interpolation of lattice
parameters (x axis) and atomic fractional coordinates (y axis) from structure snapshots in Path II.
(**c**) The local structure change during phase transition following Path I and III viewed down from
the determined atomic habit plane, (110)t or (100)m surface. The Zr-Zr distances labeled are in Å.

Chemical Society)

lattice; the o-m phase transition involves a large lattice distortion while keeping the
overall coordination.

The reaction pathway obtained from SSW-RS also reveals in detail how atoms
displace during the phase transition. The atomic movement on $(110)_t$ and $(100)_m$
in Path I and Path III is illustrated in Fig. 4c, where both two types of OR can be
generated. The $(110)_t$ and $(100)_m$ surfaces are determined to be the atomic habit
planes (interface) in the phase transition, which fulfill the following criteria: (i)
having minimum strain as evidenced by the close lattice parameters, e.g., $(110)_t$:
5.15×5.31 Å; $(100)_m$: 5.28×5.40 Å (Fig. 4c); (ii) having minimum atomic
movement in phase transition; (iii) acting as a coherent interface with close atomic
match between two phases, forming a heterophase junction.

Unlike the two lowest energy pathways, Path III is not directly leading to m-phase
but a ferroelastic transformation of t-phase. Such a reorientation of the individual
tetragonal domain is enabled by a permutation of the **b** and **c** axis in $(110)_t$ habit
plane. The t-t' phase transition goes through TS_4 that has a cubic-phase-like lattice
(P4/nbm, #125). The diagonal Zr-Zr distances in the habit plane are all 5.20 Å
(Fig. 4c), giving rise to a volume drop of 1.3% from t-phase to TS_4.

The results suggest that the OR of t-m phase transition should be dominated by
Type-C OR (Bansal and Heuer 1974). However, Type-B OR, although less often
observed, was reported experimentally in the phase transition of high temperature
zirconia single crystals (Wolten 1964) and in 3YSZ ceramics (Wu and Chiang
2011). To resolve this puzzle, the phase transition pathways under three different
external pressures (hydrostatic) at 5, 7, and 10 GPa are computed to mimic

the large stress-field that is developed at grain boundaries owing to the volume expansion during t-m phase transition. Among three pathways, only Path III is facilitated at high pressures, which turns out to be the lowest energy channel (ΔHa III $= 17.5$ meV) at 5 GPa compared to other two pathways (18.6 and 60.2 meV). This is in fact not surprising because the cubic-phase-like TS_4 has the smallest volume in all the located TSs and phases, and thus a compressive field helps to reduce the barrier greatly (the volumes of TS_1 and TS_2 are larger than t-phase, and that of TS_3 is also larger than o-phase). The result indicates that under high pressure condition the Type-B OR would be the more favorable OR for the t-m phase transition. Actually there are some experimental evidences that are consistent with this finding. For example, Chien et al. (1998) utilize Vickers microindentation experiment to induce the phase transition of Y-stabilized ZrO_2 from t-phase to m-phase. They observe the ferroelastic domain switching of t-phase together with the t-m Martensitic transition and importantly, only Type-B OR is found in the experiment. We emphasize that the presence of the o-phase does not add new OR. An important implication from current theoretical sampling on PES of ZrO_2 is that multiple energy-nearly-degenerate reaction channels can coexist in solid-to-solid phase transition and share the same OR. The knowledge of OR that is possible to obtain from experiment is in fact not enough to unravel the mechanism and kinetics of the solid-to-solid phase transition.

5.3   Graphite to Diamond Phase Transition

The graphite (G) to diamond transformation investigated by Xie et al. (2017) in 2017 is a good example to illustrate how to combine SSW and SSW-RS to resolve the mechanism of complex material structural transformation. It has long been a dream in human history (DeCarli and Jamieson 1961; Bundy and Kasper 1967; Hanneman et al. 1967; Naka et al. 1976) to convert graphite to diamond at mild reaction conditions. Modern research shows that the growth of large diamond crystals is kinetically hindered. The cubic diamond (CD), despite thermodynamically most stable among carbon allotropes above $\sim$5 GPa, is not the main product under mild static compression of graphite, $\sim$ 15 GPa and $\sim$1000 °C (Bundy and Kasper 1967; Yagi et al. 1992; Britun et al. 2004; Németh et al. 2014). In fact, the product is the dominated by hexagonal diamond (HD) and heterophase junctions. While great efforts have been devoted in past decades to understand the diamond phase growth from graphite matrix, the kinetics data computed from theory are still at odds with general experimental findings (Fahy et al. 1987; Scandolo et al. 1995; Tateyama et al. 1996; Mujica et al. 2003; Khaliullin et al. 2011; Xiao and Henkelman 2012).

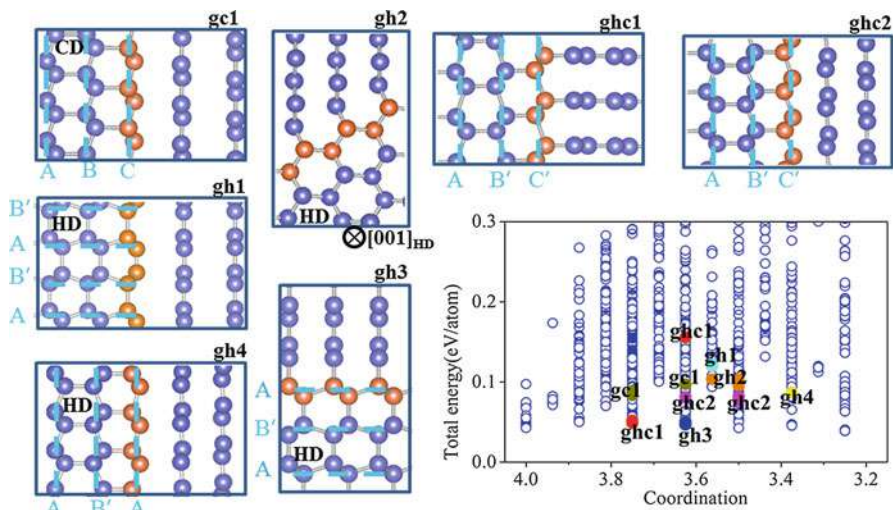
Xie et al. (2017) first used the SSW method to scan the phase space of carbon allotropes. To identify the likely intermediates during diamond growth, they focused on those less stable, less ordered heterophase junctions that are transient in kinetics. SSW simulations with the environment dependent interatomic potential (EDIP) (Marks 2000) for carbon were carried out using different supercells up to 32-atom


Fig. 5 Finding metastable heterophase junctions from SSW global PES exploration under 15 GPa. The right-bottom figure plots energy against average coordination number of 4000 structures. Different structures could have the same interface. (gh1)-to-(ghc2) show the structure of seven most stable interfaces from DFT. The dashed lines mark the close-packed planes, i.e., (111) for CD and (001) for HD. For gh2 interface, the interface is normal with $(001)_{HD}$. The interface atoms are orange colored for clarity. (Reprinted with permission from (Xie et al. 2017). Copyright 2017 American Chemical Society)

per cell at 15 GPa. The simulations were terminated until no more new types of junctions were revealed from PES exploration ($>10^6$ minima collected).

In total, more than 4000 minima were identified that are distinct from graphite and have relative low energetics (0.3 eV per atom above graphite). The energetics of the phases against the average carbon coordination number (N_c) is plotted in Fig. 5 (N_c is calculated by counting the first neighbors, where the C-C distance below 1.70 Å is regarded as bonding; N_c for diamond and graphite is 4 and 3, respectively). It shows that a large number of mixed phase intermediates (N_c in between 3 and 4) are obtained from SSW global structure search. By inspecting the geometry of all these structures closely, the metastable heterophase junctions that contain graphite component were screened out and distinguished according to the interface type and crystallographic orientation relationships (OR). There are seven types low energy heterophase junctions as indexed from gc1 to ghc2 in Fig. 5 and their associated interfaces are listed in Table 1.

For these heterophase junctions, gc1 is the only G/CD biphase junction; gh1 to gh4 are G/HD biphase junctions differing by the interfaces; and ghc1 and ghc2 are G/HD/CD three-phase junctions. HD/CD structure can be considered as a diamond structure with stacking faults on the close-packed plane. They belong to four distinct ORs as follows:

Table 1 Structure and energetics of metastable heterophase junctions in graphite-to-diamond solid phase transition. (Reprinted with permission from (Xie et al. 2017). Copyright 2017 American Chemical Society)

Name	Interface	OR_a	γ	ΔS	E_a
gc1	**$(001)_G//(111)_{CD}$**	**1**	**0.41**	**−3.7%**	**0.79**
gh1	**$(001)_G//(100)_{HD}$**	**3**	**0.23**	**0.7%**	**0.47**
gh2	$(110)_G//(1\bar{1}0)_{HD}$	3	0.24	22.6%	0.55
gh3	$(100)_G//(001)_{HD}$	3	0.35	25.2%	0.87
gh4	$(001)_G//(001)_{HD}$	4	0.42	−2.6%	0.85
ghc1	$(100)_G//(111)_{CD}$ $(100)_G//(001)_{HD}$	2,3	–	23.8%	0.84
ghc2	$(001)_G//(111)_{CD}$ $(001)_G//(001)_{HD}$	1,4	–	−3.2%	0.80

[a]Listed data include the interface planes, the crystallographic OR, the interfacial energy (γ, eV/Å^2), the reaction barrier (E_a, eV per interface atom) for the heterogeneous pathway mediated by the corresponding junction, the area misfit between connecting phases at the interface (ΔS, with respect to graphite)

OR1: (001)G//(111)CD, [100]G//[110]CD;
OR2: (001)G//(211)CD; [100]G//[110]CD;
OR3: (001)G//(100)HD, [1$\bar{1}$0]G//[001]HD;
OR4: (001)G//(001)HD, [010]G//[010]HD.

Among them, OR2 is 30 degrees off OR1, and OR4 is 90 degrees off OR3; OR2 does not occur independently but combines with OR3 to yield a C1-type three-phase junction (Scandolo et al. 1995). Only OR1 and OR3 were reported in experiment (Bundy and Kasper 1967; Yagi et al. 1992; Britun et al. 2004). For example, Britun et al. observed CD formation at 7 GPa and 1500 °C with OR1 (Britun et al. 2004).

The presence of multiple metastable heterophase junctions indicates that the kinetics of the pressure-induced graphite transformation is complex, governed by multiple anisotropic reaction channels. Xie et al. then utilized the SSW-RS simulation to determine the phase transition pathways that are mediated by these heterophase junctions.

The SSW-RS simulation starts from one heterophase junction (as listed in Table 1) and the pathways leading to G, HD, and CD phases are collected. After collecting a significant number of R/P pairs, i.e., >200 pairs for each heterophase junction, the TS was explicitly located using DFT and double-ended searching method, based on which the low energy pathways are determined by sorting the computed barriers. All the lowest energy pathways mediated by the seven different junctions were finally determined and the overall barriers of them (the highest energy TS along the pathway with respect to the graphite) are also listed in Table 1. The gh1-pathway (via gh1 junction) and gh2-pathway (via gh2 junctions) are the lowest barrier pathways, being 0.47 and 0.55 eV per interface atom (eV/ia), which is in line with the higher stability of their interfaces. The other pathways with less stable interfaces have much higher barriers, 0.75∼0.90 eV/ia.

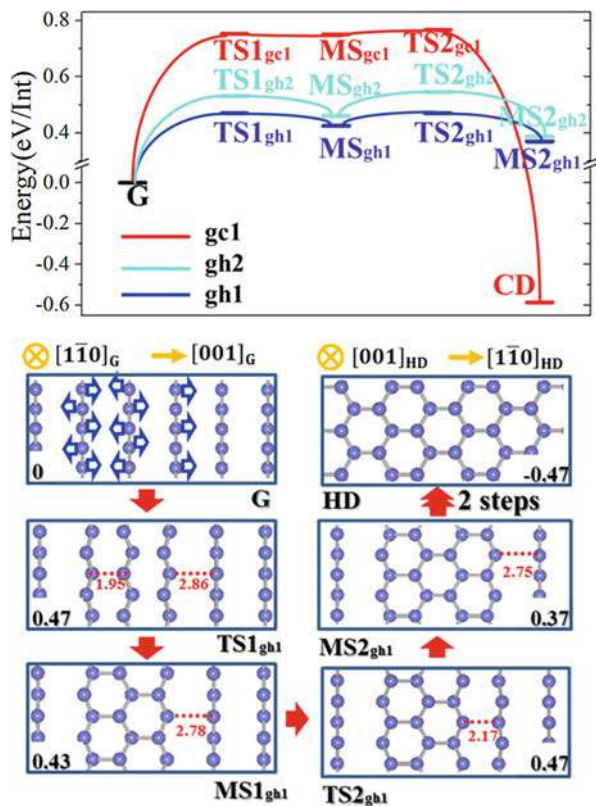
Fig. 6 Reaction energy profile for three lowest energy pathways (top panel), and reaction snapshots along the lowest energy pathway from G to HD mediated by gh1-type interface (bottom panel). The relative energy of state (eV per interface atom) is indicated in the corner. (Reprinted with permission from (Xie et al. 2017). Copyright 2017 American Chemical Society)


Figure 6 shows the reaction energy profiles of the lowest energy pathways mediated by gc1, gh1, and gh2 type interfaces. For the gh1 pathway from G to HD, it involves two intermediate states MS1 and MS2, both containing gh1 type interface. The lower overall barrier in gh1 compared to gc1 and gh2 can be attributed to the high stability of the reaction intermediates. The gh1 pathway in Fig. 6 is a representative to illustrate how atoms move during the phase transition.

The reaction initiates via the relative slipping of graphite basal plane along $[1\bar{1}0]_G$ by 1/2 C-C length (0.7 Å) followed by the compression at $[001]_G$. From G-to-MS1, the first step, the compression leads to the buckling of three neighboring graphite layers. The neighboring carbon rows along $[1\bar{1}0]_G$ in a graphite layer then displace collectively out of the basal plane at opposite directions and approach to the neighboring graphite layers. New C-C bonds are evolved at the TS ($TS1_{gh1}$) is 1.95 Å, after which a three-atomic-layer HD nucleus is created at MS1, showing the characteristic sp^3 bonding of diamond. The remaining steps, MS1-to-MS2 and MS2-to-HD, propagate the interface at $[001]_G$ with the same atom displacement pattern, leading to the growth of HD phase. The graphite basal plane evolves into $(100)_{HD}$, accompanied by 25.6% compression at $[001]_G$. In the pathway, the stability of the nascent HD nucleus (MS1) in graphite matrix dictates largely the

barrier height (TS1) of transformation, demonstrating the critical role of nucleation in kinetics.

The rate for graphite phase transition following heterogeneous pathways can be estimated: the formation of CD phase is at least 40 times slower compared to that to form HD phase at 1000 °C from microkinetics (by assuming the same prefactor). On the other hand, the reactions to CD phase and other mixed phase microstructures occur simultaneously: the rate difference is less than 1.12 times at 1000 °C. These quantities confirm HD phase is kinetically much favored, which correct the wrong prediction from collective pathways and MD results (Fahy et al. 1987; Scandolo et al. 1995; Tateyama et al. 1996; Khaliullin et al. 2011). Indeed, the G/HD composite with OR3 was commonly observed at 1000 °C (Bundy and Kasper 1967; Yagi et al. 1992; Britun et al. 2004; Németh et al. 2014), where CD phase is not formed yet; Németh et al. observed the mixed phase (CD/HD) at 2200 °C and 19 GPa (Németh et al. 2014) using transmission electron microscopy, indicating that the high temperature is a must to overcome the barrier of CD nucleation. The high HD selectivity is attributed to the presence of three low energy G/HD junctions, i.e., gh1, gh2, and gh3, orthogonal with each other, and two low energy anisotropic pathways via gh1 and gh2 junctions. These maximally stabilize HD nuclei inside graphite and allow for HD propagation in three dimensions (3D). By contrast, there is only one and high barrier gc1-pathway to form CD. Its barrier is similar to the pathways leading to the mixed phases. This indicates that the nascent CD nuclei in 3D inevitably introduce incoherent interfaces inside graphite and thus the CD growth is not favored both thermodynamically and kinetically.

6   Concluding Remarks

This chapter serves as a short overview of the SSW global optimization method and its recent application in material simulation. The SSW method is designed to combine some key features of existing theoretical methods for global structure search and reaction pathway sampling. A major feature in SSW method is the smooth structure perturbation, which mimics that in conventional MD simulations. While MD simulations meet great difficulties in overcoming high barriers, the SSW can go uphill on PES facilely by adding consecutive bias potentials along a soft curvature direction that is generated randomly and softened subsequently. The explicit consideration of the second derivation information and the repeated local relaxation are key techniques to keep the SSW trajectory close to low energy pathways.

Three examples on TiO_2, ZrO_2, and carbon are presented to demonstrate the current ability of SSW for global optimization and reaction pathway sampling. The SSW method in combination with first principles calculations can be utilized to generate a rich data on the PES of a material. It can reveal unknown new phases for constructing the phase diagram and help to map out the lowest energy pathways for understanding reaction kinetics. Perhaps more interestingly, this big data may also be utilized for machine learning, for example, to train high dimensional NN

potential of material. Considering that the NN potential is computationally much less demanding than the electronic structure calculation methods, the combination of SSW with machine learning techniques may bring a new era for material simulation in the decade to come.

First-Principles-Assisted Structure Solution: Leveraging Density Functional Theory to Solve Experimentally Observed Crystal Structures

119

Kyle Michel, Bryce Meredig, Logan Ward, and Christopher Wolverton

Contents

Abstract

FPASS (first-principles-assisted structure solution) is a global optimization method that can be used to determine the structure of a material from a powder X-ray diffraction pattern (Meredig and Wolverton, Nat Mater 12(2):123–127, 2013). Using a hybrid of Rietveld refinement and minimization of energies from density functional theory calculations, FPASS can be used to solve crystal structures with reduced guidance from experts typically required for Rietveld

refinement alone. This article presents the core concepts of the FPASS method and how it compares to other structure solution and prediction methods. A number of case studies are presented that show the breadth of structure types that have been solved using this method, including those run in a high-throughput mode. Finally, future directions and research opportunities around the FPASS method are discussed.

1   Introduction

Powder X-ray diffraction (XRD) is a common technique used to characterize the structure of a material (Cullity and Stock 2001). A sample of material is turned into a powder and then bombarded with X-rays. The diffracted intensities of those X-rays are measured in the area surrounding it. The resulting intensity pattern, which is a function of the scattering angle, will have peaks and shapes that are characteristic of the structure of the material. Once the diffraction pattern for a material has been obtained, it can be compared against libraries of patterns for known materials. This process allows for the identification of the material, or combination of materials, that are contained in the sample. However, this method for determining the phases present in a sample only works when reference patterns exist for all of those phases. When this method fails, the structure of the material must be solved in a different way.

Powder XRD patterns are a direct function of the structure of the material being characterized. In this way, they represent a reduction from a very high-dimensional space (the unit cell shape and atomic positions within it) to a much lower-dimensional space (the two-dimensional pattern of intensity vs. scattering angle). The challenge in solving structures is to reverse that reduction, that is, to determine the crystal unit cell shape and atomic coordinates from the two-dimensional, measured pattern.

The common workflow for solving a crystal structure from powder XRD data is composed of three main steps: unit cell determination, identification of atomic positions, and structure refinement (Pecharsky and Zavalij 2005). The first step, unit cell determination, is the process of inferring the parameters and symmetry of the unit cell from the relative diffraction angles, intensities, and systematic absences of diffraction peaks. The second step involves determining which arrangement of atoms within the unit cell best describes the observed diffraction pattern. The final step is to optimize the agreement between the simulated pattern of the proposed structure and the diffraction data by making fine adjustments to the proposed solution that maximize the agreement. A common, modern approach for the refinement step is Rietveld refinement, a process that not just optimizes the crystal structure parameters but also accounts for other factors (e.g., grain size) that affect the shapes of the individual diffraction peaks (Rietveld 1969).

The complexity of solution from Powder XRD lies in the often-large space of possible crystal structures and the low amount of information present in powder diffraction patterns. With an infinite amount of computing time, every possible

combination of atomic positions for a structure could be generated and then refined. Unfortunately, in reality, this process would be impossibly slow. Including the shape of the lattice, there are $3N + 3$ degrees of freedom in a structure with N atoms (if the symmetry of the structure is ignored). While this space of candidate structures is occasionally small enough for a human expert to find the solution after only a few guesses, there do exist methods to automate the solution processing for the many difficult cases. One such option is to employ global optimization algorithms.

Methods that employ global optimization to solve crystal structures are known as direct-space structure solution methods (Černý 2017). Originally developed in the early 1990s (Harris and Tremayne 1996), direct-space methods leverage the ability of global optimization algorithms to determine solutions that maximize an objective function (in this case the match to the diffraction pattern) with minimal numbers of guesses, making it possible to search intractably large solution spaces. In the following decades, scientists developed a variety of direct-space methods that employ many different global optimization algorithms, including simulated annealing (Deem and Newsam 1989), genetic algorithms (Kariuki et al. 1997), and, more recently, particle swarm optimization (Gao et al. 2017).

In addition to the size of the search space that must be explored, a second difficulty can arise during global optimization; two or more structures may be generated with very similar matches to the experimental diffraction pattern. There are several routes to resolving this ambiguity when it occurs. Of course, one can always apply domain knowledge to select which of the candidate solutions is more likely or perform additional experiments (e.g., NMR, neutron diffraction) that may differentiate structures with similar X-ray patterns. Another route is to integrate the energy of a structure into the solution process. Known as hybrid direct-space structure solution methods, they use the energy computed from empirical potentials to find which structures are most likely to be stable (Lanning et al. 2000; Putz et al. 1999). Adding structural energy as a metric during the structure solution guides the optimization algorithm away from unphysical solutions, which further speeds the solution process (Lanning et al. 2000).

These powerful concepts of efficient global optimization using the energy as a guiding function are combined in the FPASS method (First-Principles Assisted Structure Solution) (Meredig and Wolverton 2013; Ward et al. 2015, 2017). FPASS allows for structure solution from powder XRD patterns with limited human intervention. It combines global search methods, biasing based on energies obtained from first-principles calculations, and local optimization through Rietveld refinement. The details of the method are described in the next section and a number of applications in the section following that.

2 The FPASS Method

There are three main components to the FPASS method. First, a global optimization strategy is employed to search across all configurations of atoms in a crystal structure with a fixed composition in order to find structures in the neighborhood

of those likely to have been observed in experiments. Second, energies computed from density functional theory (DFT) are used to guide the selection of candidates so that structures with relatively low energies are favored to those with higher energies. Third, a local refinement of each candidate crystal structure minimizes the difference between observed and computed XRD patterns. In the end, the goal of the FPASS method is to find a crystal structure that minimizes the total energy of the structure while having a simulated diffraction pattern that most closely matches the experimentally observed one.

Density functional theory is used in FPASS due to its ability to produce the energy of a material given only its lattice parameters and positions of atoms in the unit cell (Hohenberg and Kohn 1964; Kohn and Sham 1965). This feature makes it general enough to apply to any problem for which the counts of each element in the structure are known. However, any energy function could be used in its place. For example, a classical potential, if one existed for a system, could be used to more quickly calculate energies but would be less accurate than DFT. The only requirement of the energy calculation is that it accurately ranks the relative energies of any set of structures in a single FPASS run.

A coarse search of structures with a fixed composition is performed using a genetic algorithm. Genetic algorithms mimic the evolution of a species by creating a series of generations, each a function of crossover (or mating) operations of the members of the current generation, and random mutations of the children of those operations. In the context of structure solution, each member of a generation represents a single set of atomic positions within a fixed unit cell on a lattice. A genetic algorithm is parameterized by some initial population, a set of allowed crossover operations, and a set of randomly selected mutations.

The symmetry, or space group, of a material puts constraints on the atomic positions of the atoms in the structure (Michel and Wolverton 2014). These constraints manifest in two ways. First, the space group of a material defines a set of Wyckoff sites. Each Wyckoff site contains one or more positions that are equivalent by symmetry and which must all be occupied if any one of them is; this set of positions is known as the orbit of the site. Some space groups may only have a few Wyckoff sites while others can have tens of them. Choosing which set of Wyckoff sites to occupy (some can be occupied more than once) for a structure amounts to searching over all combinations such that the number of atoms sums to the correct amount. Second, the continuous positions of the symmetrically unique atoms may be constrained by the symmetry of a Wyckoff site. In this way, an atom might be free to move in all directions on a single position of a Wyckoff site, or it may be restricted to a plane, line, or even to a specific point.

Since the number of possible combinations of Wyckoff sites can be extremely large, FPASS includes heuristics to select likely Wyckoff site occupations that are based on experimentally observed structures. In particular, a survey of the Inorganic Crystal Structure Database (ICSD) (Belsky et al. 2002) has shown that a majority of crystal structures have site occupancies such that the number of Wyckoff sites that are occupied is minimized for the number of atoms in the structure. In other words, nature tends to favor crystal structures in which the number of symmetrically

unique atoms is minimized. When a structure is generated in FPASS, the list of possible combinations of Wyckoff sites is enumerated such that atomic counts are preserved. Each of these combinations is assigned a probability that is proportional to the fraction of ICSD compounds with that number of Wyckoff sites relative to the minimum possible. For example, if the minimum number of Wyckoff sites that a structure could occupy is two, then a set of four Wyckoff sites would be assigned a probability equal to the fraction of structures in the ICSD that contained exactly twice the minimum possible number of sites. The degree to which combinations of sites are biased by this distribution is an input to each FPASS calculation. When the ICSD distribution is weighted heavily, the structures that are found in the global search are likely to be similar to those in the ICSD. Conversely, when the ICSD distribution has a small weight or is turned off entirely, the optimization is more likely to find structures that are very dissimilar to those in the ICSD.

Once a set of Wyckoff sites has been selected, atomic positions are generated so that they obey the symmetries of those sites. For example, an atom on the 2h Wyckoff site (1/3,2/3,+z) of the $P\bar{6}$ space group can occupy any position along the z axis but must have x and y coordinates equal to 1/3 and 2/3, respectively. When the coordinates of one atom on a Wyckoff site have been generated, all atoms in the orbit of that site are fixed by its symmetry.

Two values are calculated for every structure in a generation. First, the match between the experimental and simulated XRD patterns is optimized (see discussion below on Rietveld refinement). Each structure i is assigned a score S_i^{XRD} which is equal to its rank against all other structures when their matches to experiment are placed in ascending order. For example, the structure with the best agreement between experimental and simulated XRD patterns would have $S_i^{XRD} = 1$, while the structure with the worst agreement would have S_i^{XRD} equal to the number of structures in the population. Second, the total energy of each structure is calculated using DFT. When ranked from lowest energy to highest, each structure is assigned a score S_i^{DFT} equal to its position in the list. Finally, each structure is given an aggregate score:

$$S_i = S_i^{XRD} + S_i^{DFT}. \tag{1}$$

As an example, a structure with both the lowest total energy and best match to experimental XRD pattern would have $S_i = 2$. A fixed number of the best performing structures (those with the lowest values of S_i) are immediately carried over to the next generation. The remaining structures are replaced by structures generated in crossover operations where those structures with lower values of S_i are more likely to have their features carried over to the next generation as compared to structures with higher values.

The objective function described in Eq. 1 was selected because summing ranks eliminates the need to unify scales between XRD match and DFT energies. In order to avoid assigning a weight to bias the algorithm toward sampling structures with better or worse matches to the XRD pattern, the structure with the lowest energy is

selected as the candidate solution. In approximately 100 test cases, it was found that the lowest-energy structure within the constraints employed in the FPASS calculation (e.g., symmetry, unit cell parameters) and the experimentally determined crystal structure are always the same. It is possible to test whether the lowest-energy structure also has the best XRD match for new cases because the XRD match and energy are recorded for each structure evaluated by FPASS.

Crossover operations are defined in FPASS by choosing combinations of Wyckoff sites from the parent structures. Consider the case of the $P\bar{6}$ space group with four atoms. Assume that the first parent has two atoms on the 2i site and two atoms on the 2h site, while the second parent has one atom on each of the 1f, 1e, 1d, and 1c sites. During crossover, all combinations of sites that add up to four total atoms are enumerated. For example, a structure with atoms on the 2i, 1f, and 1e sites would be among the set of candidates. Each combination is assigned a weight using the ICSD-based biasing, then one of those sets of Wyckoff sites is chosen at random to be used as the child that is carried to the next generation.

With some probability, each child that is generated during the genetic algorithm will be selected to have either or both of two mutation types applied to it. In the first mutation type, the positions of atoms are randomly perturbed while ensuring that those perturbations do not break the symmetry of the structure. This mutation allows for changes to the positions of atoms on each Wyckoff site. In the second mutation type, new combinations of Wyckoff sites can be randomly selected, and atoms moved from the old sites to the new ones. When these new Wyckoff sites are selected, atoms are placed at random positions while ensuring that symmetry is preserved.

Once a set of structures has been generated, Rietveld refinement is carried out for each. The objective function during refinement is defined by Pecharsky and Zavalij (2005):

$$ R = \frac{\sum_{2\theta} \left| I_{\text{calc}} - \left(I_{\text{obs}} - I_{\text{bg}} \right) \right|}{\sum_{2\theta} \left| I_{\text{obs}} - I_{\text{bg}} \right|} \tag{2}$$

where I_{calc}, I_{obs}, and I_{bg} are the calculated, observed, and background intensities, respectively, and the sums run over angles measured in the observed pattern. The background intensity, I_{bg}, is modeled as a Chebyshev polynomial of the angle, the features of which are treated as fitting parameters during refinement. The calculated pattern for diffraction off of the plane hkl (which can be directly converted to an angle 2θ) has the following definition:

$$ I_{hkl} = K \times m_{hkl} \times LP\left(\theta\right) \times T_{hkl} \times A_{hkl} \times |F_{hkl}|^2 . \tag{3}$$

K is a scaling factor that can be optimized during refinement. m_{hkl} is the number of planes that are equivalent by symmetry to hkl (since the intensity only needs to be computed for one). $LP\left(\theta\right)$ are the Lorentz and polarization factors. T_{hkl} is the preferred grain orientation or texturing. A_{hkl} is the volume absorption of the plane.

$|F_{hkl}|^2$ is the structure factor. Each peak is broadened by multiplying the computed intensity (I_hkl) by a psuedo-Voight function centered at the peak center (2Θ). The width parameters of the pseudo-Voight function are optimized during refinement, the parameters of which are optimized during refinement. Using this function for the calculated intensity, all free parameters are adjusted during refinement in order to minimize Eq. 2.

As described, the FPASS method sits at the intersection between energy-based structure prediction and experimental solution to powder XRD patterns. There are a number of difficulties when each of these methods is used individually that FPASS can help alleviate. First, the size of the search space can be very large ($3N + 3$ degrees of freedom for N atoms when the lattice shape is not known) in pure structure prediction. However, the use of a reference powder XRD pattern can bias the search in the space of structures that are most physical. In addition, the symmetry of the space group determined from the XRD pattern will, unless it is P1, impose constraints on atomic positions and reduce the number of free variables in the optimization. Second, as already discussed, the global search methods in FPASS allow for structure solution even in the absence of an expert to drive them. Third, some elements, such as hydrogen, do not scatter X-rays strongly, and the positions of these atoms can be impossible to determine through powder XRD alone. Since the energy of structures are calculated in FPASS, the positions of these atoms can be taken from the lowest-energy configurations. In the next section, example applications of FPASS are described that take advantage of each of these features.

3   Selected Results

There are two classes of problems to which FPASS has been applied: first, to validate FPASS by confirming existing structures in the literature and, second, to solve diffraction patterns that had no known structure associated with them. In this section, a number of examples of each of these types are highlighted in order to show the breadth of problems that have been solved using this method.

3.1 Li_2O_2

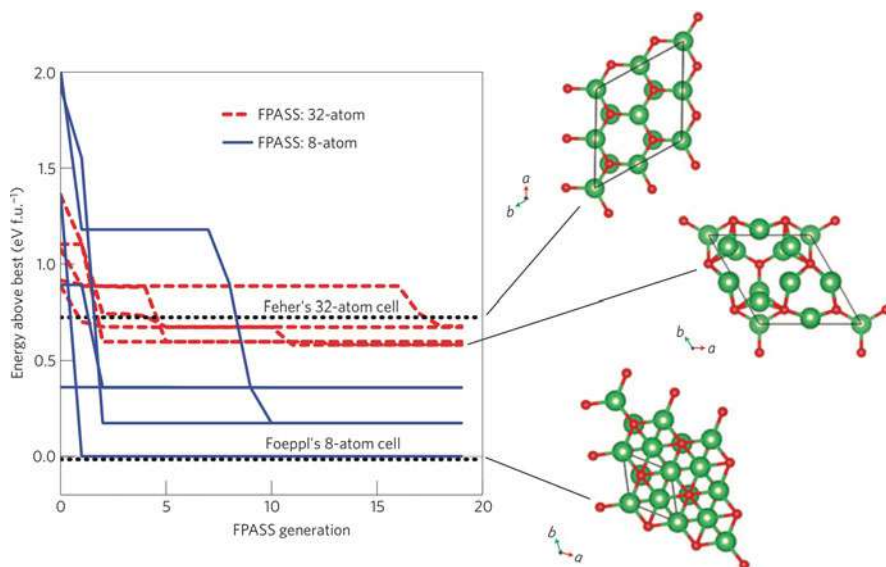
Li_2O_2 is a material that has been widely studied for use in lithium-air batteries. Given its technological importance, the structure of the material is of interest since it is needed, for example, to calculate diffusion energetics using DFT (which requires a complete crystal structure as input). Two crystal structures, both in the $P\bar{6}$ space group, had been proposed for this chemistry: one structure by Föppl (1957) with an 8-atom basis and the other by Fehér et al. (1953) with a 32-atom basis. DFT can be used to determine which of these structures has the lowest energy at $T = 0$ K. Indeed, the structure proposed by Föppl has a lower energy than that given by Fehér (Cota and de la Mora 2005; Chan et al. 2011).


Fig. 1 Energy of the best structure at each step of an FPASS optimization of Li_2O_2. Red, dashed lines use a 32-atom cell while blue, solid lines use an 8-atom cell. The structure proposed by Föppl (1957) is the lowest-energy structure found during all simulations (Meredig and Wolverton 2013)

Given the questions around the structure in this system, FPASS was applied to determine whether there might exist some other structure in the same space group with a better match to the experimental pattern (Meredig and Wolverton 2013). A 32-atom cell was generated for Li_2O_2 in the $P\bar{6}$ space group. The results for this optimization are shown in Fig. 1. These findings support those of other studies (Cota and de la Mora 2005; Chan et al. 2011) in that the Föppl structure is the lowest-energy one that exists.

3.2 MgNH

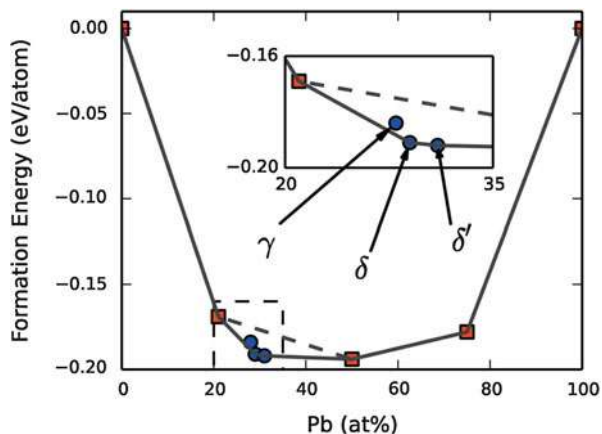
Due to the presence of hydrogen, the structure of MgNH is difficult to resolve from an XRD pattern and is also difficult to predict from energetics alone due to the complexity of the structure. In this way, MgNH is an ideal candidate for solving with FPASS since a hybrid approach can mitigate both issues. Some historical information was used in applying FPASS to this system. Previous studies of MgNH have lead researchers to conclude that the structure contains 36 atoms in its unit cell and is one of four space groups; from XRD, the $P6_3$, $P6_3/m$, and $P6_322$ were proposed (Jacobs and Juza 1969) while neutron scattering was used to suggest the $P6/m$ space group (Dolci et al. 2011). Ten different optimizations were performed in each of these four space groups, all with 36 atoms. The results of these simulations are shown in Fig. 2 (Meredig and Wolverton 2013).
Fig. 2 The energy (y axis) and relative diffraction error (x axis) for all structures generated during FPASS runs of MgNH in the P6$_3$, P6$_3$/m, P6$_3$22, and P6/m space groups. Different symbols denote the different space groups that were studied. Structures in the P6/m space group had both the lowest energy and best match to diffraction patterns during these runs (Meredig and Wolverton 2013)

From the FPASS runs that were performed, the lowest-energy structures and best matches to experimental patterns were simultaneously found in the P6/m space group. Surprisingly, the top P6/m structure also had the best agreement with the diffraction pattern for which the space group had been reported as being P6$_3$, P6$_3$/m, or P6$_3$22. This shows that non-optimal solutions can be found even when experts drive the refinement process.

3.3   Na-Pb System

The Na-Pb binary system contains three phases (γ-Na$_{13}$Pb$_5$, δ-Na$_5$Pb$_2$, and δ'-Na$_9$Pb$_4$) for which the structure has been partially but not completely solved. In all three cases, the lattice parameters and Pb positions were known, but the Na positions were not. In Fig. 3, the convex hull of DFT energies for the completely-solved structures in the Na-Pb system is shown in orange. A goal in solving the structures of the γ, δ, and δ' phases was to determine whether they would be energetically favorable compared to structures that were already solved.

The space groups of these structures had been determined to be R$\bar{3}$m for δ-Na$_5$Pb$_2$ and P6$_3$/mmc for both γ-Na$_{13}$Pb$_5$ and δ'-Na$_9$Pb$_4$ (Weston and Shoemaker 1957). In all FPASS runs, the lattice parameters and Pb positions were fixed to the experimentally determined values, while the positions of Na atoms were optimized.

Fig. 3 Convex hull for the Na-Pb system. Orange points show the phases present on the hull prior to the FPASS calculations (energies calculated with DFT for known structures). The blue points are phases that were studied using FPASS. All three phases were found to lie on the hull or were very close to it, suggesting that they are energetically stable or near to it


The structures of all three phases were determined using FPASS (Ward et al. 2015), and qualitative agreement was found with hypotheses from experiment about the Wyckoff site occupancies and positions of Na atoms (Weston and Shoemaker 1957). The energies of these newly solved structures are added to the convex hull in Fig. 3 as blue points. Clearly, all three structures are stable relative to the previously known structures. From the calculations that were performed, the δ-Na_5Pb_2 and δ'-Na_9Pb_4 phases were found to lie on the convex hull, suggesting that they are energetically stable at $T = 0$ K with respect to decomposition to other phases in the system. The γ-$Na_{13}Pb_5$ phase was found to be only slightly above the hull and is likely stabilized at finite temperature.

Importantly, it was hypothesized that the Na positions would be partially occupied in the γ-$Na_{13}Pb_5$ and δ-Na_5Pb_2 structures (Weston and Shoemaker 1957). However, the implementation of DFT used by FPASS currently supports only fully occupied sites, which means that partially occupied structures could not be explored. Therefore, these calculations put an upper bound on the energies of the structures. That is, the partially occupied structures may have even lower energies than the ones that are reported.

Of these solutions, γ-$Na_{13}Pb_5$ is particularly interesting. A common method for structure solution is to search the ICSD for structures with the same space group and relative stoichiometries of the phase in question (Curtarolo et al. 2003). However, in the case of $Na_{13}Pb_5$, no structure exists in the ICSD that has a 5:13 ratio of atoms, 36 atoms in the unit cell, and which is in the $P6_3/mmc$. In other words, the structure would not have been solvable had a global optimization method not been employed.

3.4 LiSbO₃

A monoclinic phase of $LiSbO_3$ was discovered in 2006. The structure was determined to be in the C2/m space group, while the positions of the atoms could not be
Fig. 4 Ten different structures that were solved using FPASS. Each solution started with an assumed space group and lattice parameters, and the positions within the unit were optimized for fixed composition. Each structure solution was checked for convergence and agreement with experimental patterns

determined. In addition to the C2/m structure, an orthorhombic phase is known to exist at the same composition.

Confined to the C2/m space group, FPASS found a layered structure of Li on alternate planes from Sb and O, where the O anions form an FCC lattice and the Sb anions are octahedrally coordinated with the O anions. This structure is shown in Fig. 4, and the positions of atoms are in agreement with qualitative suggestions made by (Nalbandyan et al. 2006) In DFT calculations, the energy of this structure was found to be within 1 meV/atom (higher) of the orthorhombic phase. That is, a purely energy-based structure prediction calculation would not have been able to differentiate this structure and the orthorhombic one. In fact, this is true of $T = 0$ K structure prediction for any material that has metastable or high-temperature polymorphs. The comparison to experimental XRD pattern is vital to the solution of the structure in these cases.

3.5   Other Solutions

FPASS has been used to solve many other systems, some of which are shown in Fig. 4 (Ward et al. 2017). In all cases, confidence in a solution is obtained in one or more of three ways: First, when multiple FPASS runs produce the same structure suggesting that the runs have converged. Second, when the difference between experimental and calculated patterns is sufficiently small. Third, when qualitative comparisons can be made to experimental hypotheses. Indeed, even though a complete structure might not exist, for many patterns, researchers have published theories of certain characteristics that should appear in the structure. Comparison between the FPASS structure and these hypotheses can give additional confirmation that a solution is likely correct. Of course each of these comparisons could fail on their own, but in validating FPASS calculations, as many of them are taken into account as possible before a structure is considered solved.

4   Discussion

With the reduced need for human intervention in the structure solution process, an obvious next step is to completely automate the solution of unknown diffraction patterns. To this end, a driver was developed for FPASS to which any number of diffraction patterns, along with the known lattice parameters and compositions, could be submitted (Ward et al. 2017). Each of those patterns was then solved without intervention from a human.

As a test of this system, 95 different crystal structures were selected from the monoclinic, orthorhombic, hexagonal, tetragonal, and cubic crystal families; each structure had between 1 and 30 atoms in the primitive cell. For each structure, FPASS was supplied with the composition, powder diffraction pattern, lattice parameters, and space group. FPASS was run at least 10 times for each of these 95 structures. In these runs, the correct structure was returned at least once for every one of the structures. Even more, the success rate was high for many of the structures that were studied; for 67 of the 95 structure, the best structure was found in at least 90% of the runs. One of the more difficult structures was the 29-atom primitive cell of α-Mn. Even in this case, the best structure was found in 11 out of 15 runs.

With such a large set of examples, some characteristics were observed that can be used to predict the likelihood that a new structure would be solved. It was determined that runs were more likely to succeed when diffraction patterns were of high quality. As the number of symmetrically unique atoms increased, the likelihood dropped for the same number of trials (since the number of degrees of freedom increased). Similarly, as the number of possible combinations of Wyckoff sites increase, the likelihood dropped (again due to an increase in the size of the search space). None of these observations are surprising but do confirm that high-quality diffraction patterns should be used wherever possible.

There are of course limitations to the FPASS method. One important consideration is that DFT produces energies of structures at $T = 0$ K. For structures that undergo phase transformations with increased temperature, or those structures that are metastable, the energy-based biasing will still favor structures that are lowest in energy at low temperatures. This effect should be minimized by the fact that the *best* structure is always taken as the one with optimal match between calculated and observed XRD patterns, and the search is constrained to symmetries observed in the high-temperature phase. However, in complex systems, the biasing of structures based on energies could result in too much effort being spent in the neighborhood of the $T = 0$ K structure.

Another consideration is that FPASS does not currently include any deterministic methods to find the space group or lattice parameters directly from the peak locations of an XRD pattern. Instead, FPASS requires that these values either be input to the calculation or determined during energetic minimization steps. As a result, mistakes in correctly identifying the space group or lattice parameters may result in the structure being incorrectly solved since FPASS cannot currently correct these mistakes directly from the pattern alone. Of course, integrating FPASS with

existing peak indexing software is an obvious addition to the method that would improve its accuracy.

Finally, as with all structure solution methods, FPASS requires a good-quality powder XRD pattern to match against. During refinement, a noisy pattern may produce a structure that is different than what would be obtained using a cleaner one. However, the requirement for a high-quality pattern is somewhat mitigated in hybrid structure solution methods, like FPASS, by the inclusion of structural energy.

Even with those limitations, it has been shown that the FPASS method can be used to solve complex systems that would otherwise not be tenable for structure prediction or refinement methods alone. A primary target for future work should be around automation of the steps outside of the core algorithms. Those steps include the determination of space group and lattice parameters; possible comparison to existing patterns in, for example, the Powder Diffraction File (PDF) (Faber and Fawcett 2002); and handling of multiphase systems. With those additional tools in place, FPASS can provide the foundation for solving XRD patterns with limited human intervention.

Contents

Abstract

Materials modeling of solar cell absorbers has been developing rapidly in the last few decades, thanks to the capability of density functional theory to calculate total energies and electronic structures and the development of computational algorithms to determine optical properties, band offsets, and defects in semiconductors. We give a brief introduction to the materials systems and the computation of key parameters for photovoltaic application such as the bandgap, effective mass, and optical absorption. Then we take perovskite solar cells as an example, to show how one can understand and engineer real materials through high-throughput first-principles calculations. This is followed by a short perspective.

1   Introduction

Tetrahedral coordination structures (TCS), with silicon as prototype, have been dominating solar cell research and market, since the first semiconductor solar cell was fabricated based on silicon absorber in the 1950s (Fig. 1) and followed by GaAs and CdTe. The success of TCS in the solar cell market can be ascribed not only to its superior performance but also to its extremely long-term stability. However, as derived from typical covalent systems, their electronic properties are generally defect-intolerant. An extremely low concentration of defects can significantly degrade cell performance. For crystalline Si and GaAs, high-quality crystals have been grown in expensive ways using, e.g., epitaxial growth methods. For CdTe, post-treatments are required for defect passivation so as to achieve high power conversion efficiency (PCE). Chemical "mutation" of the cation based on CdTe has also been applied and results in more ionic quaternary compounds such as $Cu_2(In,Ga)Se_4$ and $Cu_2ZnSn(S,Se)_4$. Because of the presence of multiple elements, defect control is crucial to enhance their efficiency, in particular for $Cu_2ZnSn(S,Se)_4$ (Park et al. 2018; Chen et al. 2013).

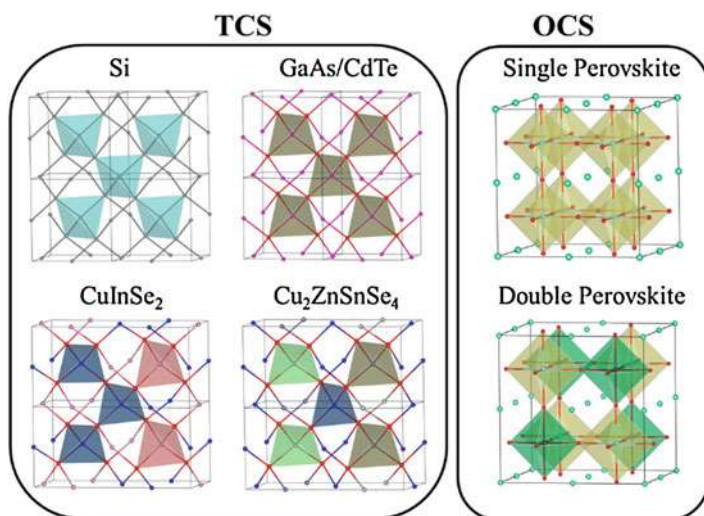
In 2010s, hybrid organic-inorganic perovskites, with $CH_3NH_3PbI_3$ as prototype, have introduced a new revolutionary class of solar cell materials, with remarkable performance and economic synthesis methods. In contrast to TCS, in this class of perovskites, corner-sharing octahedra are key structural characteristics (octahedral coordination structure (OCS)), and a unique feature is its defect tolerance. However, stability and toxicity problems are the main obstacles for commercialization. This


Fig. 1 Tetrahedral coordination structure (TCS), e.g., crystalline Si and the mutated compounds GaAs/CdTe, $CuInSe_2$, and $Cu_2ZnSnSe_4$, and octahedral coordination structure (OCS), e.g., perovskites and the mutated double perovskites, have represented two classes of structural family for solar cell absorbers. (Reorganized by permission of Wang et al. 2019)

situation has stimulated considerable interest in research, and many proposals have been made to provide suitable solutions. Unlike the success in TCS, chemical mutations on OCS are not able to result in functional semiconductors with performance comparable to $CH_3NH_3PbI_3$. Despite extensive theoretical and experimental research, unfortunately, both the stability and toxicity issues of those perovskites have not yet been solved.

As prototype compounds for TCS and OCS, respectively, silicon and α-phase $CH_3NH_3PbI_3$ have the highest symmetry as three-dimensional crystals. Alternatively, previous interest had also been directed to low-symmetry structures, which included Zn_3P_2 ($E_g \sim 1.5$ eV, PCE 6.08%) (Yin and Yan 2013; Fagen 1979; Bhushan and Catalano 1981), Cu_2S ($E_g \sim 1.21$ eV, PCE 11%) (Wang 2012; Hall et al. 1981), and FeS_2 ($E_g \sim 0.95$ eV, PCE 2.8%) (Hu et al. 2012; Bi et al. 2011). Inspired by the recent explosion in perovskite solar cell research, efforts are also being made to include perovskite derivatives in the search of improved stability, such as edge- or face-shared $A_3B_2X_9$ formula ($Cs_3Bi_2I_9$ (PCE ~1.0%), $Cs_3Sb_2I_9$ (PCE < 0.1%)), A_2BX_4 compounds, and Ruddlesden-Popper phases (Xiao et al. 2017). However, none of them has exhibited sufficiently promising properties to survive in the race for novel solar cell materials, and to date the search for novel stable high-efficiency solar cell absorbers with earth-abundant and environment-friendly elements remains an active area in materials modeling. In this chapter, by using perovskite solar cell as example, we will discuss a high-throughput screening approach to materials design for solar energy applications.

2   Perovskite Solar Cells

Organic-inorganic hybrid halide perovskite, with $CH_3NH_3PbI_3$ (MAPbI$_3$) as a prototype, represents an emerging solar cell absorber (Kojima et al. 2009; Kim et al. 2012; Lee et al. 2012; Burschka et al. 2013). Materials modeling has played an important role in understanding the properties and mechanisms responsible for their functionality (Frost et al. 2014; Yin et al. 2015). In order to optimize the strategy for designing high-performance and stable perovskite solar cells, it is crucial to understand the relationship between the performance and the intrinsic properties of the known perovskites.

2.1   Bulk Properties of MAPbI$_3$

2.1.1   Electronic Structure

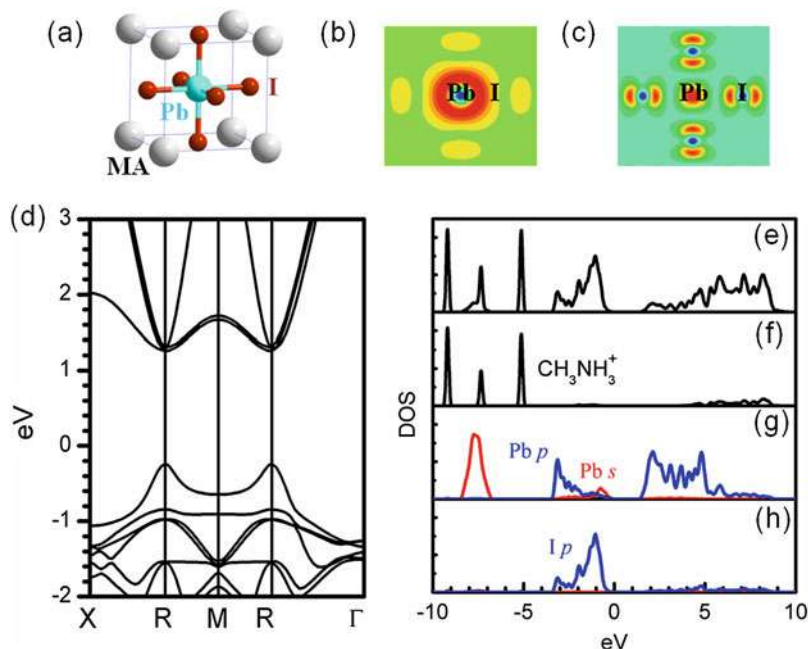
MAPbI$_3$ can exhibit cubic (space group $Pm\overline{3}m$, >330 K), tetragonal (I4/mcm, 160–330 K), and orthorhombic (Pbnm, <160 K) phases (Kawamura et al. 2002; Baikie et al. 2013; Stoumpos et al. 2013). DFT calculation shows that three phases have similar electronic and optical properties (Yin et al. 2014a). The electronic structure of MAPbI$_3$ has very weak dependence on the orientation of the MA ion,


Fig. 2 (**a**) The schematic perovskite structure of $CH_3NH_3PbI_3$. (**b**) and (**c**) are the partial charge density at CBM and VBM, respectively. (**d**) is the band structure of MAPbI$_3$. (**e**–**f**) are total DOS and $CH_3NH_3^+$, Pb, I partial DOS, respectively. The zero in DOS is referred to VBM. The Pb partial DOS has been enlarged by a factor of 5 to make clear the *s* orbital contribution. (Reprint by permission of Yin et al. 2014b)

since MA does not have obvious contribution at the band edge (Fig. 2) but donates one electron to the Pb-I framework.

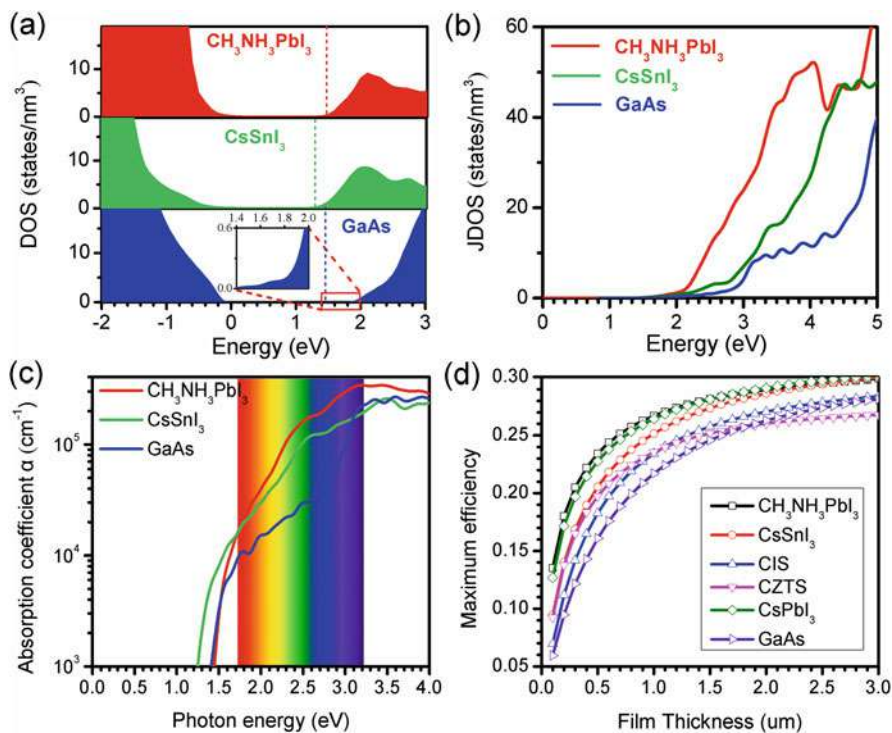
In perovskite MAPbI$_3$, MA and Pb donate one and two electrons, respectively, to three I ions, forming a bandgap about 1.50 eV (Yin et al. 2014b) between unoccupied Pb *p* orbital and occupied I *p* orbital (see Fig. 2e–h). In general, for a stable perovskite ABX$_3$, the tolerance factor, $t = (r_A + r_X) / \sqrt{2} (r_B + r_X)$, is required to be close to 1. Therefore the size of the A atom should be much larger than that of the B atom. However, Pb in the 2+ charged state is already a large ion so that it is difficult to find a single element A that is large enough to stabilize APbI$_3$. Large-size organic ions such as $CH_3NH_3^+$ can stabilize this perovskite structure but do not impact the intrinsic electronic structure of bulk APbI$_3$. CBM and VBM of MAPbI$_3$ are mainly composed of Pb *p* orbital with negligible coupling with I (Fig. 3b) and antibonding coupling between Pb^{2+} lone-pair *s* and I *p* (Fig. 3c and g) (Yin et al. 2014b). The strong *s-p* antibonding coupling makes upper valence bands dispersive (Fig. 3d) and results in small hole effective mass which is comparable with the electron effective mass, leading to ambipolar conductivity. Similarly to the case of silicon, the calculated hole and electron effective masses of $CH_3NH_3PbI_3$ (Table 1) are balanced, in contrast to conventional thin-film solar cell absorbers GaAs, CIS, CZTSe, and CdTe.


Fig. 3 (**a**) DOS of MAPbI₃, CsSnI₃, and GaAs. The VBMs are referred to as zero energy and CBMs are marked as dashed lines. (**b**) The JDOS of MAPbI₃, CsSnI₃, and GaAs. Table 1 Calculated effective masses for electrons and holes. (Reformatted from permission of Yin et al. 2014a)

	Electron effective mass (m_e)	Hole effective mass (m_e)
CH₃NH₃PbI₃	0.35	0.31
Silicon	0.26	0.29
GaAs	0.07	0.34
CuInSe₂	0.09	0.75
Cu₂ZnSnSe₄	0.10	0.26
CdTe	0.09	0.28

2.1.2 Optical Properties

Strong optical absorption, particularly in the visible light region (1.7–3.0 eV), enables absorber to harvest enough sunlight with extremely thin layer, so that the photo-generated electrons and holes do not have to travel too far to be collected, thus leading to high quantum efficiency. According to the Fermi golden rule, the

optical absorption of a semiconductor at photonic energy hω can be calculated as $\frac{2\pi}{\hbar} \int |\langle v | \hat{p} | c \rangle|^2 \frac{2}{8\pi^3} \delta(E_c(\vec{k}) - E_v(\vec{k}) - \hbar\omega) d^3k$, where $\langle v | \hat{p} | c \rangle$ is the optical transition matrix from valence band states $|v\rangle$ to conduction band states $|c\rangle$. To make the model straightforward, the transition matrix $\langle v | \hat{p} | c \rangle$ is considered to be independent of k, and the above absorption formula can be approximated as $\frac{2\pi}{\hbar} |\langle v | \hat{p} | c \rangle|^2 \int \frac{2}{8\pi^3} \delta(E_c(\vec{k}) - E_v(\vec{k}) - \hbar\omega) d^3k$, where the second term is the joint density of states (JDOS) at energy hω. Therefore, optical absorption is directly correlated with dipole transition matrix and JDOS. Calculations (Yin et al. 2014a) show that the transition matrices of $CH_3NH_3PbI_3$ and GaAs near the optical absorption edges are similar; hence the JDOS determines the optical absorption difference between these two materials as shown in Fig. 3. Electronic structure calculations show a large difference in JDOS and therefore in optical absorptions, for $CH_3NH_3PbI_3$ and GaAs. The lower part of the GaAs conduction band is derived from the dispersive s band, whereas the lower part of the $CH_3NH_3PbI_3$ conduction band is mainly composed of Pb p bands. The atomic p states have two more orbitals and more localized orbital shape than the s states. As a result, the density of states (DOS) in the lower CB of the halide perovskites is significantly higher than that of GaAs, leading to higher JDOS and, therefore, stronger optical absorption for halide perovskites. The calculated optical absorption coefficients as in Fig. 3c show that the optical absorption coefficient of $CH_3NH_3PbI_3$ is up to 1 order of magnitude higher than that of GaAs within the visible light range. In comparison to conventional thin-film solar cell absorbers such as CdTe, CIGS, and $Cu_2ZnSnSe_4$ (CZTSe), which have similar chemical characters in their CBs as GaAs, $CH_3NH_3PbI_3$ exhibits sharp optical absorption edge and strong absorption strength in the visible light range.

2.1.3 Spectroscopic Limited Maximum Efficiency (SLME)

In the Shockley-Queisser limit, one considers radiative recombination based on black-body radiation to obtain the maximum theoretical efficiency of a semiconductor solar cell using a single p-n junction. Yu and Zunger (2012) have generalized Shockley-Queisser limit by taking into account the dependence of absorption coefficient of the absorber. A new theoretical limit was thus obtained, i.e., the so-called spectroscopic limited maximum efficiency (SLME), which has been used as a screening parameter for the design of solar cell absorbers. To calculate SLME, the optical absorption spectrum should be first calculated and then combined with the sunlight spectrum to evaluate the maximum conversion efficiency dependence on film thickness. Figure 3d shows the SLME of some common light absorbers as a function of the thickness of the absorber layers, based on DFT-calculated optical absorption spectrum at the GGA-PBE (Perdew et al. 1996) level. The bandgaps are corrected and adjusted to experimental values via the scissor operator. It shows that OCS halide perovskites with direct p-p transition exhibits much higher conversion efficiencies than the conventional TCS semiconductors in thin layers. For example, $CH_3NH_3PbI_3$-based cells can have a maximum efficiency up to 21% with a 0.3 μm absorber, while at the same thickness, GaAs can only achieve 13% (Yin et al. 2014a).

2.2   Influence of Defects

Semiconductor solar cells rely on the formation of *p-n* junction. Therefore, the properties of defects and dopants are crucial. Formation energy and transition energy levels are two key parameters to evaluate the properties of defects and dopants. Apart from point defects, extended defects such as grain boundaries and dislocations also play an important role for carrier separation and recombination. In this subsection, we show how DFT calculations at the PBE level can help understand the defect behavior in perovskites (Yin et al. 2014b; Walsh et al. 2015; Kim et al. 2014; Du 2014).

2.2.1   Formation Energies of Intrinsic Defects

Since the defect formation energies depend on the environmental chemical potentials, the chemical potential for equilibrium growth of $CH_3NH_3PbI_3$ is calculated for a range of compositions, from I-rich/Pb-poor to I-poor/Pb-rich conditions (Yin et al. 2014b). All point defects in $CH_3NH_3PbI_3$ are considered, including three vacancies (V_{MA}, V_{Pb}, V_I), three interstitials (MA_i, Pb_i, I_i), two cation substitutions (MA_{Pb}, Pb_{MA}), and four antisite substitutions (MA_I, Pb_I, I_{MA}, I_{Pb}). The formation energies as a function of Fermi level position at different chemical potentials are shown in Fig. 4a, b, and c, respectively. It is interesting to find out that the conductivity of $CH_3NH_3PbI_3$ can be tuned from intrinsic good *p*-type to good *n*-type by tuning chemical potential from I-rich/Pb-poor to I-poor/Pb-rich conditions. This behavior is different from that of conventional thin-film solar cell absorber CIS(Se) and CZTS, exhibiting only *p*-type conductivity. The formation energies of typical donors (Cu_i and In_{Cu}) in CIS is much higher than that of the V_{Cu} acceptor. Therefore, the V_{Cu} acceptor dominates the conductivity of CISe (Zhang et al. 1998). In $CH_3NH_3PbI_3$, although the formation energies of the dominant donor MA_i and the dominant acceptor V_{Pb} are dependent on chemical potentials, their values ranging from -1 to 1 eV are comparable in the whole range of Fermi level. The origins of the formation of dominating V_{Pb} in $CH_3NH_3PbI_3$ resemble that of V_{Cu} in CISe, ascribed to *s-p* and *p-d* coupling, respectively (Zhang et al. 1998). The fully occupied antibonding state between Pb *s* (Cu *d*) and I *p* (Se *p*) coupling tends to break the chemical bond and form a vacancy.

2.2.2   Transition Energies of Intrinsic Defects

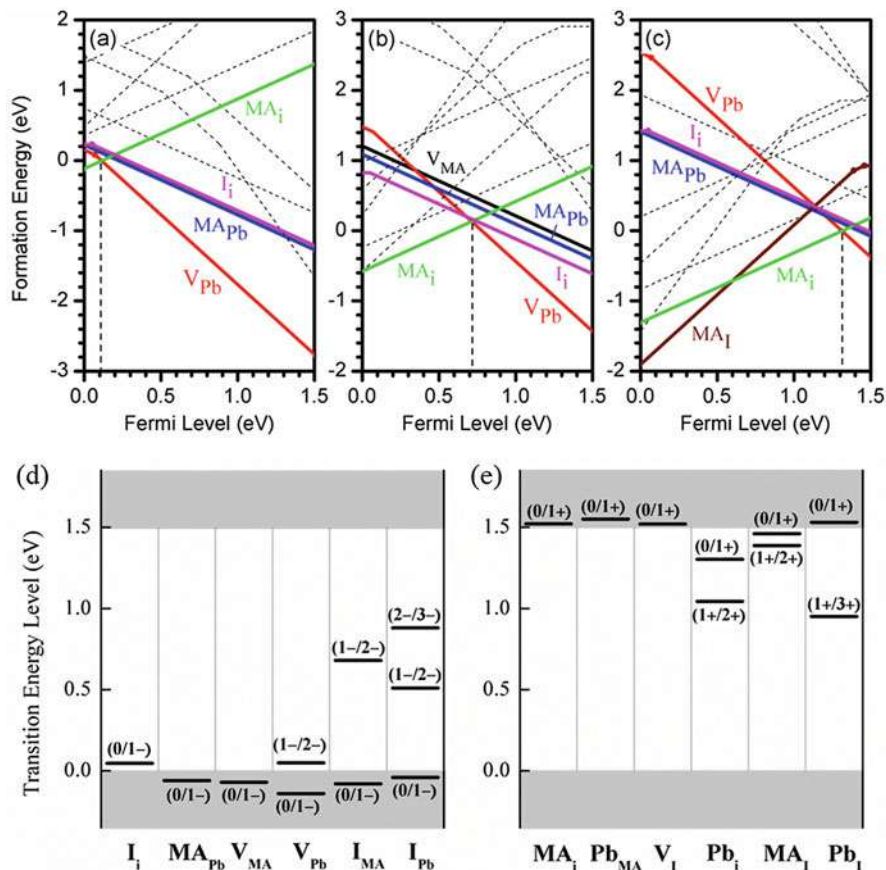
The transition energy of a defect is the Fermi level in the conduction of equal probability for the defect to be either negatively or positively charged. A deep defect, namely, giving rise to a level in the middle of bandgap, will attract carriers and act as Shockley-Read-Hall nonradiative recombination center. The high performance of polycrystalline CIGS solar cell is partially attributed to its shallow dominant defects (V_{Cu}) with transition levels only 0.03 eV above VBM (Zhang et al. 1998). On the contrary, in CZTS the dominant defect (Cu_{Zn}) has a relatively deep transition level (0.10 eV) (Chen et al. 2009), responsible for the low V_{oc} of the CZTS solar cell (Polizzotti et al. 2013). The defect transition levels of $CH_3NH_3PbI_3$ are shown in


Fig. 4 The formation energies of intrinsic point defects in $CH_3NH_3PbI_3$ at chemical potential (**a**) Pb-poor, (**b**) intermediate, and (**c**) Pb-rich conditions. Defects with much higher formation energies are displayed as dashed lines. The transition energy levels of intrinsic acceptors and donors are shown in (**d**) and (**e**), respectively. (Reprint by permission of Yin et al. 2014b)

Fig. 4. When calculating transition levels, all lattices are fully relaxed to account for the lattice contribution. We can see that the defects with low formation energies (MA_i, V_{Pb}, MA_{Pb}, I_i, V_I, and V_{MA}) have transition level less than 0.05 eV around the band edge. Meanwhile, since defects that create deep levels (I_{Pb}, I_{MA}, Pb_i, Pb_I) have high formation energies, $CH_3NH_3PbI_3$ should have rather low nonradiative recombination rate, explaining the reported long electron-hole diffusion length up to 175 μm (Dong et al. 2015).

2.2.3   Effects of Grain Boundaries

Since $CH_3NH_3PbI_3$ are grown via solution process methods (Jung and Park 2015; Baikie et al. 2013), the materials exhibit polycrystalline phases with grain

Fig. 5 (**a**) The structural model of $\Sigma 5(310)$ GB for $CH_3NH_3PbI_3$. Two identical GBs are included in the supercell to enable the periodicity. (**b**) DOS of $\Sigma 5(310)$ GB model shown in (**a**) with comparison to $CH_3NH_3PbI_3$ bulk calculated from the unit cell. (**c**–**f**) show the partial DOS of selective atoms in (**a**). The (partial) DOS are average per atom, and (**b**) and (**c**) are enlarged twice for clarity. (Reprint by permission of Yin et al. 2014a)
boundaries, which affect the photoelectric properties. In conventional thin-film solar cell absorbers such as GaAs, CIGS, CZTS, and CdTe, GBs usually create deep levels in the bandgaps that are considered detrimental for solar cell performance (Yin et al. 2013, 2014c). In contrast, DFT calculations at the PBE level show (Stoumpos et al. 2013) that GBs in $CH_3NH_3PbI_3$ are intrinsically benign which is consistent with some experimental reports (Edri et al. 2014), although other experiments show that the GBs are not as benign as proposed (Adhyaksa et al. 2018). Figure 5a shows the atomic structure of a supercell containing two $\Sigma 5(310)$ grain boundaries , a typical GB model containing wrong bonds, dangling bonds, and extra bonds. The calculated DOS (Fig. 5b) shows that the $CH_3NH_3PbI_3$ GBs do not generate any states in the gap. The shallow GB energy levels are correlated with the shallow point defects, since the atoms at GBs have similar chemical environments as individual interstitials and vacancies, which create dangling bonds and uncharacteristic bonds such as I-I bonds and Pb-Pb bonds.

3   Design of Novel Perovskite Solar Cell Absorbers

Early exploration of novel solar cell materials was based on trial and error in experiments. Inspired by the change in the nucleotide sequence of a gene or a chromosome in natural organisms, elemental "transmutation" can also be adopted in materials design (Walsh et al. 2012) and is an effective approach to tune the

bandgap, a crucial parameter for a solar cell. For example, elemental transmutation of ZnS (bandgap 2.7 eV (Madelung 2004)) via $Zn^{2+} -> Cu^{1+} -> In^{3+}$ leads to the formation of $CuInS_2$. Although the crystal structure has no major change, the bandgap is significantly reduced to 1.53 eV since the strong coupling between Cu $3d^{10}$ and O $2p^6$ pushes up the VBM, enabling $CuInS_2$ to be a good solar cell absorber. Further mutation on $CuInS_2$ leads to another environment-friendly earth-abundant solar cell absorber Cu_2ZnSnS_4. Elemental mutations have also been made to explore alternative perovskites by replacing divalent Pb^{2+} with monovalent cations such as Na^{1+}, K^{1+}, Rb^{1+}, Cu^{1+}, Ag^{1+}, Au^{1+}, In^{1+}, and Tl^{1+} and trivalent cations such as Ga^{3+}, In^{3+}, Sb^{3+}, and Bi^{3+}, all aiming to find high-efficiency Pb-free stable perovskite, even though the optoelectrical properties of double halide perovskites are found to be inferior to $CH_3NH_3PbI_3$ (Li and Yin 2018).

Apart from elemental transmutation, high-throughput calculations have been used for materials screening for novel solar cell materials, owing to increasing computational power and vast materials data accumulated in the last decades. Here, we take chalcogenide single perovskites as an example to show how high-throughput calculations can be used for screening of solar cell absorbers (Huo et al. 2018).

For high-throughput calculations, first one should choose the material systems of interest:

(i) Chemical composition – we choose 168 kinds of ABX_3 chalcogenide (including oxide) perovskites (A = Mg, Ca, Sr, Ba, Zn, Cd, Sn, Pb; B = Ti, Zr, Hf, Si, Ge, Sn, Pb; X = O, S, Se).
(ii) Second, Crystal structures – four phases including $Pm\overline{3}m$, Pnma, P63/mmc, and Pnma.

Second, key parameters including (a) stability, (b) bandgap, (c) effective mass, and (d) optical absorption should be chosen as the searching criteria. The schematic procedure for high-throughput calculations is shown in Fig. 6.

Thermodynamic stability of ABX_3 perovskites is calculated based on DFT-PBE by

$$H_f = \left(E_{ABX_3}/N_{ABX_3} - E_{AX}/N_{AX} - E_{BX_2}/N_{BX_2} \right)/5$$

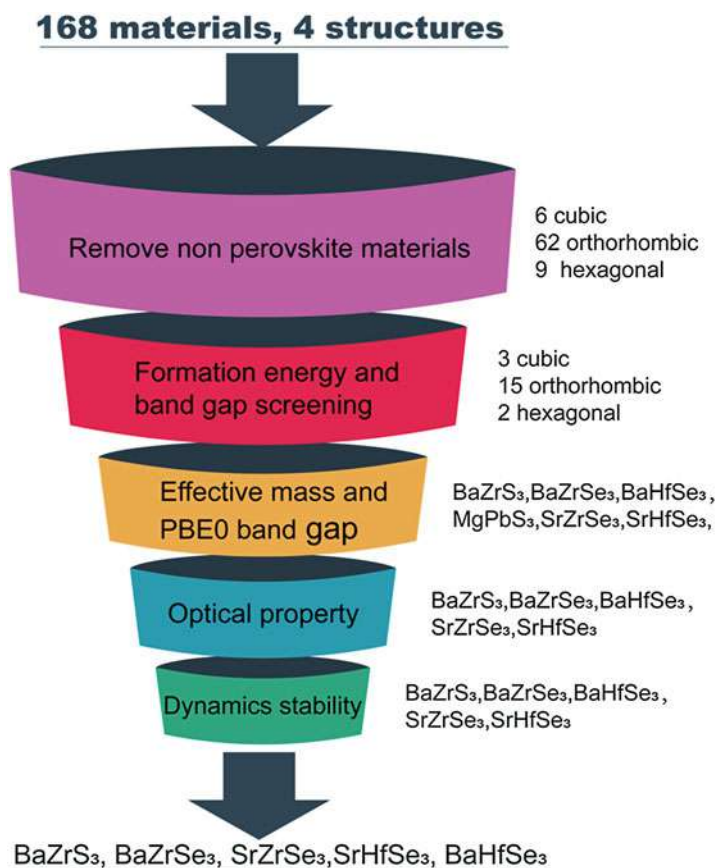
where H_f, E_{ABX3}, E_{AX}, and E_{BX2} are formation energy of ABX_3 per atom, total energies of ABX_3, AX, and BX_2, respectively. Negative/positive formation energies indicate that compounds are stable/unstable. Due to the ease of octahedral tilt, perovskite phases could be dynamically unstable despite being thermodynamically stable ($H_f < 0$). Dynamic stabilities are evaluated based on the calculated phonon spectrum. Harmonic phonon spectrum at 0 K is calculated in linear response (also known as density functional perturbation theory, DFPT (Giannozzi et al. 1991; Gonze and Lee 1997; Baroni et al. 2001)) and finite-difference supercell approach (Togo and Tanaka 2015). The room temperature phonon spectrum is obtained by Dynaphopy code (Carreras et al. 2017) which allows us to extract the microscopic


Fig. 6 Screening procedure of novel chalcogenide single perovskites for solar cell applications. (Reprint by permission of Huo et al. 2018)

anharmonic phonon properties from molecular dynamic trajectories using the mode decomposition technique (McGaughey and Larkin 2014) as reported by Sun et al. (Sun et al. 2014).

According to Shockley-Queisser limit, the optimal range of bandgap for efficient single-junction solar cell absorber is about 1.0–1.6 eV. The bandgaps of initial 168 materials with 4 different phases (totally 672 structures) are calculated based on DFT at the PBE level. Due to bandgap underestimation of PBE-DFT, materials with bandgaps in the range 0–1.1 eV were selected for further screening, and the hybrid PBE0 functional (Adamo and Barone 1999) was used to accurately determine the bandgap of selected perovskites.

The effective mass of electrons (holes) around the bottom of the conduction band (top of the valence band) is approximately fitted based on PBE-calculated band structure by $m^* = \hbar^2 \left[\frac{\partial^2 \varepsilon(k)}{\partial k^2} \right]^{-1}$, where $\varepsilon(k)$ is energy dispersion relation functions.

The absorption coefficients as a function of photon energy can be calculated via the expression $\alpha\,(E) = \frac{4\pi e}{hc} \left\{ \frac{\left[\varepsilon_1^2 + \varepsilon_2^2\right]^{1/2} - \varepsilon_1}{2} \right\}^{1/2}$, where $\varepsilon(\omega) = \varepsilon_1(\omega) + i\varepsilon_2(\omega)$ is frequency-dependent dielectric function. Usually, dense k-points are required to get a fine optical spectrum, in particular to dispersive bands, leading to high computational cost. Therefore, optical absorption spectra were calculated based on the efficient PBE functional and then simply shifted to reproduce the PBE0 value of the bandgap but keeping the spectral shape of the PBE calculations. The maximum PCE of absorber candidates are estimated via SLME as discussed in Sect. 2.1.3. Despite the absence of experimental results on chalcogenide perovskites, the predicted PCE for $CH_3NH_3PbI_3$ (26%) has been quoted as the ideal target to approach in experiment (Singh et al. 2016).

The procedures mentioned above have been recently applied to search solar cell absorbers among chalcogenide single perovskites. More computational details can be found in Huo et al. (2018). Based on the screening criteria of phase stability, thermodynamic stability, bandgap, carrier effective mass, and optical absorption, five chalcogenide perovskites $BaZrS_3$, $BaHfSe_3$, $SrZrSe_3$, $SrHfSe_3$, and $BaZrSe_3$ have been selected. Among them, $BaZrS_3$ has been successfully synthesized in experiments (Perera et al. 2016a) with a measured value of 1.73 eV for the bandgap, in good agreement with the DFT-PBE0 value of 1.78 eV (Perera et al. 2016b). Device fabrication based on chalcogenide perovskites has not yet been reported thus far.

4   Future Perspectives

The fundamental approach to materials design is to relate the structure of a material to its functional properties. Conventionally, structure-property relations can be understood in terms of existing human knowledge of materials physics and chemistry, such as elemental transmutation and high-throughput calculations as mentioned above. With the accumulation of experimental data, such as the continually expanding Inorganic Crystal Structure Database (ICSD) (https://icsd.fizkarlsruhe.de), and theoretical data, such as those from Materials Project (Jain et al. 2013), OQMD (Kirklin et al. 2015), and NoMAD (Ghiringhelli et al. 2017), the conventional style of materials design is now changing. One finds new routes of data-driven materials design to be merging.

Materials design of perovskite via machine learning (ML) has drawn much current interest. Pilania et al. trained a classification model based on a dataset of 185 experimentally known ABX_3 compounds and proposed 40 new stable perovskites (Pilania et al. 2016). Balachandran et al. applied two models based on a dataset of 390 experimentally reported ABO_3 compounds and predicted 235 new oxide perovskites (Balachandran et al. 2018). Bartel et al. proposed a new tolerance factor by ML based on 576 experimentally known ABX_3 compounds and predicted

the existence of more than a thousand inorganic and hybrid organic-inorganic double perovskites (Bartel et al. 2019). Schmidt et al. calculate 249, 984 potential cubic ABX_3 perovskites via high-throughput calculations and found that ML can reproduce the energetics data with errors around 100 meV/atom (Schmidt et al. 2017). Xie et al. established a smart crystal graph of convolutional neural networks based on DFT-calculated data in the Materials Project (Jain et al. 2013) to predict materials properties directly from crystal structures; and based on their model, 228 perovskites were deemed potentially synthesizable (Xie and Grossman 2018). Recently, through high-throughput DFT calculation, we established a database containing the decomposition energies, considered to be closely related to the thermodynamic stability of 354 halide perovskite candidates. A well-functioning ML model is trained over this theory-based database and further validated by experimental observations of perovskite formability (F_1 score, 95.9%) of 246 $A_2B(I)B(III)X_6$ compounds that are not present in the training database (Li et al. 2019).

   Nowadays machine learning is considered to represent the third generation of computational materials design, statistically driven design, preceded by first generation (computing properties from structures) and second generation (predicting structure from properties). Indeed, the basic methodology is not new and can be traced back to more than 50 years ago (Samuel 1959). Given the long-standing development of algorithms, the procedure of application is by now standard. Therefore, in our opinion, the reliability and validity of data is the crucial prerequisite for a reliable machine learning work. Natural laws are supposed to be buried in the existing training data, and the rules are only learned from these data. Much attention should be given to this aspect of the development in the field. For example, a data-cleaning procedure was recently proposed (Xu et al. 2018) to rationalize the data of perovskite formability for all the ABX_3 and $(AA´)(BB´)X_6$ perovskite compounds in Materials Projects database (Jain et al. 2013). Once combined with this type of "rationalization," we believe that machine learning has the potential to revolutionize current materials discovery (Butler et al. 2018).
